
Part 2 was introduced after Part 1 reached a length of almost 10000 pages. From now on Part 1 will remain essentially unchanged (except for the correction of errors and the inclusion of previously unrecognized book titles in one of the Part 1 sections entitled “Book Cover Gallery”). All additional citations will be included in Part 2. This includes citations dated 2019 or after; citations of previously published papers not included in Part 1; citations of some earlier papers on fluid-structure interaction; citations of some earlier papers on chaos and nonlinear dynamic response; citations of papers (published from 2014 on) from the journals, Nonlinear Dynamics, Smart Materials & Structures, Soft Matter, Earthquake Engineering & Structural Dynamics, Shock and Vibration, Mathematical Problems in Engineering and possibly from other journals not included in the list given at the beginning of Part 1. In March 2019 the citations of papers from 2014 - 2018 in International Journal of Structural Stability and Dynamics and the citations of papers from 2016 - 2018 in International Journal of Applied Mechanics were transferred from Part 1 to Part 2 in order to be able to include the list of references associated with each relevant citation without exceeding 10000 pages in Part 1.

With few exceptions, from now on all future effort on documenting the “shell buckling/vibration” field will generate additional entries only in Part 2 and in the image galleries of this website: “book cover gallery”, “shell buckling people” and “shell buckling images”.

Introduction:

MAY 2017: NEW STRATEGY USED FOR SEARCHING FOR “BUCKLING/VIBRATION” PAPERS:
I search the journals listed next for papers on buckling/vibration of thin-walled structures. From 2017 on I will search only the following journal issues published in the most recent year. This is not a complete list of journals in which “buckling/vibration” papers may appear, but it may be that most of such papers will probably continue to appear in the following journals:

Thin-Walled Structures
Journal of Constructional Steel Research
Computers & Structures
International Journal of Solids and Structures
Searches (from 2017 and on) for “buckling/vibration” papers includes the following recently added journals:
ASME Journal of Pressure Vessel Technology
Advances in Structural Engineering
Archive of Applied Mechanics
Meccanica
Latin American Journal of Solids and Structures
Computational Mechanics
Structural Engineering and Mechanics
Mechanics of Composite Materials
Mechanics of Advanced Materials and Structures
Advanced Composite Materials
Composites Science and Technology
International Journal of Steel Structures
ASME Journal of Mechanical Design
Steel and Composite Structures
Journal of Thermal Stresses
Applied Mathematical Modelling
Archive of Computational Methods in Engineering
International Journal of Mechanics and Materials in Design
International Journal of Advanced Structural Engineering
Journal of Applied Mechanical Engineering
International Journal of Applied Mechanics and Engineering
Thin Solid Films
Extreme Mechanics Letters
Proceedings of the Royal Society Series A
Applied Physics Letters

For each of the original set of above journals (the list above the heading, “from 2017 on”) I have searched for relevant papers published from 2012 – 2016, placing them under headings and over footings given in bold-faced-16-point font such as:

Many papers published in the journal, Thin-Walled Structures (2012-2016):

End of many papers published in the journal, Thin-Walled Structures (2012-2016).

For each of the above journals and for successive years I plan to search for relevant papers published from 2017 and on, placing them under headings and over footings in bold-faced 16-point font such as:

More papers published in the journal, Thin-Walled Structures (2017 and on):

End of more papers published in the journal, Thin-Walled Structures (2017 and on).

In December, 2018 I added the following journals for a search of buckling/vibration of thin-walled structures:

Nonlinear Dynamics
Google the string, “Nonlinear Dynamics” and click on the entry, “Nonlinear Dynamics – Springer”, then click on “Browse Volumes and Issues”.

Smart Materials and Structures
Google the string, “Smart Materials and Structures”, then click on “Smart Materials and Structures – IOPscience”, then look for “Journal Archive” and choose the volume and year.

Results of this December 2018 search are presented in Part 2 because Part 1 already has the maximum allowable number of pages.

I will, from time to time, GOOGLE the “Images for shell buckling” site. This large gallery contains images of and from papers on shell buckling that I may want to add to the “Bibliography” and images from links that I may want to add to the list of “Shell Buckling Links”. In this way I will be able to add citations and abstracts of papers in journals not included in the above list of journals, as well as citations and abstracts of papers published before 2012 that have not been not already included in the my very long “Bibliography”. The “Images for shell buckling” gallery will also continue to be a source of images that I may want to add to the “Shell Buckling Images” and “Book Cover Gallery” sections of this website. Of course, I will continue to add material that you send to me. Also, I include in my citations “References listed at the end of the paper” if such a list is available online. In this way, over the years, I hope to include citations of almost all “buckling/vibration” papers. However, please do not simply assume that this bibliography contains citations of ALL “buckling/vibration” papers. It is certain that I have missed and doubtless will continue to miss more than a few papers. Therefore, in your researches during specific projects please use other sources than this “shell buckling” website.

BEFORE MAY 2017: THE OLD STRATEGY USED FOR SEARCHING FOR “BUCKLING” PAPERS:
PRE-2017 OLD STRATEGY:
The following list of books and papers, etc. was constructed and continues to be constructed in a not entirely but somewhat helter-skelter manner. I make special attempts to find citations of work by my friends and colleagues in the “shell buckling” field, or citations of papers that referenced the work of my friends and colleagues who have spent much of their careers pushing back the frontiers in that field. I make some attempt to group papers by the same first or second author together, but not always. I make a minor attempt to group papers on the same subject together, but this was a very sporadic attempt and often at odds with the “same author” strategy. In the section containing early works on shell buckling I made an attempt to arrange papers more-or-less chronologically. There is some tendency for the most recent papers to be placed lower down in the file.

Some papers on fluid-structure interaction are placed at the beginning of Part 2 of this huge bibliography.

In some cases the citation of a paper is followed by a list of references (almost always in 10-point font) given at the end of that paper. This I do only when I have free access to a “pdf” file of the paper, and only when I can “cut-and-paste” the references listed at the end of that paper.

I use Google Scholar to do the searches, with many “sub-searches” with the use of search strings such as “Koiter shell buckling”, “Hutchinson shell buckling”, “Budiansky shell buckling”, “Stein shell buckling”, “Singer shell buckling”, “Almroth shell buckling”, “Simmonds shell buckling”, “Arbocz shell buckling”, “Riks shell buckling”, “Rankin shell buckling”, “Babcock shell buckling”, “Hoff shell buckling”, “Knight shell buckling”, “Noor shell buckling”, “Weller shell buckling”, “Hilburger shell buckling”, “Belytschko shell buckling”, “Chamis shell buckling”, “Stricklin shell buckling”, “Cohen shell buckling”, and so on. These GOOGLE searches bring up not only papers on shell buckling authored by these well-known researchers but
also papers in which works by these well-known researchers are cited by other authors, in other words, lots of papers. I also used search strings such as “shell buckling images”, “shell stability”, “shell wrinkling”, “shell nonlinear vibration”, “shell nonlinear dynamic response”, “thin shell nonlinear”, “phd dissertations shell buckling”, “Buckling of stiffened panels”, “nanotube buckling”, “buckling of tubes”, “thin-walled column buckling”, etc.

There are so many papers and even books in the shell buckling field that I apologize in advance for doubtless missing many of your contributions. At the time this file was initially created (March - August, 2011) there were about 500000 “hits” when the search string, “shell buckling” was entered into “GOOGLE Scholar/advanced GOOGLE search”. Here I have not much more than just scratched the surface. The vast universe of papers on the buckling and vibration of shells is like a fractal: no matter how much I narrow the search within that universe (for examples, “postbuckling composite shells” or “buckling sandwich shells” or “thermal buckling shells”, or Hutchinson buckling shells”), there still exists a vast sub-universe with essentially the same creators and characteristics as the entire “shell buckling” universe. I cannot possibly explore these universes and sub-universes completely. The shell buckling universe and its sub-universes are probably expanding faster than the cosmos itself.

The search strings, “shell buckling”, etc. also pull up papers about linear and nonlinear plate and shell vibration and dynamic response, buckling and vibration of columns and plates, stiffened plates, columns made of thin-walled segments, crushing of energy absorbing structures such as tubes and sandwich walls, wrinkling, crashworthiness papers, papers about nonlinear deformations of plates and shells with cracks, papers about new finite elements used for nonlinear analysis, and papers regarding buckling of carbon nanotubes, thin films, droplets and other “soft” structures. Therefore, many papers on these topics are cited here in addition to papers from the more traditional field of shell buckling.

END OF THE DESCRIPTION OF THE OLD STRATEGY SEARCHING FOR “BUCKLING” PAPERS

This file is a work in progress. From time to time I add more citations as I find additional old papers and new papers recently appearing in the literature.

FROM MAY 2017: THE NEW STRATEGY SEARCHING FOR BUCKLING/VIBRATION PAPERS:

In particular, there are many shell, column and beam buckling papers in the journal, Thin-Walled Structures. For example, see the website: http://www.sciencedirect.com/science/journal/02638231/109
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many papers on buckling of thin-walled columns and beams in the journal, Journal of Constructional Steel Research. For example, see the website: http://www.sciencedirect.com/science/journal/0143974X/46/1
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).
There are many “buckling” papers published in the journal, **Computers & Structures**. For example, see the website: [http://www.sciencedirect.com/science/journal/00457949](http://www.sciencedirect.com/science/journal/00457949)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Solids and Structures**. For example, see the website [http://www.sciencedirect.com/science/journal/00207683](http://www.sciencedirect.com/science/journal/00207683)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Mechanical Sciences**. For example, see the website [http://www.sciencedirect.com/science/journal/00207403](http://www.sciencedirect.com/science/journal/00207403)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Non-Linear Mechanics**. For example, see the website [http://www.sciencedirect.com/science/journal/00207462](http://www.sciencedirect.com/science/journal/00207462)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Pressure Vessels and Piping**. For example, see the website [http://www.sciencedirect.com/science/journal/03080296](http://www.sciencedirect.com/science/journal/03080296)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Impact Engineering**. For example, see the website [http://www.sciencedirect.com/science/journal/0734743X](http://www.sciencedirect.com/science/journal/0734743X)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Engineering Science**. For example, see the website [http://www.sciencedirect.com/science/journal/00207225](http://www.sciencedirect.com/science/journal/00207225)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Engineering Structures**. For example, see the website [http://www.sciencedirect.com/science/journal/01410296](http://www.sciencedirect.com/science/journal/01410296)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Composite Structures**. For example, see the website [http://www.sciencedirect.com/science/journal/02638223](http://www.sciencedirect.com/science/journal/02638223)
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).
There are many “buckling” papers published in the journal, **Composites Part B Engineering**. For example, see the website [http://www.sciencedirect.com/science/journal/13598368](http://www.sciencedirect.com/science/journal/13598368)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Finite Elements in Analysis and Design**. For example, see the website [http://www.sciencedirect.com/science/journal/0168874X](http://www.sciencedirect.com/science/journal/0168874X)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Computer Methods in Applied Mechanics and Engineering**. For example, see the website [http://www.sciencedirect.com/science/journal/00457825](http://www.sciencedirect.com/science/journal/00457825)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Structures**. For example, see the website: [http://www.sciencedirect.com/science/journal/23520124](http://www.sciencedirect.com/science/journal/23520124)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Journal of the Mechanics and Physics of Solids**. For example, see the website [http://www.sciencedirect.com/science/journal/00225096](http://www.sciencedirect.com/science/journal/00225096)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Journal of Sound and Vibration**. For example, see the website [http://www.sciencedirect.com/science/journal/0022460X](http://www.sciencedirect.com/science/journal/0022460X)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Procedia Engineering**. For example, see the website [http://www.sciencedirect.com/science/journal/18777058](http://www.sciencedirect.com/science/journal/18777058)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **European Journal of Mechanics – A/Solids**. For example, see the website [http://www.sciencedirect.com/science/journal/09977538](http://www.sciencedirect.com/science/journal/09977538)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Acta Mechanica Solida Sinica**. For example, see the website [http://www.sciencedirect.com/journal/acta-mechanica-solida-sinica/issues](http://www.sciencedirect.com/journal/acta-mechanica-solida-sinica/issues)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Structural Stability and Dynamics**. Google the string: “International Journal of Structural Stability and Dynamics”, then click on the first subheading under the entry: “International Journal of Structural Stability and Dynamics (World…”.

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **International Journal of Applied Mechanics**. Google the string: “International Journal of Applied Mechanics”, then click on the second entry, which is: “International Journal of Applied Mechanics (World Scientific)”. These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **ASME Journal of Applied Mechanics**: For example, see the website [http://appliedmechanics.asmedigitalcollection.asme.org/issues.aspx](http://appliedmechanics.asmedigitalcollection.asme.org/issues.aspx)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many reviews of “buckling” papers published in the journal, **ASME Applied Mechanics Reviews**: For example, see the website [http://appliedmechanicsreviews.asmedigitalcollection.asme.org/issues.aspx](http://appliedmechanicsreviews.asmedigitalcollection.asme.org/issues.aspx)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Journal of Composite Materials**. Google the string: “Journal of Composite Materials”, then click on the third entry, which is: “Journal of Composite Materials – All Issues – SAGE Journals”

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Experimental Mechanics**. Google the string: “Experimental Mechanics”, then click on the first entry, “Experimental Mechanics – Springer”, then, on the resulting screen, click on “All Volumes & Issues” (located on the right-hand side of the screen near the top, in blue color)

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Acta Mechanica**.
Google the string: “Acta Mechanica”, then click on the first entry, “Acta Mechanica – Springer”, then, on the resulting screen, click on “Browse Volumes & Issues”.
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Acta Mechanica Sinica. Google the string: “Acta Mechanica Sinica”, then click on the first entry, “Acta Mechanica Sinica – Springer”, then, on the resulting screen, click on “All Volumes & Issues” (located on the right-hand side of the screen near the top, in blue color). These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, AIAA Journal. For example, see the website: Google the string: “AIAA Journal”, then scroll down for a list of all issues, each of which you can click on to see authors, titles and abstract of papers. These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, International Journal of Offshore and Polar Engineering. Google the string: “International Journal of Offshore and Polar Engineering”; click on one of the volumes/issues in the upper right-hand corner. These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, International Journal of Crashworthiness. Google the string: “International Journal of Crashworthiness”, then click on the entry, “International Journal of Crashworthiness – Taylor & Francis Online”; you can then click on any Volume/Issue. These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Marine Structures. For example, see the website: http://www.sciencedirect.com/science/journal/09518339 These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Ocean Engineering. For example, see the website: http://www.sciencedirect.com/science/journal/00298018
These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Aerospace Science and Technology. For example, see the website: http://www.sciencedirect.com/science/journal/12709638

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Curved and Layered Structures. For example, see the website: https://www.degruyter.com/view/j/clss

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, ASCE Journal of Structural Engineering. Google the string: “ASCE Journal of Structural Engineering”, then click on the entry, “ASCE Journal of Structural Engineering | ASCE Library”, then, on the resulting screen, click on “ALL ISSUES”. These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Journal of Sandwich Structures and Materials. For example, see the website: http://journals.sagepub.com/loi/jsm

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, ASME Journal of Pressure Vessel Technology. For example, see the website: http://pressurevesseltech.asmedigitalcollection.asme.org/issues.aspx

These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Advances in Structural Engineering. Google the string: “Advances in Structural Engineering”, then click on the entry: “Advances in Structural Engineering – All Issues – SAGE Journals” These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, Archive of Applied Mechanics. Google the string: “Archive of Applied Mechanics”, then click on the entry: “Archive of Applied Mechanics – Springer – Springer Link”; then click on “Browse Volumes & Issues”. These papers are cited here primarily in sections under bold-faced headings that start with the words, “many papers published” (2012-2016) and “more papers published” (2017 and on).
There are many “buckling” papers published in the journal, **Meccanica**.
Google the string: “Meccanica”, then click on the entry: “Meccanica – Springer – Springer Link”; then click on “Browse Volumes & Issues”.
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Latin American Journal of Solids and Structures**.
Google the string: “Latin American Journal of Solids and Structures”, then click on the item “Archives”
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Computational Mechanics**.
Google the string: “Computational Mechanics”, then click on the entry: “Computational Mechanics – Springer – Springer Link”; then click on “Browse Volumes & Issues”
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Structural Engineering and Mechanics**.
Google the string, “Structural Engineering and Mechanics”, then click on the entry, “Structural Engineering and Mechanics” | Korea Science” and see “Volume & Issues” on your screen
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on).

There are many “buckling” papers published in the journal, **Mechanics of Composite Materials**.
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal, **Mechanics of Advanced Materials and Structures**.
Google the string, “Mechanics of Advanced Materials and Structures”, then click on the entry, “Mechanics of Advanced Materials and Structures” and scroll down to “List of Issues”
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal, **Advanced Composite Materials**.
Google the string, “Advanced Composite Materials, then click on the entry, “Advanced Composite Materials – Taylor & Francis Online” and scroll down to “List of Issues”
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal, **Composites Science and Technology**.
Google the string, “Composites Science and Technology”, then click on the entry,
“Composites Science and Technology – ScienceDirect.com” and on that screen click on “All issues”
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal. *International Journal of Steel Structures.*
Google the string: “International Journal of Steel Structures”, then click on the entry: “International Journal of Steel Structures – Springer – Springer Link”; then click on “Browse Volumes & Issues”
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal, *ASME Journal of Mechanical Design.*
Google the string: “Journal of Mechanical Design”, then click on the entry: “Journal of Mechanical Design – The American Society of Mechanical….”, then find “Browse All Issues”
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal. *Steel and Composite Structures.*
Google the string, “Steel and Composite Structures”, then click on the entry, “Steel and Composite Structures” | Korea Science” and see “Volume & Issues” on your screen.
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal, *Journal of Thermal Stresses.*
Google the string, “Journal of Thermal Stresses, then click on the entry, “Journal of Thermal Stresses – Taylor & Francis Online”, and find the list of journal issues.
These papers are cited here primarily in sections under bold-faced headings that start with the words, “more papers published” (2017 and on)

There are many “buckling” papers published in the journal, *Applied Mathematical Modelling.*
Google the string, “Applied Mathematical Modelling”, then click on the entry, “Applied Mathematical Modelling | ScienceDirect.com” and scroll way down to “View all issues”

Here is an idea which may help to compensate for my lack of completeness. Any of you may email to me, David Bushnell (email address: bush@sonic.net) your curriculum vitae (CV). Please include a close-up (head and shoulders) photograph of yourself and of course a list of your publications concerned with buckling/vibration. I will then include your CV on this website in the section called “Shell Buckling People”. A portrait photograph of yourself will be a very important part of the future assemblage of “Shell Buckling People” on this website. Therefore, make sure to include it with your buckling CV. We “buckling people” should get to know one another better, and I feel that a close-up photograph of yourself is a significant part of that. I also encourage you to include with your “buckling CV” one or more pictures of buckled shells, either actual shells that buckled unexpectedly in the “real world” or buckled shells from laboratory experiments or buckled shells from the application of theories described in one or more of your papers. When you send me such images please include a complete citation of the source so that credit can be properly given. Images of this type will continue to improve this website and keep it up-to-date. During my searches of the “shell buckling” field I encounter many such images that I obtain from the internet for inclusion on this website.

The citations listed in this file are somewhat unusual in that many of them include the affiliations of the authors and the authors’ abstracts. Recently (2018 on) I no longer include authors’ affiliations, mostly because recent papers have so many authors. In this regard, perhaps one should try to cut down on the number of authors, simply acknowledging in an “Acknowledgment” section the efforts of those who played a minor role. This will probably be more difficult for papers that involve experiments because so much effort can be expended with so little to show for it.

Some advice about abstracts:
1. Do not include what is essentially the title of your paper as the first sentence in its abstract. Anyone who sees the abstract also sees the title.
3. Be specific. Avoid vague words such as “capacity” and “reliability”. Do you mean “linear buckling” or “non-linear buckling” or “plastic collapse” or some combination? In your description stay close to the physical world by naming specific phenomena.
4. “The analysis was verified by test cases.” Be more specific.
5. Do not include math symbols or equations in your abstract.
6. Compose the abstract as a single paragraph.

Organization of this file:
This very long file lists “shell buckling” citations in the following sections:
Section 1. Especially useful papers in my opinion
Section 2. A list of mainly books on plates and shells compiled by Hans Obrecht in 2001
Section 3. Some of the review articles in Applied Mechanics Reviews or elsewhere
Section 4. Articles that are partly review articles and that partly contribute new material
Section 5. Special issues of journals with a given theme
Section 6. Books on shell buckling or on subjects related in some way to shell buckling
Section 7. Some early work on buckling of plates and shells
Section 8. There follow many, many citations on buckling and vibration of columns, plates and shells

Section 8 is by far the longest section in this file.

******************* IMPORTANT NOTE ABOUT “DOI” *******************

What is a doi?

A digital object identifier (or doi) is a standard for persistently identifying electronic documents on a digital network. A typical use of a DOI is to give a scientific paper or article a unique identifying number that can be used by anyone to locate details of the paper, and possibly an electronic copy. Unlike the URL system used on the Internet for web pages, the DOI does not change over time, even if the article is relocated. This means that you can always find a document you have referenced even if the original publisher changes its URL.

The DOI consists of a unique alphanumeric character string divided in two parts: a prefix and a suffix.

For example, a complete DOI is:

10.1000/182

where:

10.1000 is the prefix, or "publisher ID", composed by a part identifying the string as a DOI (10) and a part identifying the organization/publisher of the document (1000);

182 is the suffix, or "item ID", identifying the single object. (Typical suffixes are longer than this example.)

The suffix is assigned by the publisher and must be unique within a prefix.

The International DOI Foundation (IDF), a non-profit organisation created in 1998, is the governance body of the DOI System, which safeguards all intellectual property rights relating to the DOI System. IDF supports the development and promotion of the Digital Object Identifier system as a common infrastructure for content management, and works to ensure that any improvements made to the DOI system (including creation, maintenance, registration, resolution and policymaking of DOIs) are available to any DOI registrant, and that no third party licenses might reasonably be required to practice the DOI standard.

Creating a DOI link
A digital object identifier (DOI) can be used to cite and link to electronic documents. A DOI is guaranteed never to change, so you can use it to link permanently to electronic documents.

To find a document using a DOI

1. Copy the DOI of the document you want to open.
   The correct format for citing a DOI is as follows: doi:10.1016/j.physletb.2003.10.071
2. Open the following DOI site in your browser:
   http://dx.doi.org
3. Enter the entire DOI citation in the text box provided, and then click Go.

Section 1: Some Especially Useful Papers in my opinion:

For an important review of NASA design recommendations relating to shell stability, see the file, 1998nasa.pdf, by Michael P. Nemeth and James H. Starnes, Jr.:

ABSTRACT: A summary of the existing NASA design criteria monographs for the design of buckling-resistant thin-shell structures is presented. Subsequent improvements in the analysis for nonlinear shell response are reviewed, and current issues in shell stability analysis are discussed. Examples of nonlinear shell responses that are not included in the existing shell design monographs are presented, and an approach for including reliability-based analysis procedures in the shell design process is discussed. Suggestions for conducting future shell experiments are presented, and proposed improvements to the NASA shell design criteria monographs are discussed.

http://handle.dtic.mil/100.2/ADA162723

ABSTRACT: This work summarizes the technical literature dealing with buckling and post-buckling behavior of laminated composite plates and shell panels. Emphasis is given to modern materials used in the aerospace industry having fiber-matrix constituents (e.g., glass-epoxy, boron-epoxy, graphite-epoxy, boron-aluminum), but other applications are also considered (e.g., plywood, paperboard). Geometric configurations taken up are either flat (plates) or cylindrically curved (shells), and have rectangular planform. All possible types of loading conditions and edge constraint conditions are considered. Both symmetrically and unsymmetrically laminated configurations are included, with symmetrical laminates represented by orthotropic or anisotropic plate or shell theory. Complicating effects dealt with include: internal holes, shear deformation, sandwich plates with soft cores, local instability, inelastic materials, hygrothermal effects and stiffeners. Approximately 400 references are used. Extension numerical results are presented in graphical and tabular form. Both theoretical and experimental results are summarized.

Jin Guang Teng (Department of Civil and Structural Engineering, Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong) “Buckling of thin shells: Recent advances and trends”, Applied Mech. Reviews, Vol. 49, No. 4, pp. 263-274, April 1996, DOI: 10.1115/1.3101927

ABSTRACT: This paper provides a review of recent research advances and trends in the area of thin shell buckling. Only the more important and interesting aspects of recent research, judged from a personal view point, are discussed. In particular, the following topics are given emphasis: (a) imperfections in real structures
and their influence; (b) buckling of shells under local/non-uniform loads and localized compressive stresses; and (c) the use of computer buckling analysis in the stability design of complex thin shell structures.

ABSTRACT: The perturbation method and the continuation method are the two most popular techniques for the solution of finite element equations that describe instability phenomena. This paper presents a summary of the principles involved and describes some trends in the development of these techniques.

ABSTRACT: Many shell stability problems can be analyzed following the quasi static approach, i.e. with methods that solve the static equations of equilibrium. This paper focuses on some particular points of this approach. There are cases, however, mode jumping for example, where the methods of statics do not longer suffice and where it becomes necessary to combine the methods of statics with procedures for the integration of the equations of motion. The latter idea is illustrated with an example that was analyzed with the shell finite element code STAGS.

ABSTRACT: This paper overviews the efforts that led to resolution of the 20th century conundrum in elastic stability of shells. In particular, the dramatic disagreement between theoretical and experimental results and the subsequent introduction of the empirical knockdown factor, is discussed in detail. The mismatch between theory and experiment was qualitatively explained by Warner Tjardus Koiter in his now famous thesis, as well as in the paper by Lloyd H. Donnell and C.C. Wan. However, these studies did not offer means for rigorous, theoretical derivation of the knockdown factor for the shells with generic imperfection patterns encountered in practice. Numerous attempts to resolve the conundrum via deterministic theoretical, experimental and probabilistic analyses remained unsuccessful. The conundrum consists in two facts. On one hand, it consists of the impossibility of using of hundreds and perhaps thousands of deterministic studies in predicting the rigorous knockdown factors. On the other hand, it lies in the fact that Wynstone Barrie Fraser and Bernard Budiansky (1969) [157] and numerous other investigators, although recognizing the need to utilize probabilistic approach to resolve the above conundrum, asserted that the buckling load of stochastic structures was a deterministic quantity. Some investigators suggested using that result as the design load. In 1979, this author lucked out on reliability-based theoretical means for derivation of the knockdown factor and its judicious allocation.

ABSTRACT: Current procedures of buckling load estimation for thin-walled structures may provide very conservative estimates. Their refinement offers the potential to use structure and material properties more efficiently. Due to the large variety of design variables, for example laminate layup in composite structures, a prohibitively large number of tests would be required for experimental assessment, and thus reliable numerical techniques are of particular interest. The purpose of this paper is to analyze different methods of numerical buckling load estimation, formulate simulation procedures suitable for commercial software and give recommendations regarding their application. All investigations have been carried out for cylindrical composite shells; however similar approaches are feasible for other structures as well. A single perturbation load approach is reproduced and modified. Buckling behavior for negative values of the perturbation load is examined and a pattern similar to a positive perturbation load is observed. Simulations with three perturbation forces show a decreased (i.e. more critical) value of the buckling load compared to the single perturbation load approach. Global and local dynamic perturbation approaches exhibit a behavior suitable for lower bound estimation for structures with arbitrary geometries.

ABSTRACT: Spherical composite ribbed shell is made of thin reinforced concrete shell and composite ribs, which has many advantages such as large span, high rigidity, and large bearing capacity and low cost. It is one of the urgent issues to considering the mechanical performance under dynamic loading. Based on nonlinear finite element theory, a numerical calculation model is built, and then the dynamic response of composite ribbed shell under step load and seismic wave are respectively discussed. The results shows: under the vertical step load, a positive symmetric deformation appeared in unstable status; under horizontal step loads, an anti symmetric deformation emerged. While as the seismic wave was exerting, structural damage caused by thin concrete shell damage and plastic deformation development, namely it was the synthetic action result of structural stiffness weaken and P-△ effect from geometric nonlinear, so structure damage was the comprehensive effect of strength failure and dynamic instable.

PARTIAL INTRODUCTION: In order to produce efficient, reliable designs & to avoid unexpected catastrophic failure of structures of which thin shells are important components, the engineer must understand the physics of shell buckling. The objective of this survey is to convey to the reader a “feel” for shell buckling, whether it be due to nonlinear collapse, bifurcation buckling, or a combination of these modes. …

(2) Chair of Computational Mechanics, Technical University of Munich, Germany

ABSTRACT: It is apparent that physics and numerics are strongly linked in every serious undertaking in computational mechanics. This is in particular pronounced when the matter of study excels through a very sophisticated, even sometimes tricky physical behaviour. Such a delicate characteristic is the trademark of shell structures, which are the most often used structural components in nature and technology. This outstanding position in the hierarchy of all structures is due to their curvature allowing to carry transverse loading in an optimal way by in-plane membrane actions, despite an often extreme slenderness. As typical for optimized systems their performance might be on the one hand excellent, but can also be extremely sensitive to certain parameter changes on the other hand. This prima donna like mechanical behaviour with all its sensitivities is of course carried over to any numerical scheme. In other words it is a fundamental precondition to understand the principle features of the load carrying mechanisms of shells before designing and applying any numerical formulation. The present study addresses this peculiar interrelation between physics and numerics. At first typical characteristics of shell structures are described; this include their benefits but also their extreme sensitivities. In the second part these aspects are reflected on related computational models and numerical procedures. This discussion is carried through a number of selected problems and examples. It need to be said that the paper is the outcome of a general plenary lecture addressing fundamental aspects rather than concentrating on a specific formulation or numerical scheme.

INTRODUCTION:

1.1 Historical Remarks

Thin-walled structures like plates and shells are the most common construction elements in nature and technology. This is independent of the specific scale; they might be small like cell membranes and tiny machine parts or very large like fuselages and cooling towers. This preference to apply walls as thin as possible is a natural optimization strategy to reduce dead load and to minimize construction material. In addition to the slenderness, the advantageous effect of curvature is utilized in shell structures allowing to carry transverse loading in an optimal way, a design principle already known to the ancient master builders. Their considerable heuristic knowledge allowed them to create remarkable buildings, like the Roman Pantheon (115–126) and the Haghia Sophia (532–537) in Constantinople, still existing today. It was not before the Renaissance that scientists began to mathematically idealize the structural response, a process that we denote nowadays as modeling and simulation.

Already, Leonardo da Vinci (1452–1519) stated (Codex Madrid I) a principle that later on emerged to a beam model. The subsequent process, associated with names like Galileo (1564–1642), Mariotte (1620–1684),
Leibniz (1646–1716), Jakob I Bernoulli (1654–1705), Euler (1707–1783), Coulomb (1736–1806), and Navier (1785–1836), led to what we call today Euler–Bernoulli beam theory (Timoshenko, 1953; Szabo, 1979). This development was driven by the ingenious ideas to condense the complex three-dimensional situation to the essential ingredients of structural response like stretching, bending, torsion, and so on, and to cast this into a manageable mathematical format. The inclusion of transverse shear deformation is attributed (1859) to Bresse (1822–1883) and extended (1921) to dynamics by Timoshenko (1878–1972), whose name has established itself as a common denomination for this model. Extensions to further effects like uniform and warping torsion, stability problems, cross-sectional distortion, and further refinements, for example, including higher-order kinematics, follows in the nineteenth and twentieth century.

The development of the theory of masonry arches and vaults had its own history, also starting with Leonardo da Vinci (for a detailed elaboration on this subject confer Benvenuto (1991)). The primary aspect in this context was the description of failure mechanisms, a problem investigated up to the present time (see e.g. the valuable work of Heyman). Also, Robert Hooke's (1635–1703) ‘Riddle of the Arch’ has to be referred to, phrased in a Latin anagram ‘Ut pendet continuum flexile, sic stabit contigum inversum rigidum’ (literally translated: As the flexible cable hangs, the inverted arch stands). It constitutes a form-finding principle for arches and shells (Mainstone, 1975), which became known as the inverted chain and membrane principle, often applied in the sequel. Christopher Wren's construction of St. Paul Cathedral in London, Poleni's experiment for the rehabilitation of the cupola of St. Peter in Rome, Rondelet's French Pantheon, Gaudi's work in Catalonia up to modern shell designs by Otto and Isler are based on this principle (Ramm and Reitinger, 1992).

The history of the development of two-dimensional plate theories has its own peculiarities (Timoshenko, 1953; Szabo, 1979). Inspired by Chladni's (1756–1827) experiments with vibrating plates, Jakob II Bernoulli (1759–1789) formulated a grid model of overlapping beams, neglecting the twisting mode. This was corrected by others later on. The related competition proposed by the French Academy and Sophie Germain's (1776–1831) various trials to win the prize and the involvement of Lagrange (1736–1813) became famous. They and others like Poisson (1781–1840) and Navier derived the proper differential equation; however, they still had some shortcomings in their result, in particular, with respect to the involved elastic constants. Kirchhoff (1824–1887) finally removed all doubts in 1850 (Kirchhoff, 1850) and is credited as the founder of modern plate theory. It took almost a century before E. Reissner (1913–1996) (Reissner, 1944; Reissner, 1945) and Mindlin (1906–1987) (Mindlin, 1951) extended the model including the role of transverse shear deformations. Innumerable modifications and extensions, like anisotropy, large deformation (v. Kármán plate theory), higher-order theories, and so on, have been derived over the years.

It is interesting that the initial derivation of a shell formulation was also motivated primarily by vibration problems. Euler developed in 1764 a model to simulate the tones of bells, cutting the axisymmetric structure into rings, applying curved beam models and leaving out the meridional effects. Also, here it took over a century before a consistent theory of thin shells had been derived by Love (1888) (August E. H. Love, 1863–1940). It is based on Kirchhoff's method and thus became known as the Kirchhoff–Love model. For a description of the subsequent emergence of this shell model and the related controversies among Love and his contemporaries on the role of the boundary conditions of both the membrane and the bending part (in particular Lord Rayleigh (1842–1919) and Lamb (1849–1934)), we refer to the article by Calladine (1988), which is worth reading. The need for detailed solutions has driven research in the first half of the twentieth century. Names like H. Reissner, Meissner, Geckeler, Flügge, Vlassov, Novozhilov have to be mentioned, to name just a few; later on further refinements have been introduced by E. Reissner, Gol'denveizer, Koiter, Naghdi, and many others. The inclusion of transverse shear deformations sometimes linked to the name of Naghdi today mostly is referred
to as a Reissner–Mindlin formulation, in recognition of their extended plate theories.

The series of names in connection with shell formulations could be continued forever; there are very few topics in structural mechanics where so many investigations have been published. Even for experts, it is hardly possible to have an overall view on the number of special finite element models developed so far. This is a strong indication for the complexity of the involved mechanics on the one hand and their practical relevance on the other hand.

It is obvious that the early developments of theories for thin-walled structures were governed primarily by the main applications in those times, namely, buildings in architecture. Since the industrial revolution, the picture changed completely: now other applications, for example, in mechanical engineering, in vehicle and aerospace industry, in biomechanics, and so on, became dominant and the driving force for further developments.

Large displacements, rotations and strains, buckling, composites, material nonlinearities, coupled problems, multiscale and multiphysics, solution methods, and higher-order formulations are a few keywords for problems that have been extensively investigated in the last few years. The finite element method as a discretization concept is absolutely predominant. An interesting example as to how the finite element developments have influenced the selection of specific structural models is the early shift from Kirchhoff–Love formulations to those with Reissner–Mindlin kinematics for plate and shell elements. It is motivated mainly by the reduced compatibility requirements, although from the practical point of application, the Kirchhoff–Love model is often sufficient.

In times where computer capacity has become so powerful and the simulation tools have reached such a high level of sophistication, we should not forget the main driving force of our ancestors: concentration on the essentials and reduction to the principal mechanical behavior of thin-walled structures (Ramm and Wall, 2004).

1.2. Overview

This paper concentrates on the mathematical modeling of nonlinear mechanics of thin-walled structures in view of associated finite element formulations. This means that we will primarily focus on formulations for structural models as prerequisite for derivation of finite elements, rather than specific ‘elementology’. The main emphasis is put on shells, including the special case of flat plates, turning into shells anyway in the nonlinear regime. The derivations are kept as general as possible, including thick and layered shells (laminated or sandwich structures), as well as anisotropic and inhomogeneous materials from the outset. Throughout Section 4.4, we will specify the corresponding restrictions and assumptions to obtain the classical 5-parameter shell formulation predominantly used for standard shell problems in the context of finite element analysis.

In most part of the text, we restrict ourselves to static problems within the framework of geometrically nonlinear elasticity, neglecting time dependence and inertia effects. The extension into the materially nonlinear area is a straightforward procedure. It is believed that this does not mean a too strong restriction in view of the underlying motivation.

It is a well cultivated tradition to let review articles start with the remark that a complete overview of existing methods and appropriate literature is utterly impossible. The multitude of existing concepts, methods, and implementations, as well as scientific papers, text books, and yet other review articles would effectively prohibit an exhaustive overview. J. E. Marsden and T. J. R. Hughes remark in what they call the ‘disclaimer’ of their
famous book on Mathematical Foundations of Elasticity (Marsden and Hughes, 1983) that

‘This book is neither complete nor unbiased. Furthermore, we have not mentioned many deep and highly erudite works, nor have we elucidated alternative approaches to the subject. Any historical comments we make on subjects prior to 1960 are probably wrong, and credits to some theorems may be incorrectly assigned.’

Although the present paper is neither a book nor covers such a broad field like the textbook by Marsden and Hughes (1983), it clearly shares the quoted property. We therefore directly head toward the ideas and inspirations driving the authors during the compilation of the paper at hand.

Motivations for concerning oneself with the present subject are many. They might be of purely scientific nature or driven by the need to find the necessary level for the mechanical content of a model or to have a reliable element as a tool for certain applications one might have in mind. Interest in the mathematical formulation and resulting numerical properties of finite elements for thin-walled structures may also arise when simply applying certain finite element formulations available in scientific or commercial codes. While trying to provide useful information for practitioners and users of commercial finite element codes, this treatise clearly addresses a readership with a scientific background, both things not being mutually exclusive anyway.

When developing and applying a finite element formulation for thin-walled structures, one comes across a couple of questions. Which mechanical effects should be included and which can be neglected? Is it better to start from a shell theory or develop continuum-based elements along the lines of the degenerated solid approach? And what about geometrically exact models? Which simplifications are useful – and admissible? Which consequences does the formulation have for the finite element model? Which parameterization of degrees of freedom are sensible for the applications one has in mind? Should drilling degrees of freedom be included in a shell formulation or not? There are many, many more questions.

It is in this spirit that we try to give an overview of the various decisions that one implicitly makes when choosing a specific theory or finite element formulation, respectively. Although such an overview is necessarily incomplete, it should not cover only a mere register of umpteen different plate and shell finite elements along with their alleged pros, cons, and limitations; to be even more specific, this aspect will be very limited in the present contribution.

By doing this, we carefully separate model decisions and the finite element formulation. The former addresses those approximations that are made while formulating the continuous theory. The latter is concerned with additional approximation errors, coming into play along with discretization and finite element formulation. While these numerical errors eventually vanish with mesh refinement, the model errors, inherent to the theory, persist. Distinguishing this is crucial for a sophisticated determination of feasible methods and a competent interpretation of numerical results.

References: The list of references is very long and would require a lot of editing to conform to the format of this bibliography.

-----end of the the Bischoff et al entry-----
ABSTRACT: Recent advances in shell buckling research are reviewed. Five separate subject areas are covered: elastic postbuckling behavior and imperfection sensitivity, plastic buckling, dynamic buckling, experiments and computations. Recent history of the research is presented emphasizing important advances in understanding. Areas of needed research and current trends are pointed out.

ABSTRACT: The present paper provides a unified, general presentation of the basic theory of the buckling and post-buckling behavior of elastic structures in a form suitable for application to a wide variety of special problems. The notation of functional analysis is used for this purpose. Before the general analysis, simple conceptual models are used to elucidate the basic concepts of bifurcation buckling, snap buckling, imperfection sensitivity, load-shortening relations, and stability. The energy approach, the virtual-work approach, and mode interaction are discussed. The derivations and results are applicable to continua and finite-dimensional systems. The virtual-work and energy approaches are given separate treatments, but their equivalence is made explicit. The basic concepts of stability occupy a secondary position in the present approach.

ABSTRACT: The weights of optimal compression structures of several types are estimated. Minimum weights of columns having solid square or circular cross-sections are compared with those of similar metal–foam-filled tubes, hollow tubes and tubes whose walls are foam-core sandwiches. Similarly, the minimum (of near-minimum) weights of wide sandwich compression panels are studied along with those of hat-stiffened, solid-skin panels and panels in which the skins and stiffeners are themselves metal–foam-core sandwiches. In these studies, weight comparisons are made on the basis of appropriate structural indices and compressive strength is the only failure criterion. These studies provide baseline comparisons that ignore other possible design constraints, such as longitudinal stiffness, minimum gage and cost.

ABSTRACT: A review of experimental data and elementary theoretical formulas for compressive failure of polymer matrix fibre composites indicates that the dominant failure mode is by plastic kinking. Initial local fibre misalignment plays a central role in the plastic kinking process. Theoretical analyses and numerical results for compressive kinking are presented, encompassing effects of strain-hardening, kink inclination, and applied shear stress. The assumption of rigid fibres is assessed critically, and the legitimacy of its use for polymer matrix composites is established.

PARTIAL ABSTRACT: The overall performance of sandwich structures depends in general on the properties of the facesheets, the core, the adhesive bonding the core to the skins, as well as geometrical dimensions. Sandwich beams under general bending, shear and in-plane loading display various failure modes. Their initiation, propagation and interaction depend on the constituent material properties, geometry, and type of loading. Failure modes and their initiation can be predicted by conducting a thorough stress analysis and applying appropriate failure criteria in the critical regions of the beam. This analysis is difficult because of the nonlinear and inelastic behavior of the constituent materials and the complex interactions of failure modes. Possible failure modes include tensile or compressive failure of the facesheets, debonding at the core/facesheet interface, indentation failure under localized loading, core failure, wrinkling of the compression facesheet, and global buckling. In the present work failure modes of sandwich beams were studied. Facesheet materials were typically unidirectional and carbon fabric/epoxy and glass fab-ric/vinylester. Core materials discussed include four types of a closed-cell PVC foam (Divinycell H80, H100, H160 and H250, with densities of 80, 100, 160 and 250 kg/m$^3$, respectively) and balsa wood. The facesheet and core materials were fully characterized mechanically. The various failure modes were studied separately and both initiation and ultimate failure were determined. Following initiation of a particular failure mode, this mode may trigger and interact with other modes and final failure may follow a different failure path. The transition from one failure mode to another for varying loading or state of stress and beam dimensions was discussed. Experimental results were compared with analytical predictions.

VI. Summary and Discussion
ABSTRACT: Koiter [1] was the first to formulate an asymptotic expansion to investigate postbuckling behavior and imperfection sensitivity of elastic structures. Since then, a large number of analyses of particular structures have appeared as well as some new expansions aimed at specific problems, such as interaction between buckling modes associated with simultaneous or nearly simultaneous buckling modes. In this contribution, various methods of this kind are discussed and compared as regards applicability and ease of use. Focus will be on Koiter's slowly varying local mode amplitude [2] and [3], on Byskov & Hutchinson's expansion [4] and on Peek & Kheyrkhahan's method [5], which enlarged the scope of the previous expansions in that it covers nonlinear prebuckling states, also. Other important contributions a number of which are based on these methods are also discussed. On the other hand, many important works, e.g. the comprehensive paper by Hunt [6] will not be mentioned in any detail. The accuracy of the methods as well as their mathematical complexity and ease of use are compared. Finally, in view of today's inexpensive and powerful computers, an obvious question is concerned with whether full analyses must always be preferred because asymptotic expansions are obsolete.

ABSTRACT: Carbon nanotubes subject to large deformations reversibly switch into different morphological patterns. Each shape change corresponds to an abrupt release of energy and a singularity in the stress-strain curve. These transformations, simulated using a realistic many-body potential, are explained by a continuum shell model. With properly chosen parameters, the model provides a remarkably accurate “roadmap” of nanotube behavior beyond Hooke's law.

ABSTRACT: The paper attempts a broad overview of the vast field of stability of structures, including elastic and anelastic structures, static and dynamic response, linear and non-linear behavior, energy approach, thermodynamic aspects, creep stability and fracture or damage-induced instability. The importance of stability theory to various fields of engineering and applied science is pointed out and the history of the discipline is briefly sketched. The principal accomplishments are succinctly reviewed, and fruitful recent trends, particularly the stability analysis of damage localization and fracture, are emphasized.

Object and Scope of the Project:
The main objective of this study is to develop a set of numerical methods suitable for investigating the load-deflection and bifurcation characteristics of structures for which significant nonlinear behavior is possible. The methods are applicable to a wide variety of structures, but will be examined in detail only with reference to one of the simplest types of structures possessing the necessary complications in behavior - the planar arch under a concentrated load.

ABSTRACT: A version of nonlocal elasticity theory is employed to develop a nonlocal Benoulli/Euler beam model. Some representative problems are solved to illustrate the magnitude of predicted nonlocal effects. Particular attention is paid to cantilever beams which are often used as actuators in small scale systems.

ABSTRACT: Most natural (or biological) materials are complex composites whose mechanical properties are often outstanding, considering the weak constituents from which they are assembled. These complex structures, which have risen from hundreds of million years of evolution, are inspiring Materials Scientists in the design of novel materials. Their defining characteristics, hierarchy, multifunctionality, and self-healing capability, are illustrated. Self-organization is also a fundamental feature of many biological materials and the manner by which the structures are assembled from the molecular level up. The basic building blocks are described, starting with the 20 amino acids and proceeding to polypeptides, polysaccharides, and polypeptides–saccharides. These, on their turn, compose the basic proteins, which are the primary constituents of ‘soft tissues’ and are also present in most biominerals. There are over 1000 proteins, and we describe only the principal ones, with emphasis on collagen, chitin, keratin, and elastin. The ‘hard’ phases are primarily strengthened by minerals, which nucleate and grow in a biomediated environment that determines the size, shape and distribution of individual crystals. The most important mineral phases are discussed: hydroxyapatite, silica, and aragonite. Using the classification of Wegst and Ashby, the principal mechanical characteristics and structures of biological ceramics, polymer composites, elastomers, and cellular materials are presented. Selected systems in each class are described with emphasis on the relationship between their structure and mechanical response. A fifth class is added to this: functional biological materials, which have a structure developed for a specific function: adhesion, optical properties, etc. An outgrowth of this effort is the search for bioinspired materials and structures. Traditional approaches focus on design methodologies of biological materials using conventional synthetic materials. The new frontiers reside in the synthesis of bioinspired materials through processes that are characteristic of biological systems; these involve nanoscale self-assembly of the components and the development of hierarchical structures. Although this approach is still in its infancy, it will eventually lead to a plethora of new materials systems as we elucidate the fundamental mechanisms of growth and the structure of biological systems.

ABSTRACT: Complete spherical shells with radius-to-thickness ratios of from 1570 to 2120 were produced by electroforming. For specimens of good quality and for optimum testing conditions, buckling pressures up to 86 percent of the classical value were obtained. The effect of loading-system characteristics was examined by pressurizing spherical shells in rigid and soft systems and no difference in buckling pressure was observed. It
was found that buckling behavior is strongly influenced by the nature and severity of flaws or imperfections; i.e., low buckling pressures can be correlated with the presence of severe flaws or nonuniformities.

References listed at the end of the paper:

ABSTRACT: Buckling of a series of thin-metal, shallow spherical shells under a uniform hydrostatic pressure has been investigated. Stress and deformation histories, as well as the critical buckling pressure and the post-buckling behavior, have been determined. Comparisons with theoretical analyses for buckling of spherical caps are given. Results are presented for an initial phase of a stability study of truncated conical sections which have been subjected to combinations of axial load and lateral pressure. A series of roll-formed and butt-welded, truncated aluminum conical shells with a 75-deg base angle have been tested. Buckle modes for axial-load condition alone, lateral-pressure load alone and combinations of these loading conditions are described. Interaction curves for the conditions investigated are given.

Photographic sequences show the transition from the unbuckled state to the fully buckled configuration for four types of loading: axial compression, torsion, external (hydrostatic) pressure and a suddenly applied external pressure.

ABSTRACT: In order to better understand the mechanism of elastic shell buckling, photographs of the buckling process were obtained for thin cylindrical shells subjected to four types of loading: axial compression, torsion, external (hydrostatic) pressure and a suddenly applied external pressure.

References listed at the end of the paper:

Chuen-Yuan Chia, 1967, Finite deflections of thin shallow spherical shells under axisymmetric line load and uniform pressure, ASME J. Appl. Mech., 34(4), 1022-1024,

ABSTRACT: The problem of the finite displacement and buckling, of a shallow spherical dome is investigated both theoretically and experimentally. Experimental results seem to indicate that the classical criterion of buckling is applicable to very shallow spherical domes for which the theoretical calculation was made. A transition to energy criterion for higher domes is also indicated.

ABSTRACT: Expressions for the physical tangential and bending strains of nonlinear thin elastic shell theory in nonorthogonal coordinates are derived in a new, relatively compact form. The geometric and physical significance of the results is interpreted, where possible. In addition, the quantities describing the differential geometry of a deformed surface are also given. All results obtained are exact in the sense that no restrictions are imposed on the magnitude of strains in the derivations. The expressions for the nonlinear case are compared with the corresponding formulas of the linear theory. The results obtained together with further results to be published on the strains of the parallel surface, the statics of shells, and constitutive relations find direct application in the analysis of the nonlinear behavior of thin shells.

ABSTRACT: Elastic stability of clamped shallow spherical shells subjected to a small finite-area load at the apex is studied experimentally. Upper and lower critical buckling loads and prebuckled and postbuckled deflections are found for λ between 10 and 17. Buckling modes have been observed and defined. Nonaxisymmetric deformations are noted. Shells for λ less than 8 1/2 exhibit plastic behavior and do not buckle.

ABSTRACT: The European Standard for Shell Strength and Stability has many provisions for the global analysis of shell structures using finite element analysis. Three alternative treatments are permitted: a simple linear analysis (LA) giving stress resultants to be compared with simple algebraic hand calculation strength assessment rules, a fully fledged nonlinear analysis, with material and geometric nonlinearities as well as properly characterised imperfections (GMNIA), and an intermediate treatment that requires only two strength assessments: linear bifurcation (LBA) and plastic limit (MNA). Because of the sensitivity of shell buckling to different forms and different amplitudes of imperfection, which depend strongly on the stress state, the GMNIA procedure is very onerous. This paper gives a brief outline of the design process and the relationship between algebraic and computational strength assessments. It then discusses the challenges facing the user of the LBA-MNA procedure and resolves some of the uncertainties surrounding it.

Section 3: Some of the Review Articles in Applied Mechanics Reviews or Elsewhere

N. J. Hoff, “A survey of the theories of creep buckling”, AFOSR-TN-60-382; SUDAER-80, June 1, 1958 ABSTRACT: A survey is presented of the theories of buckling of structural elements whose material is subject to creep deformations. Two fundamentally different approaches to the solution of the buckling problem are discussed. In one, the structural element is assumed to be perfect and perfectly centered under the load and buckling is initiated by a disturbance in the configuration. In the second, the creep deformations begin in consequence of the deviation of the un loaded centerline or median plane of the structural eleme from the line of
load application. In both cases the element has a finite lifetime. A critical time of creep buckling is defined beyond which the element cannot be used to carry the prescribed loads.

ABSTRACT: The purpose of the present survey is to review the analysis of composite materials from the applied mechanics and engineering science point of view. The subjects under consideration will be analysis of the following properties of various kinds of composite materials: elasticity, thermal expansion, moisture swelling, viscoelasticity, conductivity (which includes, by mathematical analogy, dielectrics, magnetics, and diffusion), static strength, and fatigue failure.

ABSTRACT: A survey is presented which includes the buckling of shells under loads for which the shell is sensitive to initial imperfections. Results for such cases show that improvements in experiment and theory have produced previously unobtainable agreement. The necessity of the correct (and consistent) theoretical specification of boundary conditions is then demonstrated. Recent stiffened cylinder results are surveyed to expose the large effects on the buckling strength of internal or external stiffening, axial load applied eccentric to the wall neutral surface, and the addition of small meridional curvature.

ABSTRACT: A brief description of the essential nature of shell theory and the shell equations is followed by a survey, with examples, of the types of shell problems that are of important concern to the structural designer and, therefore, of interest to the shell analyst. The principal approaches to the shell problem solution are
outlined and some of the important effects that the computer has had on shell analysis and the analyst are
discussed. Deficiencies in shell technology, requiring additional research, are indicated.

ABSTRACT: The concept of finite elements for the analysis of shells is developed here with several important
advances. Firstly, the Kirchhoff theory of shells is refined to include a transverse shear deformation. The refined
theory admits simpler approximating functions while preserving continuity at the intersections of elements.
Secondly, the motion of the element is decomposed into a rigid body motion followed by a deformation. The
decomposition serves to extend existing formulations for linearly elastic elements to problems involving finite
rotations and buckling. Thirdly, the Lagrange equations are introduced to derive the equations of the discrete
system. The method yields the consistent inertial terms for any manner of motion, oscillatory or transient.
Finally, the simplest approximating polynomials are introduced in the context of the shear-deformation theory.
Further simplification is achieved by the introduction of constraints analogous to the Kirchhoff hypothesis of
the continuum theory. The constraints provide a rational basis for neglecting the contribution of transverse shear
in the strain energy. The resulting approximation converges rapidly to the Kirchhoff theory for examples cited.

Carlos A. Felippa (1) and Ray W. Clough (2)
INTRODUCTION: The finite element method (FEM) is a numerical discretization procedure which permits the analysis of complex boundary value problems by an extension of the techniques originally used in the structural analysis of ordinary framed systems. The method has been extensively used in the field of structural mechanics, especially by the aircraft industry, but it has recently been applied to a wide range of nonstructural problems. The initial development of the FEM in the field of structural mechanics can be traced back to efforts, in the early 1950s, to formulate a satisfactory numerical procedure for the stress analysis of airplane wing panels [1]. The name of the method was introduced in [2], which was concerned with more general civil engineering applications. Two parallel developments were responsible for the widespread acceptance of the method: (a) The formulation of the matrix transformation theory of structures [3,4], which provided a very efficient and elegant means for simplifying the notation and organizing the computations. (b) The introduction of high-speed digital computers.

The purpose of this paper is to describe the mathematical foundations of the FEM and to present a brief summary of techniques for its practical application. In addition, results of a few specific FEM analyses are presented which demonstrate its versatility and accuracy, and also the basic steps in a FEM computer program are listed and discussed. A rather extensive list of references is included at the end of the paper in order to make available the wide and varied body of literature which already has been published on this rather new analytical technique.

ABSTRACT: This paper contains an assessment of current shell analysis capability. The assessment is based on work conducted at the Lockheed Palo Alto Research Laboratory under contract to the Air Force Flight Dynamics Laboratory. In addition to surveying the open literature, information for the study was gathered during a series of visits made to organisations throughout the United States at which there is an active shell analysis research effort. More than 40 industrial concerns, government agencies and universities have been visited to date. During each visit, technical personnel working in the area of shell analysis were interviewed to determine the scope of their present analysis capability, to learn of current research activities and to discuss computer methods of shell analysis in general.

ABSTRACT: A development of the finite element method for thin shell instability analysis is presented, covering three principal aspects:
1. representation of shell geometry
2. representation of element behavior
3. algorithmic tools for solution of the large-order systems of nonlinear algebraic equations which characterize various phases of shell instability.

Two shell elements are described, an arbitrary quadrilateral and a triangle, and numerical results are presented for two widely-employed comparison problems for linear (stable) analysis. Two shell problems which include instability effects are also solved.

ABSTRACT: Fifteen years of research, development, and application of the finite element concept, primarily to structural analysis, has yielded a host of techniques for computer implementation. The importance of using these techniques is shown by an estimated reduction in total computer costs by a factor of 20 over not using them. This paper describes the techniques which play an important role in currently available computer software. It indicates research work in the engineering literature which can be expected to stimulate development of new techniques in the next decade. It concludes that the thrust for better techniques will be provided by the expanding need for software in newer applications such as nuclear fusion, fracture mechanics, bioengineering simulations, and vehicle crashes. New techniques will yield computer software which more highly automates finite element use, will more efficiently solve large sets of equations, and which will be engineering discipline transportable.

David Bushnell (Lockheed Missiles and Space Company, Palo Alto, California USA), “Thin shells”. In Programs, Surveys, Assessments, and Availability, edited by Walter Pilkey and Nicholas Perrone, University of Virginia Press, 1974

ABSTRACT: A brief review of the available static buckling theory for both geometrically ‘perfect’ and ‘imperfect’ anisotropic composite circular cylinders is presented for various loading configurations. For comparison purposes, relevant experimental data are discussed, including recent combined loading test results and recommendations are made concerning the design of composite cylinders.

ABSTRACT: This report summarizes the first phase of a study of nonlinear structural analysis computer codes for rocket nozzle stress analysis. A brief summary of nonlinear structural mechanics is given, along with a discussion of features desired for rocket nozzle thermomechanical stress analysis. Several computer codes are evaluated, and four codes are selected for further study in a subsequent phase of this work. Two of the selected codes employed linear elastic material behavior, while the remaining codes employed fully nonlinear behavior. The codes selected for this study were SAAS III, TEXGAP, NONSAP, and NEPSAP. It should be noted that none of the codes selected for this study contained all of the features desired for structural analysis of modern rocket nozzles; however, it is anticipated that future versions of these codes will contain the desired features.

ABSTRACT: Advances in the limits of structural use in the aereospace and nuclear power industries over the past years have increased the requirements upon the applicable analytical computer programs to include accurate capabilities for inelastic and transient dynamic analyses. In many minds, however, this advanced capability is unequivocally linked with the large scale, general purpose, finite element programs. This idea is also combined with the view that such analyses are therefore prohibitively expensive and should be relegated to the “last resort” classification. While this, in the general sense, may indeed be the case, if the user needs only to analyze structures falling into limited categories, however, he may find that a variety of smaller special purpose programs are available which do not put an undue strain upon his resources. One such structural category is shells of revolution. This survey of programs will concentrate upon the analytical tools which have been developed predominantly for shells of revolution. The survey will be subdivided into three parts: (a) consideration of programs for transient dynamic analysis; (b) consideration of programs for inelastic analysis and finally; (c) consideration of programs capable of dynamic plasticity analysis. In each part, programs based upon finite difference, finite element, and numerical integration methods will be considered. The programs will be compared on the basis of analytical capabilities, and ease of idealization and use. In each part of the survey sample problems will be utilized to exemplify the state-of-the-art.

ABSTRACT: The safety analysis of nuclear reactors often involves the solution of non-linear, transient structure-continuum problems. Many general-purpose and special-purpose programs are available for this class
of problems. The methods of integration found in these programs are described, particularly from the viewpoint of computational efficiency for the various classes of problems that are found in reactor safety analysis. These methods are subdivided into two categories: explicit and implicit. The methods are summarized along with their advantages and disadvantages and some recent results on their stability and accuracy. Customary practice in the use of these methods is outlined. The programs used in reactor structural safety analysis are surveyed and their salient features tabulated.

ABSTRACT: This paper presents a survey of the formulations and solution procedures for nonlinear static and dynamic structural analysis. The formulations covered include the pseudo force method, the total Lagrangian method, the updated Lagrangian method, and the convected coordinate method. The relationship of each principle to the basic principle of virtual work is presented. For static analysis, the solution by direct minimization of the total potential, Newton-Raphson and modified Newton-Raphson, and the first and second order self correcting method are reviewed and put in proper perspective. It is concluded that the most efficient methods for static problems are the modified Newton-Raphson and the first order self correcting methods. For dynamic nonlinear analysis, a new method based on modal analysis using the pseudo force method is presented. Numerical results for the highly nonlinear dynamic response of a shallow cap (lambda = 6) under a step load at the apex shows the method to be 5 times faster than the Houbolt solution procedure. Other methods surveyed include the Newmark beta method, the Wilson method, central differences, and the stiffly stable solution procedure of Park.

ABSTRACT: The paper presents a classification of mathematical commonly encountered in connection with solution of non-linear finite element problems. The principal methods for numerical solution of the non-linear equations are surveyed and discussed. Special emphasis is placed upon the description of an automatic load incrementation procedure with equilibrium iterations. It is shown how this algorithm can be adapted for solving problems involving instabilities, snap-through and snap-back. A simple scalar quantity denoted the current stiffness parameter is suggested; this parameter is used to characterize the overall behaviour of non-linear problems. It can also be used as a steering parameter in the solution process. The use of the present technique is illustrated by several examples.

ABSTRACT: On the basis of a survey conducted in 1974 [1] on the availability and capability of general
purpose programs for plastic analysis, it is safe to assume that there are now a vast body of users of such programs. The objective of this paper is to familiarize these users with the assumptions and models generally employed in describing nonlinear material behavior. The treatment of plasticity within static and dynamic structural analysis is briefly reviewed with the discussion focused on some recent theoretical and computational advances. Some prophetic comments are given that are concerned with the future direction of existing capabilities and problem areas that will benefit from their extensions.

Leissa, A. W., “An Interpretive Study of Plate and Shell Buckling”, Ohio State University Research Foundation, Columbus, 10 June 1983, Accession Number: ADA140487, Handle / proxy Url: http://handle.dtic.mil/100.2/ADA140487
ABSTRACT: The objective of the proposed research was to search the literature and locate all information relevant to plate and shell buckling; to collect the relevant journal articles, books, reports, theses, conference proceeding papers; to digest, summarize, organize and integrate the useful knowledge found and to make interpretative assessments; to determine problems where further research is needed; to produce a typed manuscript and ink drawings suitable for publishing a set of monographs; to clarify and unify the fields of plate and shell buckling.

ABSTRACT: A brief overview is presented of considerations involved in the buckling of composite plates made of laminae having continuous, parallel fibers. Such plates are governed by orthotropic or anisotropic plate buckling theory for laminates which are symmetrically stacked with respect to the plate midplane. Unsymmetric laminates require a more complicated theory with bending-stretching coupling. Additional complicating factors are considered, including: interior holes, shear deformation, sandwich construction involving other materials, local effects, nonlinear stress-strain relationships, hygrothermal effects, and external stiffeners. Postbuckling behavior and the effects of initial imperfections are also described. Some representative results from the extensive literature (352 references) are included to aid in describing the various effects.
PARTIAL INTRODUCTION: In order to produce efficient, reliable designs & to avoid unexpected catastrophic failure of structures of which thin shells are important components, the engineer must understand the physics of shell buckling. The objective of this survey is to convey to the reader a “feel” for shell buckling, whether it be due to nonlinear collapse, bifurcation buckling, or a combination of these modes. … (list of references is given below, at the end of the section, “Early works…”).

ABSTRACT: A brief survey of plastic buckling of axially compressed cylindrical shells is given. Results of nonlinear finite element analyses of several axially compressed, ring-stiffened, steel, cylindrical shells are presented, including comparisons with tests conducted at Chicago Bridge and Iron Co. and at the Los Alamos National Laboratory (LANL). Some of the LANL specimens with radius-to-thickness ratio of about 450 have reinforced circular openings that cut across various numbers of ring stiffeners. These cylindrical shells are loaded by enforced axial displacement applied to thick aluminum end plates halfway between the axis of
revolution and the shell wall. Measured imperfections are included in the analysis of one ring-stiffened specimen without any cutout. Inclusion of the imperfection field reduces the predicted collapse load by only eight percent. Reinforced openings that cut one or two or three rings reduce the collapse load by 14, 21 and 22 percent, respectively. Agreement between test and theory for the nonuniformly compressed LANL specimens is within 14 percent, even with initial imperfections neglected in the analysis.

ABSTRACT: The phenomenon of static collapse, henceforth called ‘buckling’, is first illustrated by the behavior of a fairly thick cylindrical shell, which under axial compression deforms at first axisymmetrically and later nonaxisymmetrically. Thus, static buckling encompasses two modes of behavior, nonlinear collapse at the maximum point in a load versus deflection curve and bifurcation buckling. Accurate prediction of critical loads corresponding to either mode in the plastic range of material behavior requires a simultaneous accounting for moderately large deflections and nonlinear, irreversible, path-dependent material. A survey is given of plastic buckling, which spans three areas: asymptotic analysis of postbifurcation behavior of perfect and imperfect simple structures, general nonlinear analysis of arbitrary structures, and nonlinear analysis for collapse at a maximum load and bifurcation buckling of shells of revolution. In the survey of general nonlinear structural analysis, some emphasis is given to strategies for solving the governing nonlinear equations incrementally. Numerous examples, generated primarily with the STAGS computer program, which was developed by Almroth and his colleagues, reveal many complex modes of buckling behavior.

ABSTRACT: A comprehensive survey is provided for the formulation and solution techniques of finite element applications in nonlinear continuum mechanics problems. The survey discusses the Lagrangian, the updated Lagrangian, and the Eulerian formulations. It is shown that many analysts describe relative or updated Lagrangian formulation under the name of Eulerian formulation. Hence, little effort has been devoted to the development of a consistent Eulerian formulation. The applications, limitations and suitability of each formulation to both material and geometrical nonlinear problems are discussed. In the solution methods, exact equilibrium, approximate equilibrium and self-correcting techniques are discussed. An emphasis is given to the applicability of these methods to particular nonlinear problems and to recent developments and modifications of each method to suit a particular nonlinear field.

Knight, Norman F, Jr and Starnes, James H, Jr, “Developments in Cylindrical Shell Stability Analysis”, NASA no. 19980019015. Stability Analysis of Plates and Shells; UNITED STATES; 1998

ABSTRACT: The paper attempts a broad overview of the vast field of stability of structures, including elastic and anelastic structures, static and dynamic response, linear and non-linear behavior, energy approach, thermodynamic aspects, creep stability and fracture or damage-induced instability. The importance of stability theory to various fields of engineering and applied science is pointed out and the history of the discipline is briefly sketched. The principal accomplishments are succinctly reviewed, and fruitful recent trends, particularly the stability analysis of damage localization and fracture, are emphasized.
(Reference listed at the end of this paper are included in the “Bazant” citation near the end of Section 1)

ABSTRACT: This article attempts to review the main results in the vast field of stability of structures. The classical field of elastic stability is covered succinctly. The coverage emphasizes the modern problems of anelastic structures exhibiting plasticity and creep, and especially structures disintegrating due to localized fracture and distributed damage. The treatment encompasses thin or slender structures, i.e. the columns, frames, arches, thin-walled beams, plates, and shells, as well as massive but soft bodies buckling three-dimensionally, and includes the static as well as dynamic concepts of stability, dynamic instability of nonconservative systems, energy methods for discret and continuous structures, thermodynamics of structures, postcritical behavior, and imperfection sensitivity. The legacy of Ludwig Prandtl, who is commemorated by the present Special Issue, is briefly highlighted. The mathematics is kept to the bare minimum, and the derivations as well as the differential equations are omitted. Man attention is paid to the physical causes, mechanisms, and results. Only the main literature sources in this vast field are cited.

ABSTRACT: As shown three decades ago, in situations where the initial stresses before buckling are not negligible compared to the elastic moduli, the geometrical dependence of the tangential moduli on the initial stresses must be taken into account in stability analysis, and the stability or bifurcation criteria have different forms for tangential moduli associated with different choices of the finite strain measure. So it has appeared paradoxical that, for sandwich columns, different but equally plausible assumptions yield different formulas,
Engesser’s and Haringx’ formulas, even though the axial stress in the skins is negligible compared to the axial elastic modulus of the skins and the axial stress in the core is negligible compared to the shear modulus of the core. This apparent paradox is explained by variational energy analysis. It is shown that the shear stiffness of a sandwich column, provided by the core, generally depends on the axial force carried by the skins if that force is not negligible compared to the shear stiffness of the column (if the column is short). The Engesser-type, Haringx-type, and other possible formulas associated with different finite strain measures are all, in principle, equivalent, although a different shear stiffness of the core, depending linearly on the applied axial load, must be used for each. The Haringx-type formula, however, is most convenient because it represents the only case in which the shear modulus of the core can be considered to be independent of the axial force in the skins and to be equal to the shear modulus measured in simple shear tests (e.g., torsional test). Extensions of the analysis further show that Haringx’s formula is preferable for a highly orthotropic composite because a constant shear modulus of the soft matrix can be used for calculating the shear stiffness of the column, and further confirm that Haringx’s buckling formula with a constant shear stiffness is appropriate for helical springs and built-up columns (laced or battened).

References listed at the end of the paper is a state of the art survey of the general area of buckling and postbuckling of thin-walled, geometrically imperfect, cylinders of various constructions, when subjected to destabilizing loads. The survey includes discussion of imperfection sensitivity and of the effect of various defects on the critical conditions.

ABSTRACT: Thin-walled cylinders of various constructions are widely used in simple or complex structural configurations. The round cylinder is commonly found in tubing and piping, and in offshore platforms. Depending on their use, these cylinders are subjected (in service) to individual and combined application of external loads. In resisting these loads the system is subject to buckling, a failure mode which is closely associated with the establishment of its load-carrying capacity. Therefore, the system buckling and postbuckling behavior have been the subject of many researchers and investigators both analytical and experimental. The paper is a state-of-the-art survey of the general area of buckling and postbuckling of thin-walled, geometrically imperfect, cylinders of various constructions, when subjected to destabilizing loads. The survey includes discussion of imperfection sensitivity and of the effect of various defects on the critical conditions.

ABSTRACT: On the occasion of the 100th anniversary of A.E.H. Love's fundamental paper on thin elastic shell theory, the present article summarizes a line of developments on shells of revolution related to the Love-Kirchhoff hypotheses which form the basis of Love's theory. The summary begins with the Günther-Reissner formulation of the linear theory which is shown to contain the classical first approximation shell theory as a special case. The static-geometric duality is deduced as a natural and immediate consequence of the more general theory. The repeated applications of this duality greatly simplify the solution process for boundary-value problems in shell theory, including the classical reduction of the axisymmetric bending problem and related recent reductions of shell equations for more general loadings to two simultaneous equations for a stress function and a displacement variable. In the nonlinear range, the article confines itself to Reissner's geometrically nonlinear theory of axisymmetric deformation of shells of revolution and Marguerre's shallow shell theory with special emphasis on recent results for elastic membranes, buckling of shells of revolution and applications of asymptotic methods. With fondness and appreciation, the authors dedicate this article to their teacher, collaborator and friend, Professor Eric Reissner, in the year of his seventy-fifth anniversary.

Z. Waszczyszyn (Institute of Structural Mechanics, Cracow Technological University, Poland), “Multiple subvolume models for the analysis of inelastic behaviour of metals”, Delft University of Technology, The Netherlands Memorandum M-594, June 1988

ABSTRACT: A review of papers devoted to formulation and applications of Multiple Subvolume (MS) models is given. Special attention is paid to the identification procedure of model parameters. The simplest MS model (MSPM), composed of elastic, perfect plastic components is considered in detail. Simple and refined identifications of model parameters are discussed with special attention turned out on the procedure used in the STAGS-A computer code. More complicated, strain-hardening and time-dependent MS mardels are shortly discussed.

Dhalla (Westinghouse Electric Corporation, PO Box 158, Madison, PA 15663, USA), “Nonlinear structural analysis methods and their application to elevated temperature design: A US perspective”, Nuclear Engineering and Design, Vol. 114, No. 3, June 1989, pp. 415-436, doi:10.1016/0029-5493(89)90119-2 ABSTRACT: Technological advances over the last two decades have been assimilated into the routine design of Liquid Metal Reactor (LMR) structural components operating at elevated temperatures. The mature elevated temperature design technology is based upon: (a) an extensive material data base, (b) recent advances in nonlinear computational methods, and (c) conservative design criteria based upon past successful and reliable operating experiences with petrochemical and nonnuclear power plants. This survey paper provides a US perspective on the role of nonlinear analysis methods used in the design of LMR plants. The simplified and detailed nonlinear analysis methods and the level of computational effort required to qualify structural components for safe and reliable long-term operation are discussed. The paper also illustrates how a detailed nonlinear analysis can be used to resolve technical licensing issues, to understand complex nonlinear structural behavior, to identify predominant failure modes, and to guide future experimental programs.

The work is centred on the practical analysis methods used in construction codes to account for the strain-buckling of thin and slender structures. Methods proposed in the literature concerning past and present studies are summarized. Experimental, theoretical and numerical methods are considered. Methods applicable to design and their degree of validation are indicated.

ABSTRACT: A first attempt is made to review the advances of the formulations for thin shell finite elements in the form of flat plates, axisymmetrical shells and curved shells. The Discrete Kirchhoff Theory shell elements and the degenerated shell elements are discussed. Experiences in shear and membrane lockings are elaborated. The survey is further illustrated with some extensions and applications to cases such as static and dynamic responses, static and dynamic bucklings, laminated composites, random loadings and random structural and material properties. In all cases, studies of the effects of geometric and material nonlinearities are discussed.

ABSTRACT: This paper surveys about 350 publications related to the finite element models of moderately thick shells, concentrating on those related to consistent displacement and stress/mixed/hybrid models. A geographic-chronological criterion has been used in order to review the main ideas and their development in time. The survey is complete enough to show the trends. The ideas of such a list is to help those readers who are interested in special problems of the applications of the finite element method in the analysis of moderately thick shells.

ABSTRACT: The critical points of the generalized complementary energy variational principles are clarified. An open problem left by Hellinger and Reissner is solved completely. A pure complementary energy (involving the Kirchhoff type stress only) is constructed. We prove that the well-known generalized Hellinger-Reissner’s energy $L(u,s)$ is a saddle point functional if and only if the Gao-Strang gap function is positive. In this case, the system is stable and the minimum potential energy principle is equivalent to a unique maximum dual variational principle. However, if this gap function is
negative, then $L(u,s)$ is a so-called $\partial^*$-critical point functional. In this case, the system has two extremum complementary principles. An interesting triality theorem for nonconvex variational problem is discovered, which can be used to study nonlinear bifurcation problems, phase transitions, variational inequality, and other things. In order to study the shear effects in frictional post-buckling problems, a new second order 2-D nonlinear beam model is developed. Its total potential is a double-well energy. A stability criterion for post-buckling analysis is proposed, which shows that the minimax complementary principle controls a stable buckling state. The unilateral buckling state is controlled by a minimum complementary principle. However, the maximum complementary principle controls the phase transitions.

ABSTRACT: Some properties of the tensor algebra on manifolds are discussed with respect to the classical tensor algebra of continuum mechanics. Basic definitions and relations of linear maps are briefly recalled and applied to tensor spaces, where special attention is focused to the definition of dual and transposed maps. As application to nonlinear continuum mechanics, algebraic pull-back and push-forward maps, and Lie-like time derivatives associated with linear maps are defined and used to build up commutative schemes for deformation measures, objective deformation rates, stresses, and frame-invariant forms of the stress power. The transition to the classical formulation of tensor algebra by identifying vector spaces and their duals is examined. It is shown how this concept enables a straight-forward derivation of the Doyle-Ericksen formula and its possible variants.

ABSTRACT: The increasing complexity of engineering systems has sparked rising interest in multidisciplinary optimization (MDO). This paper surveys recent publications in the field of aerospace, in which the interest in MDO has been particularly intense. The primary challenges in MDO are computational expense and organizational complexity. Accordingly, this survey focuses on various methods used by different researchers to address these challenges. The survey is organized by a breakdown of MDO into its conceptual components, reflected in sections on mathematical modelling, approximation concepts, optimization procedures, system sensitivity, and human interface. Because the authors' primary area of expertise is in the structures discipline, the majority of the references focus on the interaction of this discipline with others. In particular, two sections at the end of this review focus on two interactions that have recently been pursued with vigour: the simultaneous optimization of structures and aerodynamics and the simultaneous optimization of structures with active control.

ABSTRACT: Considerable research interest has been directed towards the use of composite materials for crashworthiness applications, because they can be designed to provide impact energy absorption capabilities which are superior to those of metals when compared on a weight basis. This review draws together information from a variety of sources to compare the findings of researchers in this field. The anisotropy of composite materials means that there are a great number of variables controlling mechanical behaviour and much of the investigative experimental work conducted in this area has concentrated on composite tubular specimens. The material, geometrical and experimental factors which have been shown to affect the energy absorption capability of such samples are related and a comparison is made of some of the specific energy absorption values which have been quoted in the literature. A selection of methods for predicting composite material energy absorption capability is presented and consideration is given to some of the more practical aspects of employing composite materials for crashworthiness purposes.

ABSTRACT: This paper addresses the prediction of the behaviour of buried pipelines when they are considered to be shell structures and subjected to curvatures that exceed their limit points. It surveys work carried out at the University of Alberta over a period of approximately six years. The work considers the development of local buckling, and the softening, strain localization and wrinkling that characterize the behaviour of pipeline structures, and the relation between these phenomena. It offers a phenomenological explanation of the mechanism by which wrinkling develops in the post-buckling behaviour of structures. It then demonstrates that the experimental and analytical results of studies of pipe behaviour are consistent with this mechanism. The results of finite element analyses are compared with two series of tests on full-sized industrial pipe. The tests provide a database for the behaviour of the pipe against which the validity of the analyses can be established. Comparisons are made with respect to moment-curvature curves and postbuckling configurations. It is concluded that modern finite element analysis when properly done is capable of closely predicting the behaviour of the pipe when it is subjected to large deformations that carry it deeply into the postbuckling range.

Ray W. Clough and Edward L. Wilson (Department of Structural Engineering, University of California, Berkeley, California, USA), “Early finite element research at Berkeley”, Fifth U.S. National Conference on Computational Mechanics, Aug. 4-6, 1999

ABSTRACT: Significant finite element research was conducted at the University of California at Berkeley during the period 1957 to 1970. The initial research was a direct extension of classical methods of structural analysis which previously had been restricted to one-dimensional elements. The majority of the research conducted was motivated by the need to solve practical problems in Aerospace, Mechanical and Civil Engineering. During this short period the finite element method was extended to the solution of linear and nonlinear problems associated with creep, incremental construction or excavation, crack closing, heat transfer, flow of water in porous media, soil consolidation, dynamic response analysis and computer assisted learning of structural analysis. During the last six years of this period the fields of structural analysis and continuum mechanics were unified. The computer programs developed during this early period at Berkeley were freely distributed worldwide allowing practicing engineers to solve many new problems in structural mechanics. Hence, the research was rapidly transferred to the engineering profession. In many cases the research was used professionally prior to the publication of a formal paper.

ABSTRACT: This paper gives a survey of works on the theory of toroidal shells which were done by our two universities in recent years. (49 references)

ABSTRACT: There is an increasing usefulness of exact three-dimensional analyses of elastic cylinders and cylindrical shells in composite materials applications. Such analyses are considered as benchmarks for the range of applicability of corresponding studies based on two-dimensional and/or finite element modeling. Moreover, they provide valuable, accurate information in cases that corresponding predictions based on that later kind of approximate modeling is not satisfactory. Due to the complicated form of the governing equations of elasticity, such three-dimensional analyses are comparatively rare in the literature. There is therefore a need for further developments in that area. A survey of the literature dealing with three-dimensional dynamic analyses of cylinders and open cylindrical panels will serve towards such developments. This paper presents such a survey within the framework of linear elasticity.

ABSTRACT: This article presents a review of the research work related to the mechanical behavior of non-circular cylindrical shells and shell segments. To this end, after a brief reference to the basic nomenclature that is mainly used, it initially provides quite a general framework for most of the relevant governing equations employed in the relevant literature. It proceeds with a review of the corresponding dynamic analyses, which are primarily grouped according to the geometrical configuration of the noncircular shell considered and secondarily according to the type of the mathematical model employed. These deal with the dynamics of closed cylindrical shells and open cylindrical panels based on classical (CST) or transverse shear deformable shell theories (SDST). The static analyses reviewed next are divided according to the nature of the physical problem considered and deal with small as well as with large deflections of statically loaded non-circular cylindrical shells. These include both linearized and geometrically nonlinear elastic stability analyses as well as the very few relevant studies that assumed an elastic-plastic response of the shell material constitution. This review article contains 196 references.

ABSTRACT: A general overview of some recent developments related with the modeling and stability of sandwich structures is presented in this paper. The survey covers a number of issues related with the geometrically linear and non-linear formulations of curved and flat sandwich constructions featuring laminated anisotropic face sheets, and associated stability problems. Issues related with the enhancement of the load carrying capacity of sandwich panels resulting in the increase of the buckling strength, the reduction of the intensity of a snap-through buckling and even of its removal are also addressed. The provided list of references is not exhaustive, in the sense that it is mainly connected with topics of sandwich constructions in which the first author of this paper has been involved during a good part of his research activity. Moreover, the displayed
results illustrating some basic trends concern not only the ones previously obtained by the authors of this survey-paper, but also several others, presented here for the first time.

ABSTRACT: The three-dimensional theory of laminated plates and shells has been developed by Chao et al.[10–13, 62, 63] with many applications to impact and shock modal analyses. In this research, a complete survey of the literature is made on the free vibration natural frequencies of simply supported rectangular plates. Various boundary conditions are composed of fixed pin, hinge-roller, and sliding pin supported edges. The lowest frequencies are obtained in the present study in comparison with those in earlier studies as a result of the close natural state reached in keeping with the three-dimensional boundary and interlaminar continuity conditions via a 3-D augmented energy variational approach.

ABSTRACT: The evolution of matrix structural analysis (MSA) from 1930 through 1970 is outlined. Highlighted are major contributions by Collar and Duncan, Argyris, and Turner, which shaped this evolution. To enliven the narrative the outline is configured as a three-act play. Act I describes the pre-WWII formative period. Act II spans a period of confusion during which matrix methods assumed bewildering complexity in response to conflicting demands and restrictions. Act III outlines the cleanup and consolidation driven by the appearance of the direct stiffness method, through which MSA completed morphing into the present implementation of the finite element method (FEM). No attempt is made at chronicling the more complex history of FEM itself.

ABSTRACT: The origination, stability, and postcritical behavior of delaminations under quasi-static, cyclic, and dynamic loads are analyzed. Some problems for further investigations are discussed.

[116] Ren W, Mingbao H, Zhuping H, Qingchun Y. An experimental study on the dynamic axial plastic buckling of cylindrical

ABSTRACT: Most natural (or biological) materials are complex composites whose mechanical properties are often outstanding, considering the weak constituents from which they are assembled. These complex structures, which have risen from hundreds of million years of evolution, are inspiring Materials Scientists in the design of novel materials. Their defining characteristics, hierarchy, multifunctionality, and self-healing capability, are illustrated. Self-organization is also a fundamental feature of many biological materials and the manner by which the structures are assembled from the molecular level up. The basic building blocks are described, starting with the 20 amino acids and proceeding to polypeptides, polysaccharides, and polypeptides–saccharides. These, on their turn, compose the basic proteins, which are the primary constituents of ‘soft tissues’ and are also present in most biominerals. There are over 1000 proteins, and we describe only the principal ones, with emphasis on collagen, chitin, keratin, and elastin. The ‘hard’ phases are primarily strengthened by minerals, which nucleate and grow in a biomediated environment that determines the size, shape and distribution of individual crystals. The most important mineral phases are discussed: hydroxyapatite, silica, and aragonite. Using the classification of Wegst and Ashby, the principal mechanical characteristics and structures of biological ceramics, polymer composites, elastomers, and cellular materials are presented. Selected systems in each class are described with emphasis on the relationship between their structure and mechanical response. A fifth class is added to this: functional biological materials, which have a structure developed for a specific function: adhesion, optical properties, etc. An outgrowth of this effort is the search for bioinspired materials and structures. Traditional approaches focus on design methodologies of biological materials using conventional synthetic materials. The new frontiers reside in the synthesis of bioinspired materials through processes that are characteristic of biological systems; these involve nanoscale self-assembly of the components and the
development of hierarchical structures. Although this approach is still in its infancy, it will eventually lead to a plethora of new materials systems as we elucidate the fundamental mechanisms of growth and the structure of biological systems.

http://www.academia.edu/7423161/Progressive_Failure_Analysis_of_Laminated_Composite_Shells_A_Review

ABSTRACT: Recent advances in structural analysis and design technology for buckling-critical shell structures are discussed. These advances include a hierarchical analysis strategy that includes analyses that range from classical analysis methods to high-fidelity nonlinear finite element analysis methods, reliability based design methods, the development of imperfection data bases, and the identification of traditional and nontraditional initial imperfections for composite shell structures. When used judiciously, these advances provide the basis for a viable alternative to the traditional and conservative lower-bound design philosophy of the 1960s. These advances also help answer the question of why, after so many years of concentrated research effort to understand the behavior of buckling-critical thin-walled shells, one has not been able to improve on this conservative lower-bound design philosophy in the past.

ABSTRACT: Laminated composite shells are increasingly being used in various engineering applications including aerospace, mechanical, marine, and automotive engineering. With the increasing awareness of and sensitivity to structural noise and vibration, research covering the dynamic behavior of composite shells has received considerable attention. The purpose of this article is to review most of the recent research done in this field. Review of the literature on the dynamic behavior of homogeneous shells is covered in Part 2 of this article to be published in the September 2002 issue of AMR. Research on shell dynamics is found to be mainly free vibration analyses. The review is conducted with emphasis given to the theory being applied (thin, thick, 3D, nonlinear, ...), the analysis method (exact, Ritz, finite elements, ...), complicating effects (initial stress, imperfection, added masses and springs, elastic supports, rotating shells, and others), and the various shell geometries that were subject to vibration research (cylindrical, conical, spherical, and others). There are 374 references cited in this review article.
ABSTRACT: Shell-like structures are used in various engineering applications including civil, aerospace, mechanical, marine, and automotive engineering. This article reviews most of the recent research done in the field of dynamic response of homogeneous shells with special attention to free vibrations. Literature on dynamics of laminated composite shells was reviewed in Part 1 published in the July 2002 issue of AMR. Emphasis is given to the theory being applied (thin, thick, 3D, nonlinear,...), the shell geometries that were subject to dynamics research (cylindrical, conical, spherical,...), the analysis method (exact, Ritz, finite elements,...), and the various complicating effects (initial stress, imperfection, added masses and springs, elastic supports, rotating shells, interaction with fluids, and others). This review article contains 606 references.

ABSTRACT: Laminated composite shells are frequently used in various engineering applications including aerospace, mechanical, marine, and automotive engineering. This article reviews the recent literature on the static analysis of composite shells. It follows up with the previous work published by the first author [1-4] and it is a continuation of another recent article that focused on the dynamics of composite shells [3]. This paper reviews most of the research done in recent years (2000-2010) on the static and buckling behavior (including postbuckling) of composite shells. This review is conducted with an emphasis on the analysis performed (static, buckling, postbuckling, and others), complicating effects in both material (e.g. piezoelectric) and structure (e.g. stiffened shells), and the various shell geometries (cylindrical, conical, spherical and others). Attention is also given to the theory being applied (thin, thick, 3D, nonlinear…). However, more details regarding the theories have been described in previous work [1,3]

ABSTRACT: Stiffened panels made out of isotropic or anisotropic materials are being extensively used as structural elements for aircraft, maritime, and other structures. In order to maintain stiffness and strength with light weight, new design techniques must be employed when utilising these materials. Their stability, ultimate strength and loading capacity are the key issues pertaining to these engineering structures which have attracted a number of investigators to undertake indepth research, either in an academic or actual engineering context. This paper provides an extensive review of the research which has been conducted in recent years (2000-2012) on the buckling and post-buckling response of isotropic and composite stiffened plate and shell structures related to analysis and experiment. The key objective of this review article is to collate the research performed in the area of buckling and post-buckling behaviour of stiffened structures, thereby giving a broad perspective of the state-of-the-art in this field.

ABSTRACT: Stiffened panels made out of isotropic or anisotropic materials are being extensively used as structural elements for aircraft, maritime, and other structures. In order to maintain stiffness and strength with light weight, new design techniques must be employed when utilising these materials. Their stability, ultimate strength and loading capacity are the key issues pertaining to these engineering structures which have attracted a number of investigators to undertake in-depth research, either in an academic or actual engineering context. This paper presents a review of the optimisation techniques applied to buckling and post-buckling of stiffened panels. Papers published in the period from 2000 to May 2015 have been taken into consideration. The topic is addressed by identifying the most significant objectives, targets and issues, as well as the optimisation formulations, optimisation algorithms and models available. Finally a critical discussion, giving some practical advice and pointing out the most common issues involved in optimisation of buckling and post-buckling of stiffened panels, is provided.

ABSTRACT: The present paper is devoted to a state-of-the-art review on the computational treatment of laminated composite and sandwich panels. Over two hundred texts have been included in the survey with the focus put on theoretical models for multilayered plates and shells, and FEM implementation of various computational concepts. As a result of the review, one could notice a lack of a single numerical model capable for a universal representation of all layered composite and sandwich panels. Usually, with the increase of the range of rotations considered in the particular model, one can observe the decrease of the degree of complexity of the through-the-thickness representation of deformation profiles.

ABSTRACT: In this review, I shall discuss some of the aspects of the Mechanics of Solid Deformable Media, which have been for more than half a century among my main research priorities. It is somewhat difficult to write about research to which one has devoted his life. First of all, because you have to write about yourself, describing personal feelings—successes and failures, triumphs and defeats. It is hardly going to be of major interest for the readers. Thus, I am just going to note down, with corresponding comments some results, obtained by my colleagues, followers and myself. I think this can be rather interesting for junior researchers, who have not tasted yet the joy of success and the bitterness of the failure. This might be interesting as well for the mature scholars with relatively high self-esteem, willing to present each and every obtained result as a discovery—classical theory to be followed. The weight of a scientific result is evaluated by time. Time and coming generations of researchers will show the place in science of all results, even those which are widely advertised.

ABSTRACT: The aim of this paper is to provide a contemporarily relevant survey of studies on non-linear vibrations of shell-type structures. The effects of geometrical non-linearity, and specific difficulties encountered in non-linear dynamic analysis of shell-type structures are presented and discussed. Studies on non-linear vibrations of shells are categorized by different shell configurations (shapes) in a chronological order. Also, the most commonly used methods of modelling and solution are reviewed and commented. Published reviews on non-linear vibrations of shell-type structures including complicating effects of anisotropy, initial stress, added mass, elastic foundation, stiffeners, open geometry (singly and doubly curved), transverse shear deformations, torsion, and interaction with fluid are also surveyed. Comments on the previous non-linear works are presented and some orientations for future research are suggested. Another purpose of this paper is to provide engineers, scientists and researchers with a list of 175 references, which should be very useful for locating relevant existing literature quickly.

ABSTRACT: The present literature review focuses on geometrically non-linear free and forced vibrations of shells made of traditional and advanced materials. Flat and imperfect plates and membranes are excluded. Closed shells and curved panels made of isotropic, laminated composite, piezoelectric, functionally graded and hyperelastic materials are reviewed and great attention is given to non-linear vibrations of shells subjected to normal and in-plane excitations. Theoretical, numerical and experimental studies dealing with particular dynamical problems involving parametric vibrations, stability, dynamic buckling, non-stationary vibrations and chaotic vibrations are also addressed. Moreover, several original aspects of non-linear vibrations of shells and panels, including (i) fluid–structure interactions, (ii) geometric imperfections, (iii) effect of geometry and boundary conditions, (iv) thermal loads, (v) electrical loads and (vi) reduced-order models and their accuracy including perturbation techniques, proper orthogonal decomposition, non-linear normal modes and meshless methods are reviewed in depth.

ABSTRACT: This review paper aims to present an updated review of papers, conference papers, books, dissertations dealing with nonlinear vibrations of circular cylindrical thin shells. This paper surveyed mathematically, experimentally, analytically, numerically analyzed vibrations of cylindrical shells. This includes shells of open type, closed type, with and without fluid interactions; shells subjected to free and forced vibrations, radial harmonic excitations, seismically excitations; perfect and imperfect shell structures of various materials with different boundary conditions. This paper presented 210 reference papers in alphabetical order. This paper is presented as Geometrically nonlinear shell theories, Free and forced vibrations under radial harmonic excitation, Imperfect shells, shells subjected to seismic excitations, References.

ABSTRACT: principal achievements of science and engineering in the sphere of design, construction, and static, vibrational, and buckling analysis of thin-walled constructions and buildings in the shape of hyperbolic
surfaces of revolution are summarized in this review article. These shells are useful as hyperbolic cooling
towers, TV towers, reinforced concrete water tanks, and arch dams. They are also used as supports for electric
power transmission lines and as high chimneys. Several public and industrial buildings having the hyperbolic
form are described in the review. The basic results of theoretical and experimental investigations of stress-strain
state, buckling, and vibration are summarized. The influence of temperature and moisture on the stress-strain
state of the shells in question is also analyzed. This review article contains 261 references.

ABSTRACT: This survey is devoted to recent achievements in the field of asymptotic approaches. Here we
consider the asymptotics in relation to completely new and sometimes unexpected parameters. Some procedures
leading to improvement and isolation of the essential analytical structure of the perturbation series are
presented. It is also shown that many problems of perturbation theory, which seem to be relatively simple at a
first glance, are still far from completely solved. Different asymptotic techniques to solve the same problem and
their influence on the results are briefly illustrated and discussed. This review paper contains 310 references.

“Review of studies on geometrically nonlinear vibrations and dynamics of circular cylindrical shells and
panels, with and without fluid-structure interaction”, Appl. Mech. Rev., Vol. 56, No. 4, July 2003, pp. 349-
381, doi:10.1115/1.1565084, 356 references.
ABSTRACT: This literature review focuses mainly on geometrically nonlinear (finite amplitude) free and
forced vibrations of circular cylindrical shells and panels, with and without fluid-structure interaction. Work on
shells and curved panels of different geometries is but briefly discussed. In addition, studies dealing with
particular dynamical problems involving finite deformations, eg, dynamic buckling, stability, and flutter of
shells coupled to flowing fluids, are also discussed. This review is structured as follows: after a short
introduction on some of the fundamentals of geometrically nonlinear theory of shells, vibrations of shells and
panels in vacuo are discussed. Free and forced vibrations under radial harmonic excitation (Section 2.2),
parametric excitation (axial tension or compression and pressure-induced excitations) (Section 2.3), and
response to radial transient loads (Section 2.4) are reviewed separately. Studies on shells and panels in contact
with dense fluids (liquids) follow; some of these studies present very interesting results using methods also
suitable for shells and panels in vacuo. Then, in Section 4, shells and panels in contact with light fluids (gases)
are treated, including the problem of stability (divergence and flutter) of circular cylindrical panels and shells
coupled to flowing fluid. For shells coupled to flowing fluid, only the case of axial flow is reviewed in this
paper. Finally, papers dealing with experiments are reviewed in Section 5. There are 356 references cited in this
article.

ABSTRACT: Thin-walled cylinders of various constructions are widely used in simple or complex structural configurations. The round cylinder is commonly found in tubing and piping, and in offshore platforms. Depending on their use, these cylinders are subjected (in service) to individual and combined application of external loads. In resisting these loads the system is subject to buckling, a failure mode which is closely associated with the establishment of its load-carrying capacity. Therefore, the system buckling and postbuckling
behavior have been the subject of many researchers and investigators both analytical and experimental. The paper is a state-of-the-art survey of the general area of buckling and postbuckling of thin-walled, geometrically imperfect, cylinders of various constructions, when subjected to destabilizing loads. The survey includes discussion of imperfection sensitivity and of the effect of various defects on the critical conditions.

ABSTRACT: Soon after the discovery of carbon nanotubes, it was realized that the theoretically predicted mechanical properties of these interesting structures—including high strength, high stiffness, low density and structural perfection—could make them ideal for a wealth of technological applications. The experimental verification, and in some cases refutation, of these predictions, along with a number of computer simulation methods applied to their modeling, has led over the past decade to an improved but by no means complete understanding of the mechanics of carbon nanotubes. We review the theoretical predictions and discuss the experimental techniques that are most often used for the challenging tasks of visualizing and manipulating these tiny structures. We also outline the computational approaches that have been taken, including ab initio quantum mechanical simulations, classical molecular dynamics, and continuum models. The development of multiscale and multiphysics models and simulation tools naturally arises as a result of the link between basic scientific research and engineering application; while this issue is still under intensive study, we present here some of the approaches to this topic. Our concentration throughout is on the exploration of mechanical properties such as Young’s modulus, bending stiffness, buckling criteria, and tensile and compressive strengths. Finally, we discuss several examples of exciting applications that take advantage of these properties, including nanoropes, filled nanotubes, nanoelectromechanical systems, nanosensors, and nanotube-reinforced polymers. This review article cites 349 references.

ABSTRACT: Mechanical properties of carbon nanotubes are discussed based on recent advances in both modeling and experiment.

INTRODUCTION: Significant progress has been made in the area of nanoscale science and technology in the past decade. As one of the most interesting nanomaterials, carbon nanotubes (CNT) have received significant attention in terms of fundamental properties measurements and potential applications. This is largely due to the impressive physical properties as revealed from both theoretical and experimental studies. For example, the electrical properties of CNT may be tuned by mechanical deformation. Such properties are of great interest for applications such as sensors or smart materials. The study of these properties is multi-disciplinary and involves various branches of science and engineering. Steady progress has been made in exploring the mechanical properties and potential applications of two types of CNTs: single-walled carbon nanotubes (SWCNT) and multi-walled carbon nanotubes (MWCNT). The measured specific tensile strength of a single layer of a multi-walled carbon nanotube can be as high as 100 times that of steel, and the graphene sheet (in-plane) is as stiff as diamond at low strain. These mechanical properties motivate further study of possible applications for
ABSTRACT: Carbon nanotubes are unique tubular structures of nanometer diameter and large length/diameter ratio. The nanotubes may consist of one up to tens and hundreds of concentric shells of carbons with adjacent shells separation of ~0.34 nm. The carbon network of the shells is closely related to the honeycomb arrangement of the carbon atoms in the graphite sheets. The amazing mechanical and electronic properties of the nanotubes stem in their quasi-one-dimensional (1D) structure and the graphite-like arrangement of the carbon atoms in the shells. Thus, the nanotubes have high Young’s modulus and tensile strength, which makes them preferable for composite materials with improved mechanical properties. The nanotubes can be metallic or semiconducting depending on their structural parameters. This opens the ways for application of the nanotubes as central elements in electronic devices including field-effect transistors (FET), single-electron transistors and rectifying diodes. Possibilities for using of the nanotubes as high-capacity hydrogen storage media were also considered. This report is intended to summarize some of the major achievements in the field of the carbon nanotube research both experimental and theoretical in connection with the possible industrial applications of the nanotubes.

ABSTRACT: This survey paper comprises 5 sections. In Section 1, the reader is introduced to the world of carbon nanotubes where their structural form and properties are highlighted. Section 2 presents the various buckling behaviors exhibited by carbon nanotubes that are discovered by carbon nanotube researchers. The main factors, such as dimensions, boundary conditions, temperature, strain rate and chirality, influencing the buckling behaviors are discussed in Section 3. Section 4 presents the continuum models, atomistic simulations and experimental techniques in studying the buckling phenomena of carbon nanotubes. A summary as well as recommendations for future research are given in Section 5. Finally a large body of papers, over 200, is given in the reference section. It is hoped that this survey paper will provide the foundation knowledge on carbon nanotube buckling and inspire researchers to advance the modeling, simulation and design of carbon nanotubes for practical applications.

Hiroyuki Shima, Division of Applied Physics, Faculty of Engineering, Hokkaido University, Japan, “Buckling of Carbon Nanotubes: A State of the Art Review”, Materials 2012, 5, 47-84; doi:10.3390/ma5010047
ABSTRACT: The nonlinear mechanical response of carbon nanotubes, referred to as their “buckling” behavior, is a major topic in the nanotube research community. Buckling means a deformation process in which a large strain beyond a threshold causes an abrupt change in the strain energy vs. deformation profile. Thus far, much effort has been devoted to analysis of the buckling of nanotubes under various loading conditions: compression, bending, torsion, and their certain combinations. Such extensive studies have been motivated by (i) the structural resilience of nanotubes against buckling and (ii) the substantial influence of buckling on their physical
properties. In this contribution, I review the dramatic progress in nanotube buckling research during the past few years. 212 references cited:

4. See Appendix10.3 for the delicate issue about who should be credited as the first person to discover carbon nanotubes.

6. Together with the three famous nanocarbons, “nanodiamond” deserves attention as the fourth member of nanocarbon materials, being classic yet novel. Nanodiamond was initially synthesized by Volkov [7] in 1963, and recently, a wide variety of applications has been proposed; see References [8,9] for instance.

10. A forthcoming monograph [11], which covers broad topics of carbon nanotube deformation, including buckling, will be of great help to readers who are interested in the subject.

Hasegawa, M.; Nishidate, K. Radial deformation and stability of single

122. Recently, shell buckling behavior of short nanotubes with aspect ratio ~1 or less was considered, showing the significant dependence of the buckling strain on the nanotube length [123].

124. The critical strain of shell buckling is inversely proportional to the tube diameter [125].

126. Similar sequential transitions can be observed when a SWNT is bent [68]. See Section 6.3 for details.

130. The actual direction of the applied force deviates from the exact axial one by approximately 15 degrees, as indicated in Figure 2(a).

131. The instability at (8) and the sharp rise at (9) during unloading stem from the tip pulled out of the contact, while the nanotube end remains in contact.

135. For larger radius SWNTs, the peanut-like deformed structure can be transformed to dumbbell-like configurations by van der Waals (vdW) attractions between the opposite walls of nanotubes. The latter structure is energetically stable even when the applied force is unloaded.

146. Yang, X.; Wu, G. The study of structural, electronic and optical properties of double-walled carbon nanotube bundles under hydrostatic pressure. EPL 2008, 81, 47003.

148. A radial pressure large enough to cause corrugation can be achieved by electron-beam irradiation [149]; the self-healing nature of eroded carbon walls gives rise to a spontaneous contraction that exerts a high pressure on the inner walls to yield their radial corrugation [60].

150. The authors in Reference [63] say that this conclusion was motivated by an experimental fact that cross sections of MWNTs synthesized in the presence of nitrogen are polygonal shapes rather than circular shapes [151,152]. It was argued that the polygonization may result from the interlayer thermal contraction upon cooling or interwall adhesion energy owing to the increased interwall commensuration [151].

153. Prior to structural optimization, the initial cross sections of all the MWNTs are of circular shape and the interwall spacing is 0.359 nm, which is 0.19 nm larger than the equilibrium spacing of two graphene sheets (=0.34 nm).

168. Interestingly, a buckled SWNT in the TBR is fully reversible. If bending is stopped before the second discontinuity occurs, unbending recovers the cross-sectional shapes at the buckling point.

085503.

181. The Yoshimura pattern is a special kind of surface deformation mode occurring in thin-walled cylindrical shells subjected to large lateral load. It is named after Prof. Yoshimura [182], a Japanese theoretician of fracture mechanics, and its profile is characterized by a periodic diamond-like corrugation.

183. Interestingly, the energetic cost of MWNT buckling under bending is altered by inserting cross-linking (i.e., sp³ covalent bonding) between adjacent walls, as presented in References [184,185].

ABSTRACT: The first part of this paper describes some important underlying themes in the mathematical theory of continuum mechanics that are distinct from formulating and analyzing governing equations. The main part of this paper is devoted to a survey of some concrete, conceptually simple, pretty problems that help illuminate the underlying themes. The paper concludes with a discussion of the crucial role of invariant constitutive equations in computation.

ABSTRACT: The research and development in composite mechanics are reviewed from 1965 to 2006. The review covers micromechanics, macromechanics failure theories, impact resistance, structural analysis, plate and panel buckling, shell buckling, progressive fracture, containment, and probabilistic composite simulation. A few remarks are included about aerodynamic loads and a new all composite engine concept. Most of the sample cases are from the author's own research since this research covers all aspects of composites and since this avoids the permissions required by other authors when their results are included. References are cited as appropriate so that the reader can further look in any specific area.

ABSTRACT: This paper reviews most of the recent research done in the field of dynamic stability/dynamic instability/parametric excitation/parametric resonance characteristics of structures with special attention to parametric excitation of plate and shell structures. The solution of dynamic stability problems involves derivation of the equation of motion, discretization, and determination of dynamic instability regions of the structures. The purpose of this study is to review most of the recent research on dynamic stability in terms of the geometry (plates, cylindrical, spherical, and conical shells), type of loading (uniaxial uniform, patch, point loading …), boundary conditions (SSSS, SCSC, CCCC …), method of analysis (exact, finite strip, finite
difference, finite element, differential quadrature, and experimental ...), method of determination of dynamic instability regions (Lyapunovian, perturbation, and Floquet’s methods), order of theory being applied (thin, thick, three-dimensional, nonlinear ...), shell theory used (Sanders’, Love’s and Donnell’s), materials of structures (homogeneous, bimodulus, composite, FGM ...), and the various complicating effects such as geometrical discontinuity, elastic support, added mass, fluid structure interactions, nonconservative loading and twisting, etc. The important effects on dynamic stability of structures under periodic loading have been identified and influences of various important parameters are discussed. A review of the subject for nonconservative systems in detail will be presented in Part 2. This review paper cites 156 references.

ABSTRACT: The principal advances in the design and construction, as well as the static, vibrational, and buckling analysis of thin-walled structures and buildings in the shape of general and axisymmetric ellipsoidal shells are summarized in this review. These shells are particularly useful as internally pressurized vessels or as heads and bottoms of cylindrical tanks and vessels. Reinforced concrete and structural steel domes of buildings, air-supported rubber-fabric shells, and underwater pressure vessels are also made in the form of ellipsoidal shells. Knowing the geometry of ellipsoids, one can solve various problems in physics, optics, and so on. Basic results of theoretical and experimental investigations of the stress-strain state, buckling, and natural and forced vibrations contained in 209 references are presented in the review. The influence of temperature on the stress-strain state of the shells in question is also discussed. Some parts of the review are also devoted to an analysis of the literature on the stress-strain state of ellipsoidal and torispherical heads of pressure vessels with openings.

“Modeling and analysis of functionally graded materials and structures”, Applied Mechanics Reviews,

ABSTRACT: This paper presents a review of the principal developments in functionally graded materials (FGMs) with an emphasis on the recent work published since 2000. Diverse areas relevant to various aspects of theory and applications of FGM are reflected in this paper. They include homogenization of particulate FGM, heat transfer issues, stress, stability and dynamic analyses, testing, manufacturing and design, applications, and fracture. The critical areas where further research is needed for a successful implementation of FGM in design are outlined in the conclusions.

ABSTRACT: For better crashworthiness performance, vehicles must protect its occupants by maintaining structural integrity and converting the large amount of kinetic energy into other forms of energy in a controllable and predictable manner in a crash situation. In doing so, lower crushing force would provide better safety for the vehicle occupants. This paper reviews the axial response of “modified” tubular sections with imperfections and fillers subjected to axial impact loads relevant to the field of structural crashworthiness. The use of imperfections sets the mode and initiation of collapse of a tube at a specific location and reduces the maximum crush force, hence improving the energy-absorbing characteristics of tubular structures. The types of imperfections discussed include prebuckle, parallel and dished indentations, cutouts, stiffeners, fillers, and wrapping.

ABSTRACT: Structural elements, which deform inelastically, are often used in energy-absorbing devices due to their simple design and the high efficiency achieved by several buckling deformation mechanisms. The application of light ductile materials in transportation systems and increased loading intensity requires studies on the influence of the rate of loading and material characteristics on dynamic buckling behavior. The present review article is focused on summarizing the state of the art related to the inelastic dynamic stability and postbuckling behavior of various basic structural members. In particular, studies on the dynamic response of axially loaded idealized elastic-plastic models, rods, shells with circular and square cross sections, and long tubes are discussed with consideration given to the influence of the geometric and material characteristics as
well as the loading conditions on the buckling phenomena observed in these structural elements. The findings from the theoretical and experimental investigations on the phenomenon of dynamic inelastic buckling reported in this review article are based on 118 references.

ABSTRACT: Recent research effort into some aspects of strength, static stability, and structural optimization of horizontal pressure vessels is reviewed in this paper. Stress concentrations at the junction of cylinder-ellipsoidal end closures are covered in detail. This in turn establishes efficient choices for wall thicknesses in the vessel. Detailed account of stresses for flexible supports of a horizontal cylindrical shell is provided. Dimensions of support components, which assure the minimum stress concentrations between a horizontal shell and its support, are calculated. In particular, the wall thickness is found for vessels being loaded by the weight of its content and placed on two supports. Stability issues are also reviewed in this paper. In particular, attention is paid to the stability of cylinder under external pressure and to the stability of end closures. The latter are loaded by internal or external pressure. Apart from buckling and plastic loads, the ultimate load carrying capacity, i.e., burst pressure, for internally pressurized heads is also examined. On a practical side, aboveground and underground cases are discussed. In the latter case of underground vessels the reinforcement by internal rings is assessed. The optimization part of this paper deals with the effective choice of the end closure depth and the shape of its meridian. The overriding aim here is to examine the stress concentrations and the ways in which they can be mitigated. The optimal shape of closures is also searched for, with respect to the maximum buckling pressure for a given mass of the head. In the case of internal pressure the maximum of plastic load is sought within a specified class of meridional profiles. Finally, optimal sizing of whole vessels is discussed for slender and compact geometries. Extensive references are made to relatively recent and ongoing work related to the above topics. This paper has 287 references and 50 figures.

ABSTRACT: This review aims to complement a milestone monograph by Singer et al. (2002, Buckling Experiments—Experimental Methods in Buckling of Thin-Walled Structures, Wiley, New York). Practical aspects of load bearing capacity are discussed under the general umbrella of “buckling.” Plastic loads and burst pressures are included in addition to bifurcation and snap-through/collapse. The review concentrates on single and combined static stability of conical shells, cylinders, and their bowed out counterpart (axial compression and/or external pressure). Closed toroidal shells and domed ends onto pressure vessels subjected to internal and/or external pressures are also discussed. Domed ends include: torispheres, toricones, spherical caps, hemispheres, and ellipsoids. Most experiments have been carried in metals (mild steel, stainless steel, aluminum); however, details about hybrids (copper-steel-copper) and shells manufactured from carbon/glass fibers are included in the review. The existing concerns about geometric imperfections, uneven wall thickness, and influence of boundary conditions feature in reviewed research. They are supplemented by topics like

J. Blachut (1) and K. Magnucki (2)
(1) The University of Liverpool, Mechanical Engineering, Liverpool, U.K

imperfections in axial length of cylinders, imperfect load application, or erosion of the wall thickness. The latter topic tends to be more and more relevant due to ageing of vessels. While most experimentation has taken place on laboratory models, a small number of tests on full-scale models are also referenced.

Osama Bedair (AMEC Americas Ltd., 116 Mount Aberdeen Manor SE, Calgary, AB, T2Z 3N8, Canada),

ABSTRACT: Stiffened plates and shells are encountered in many engineering applications. Several analytical and numerical procedures were developed over the past decades for analysis of these structures. Empirical and simplified analytical models were also developed to estimate their ultimate strength for various limit states. The paper reviews and pieces together engineering work developed for all the applications. The first part reviews the analytical, numerical, and orthotropic plate procedures that were developed for analysis of stiffened plates and shells. The structural idealization, the theoretical basis, and the merits of each method are also discussed. The second part of the paper reviews the design philosophies that were developed to predict the ultimate strength of these structures. The influence of various parameters affecting the structural performance, such as geometric and material imperfections, stiffener profile, etc., is discussed. The optimization procedures to minimize the weight of the structure are also reviewed. The paper offers a comprehensive and unique “reference-manual” for all types of stiffened plate applications. ABSTRACT: This paper reviews some topics related to the advances and applications of structural impact dynamics in recent years. Dynamic behavior of structural members including tubes, beams and plates under axial or transverse loading, and cellular materials and sandwich structures under impact or blast loading are summarized here. The research methodology involves experimental studies, theoretical modeling, as well as numerical simulations. However, as we mainly focus on the longer time dynamic responses of structures and cellular materials, studies of stress wave propagation and the material’s strain-rate sensitivity are not included.

“Review: Constrained finite strip method developments and applications in cold-formed steel design”, Thin-Walled Structures, Vol. 81, pp 2-18, August 2014

ABSTRACT: The stability of thin-walled members is decidedly complex. The recently developed constrained Finite Strip Method (cFSM) provides a means to simplify thin-walled member stability solutions through its ability to identify and decompose mechanically meaningful stability behavior, notably the formal separation of local, distortional, and global deformation modes. The objective of this paper is to provide a review of the most recent developments in cFSM. This review includes: fundamental advances in the development of cFSM; applications of cFSM in design and optimization; identifying buckling modes and collapse mechanisms in shell finite element models; and, additional stability research initiated by the cFSM methodology. A brief summary of the cFSM method, in its entirety, is provided to explain the method and highlight areas where research remains active in the fundamental development. The application of cFSM to cold-formed steel member design and optimization is highlighted as the method has the potential to automate generalized strength prediction of thin-walled cold-formed steel members. Extensions of cFSM to shell finite element models is also highlighted, as this provides one path to bring the useful identification features of cFSM to general purpose finite element models. A number of alternative methods, including initial works on a constrained finite element method, initiated by cFSM methods, are also detailed as they provide insights on potential future work in this area. Research continues on fundamentals such as methods for generalizing cFSM to arbitrary cross-sections, improved design and optimization methods, and new ideas in the context of shell finite element method applications.
ABSTRACT: The fracture mechanics of plates and shells under membrane, bending, twisting, and shearing loads are reviewed, starting with the crack tip fields for plane stress, Kirchhoff, and Reissner theories. The energy release rate for each of these theories is calculated and is used to determine the relation between the Kirchhoff and Reissner theories for thin plates. For thicker plates, this relationship is explored using three-dimensional finite element analysis. The validity of two-dimensional (plate theory) solutions to actual three-dimensional objects is analyzed and discussed. Crack tip fields in plates undergoing large deflection are analyzed using von Kármán theory. Solutions for cracked shells are discussed as well. A number of computational methods for determining stress intensity factors in plates and shells are discussed. Applications of these computational approaches to aircraft structures are examined. The relatively few experimental studies of fracture in plates under bending and twisting loads are also reviewed. There are 101 references cited in this article.

ABSTRACT: It is 100 years since the well-known Mohr-Coulomb strength theory was established in 1900. A considerable amount of theoretical and experimental research on strength theory of materials under complex stress state was done in the 20th Century. This review article presents a survey of the advances in strength theory (yield criteria, failure criterion, etc) of materials (including metallic materials, rock, soil, concrete, ice,
iron, polymers, energetic material, etc) under complex stress, discusses the relationship among various criteria, and gives a method of choosing a reasonable failure criterion for applications in research and engineering. Three series of strength theories, the unified yield criterion, the unified strength theory, and others are summarized. This review article contains 1163 references regarding the strength theories. This review also includes a brief discussion of the computational implementation of the strength theories and multi-axial fatigue.

ABSTRACT: Due to advancements made in 3D weaving process, 3D woven composites have evolved as an attractive structural material for multi-directional load bearing and impact applications, due to their unique transverse properties such as stiffness, strength, fracture toughness and damage resistance. Substantial progress has been made in recent years for the development of new modeling techniques in design and analysis to understand the unique mechanical behavior of 3D woven composites. This paper systemically reviews the modeling techniques along with their capabilities and limitations for characterization of the micro-geometry, mechanical/thermo-mechanical behavior and impact behavior of 3D woven composites. Advantages, disadvantages and applications of 3D woven composites have also been delineated. In addition, this reference list provides a good database for future research on 3D woven composites.

ABSTRACT and OBJECTIVES: The purpose of this study is to review many of the available design guidelines for unidirectional tape, laminated aerospace composite panels. Guidelines for bonded and bolted joints, cutouts, and durability and damage tolerance are also presented, as they strongly influence designs for production aircraft. These guidelines are accompanied by explanations of why each one was generated and the influence each one has on the structural performance of various aircraft components. Most of these guidelines were developed during actual construction of relatively simple aircraft components in the late 1960s and early 1970s. Unfortunately, generally available literature detailing the derivation of these guidelines is scarce; hence, it was made necessary to obtain information directly from various aerospace engineering organizations and notes presented in lectures. The scarcity of formal documentation may also be due, in part, to the fact that many lessons were learned when unpredicted failures occurred during early development programs that are only now being declassified.

The present review is focused on composite laminates made of graphite fibers embedded in a polymer matrix since use of such laminates is increasing in highly loaded aerospace primary structures. Simple analyses and data are presented to illustrate the basis for many of the guidelines.

The objective of this review is to (1) gather the design guidelines currently used for structural design and analysis of unidirectional tape laminates, (2) review their derivation, and (3) explain their ranges of application. Many of these guidelines have served the aerospace industry for close to three decades as they were developed for fighter/attack aircraft structural components being designed in the late 1960s. Attention was directed towards production aircraft that were to be certified for operating lives on the order of 6,000 flight hours. By gathering together these guidelines and critically evaluating their derivation, it is feasible to assess situations under which they can be safely relaxed or even ignored. Such an assessment is performed for a spar cap
composed entirely of unidirectional plies proposed for unmanned air vehicles under development for NASA’s ERAST program.

ABSTRACT (not available)

ABSTRACT: Aviation safety can be greatly enhanced through application of computer simulations of crash impact. Unlike automotive impact testing, which is now a routine part of the development process, crash testing of even small aircraft is infrequently performed due to the high cost of the aircraft and the myriad of impact conditions that must be considered. Crash simulations are currently used as an aid in designing, testing, and certifying aircraft components such as seats to dynamic impact criteria. Ultimately, the goal is to utilize full-scale crash simulations of the entire aircraft for design evaluation and certification. The objective of this publication is to describe “best practices” for modeling aircraft impact using explicit nonlinear dynamic finite element codes such as LS-DYNA, DYNA3D, and MSC.Dytran. Although “best practices” is somewhat relative,
the authors’ intent is to help others to avoid some of the common pitfalls in impact modeling that are not generally documented. In addition, a discussion of experimental data analysis, digital filtering, and test-analysis correlation is provided. Finally, some examples of aircraft crash simulations are described in four appendices following the main report.

“A Review on Recent Contribution of Meshfree Methods to Structure and Fracture Mechanics Applications”,
DOI: 10.1155/2014/247172

ABSTRACT: Meshfree methods are viewed as next generation computational techniques. With evident limitations of conventional grid based methods, like FEM, in dealing with problems of fracture mechanics, large deformation, and simulation of manufacturing processes, meshfree methods have gained much attention by researchers. A number of meshfree methods have been proposed till now for analyzing complex problems in various fields of engineering. Present work attempts to review recent developments and some earlier applications of well-known meshfree methods like EFG and MLPG to various types of structure mechanics and fracture mechanics applications like bending, buckling, free vibration analysis, sensitivity analysis and topology optimization, single and mixed mode crack problems, fatigue crack growth, and dynamic crack analysis and some typical applications like vibration of cracked structures, thermoelastic crack problems, and failure transition in impact problems. Due to complex nature of meshfree shape functions and evaluation of integrals in domain, meshless methods are computationally expensive as compared to conventional mesh based methods. Some improved versions of original meshfree methods and other techniques suggested by researchers to improve computational efficiency of meshfree methods are also reviewed here.

ABSTRACT: The paper reviews literature on buckling of conical shells subjected to three loading conditions: (i) axial compression only, (ii) external pressure only and (iii) combined loading. The review is from the theoretical as well as experimental points of view. This review covers known experiments on cones from (1958 – 2012). The literature review is split thematically into the following categories: theoretical prediction of axially compressed cones, theoretical prediction of externally pressurized cones, theoretical prediction of cones under combined loading, buckling experiments on axially compressed cones, buckling experiments on externally pressurized cones, buckling experiments on cones subjected to combined loading, buckling experiments on composite conical shells, equivalent cylinder approach, effect of initial geometric imperfection on the buckling behaviour of cones and effect of imperfect boundary conditions on the buckling behaviour of cones.

why buckling responses have certain advantages and are especially suitable for these particular applications.

this topical review is to showcase the recent advances in buckling-induced smart applications and to explain why buckling responses have certain advantages and are especially suitable for these particular applications.

ABSTRACT: A paradigm shift has emerged over the last decade pointing to an exciting research area dealing with the harnessing of elastic structural instabilities for 'smart' purposes in a variety of venues. Among the different types of unstable responses, buckling is a phenomenon that has been known for centuries, and yet it is generally avoided through special design modifications. Increasing interest in the design of smart devices and mechanical systems has identified buckling and postbuckling response as a favorable behavior. The objective of this topical review is to showcase the recent advances in buckling-induced smart applications and to explain why buckling responses have certain advantages and are especially suitable for these particular applications.
Interesting prototypes in terms of structural forms and material uses associated with these applications are summarized. Finally, this review identifies potential research avenues and emerging trends for using buckling and other elastic instabilities for future innovations.

Some Surveys by Jaroslav Mackerle:

ABSTRACT: This paper is offered as a practical guide to sources of information on the finite element (FE) and boundary element (BE) techniques and software. It is intended for use by practical engineers, researchers and potential buyers of software as a help to find their way through the varying forms of literature. Reviewed are books, periodicals, bibliographies, abstracting journals, and databases.

ABSTRACT: The paper gives a bibliographical review of the finite element methods (FEMs) applied for the analysis of pressure vessel structures/components and piping from the theoretical as well as practical points of view. The range of applications of FEMs in this area is wide and cannot be presented in a single paper; therefore the aim of this review is to give the reader an encyclopaedic view of the different possibilities that exist today for the finite element analysis in the fields of pressure vessels and piping. The bibliography at the end of the paper contains approximately 1900 references to papers, conference proceedings and theses/dissertations on the subject that were published in 1976–1996. These are classified in the following categories: linear and non-linear, static and dynamic, stress and deflection analysis; stability problems; thermal problems; fracture mechanics problems; contact problems; fluid-structure interaction problems; manufacturing of pipes and tubes; welded pipes and pressure vessel components; development of special finite elements for pressure vessels and pipes; finite element software; and other topics. Also finite element software, general purpose and special purpose codes, used for the analysis of pressure vessels and pipes are briefly discussed and presented.

ABSTRACT: This paper gives a bibliographical review of the finite-element methods applied to the analysis and simulation of polymers. The bibliography at the end of the paper contains references to papers, conference proceedings and theses/dissertations on the subject that were published between 1976 - 1996. The following topics are included: polymer flow and mixing simulation; polymer processing; thermal analysis of polymers; fracture mechanics of polymers; modelling polymer behaviours and their mechanical properties; practical polymer applications in engineering; other topics.

ABSTRACT: This bibliography contains references to papers, conference proceedings and theses/dissertations dealing with stability problems and finite element and boundary element analyses that were published in 1994–1996.

ABSTRACT: This bibliography contains references to papers, conference proceedings and theses/dissertations dealing with finite element and boundary element analyses of fluid–structure interaction problems that were published in 1995–1998.

ABSTRACT: A bibliographical review of the finite element methods (FEMs) applied for the linear and nonlinear, static and dynamic analyses of basic structural elements from the theoretical as well as practical points of view is given. The bibliography at the end of the paper contains 1,726 references to papers, conference proceedings and theses/dissertations dealing with the analysis of beams, columns, rods, bars, cables, discs, blades, shafts, membranes, plates and shells that were published in 1996-1999.

Jaroslav Mackerle, (Linköping Institute of Technology, Department of Mechanical Engineering, Linköping, Sweden), “Finite element linear and nonlinear, static and dynamic analysis of structural elements, an

ABSTRACT: This paper gives a bibliographical review of the finite element methods (FEMs) applied for the linear and nonlinear, static and dynamic analyses of basic structural elements from the theoretical as well as practical points of view. The bibliography at the end of the paper contains more than 1330 references to papers, conference proceedings and theses/dissertations dealing with the analysis of beams, columns, rods, bars, cables, discs, blades, shafts, membranes, plates and shells that were published in 1999–2002.

ABSTRACT: This bibliography contains references to papers, conference proceedings and theses/dissertations dealing with the linear and nonlinear finite element and boundary element analyses of shells that were published in 1999–2001.

ABSTRACT: Gives a bibliographical review of the finite element analyses of sandwich structures from the theoretical as well as practical points of view. Both isotropic and composite materials are considered. Topics include: material and mechanical properties of sandwich structures; vibration, dynamic response and impact problems; heat transfer and thermomechanical responses; contact problems; fracture mechanics, fatigue and damage; stability problems; special finite elements developed for the analysis of sandwich structures; analysis of sandwich beams, plates, panels and shells; specific applications in various fields of engineering; other topics. The analysis of cellular solids is also included. The bibliography at the end of this paper contains 655 references to papers, conference proceedings and theses/dissertations dealing with presented subjects that were published between 1980 and 2001.

SECTION 8 of the paper:

8. Stability problems

An important factor for the sandwich structural integrity is the design against buckling. The interaction between the stiff faces and flexible core has a strong influence on the initial buckling load and the subsequent post-buckling which can be unstable on the contrary from isotropic materials.

This section deals with elastic instability and buckling. Another local buckling that can occur is the face wrinkling. Papers are listed that investigate the effect of coupling between faces and the core on the stability of sandwich structures.

The main topics include: linear and nonlinear stability analysis; static and dynamic buckling of sandwich structures; thermal buckling; pre-buckling analysis; post-buckling analysis; nonlinear post-buckling analysis; post-buckling analysis of debonded sandwich structures; strain-rate dependent buckling; local buckling behavior; effect of boundary conditions; parametric studies.

Type of structure: sandwich beams, plates, shells and panels; composite sandwich structures; soft-core and hard-core sandwich plates; stiffened sandwich panels; prestressed sandwich arches; curved sandwich panels; honeycombs.

References listed for the category, “6A.6 Stability problems”:

ABSTRACT: This paper gives a bibliographical review of the finite element methods applied to the analysis and simulation of welding processes. The bibliography is an addendum to the finite element analysis and simulation of welding: a bibliography (1976-96) published in Modelling Simul. Mater. Sci. Eng. (1996) 4 501-33. The added bibliography at the end of this paper contains approximately 550 references to papers and conference proceedings on the subject that were published in 1996-2001. These are classified in the following categories: modelling of welding processes in general; modelling of specific welding processes; influence of geometrical parameters; heat transfer and fluid flow in welds; residual stresses and deformations in welds; fracture mechanics and welding; fatigue of welded structures; destructive and non-destructive evaluation of weldments and cracks; welded tubular joints, pipes and pressure vessels/components; welds in plates and other structures/components.

End of surveys by Jaroslav Mackerle

Encyclopedia entry that defines “functionally Graded Materials (FGM):

BEGINNING OF ARTICLE: A functionally graded material (FGM, or sometimes also ‘‘gradient material’’) is characterized by a gradual change of material properties with position. The property gradient in the material is caused by a position-dependent chemical composition, micro-structure, or atomic order. The spatial extension of the gradient may differ: in a bulk FGM the property variation extends over a large part of the material, whereas in a graded coating or joint it is restricted to the surface of the material or a small interfacial region. Although FGMs attracted scientific interest only towards the end of the twentieth century, these materials are not new. In fact, spatial variations in the microstructure of materials have been exploited for millions of years by living organisms. In many structures found in plants, microstructural gradients are formed in order to produce optimum structural and functional performance with minimum material use. An example is the culm of bamboo, which consists of high-strength natural fibers embedded in a matrix of ordinary cells (Fig. 1(a)). The fiber content is not homogeneous over the entire cross-section of the culm but decreases from outside to inside (Fig. 1(b)). This gradation in fiber content is a natural adaptation of the plant to flexural loads—the fiber content is high only in those sections where the highest stresses occur.

There are also some examples of early synthetic materials taking advantage of property gradients such as case-hardened steels in which a hard surface is combined with a tough interior. Nevertheless, it was only in 1987 that Japanese scientists conceived graded materials as a new concept and defined an FGM as an ‘‘inhomogeneous composite, in which the material’s mechanical, physical, and chemical properties change continuously, and which have no discontinuities within the material’’ (Hirai et al. 1987). Meanwhile it has become common
practice to use the term FGM not only for composites, but also for all materials with a macroscopic property gradient (see definition at the beginning of the article). Thus, materials containing only one phase such as graded glasses or graded single crystals are also FGMs. In such materials the spatial property variation is caused by a gradient in chemical composition. Nevertheless, the vast majority of FGMs are composite materials with a macroscopic micro-structural gradient. For example, the composite may contain a spatially varying volume fraction of one of the phases (Fig. 2(a)). In this case, the gradient material can be conveniently described by the use of a transition function \( f(x,y,z) \), where \( f \) is the volume fraction of one of the phases as a function of position. In many practical cases the compositional variation will be restricted to one coordinate, \( z \), and the different gradients can then be described by a so-called transition function of the type: \( f(z) = (z/d)^p \), where \( f \) denotes the volume fraction of one of the phases, \( d \) is the thickness of the graded region, and \( p \) is the so-called gradation exponent. However, a composition gradient is not inherent to all FGMs. Microstructural gradients may also be obtained in composites by changing the shape (Fig. 2(b)), orientation (Fig. 2(c)), or size (Fig. 2(d)) of the dispersed phase.

Properly designed property gradients in materials lead to a performance that cannot be achieved with a homogeneous material or by the joining of two different materials. The gradient can thus be regarded as an additional material design parameter which may be adapted and optimized to meet the requirements of a particular application. This leads to the unusual situation that the performance of the material is strongly influenced by geometric factors such as the shape of the material, and the extension and profile of the property gradient. Thus, a gradient material cannot be fully characterized by materials constants only, and already comprises certain aspects of the design of a component.

Most of the theoretical research on FGMs has been devoted to their macroscopic mechanical and thermal behavior and there has been considerable progress in understanding the effects of gradients on the stress distribution within such materials (reviewed by Suresh and Mortensen 1998). A gradation of the elastic modulus and/or of the thermal expansion coefficient...

ABSTRACT: Cylindrical steel storage tanks are shells designed to store different types of products such as liquids or grain. The thickness of the shell is calculated to withstand the circumferential stress resulting from the hydrostatic pressure due to the stored product. A unique situation when there is no stored product leads to the vulnerability of the shell to buckle when there is wind load due to external pressure. There are two major types of buckling modes: local and general. The local buckling mode is studied analytically in various studies and is easy to mitigate. The general buckling mode can be more damaging to the tank and more costly to mitigate. The prevention of general buckling due to wind load pressure is achieved through the addition of stiffener rings. However, the stiffener rings design procedure used by various design standards has little known background. This paper reviews the current design approach’s origin and explains a semi-analytical justification for it. The unfolding of the design expressions can lead to more freedom in design variables selection leading to more economical designs.

ABSTRACT: The serious discrepancy between theoretical and experimental results for the buckling load of axially compressed cylindrical shells is well known. This paper presents results of a test program specifically designed to throw some light on the causes of the discrepancy. Ten nominally identical nickel cylinders were fabricated by electrodeposition and tested under both dead-weight and controlled end-shortening conditions. The test results indicate the following: the buckling load under usual laboratory conditions depends on the properties of the test specimen itself rather than on the testing environment, the buckling loads under dead-weight and controlled end-shortening conditions are the same, a sharp puff of air during loading can cause buckling at a considerably reduced load level, minimization of initial imperfections in the test specimens greatly increases the buckling load, and the magnitude of the minimum postbuckling equilibrium load is relatively insensitive to initial imperfections.

ABSTRACT: The elastic collapse of thin orthotropic elliptical cylindrical shells subject to pure bending alone or combined bending and uniform normal pressure loads has been studied. Nonlinear finite deflection thin shell theory is employed and this reduces the problem to a set of nonlinear ordinary differential equations. The resulting two-point nonlinear boundary-value problem is then linearized, using quasi-linearization, and solved numerically by the “shooting technique.” Some experimental work has been carried out and the results are compared with the theoretical predictions.

Noor, A. K. and Peters, J. M. (George Washington University, MS-269, NASA Langley Research Center,
ABSTRACT: The developments of an existing 48 degrees-of-freedom (d.o.f.), curved, quadrilateral, thin shell element, for materially and geometrically nonlinear static analysis of shell structures, are extended for the study of dynamic responses of nonlinear shells. The variable-order polynomial representations of the shell surface and the non-axisymmetric definition of the shell boundaries allow the study of the dynamic behaviour of a class of shell structures more general than those treated by using flat plate elements and elements with assumptions of axisymmetry. The equations of motion are based on a Lagrangian frame of reference. A combination of step-by-step and iterative procedures is used for the solution of nonlinear equations. The incremental equations of motion are linearized for computation purposes, and an algorithm for numerical integration based on Newmark's generalized operator for dynamic analysis, using optional iteration, is adopted. The flow theory of plasticity is used in the inelastic range, and perfectly plastic or isotropic strain hardening materials are considered. The spread of plastic zones in the thickness direction is treated by using a layered model. Numerical examples presented include the dynamic analyses of a square plate, a circular annulus, a cylindrical panel and a spherical cap. Comparisons with existing solutions demonstrate the validity and accuracy of the present developments.

SUMMARY: Since the mid-1960s when the forms of curved shell finite elements were originated, including those pioneered by Professor Gallagher, the published literature on the subject has grown extensively. The first two present authors and Liaw presented a survey of such literature in 1990 in this journal. Professor Gallagher maintained an active interest in this subject during his entire academic career, publishing milestone research works and providing periodic reviews of the literature. In this paper, we endeavor to summarize the important literature on shell Finite elements over the past 15 years. It is hoped that this will be a be a fitting tribute to the pioneering achievements and sustained legacy of our beloved Professor Gallagher in the area of shell finite elements. This survey includes: the degenerated shell approach; stress-resultant-based formulations and Cosserat surface approach; reduced integration with stabilization; incompatible modes approach; enhanced strain formulations; 3-D elasticity elements; drilling d.o.f. elements; co-rotational approach; and higher-order theories for composites.

ABSTRACT: A review of the progress in the stability analysis and design of concrete shells in the last two decades is presented. The decisive developments in the finite element analysis is stressed, but not examined in detail, since it is outside the scope of this review. Main attention is directed to the review of some approximate methods of buckling design of shells typically embodied in recommendations, guidelines or codes, primarily the IASS Recommendations of 1979 and the Kollár IASS Proposal of 1993. These two approaches are discussed in detail, and further modifications to the procedure are offered. The procedure is summarized in Section 5.

ABSTRACT: In this chapter dynamic stability loss of rectangular shells is addressed. A background containing types of dynamic buckling and prefect constructions, as well as the concept of finite-time stability, is given in Sects.4.1–4.3. Mathematical modeling of dynamical systems, problems of synchronization, chaos, and quasi-periodicity are also briefly revisited. Sections. 4.6–4.10 refer to both static and dynamic bifurcations and their numerical estimations. Stability loss of homogeneous shells subjected to an action of transversal loads is rigorously studied in Sect. 4.11.

“Stress-driven buckling patterns in spheroidal core/shell structures”, Proceedings of the National Academy of
ABSTRACT: Many natural fruits and vegetables adopt an approximately spheroidal shape and are characterized by their distinct undulating topologies. We demonstrate that various global pattern features can be reproduced by anisotropic stress-driven buckles on spheroidal core/shell systems, which implies that the relevant mechanical forces might provide a template underpinning the topological conformation in some fruits and plants. Three dimensionless parameters, the ratio of effective size/thickness, the ratio of equatorial/polar radii, and the ratio of core/shell moduli, primarily govern the initiation and formation of the patterns. A distinct morphological feature occurs only when these parameters fall within certain ranges: In a prolate spheroid, reticular buckles take over longitudinal ridged patterns when one or more parameters become large. Our results demonstrate that some universal features of fruit/vegetable patterns (e.g., those observed in Korean melons, silk gourds, ribbed pumpkins, striped cavern tomatoes, and cantaloupes, etc.) may be related to the spontaneous buckling from mechanical perspectives, although the more complex biological or biochemical processes are involved at deep levels.

ABSTRACT: The load-carrying capability of spherical shells under external pressure has been the subject of a long history and many theoretical and experimental studies have been carried out. However, from a comparative study on the design rules for the minimum thickness of the deep manned spherical shells from various classification societies, significant differences have been found. This indicates that these design rules need to be updated and unified like Common Structural Rules for tankers and bulk carriers. In order to lay a foundation for this target, a systematic study is carried out to develop a consistent calculation method for predicting the ultimate strength of spherical pressure hull under external pressure. This is the first paper of a series of three for reporting this study and in this paper, a critical review on the buckling and ultimate strength of spherical pressure hulls is carried out and further problems to be studied are identified. This could lay a solid foundation for the further study.

ABSTRACT: A review of conventional testing methods for applying external hydrostatic pressure to buckling-
critical shells is presented. A new “volume-control” pressure testing method, aimed at preventing catastrophic specimen failures and improving control of specimen deformation near the critical load, is also introduced. The implementation of conventional and volume-control systems in an experimental program involving the destructive pressure testing of ring-stiffened cylinders is described. The volume control method was found to improve control of the specimen deformations, especially near the critical load, and catastrophic failures observed while using a conventional setup were avoided. The quasi-static tracking of post-collapse load-deformation relationships for snap-through buckling behaviour was possible while using a volume-control system, but precise control of dynamic shell deformations during buckling was not achieved for specimens failing with large buckling lobes. Expressions for estimating the available control over specimen deformations for pressure testing systems are presented.

ABSTRACT: A framework for the design of submarine pressure hulls using nonlinear finite element (FE) analysis is presented in order to improve upon the conventional analytical-empirical design procedure. A numerical methodology is established that allows the collapse pressure of a hull to be predicted with controlled accuracy. The methodology is characterized by quasi-static incremental analysis, including material and geometric nonlinearities, of FE models constructed from shell elements. The numerical methodology is used with ANSYS to predict the results of 47 collapse experiments on small-scale ring-stiffened cylinders representative of submarine hulls. A probabilistic analysis is applied to the experimental-numerical comparisons in order to estimate the accuracy of the FE methodology and derive a partial safety factor (PSF) for design. It is demonstrated that a high level of accuracy, within 10% with 95% confidence, can be achieved if the prescribed FE methodology is followed. Furthermore, it is shown that the PSF for design does not need to be very large, even if a high degree of statistical confidence is built in. The designer can be 99.5% confident that the FE error has been accounted for by dividing the predicted collapse pressure by a PSF=1.134.

ABSTRACT: This paper examines the application of structural reliability analysis to submarine pressure hulls...
to clarify the merits of probabilistic approach in respect thereof. Ultimate strength prediction methods which take the inelastic behavior of ring-stiffened cylindrical shells and hemi-spherical shells into account are reviewed. The modeling uncertainties in terms of bias and coefficient of variation for failure prediction methods in current design guidelines are defined by evaluating the compiled experimental data. A simple ultimate strength formulation for ring-stiffened cylinders taking into account the interaction between local and global failure modes and an ultimate strength formula for hemispherical shells which have better accuracy and reliability than current design codes are taken as basis for reliability analysis. The effects of randomness of geometrical and material properties on failure are assessed by a preliminary study on reference models. By evaluation of sensitivity factors important variables are determined and comparisons are made with conclusions of previous reliability studies.

ABSTRACT: The use of cylindrical shells in the aerospace industry is widespread as load carrying structures. This paper addresses the buckling capability of a cylindrical shell under a compressive axial load using finite element analysis and shows how variability in manufacturing processes, such as ovalization of a cylindrical duct, can affect the buckling capability of these parts. Results show that, as expected, buckling capability of a thin cylinder is significantly affected by out of roundness. Out of roundness of 1%, 10%, 50% and 100% of the shell thickness resulted in a reduction in buckling capability of 8.3%, 37.8% 65.9% and 75%, respectively. Finite element results were calibrated to and were in good agreement with the theoretical solution for a perfectly round cylinder under axial compression.

ABSTRACT: This paper investigates experimentally the bending of inflatable cylindrical cantilevered beams made of modern fabric materials. A dimensionless form of load vs deflection has been developed to characterize and generalize the bending behavior of the inflatable cylindrical cantilevered beams of different sizes, materials, and inflation pressures in a unified way for easy application. The dimensionless form of experimental results demonstrates that the inflatable beams, highly or lightly inflated, can be modeled by the Euler beam theory accurately before wrinkle occurs. The initial wrinkle is hardly noticeable in the experiments and the transition from non-wrinkle to wrinkle is mainly defined by the slope change of load-deflection curve. Compared with the experimental data, the strain-based wrinkle moment provides a lower bound prediction while the stress-based wrinkle moment gives an upper bound prediction. In the post-wrinkle stage, the Euler beam theory using a nonlinear moment-curvature model gives an upper bound estimation of load-deflection
relationship while the finite element analysis based on membrane theory gives a lower bound estimation. The actual collapse moment is hard to measure in experiments due to the inflatable beam becomes unstable in the collapsed stage. However, the trends of experimental results show that the stress-based collapse moment gives the upper limit prediction and the strain-based collapse moment does not agree with the experimental data.

ABSTRACT: Laminated composite shells are frequently used in various engineering applications in the aerospace, mechanical, marine, and automotive industries. This article follows a previous book and review articles published by the leading author (Qatu, 2004, 2002, 1989, 1992, 1999 1, 2, 3, 4 and 5). It reviews most of the research done in recent years (2000–2009) on the dynamic behavior (including vibration) of composite shells. This review is conducted with emphasis on the type of testing or analysis performed (free vibration, impact, transient, shock, etc.), complicating effects in material (damping, piezoelectric, etc.) and structure (stiffened shells, etc.), and the various shell geometries that are subjected to dynamic research (cylindrical, conical, spherical and others). A general discussion of the various theories (classical, shear deformation, 3D, non-linear etc.) is also given. The main aim of this review article is to collate the research performed in the area of dynamic analyses of composite shells during the last 10 years, thereby giving a broad perspective of the state of art in this field. This review article contains close to 200 references.

ABSTRACT: Budget and schedule restrictions sometimes require naval submarines to be operated with unrepaird corrosion damage to the pressure hull. It is important to understand the effects of corrosion wastage on the structural capacity of the hull, so that appropriate diving depth restrictions can be imposed if necessary. The current paper presents an experimental study of the interaction of material behavior with corrosion defects, especially with respect to their effect on overall elasto-plastic collapse of pressure hulls. Twenty ring-stiffened cylinders, representative of submarine pressure hulls failing by overall collapse, were machined from high- and low-grade aluminum alloy tubes. Artificial general corrosion damage was introduced in selected specimens by machining away material from the outside of the cylinder shell in rectangular patches of uniform depth. The cylinders were monotonically loaded to collapse under external hydrostatic pressure. One corroded cylinder was repeatedly loaded past the yield limit before the collapse test in order to study the effect of cyclic plastic loading on its ultimate collapse strength. Overall collapse pressures for corroded cylinders with a variety of patch sizes and depths and material strengths were reduced by, on average, 0.85 times the depth of thinning divided by the original shell thickness. The collapse strength of corroded cylinders was found to be more sensitive to the shape of the stress-strain curve than for intact specimens. Higher levels of strain hardening and ductility were found to improve the performance of damaged cylinders. Permanent deformations in the cyclically loaded cylinder, as measured with strain gauges, grew with each constant-amplitude load cycle; however, the additional deformations tended towards zero with increasing number of cycles, and a subsequent collapse test indicated that the cyclic loading did not affect the collapse pressure. The sensitivity of overall collapse to material strength is related to not only the yield stress, but also the plastic reserve of the material; higher levels of strain hardening and ductility increase overall collapse strength of hulls, especially those with general corrosion damage. The effect of a given level of corrosion thinning is less severe for cylinders with relatively greater levels of strain hardening. It is unlikely that cyclic plastic loading of corroded hulls will lead to premature collapse at a load level below the monotonic collapse pressure.

ABSTRACT: The best available guide to the elastic stability of large structures, this volume was co-authored by world-renowned authorities on engineering mechanics. It ranges from theoretical explanations of 2- and 3-D stress and strain to practical applications such as torsion, bending, thermal stress, and wave propagation through solids. Equally valuable as text or reference. 1961 edition.

---Book
**On the stability of elastic equilibrium** by Warner Tjardus Koiter, National Aeronautics and Space Administration, 1967, 202 pages

---Book
**W.T. Koiter's elastic stability of solids & structures**, by Heijden Arnold van der, Hutchinson John, Achenbach Jan, October 2008, (publisher not given), Lavoisier Librarie, 216 pages

ABSTRACT: This book deals with the elastic stability of solids and structures, on which Warner Koiter was the world's leading expert. It begins with fundamental aspects of stability, relating the basic notions of dynamic stability to more traditional quasi-static approaches. The book is concerned not only with buckling, or linear instability, but most importantly with nonlinear post-buckling behavior and imperfection-sensitivity. After laying out the general theory, Koiter applies the theory to a number of applications, with a chapter devoted to each. These include a variety of beam, plate, and shell structural problems and some basic continuum elasticity problems. Koiter's classic results on the nonlinear buckling and imperfection-sensitivity of cylindrical and spherical shells are included. The treatments of both the fundamental aspects and the applications are completely self-contained. This book was recorded as a detailed set of notes by Arnold van der Heijden from W. T. Koiter's last set of lectures on stability theory, at TU Delft. Only book published based on Koiter's lectures. It deals with the elastic stability of solids and structures, the subject for which Koiter was the world's leading expert. He created much of field covered in this book. Includes coverage of nonlinear post-buckling behavior and imperfection-sensitivity, for which Koiter is most famous. Theory is applied to numerous applications.

SUMMARY: This highly regarded hardcover engineering manual is mainly concerned with three important aspects of elasticity theory: finite elastic deformations, complex variable methods for two-dimensional problems for both isotropic and aeolotropic bodies, and shell theory. Also discussed are three-dimensional problems for isotropic and transversely isotropic bodies. Chapter 1, devoted to mathematical preliminaries, includes a summary of tensors for workers unfamiliar with those notations. Subsequent chapters deal with the general theory of elasticity for finite deformations, solutions of a number of special problems, mostly for incompressible isotropic bodies, a theory of small deformations superposed on finite deformations, classical infinitesimal theory of elasticity, the theory of plane strain, plate theory, plane problems for isotropic bodies, and for aeolotropic bodies. The last chapters, 10-16, are devoted to the theory of shells. For this second edition, the authors added material on thermodynamics, as well as a new chapter dealing with methods of deriving membrane theory, inextensional theory, and bending theory, by asymptotic expansions of the three-dimensional linear elastic equations. Unabridged Dover republication of the second edition published by Oxford University Press, 1968.

Description:
We experience elasticity everywhere in daily life: in the straightening or curling of hairs, the irreversible deformations of car bodies after a crash, or the bouncing of elastic balls in ping-pong or soccer. The theory of elasticity is essential to the recent developments of applied and fundamental science, such as the bio-mechanics of DNA filaments and other macro-molecules, and the animation of virtual characters in computer graphics and materials science. In this book, the emphasis is on the elasticity of thin bodies (plates, shells, rods) in connection with geometry. It covers such topics as the mechanics of hairs (curled and straight), the buckling instabilities of stressed plates, including folds and conical points appearing at larger stresses, the geometric rigidity of elastic shells, and the delamination of thin compressed films. It applies general methods of classical analysis, including advanced nonlinear aspects (bifurcation theory, boundary layer analysis), to derive detailed, fully explicit solutions to specific problems. These theoretical concepts are discussed in connection with experiments. The book is self-contained. Mathematical prerequisites are vector analysis and differential equations. The book can serve as a concrete introduction to nonlinear methods in analysis.

The main properties that make carbon nanotubes (CNTs) a promising technology for many future applications are: extremely high strength, low mass density, linear elastic behavior, almost perfect geometrical structure, and nanometer scale structure. Also, CNTs can conduct electricity better than copper and transmit heat better than diamonds. Therefore, they are bound to find a wide, and possibly revolutionary use in all fields of engineering. The interest in CNTs and their potential use in a wide range of commercial applications; such as nanoelectronics, quantum wire interconnects, field emission devices, composites, chemical sensors, biosensors, detectors, etc.; have rapidly increased in the last two decades. However, the performance of any CNT-based nanostructure is dependent on the mechanical properties of constituent CNTs. Therefore, it is crucial to know the mechanical behavior of individual CNTs such as their vibration frequencies, buckling loads, and deformations under different loadings. This title is dedicated to the vibration, buckling and impact behavior of CNTs, along with theory for carbon nanosensors, like the Bubnov-Galerkin and the Petrov-Galerkin methods, the Bresse-Timoshenko and the Donnell shell theory.

This book provides an in-depth treatment of the study of the stability of engineering structures. Contributions from internationally recognized leaders in the field ensure a wide coverage of engineering disciplines in which structural stability is of importance, in particular the analytical and numerical modelling of structural stability applied to aeronautical, civil, marine and offshore structures. The results from a number of comprehensive experimental test programs are also presented, thus enhancing our understanding of stability phenomena as well as validating the analytical and computational solution schemes presented. A variety of structural materials are investigated with special emphasis on carbon-fibre composites, which are being increasingly utilized in weight-critical structures. Instabilities at the meso- and micro-scales are also discussed. This book will be particularly relevant to professional engineers, graduate students and researchers interested in structural stability.

CONTENTS: Experimental Studies of Stiffened Composite Panels under Axial Compression, Torsion and Combined Loading (H Abramovich); Buckling and Postbuckling Tests on Stiffened Composite Panels and Shells (C Bisagni); Mode-Jumping in Postbuckling Stiffened Composite Panels (B G Falzon); The Development of Shell Buckling Design Criteria Based on Initial Imperfection Signatures (M W Hilburger); Stability Design of Stiffened Composite Panels Simulation and Experimental Validation (A Kling); Anisotropic Elastic Tailoring in Laminated Composite Plates and Shells (P M Weaver); Optimization of Stiffened Panels using Finite Strip Models (R Butler & W Liu); Stability of Tubes and Pipelines (H A Rasheed & S A Karamanos); Imperfection-Sensitive Buckling and Postbuckling of Spherical Shell Caps (S Yamada & M Uchiyama); Nonlinear Buckling in Sandwich Struts: Mode Interaction and Localization (M A Wadee); The Boundary Element Method for Buckling and Postbuckling Analysis of Plates and Shells (M H Aliabadi & P M Baiz); Progressive Failure in Compressively Loaded Composite Laminated Panels: Analytical, Experimental and Numerical Studies (S Basu et al.); Micro- and Meso-Instabilities in Structured Materials and Sandwich Structures (T Daxner et al.).

**Mechanics of composite materials** by Robert Millard Jones, Taylor & Francis, 1999, 519 pages

ABSTRACT: This book balances introduction to the basic concepts of the mechanical behavior of composite materials and laminated composite structures. It covers topics from micromechanics and macromechanics to lamination theory and plate bending, buckling, and vibration, clarifying the physical significance of composite materials. In addition to the materials covered in the first edition, this book includes more theory-experiment comparisons and updated information on the design of composite materials.

--------Book

--------Book

ABSTRACT: A greater use of composite materials in many areas of engineering has led to a greater demand for engineers versed in the design of structures made from such materials. This text offers students and engineers tools for designing practical composite structures. Among the topics of interest to the designer are stress-strain relationships for a wide range of anisotropic materials; bending, buckling, and vibration of plates; bending, torsion, buckling, and vibration of solid as well as thin-walled beams; shells; hygrothermal stresses and strains; finite element formulation; and failure criteria. More than 300 illustrations, 50 fully worked problems, and material properties data sets are included.

--------Book

ABSTRACT: This book compiles techniques used to analyze composite structural elements ranging from beams through plates to stiffened shells. The content is suitable for graduate-level students with a basic background in mechanics of composite materials. Moreover, this book will be placed in an active spot on the bookshelves of composite structures designers as well as researchers.

--------Book

PARTIAL PREFACE: As composite materials are used more extensively, a constant source of concern is the effect of foreign objects impacts. Such impacts can reasonably be expected during the life of the structure and can result in internal damage that is often difficult to detect and can cause severe reductions in the strength and stability of the structure. This concern provided the motivation for intense research resulting in hundreds of journal and conference articles. Important advances have been made, and many aspects of the problem have been investigated. One would need to study a voluminous literature in order to get an appreciation for this new research area. After writing three comprehensive literature reviews on the topic of impact on composite materials, I felt that there was a need to present this material in book form. The study of impact on composite
structures involves many different topics, including contact mechanics, structural dynamics strength, stability, fatigue, damage mechanics and micromechanics….

-------Book

-------Book
DESCRIPTION: Buckling of structural elements has intrigued students for nearly three centuries. First, Euler studied bar buckling in the mid-18th century. Then, Bryan treated plate buckling in the late 19th century. Finally, shell buckling was a 20th-century pursuit of Timoshenko, Donnell, Flügge, and von Kármán, among many other notables. This graduate text and reference work is aimed at those involved in mechanical, civil, aerospace, and ocean engineering, as well as engineering mechanics. Fundamental buckling behavior is studied for three basic structural elements: one-dimensional bars, two-dimensional plates, and three-dimensional shells. The approach features a consistent energy-based formulation after Langhaar. The final topic in each of the chapters on bars, plates, and shells is an introduction to the essence of design for each structural element. Author Robert M. Jones, an ASME Fellow, is Professor Emeritus of Engineering Science and Mechanics

-------Book
Hui-Shen Shen, **Functionally Graded Materials: Nonlinear Analysis of Plates and Shells**, CRC Press, Jan 15, 2009, 280 pages
DESCRIPTION: Initially designed as thermal barrier materials for aerospace applications and fusion reactors, functionally graded materials (FGMs) are now widely employed as structural components in extremely high-temperature environments. However, little information is commonly available that would allow engineers to predict the response of FGM plates and shells subjected to thermal and mechanical loads. Functionally Graded Materials: Nonlinear Analysis of Plates and Shells is the first book devoted to the geometrically nonlinear response of inhomogeneous isotropic and functionally graded plates and shells. Concerned that the high loads common to many structures may result in nonlinear load–deflection relationships due to large deformations, author Hui-Shen Shen has been conducting investigations since 2001, paying particular attention to the nonlinear response of these plates and shells to nonlinear bending, postbuckling and nonlinear vibration. Nearly all the solutions presented are the results of investigations conducted by the author and his collaborators. The rigor of these investigative procedures allows the results presented within these pages to stand as a benchmark against which the validity and accuracy of other numerical solutions may be measured

Description: As the theories and methods have evolved over the years, the mechanics of solid bodies has become unduly fragmented. Most books focus on specific aspects, such as the theories of elasticity or plasticity, the theories of shells, or the mechanics of materials. While a narrow focus serves immediate purposes, much is achieved by establishing the common foundations and providing a unified perspective of the discipline as a whole. Mechanics of Solids and Shells accomplishes these objectives. By emphasizing the underlying assumptions and the approximations that lead to the mathematical formulations, it offers a practical, unified presentation of the foundations of the mechanics of solids, the behavior of deformable bodies and thin shells, and the properties of finite elements. The initial chapters present the fundamental kinematics, dynamics, energetics, and behavior of materials that build the foundation for all of the subsequent developments. These are presented in full generality without the usual restrictions on the deformation. The general principles of work and energy form the basis for the consistent theories of shells and the approximations by finite elements. The final chapter views the latter as a means of approximation and builds a bridge between the mechanics of the continuum and the discrete assembly. Expressly written for engineers, Mechanics of Solids and Shells forms a reliable source for the tools of analysis and approximation. Its constructive presentation clearly reveals the origins, assumptions, and limitations of the methods described and provides a firm, practical basis for the use of those methods.

Partial Preface to the Second Edition:
During the nine years since the publication of the first edition of this book, there has been substantial progress on the treatment of well-set problems of nonlinear solid mechanics. The main purposes of this second edition are to update the first edition by giving a coherent account of some of the new developments, to correct errors, and to refine the exposition. Much of the text has been rewritten, reorganized, and extended. The philosophy underlying my approach is exactly that given in the following (slightly modified) Preface to the First Edition. In particular, I continue to adhere to my policy of eschewing discussions relying on technical aspects of theories of nonlinear partial differential equations (although I give extensive references to pertinent work employing such methods). Thus I intend that this edition, like the first, be accessible to a wide circle of readers having the traditional prerequisites given in Sec. 1.2.
I welcome corrections and comments. In due time, corrections will be placed on my web page: [http://www.ipst.umd.edu/Faculty/antman.htm](http://www.ipst.umd.edu/Faculty/antman.htm).

Partial Preface to the First Edition:
The scientists of the seventeenth and eighteenth centuries, led by Jas. Bernoulli and Euler, created a coherent theory of the mechanics of strings and rods undergoing planar deformations. They introduced the basic concepts of strain, both extensional and flexural, of contact force with its components of tension and shear force, and of contact couple. They extended Newton’s Law of Motion for a mass point to a law valid for any deformable
body. Euler formulated its independent and much subtler complement, the Angular Momentum Principle. (Euler also gave effective variational characterizations of the governing equations.) These scientists breathed life into the theory by proposing, formulating, and solving the problems of the suspension bridge, the catenary, the velaria, the elastica, and the small transverse vibrations of an elastic string. (The level of difficulty of some of these problems is such that even today their descriptions are seldom vouchsafed to undergraduates. The realization that such profound and beautiful results could be deduced by mathematical reasoning from fundamental physical principles furnished a significant contribution to the intellectual climate of the Age of Reason.) At first, those who solved these problems did not distinguish between linear and nonlinear equations, and so were not intimidated by the latter.

--------Book
*An introduction to the elastic stability of structures* by George J. Simitses, Prentice-Hall, 1976, 253 pages

--------Book

--------Book

ABSTRACT: The ability of a structural assembly to carry loads and forces determines how stable it will be over time. Viewing structural assemblages as comprising columns, beams, arches, rings, and plates, this book will introduce the student to both a classical and advanced understanding of the mechanical behavior of such structural systems under load and how modeling the resulting strains can predict the overall future performance the stability of that structure. While covering traditional beam theory, the book is more focused on elastic theory in keeping with modern approaches. This text will be an expanded and updated version a similar, previously published book, but with pedagogical improvements and updated analytical methods. This engineering textbook will provide a focused treatment on the study of how structures behave and perform when under stress loading, including plastic deformation and buckling. All advanced engineering students studying engineering mechanics, structural analysis and design, fatigue and failure, and other related subjects need to have this knowledge, and this book will provide it in a thorough and coherent fashion. Written by two of the world's leading engineering professors in this subject area, the pedagogy has been classroom-tested over many years and should find a receptive readership among both students and instructors. An understandable introduction to the theory of structural stability, useful for a wide variety of engineering disciplines, including mechanical, civil and aerospace engineering Covers both static and dynamic loads, for both conservative and nonconservative systems. Emphasizes elastic behavior under loads, including vertical buckling, torsional buckling and nonlinear affects of structural system buckling and stability Case examples to illustrate real-world applications of Stability Theory.
Theory of elastic stability: analysis and sensitivity by Luis Augusto Godoy, Taylor & Francis, 2000, 434 pages
ABSTRACT: This book gives a unified presentation of the field of stability. Buckling and post-buckling states are studied on the basis of total potential energy of structural systems. Emphasis is placed throughout the text on post-buckling analysis and behaviour. The sensitivity of buckling and post-buckling states to changes in design parameters is also discussed as well as changes due to imperfections and damage.

Thin-walled structures with structural imperfections: analysis and behavior, by Luis Augusto Godoy, 1996, Pergamon (indicated on cover) or Elsevier Science Ltd (indicated inside), ISBN 0-08-042266-7

ABSTRACT: Rapid advances in analytical methods and computing enable engineers to apply stability/stiffness methods to increasingly complex real-life cases. This advanced and graduate-level text and self-tutorial teaches readers to understand and to apply analytical design principles across the breadth of the engineering sciences. Emphasizing fundamentals, the book addresses the stability of key engineering elements such as rigid-body assemblage, beam-columns, rigid frames, thin plates, arches, rings, or shells. Each chapter contains numerous worked-out problems that clarify practical application and aid comprehension of the basics of stability theory, plus end-of-chapter review exercises. Others key features are the citing and comparison of different national building standards, use of non-dimensional parameters, and many tables with much practical data and simplified formula, that enable readers to use them in the design of structural components.
---Book

**Stability of elastic structures** edited by Nikolai Anatolevich Alfutov, Springer, 2000, 337 pages

ABSTRACT: The subject discussed in this book is the stability of thin-walled elastic systems under static loads. The presentation of these problems is based on modern approaches to elastic-stability theory. Special attention is paid to the formulation of elastic-stability criteria, to the statement of column, plate and shell stability problems, to the derivation of basic relationships, and to a discussion of the boundaries of the application of analytic relationships. The author has tried to avoid arcane, nonstandard problems and elaborate and unexpected solutions, which bring real pleasure to connoisseurs, but confuse students and cause bewilderment to some practical engineers. The author has an apprehension that problems which, though interesting, are limited in application can divert the reader's attention from the more prosaic but no less sophisticated general problems of stability theory.

---Book

ABSTRACT: The up-to-date edition of the classic guide--from leading experts in structural stability theory and research. First published in 1960, the Guide to Stability Design Criteria for Metal Structures is the reference of choice for civil and structural engineers seeking reliable, in-depth coverage of stability problems and research. This extensively revised Fifth Edition bridges theory and practice to offer simplified and refined procedures both for design and for the assessment of design limitations, as well as detailed guidance on design specifications, codes, and standards concerning the stability of metal structures. Written by members of Structural Stability Research Council task groups and other specialists, all material has been updated to reflect recent developments in each subject area. The Fifth Edition features eight new chapters covering the latest procedures in horizontal curved steel I-girders, composite columns and structural systems, stability of angle members, bracing, frame stability, doubly curved shells and shell-like structures, stability under seismic loading, and stability analysis by the finite element method. Complete with over 100 new illustrations, plus references, technical memoranda, and name and subject indexes, the Guide to Stability Design Criteria for Metal Structures, Fifth Edition is ready to go to work for a new generation of structural and civil engineers in their daily practice.

**Shell Stability Handbook**
Author: Lars A. Samuelson, Sigge Eggwertz
SUMMARY: The Shell Stability Handbook is a handbook for calculation of the carrying capacity of shell structures with respect to buckling. The aim has been to develop a branch independent handbook which gives conservative estimates of the carrying capacity. The safety factors which should be used in a certain case must be taken from the applicable code for the considered structure, e.g. pressure vessel codes, steel structure codes etc. Initiator behind the handbook is Professor Lars A. Samuelson who already in the seventies during his time at the Aeronautical Research Institute of Sweden felt a strong need for such a handbook. The development of the handbook, which also included substantial research in the field of shell stability, started in 1982. The first Swedish edition was published in 1990.

Book

Book

Book
ABSTRACT: Stop searching through the endless amount of literature to find the most recent information on plate buckling. The authors of Handbook of Thin Plate Buckling and Post Buckling have already done the work for you. Detailed and clearly written, the book contains a comprehensive, up-to-date treatment of the buckling and postbuckling behavior of perfect and imperfect thin plates. The authors study, in detail and with specific solved examples, the essential factors that influence critical buckling loads, initial mode shapes, and postbuckling behavior for thin plates. Through their analysis of rectangular, circular, and annular plates, they present valuable information, some of which has never before been published in book form. Such topics include hygrothermal buckling, viscoelastic and plastic buckling, and buckling of various thickness plates. With this important collection, the Handbook of Thin Plate Buckling and Post Buckling provides you with a one-stop source of current research findings.

Book
ABSTRACT: Contributed by leading authorities in the field from around the world, this text provides a comprehensive insight into buckling and postbuckling. Basic theory, methods of buckling analysis and their application, the effect of external variables such as temperature and humidity on the buckling response and buckling tests are all covered.

Book
Introduction to composite materials, by Stephen W. Tsai and H. Thomas Hahn, CRC Press, 1980, 457 pages, COMMENTS: A widely used basic text by two recognized authorities. A unified and disciplined approach; advanced concepts reduced to easy-to-use charts, formulas and numerical examples.
Composites Design, by Stephen W. Tsai, Think Composites, 1987, 512 pages

Theory of composites design, by Stephen W. Tsai, Think Composites, 1992, 225 pages

Hull, D., An Introduction to Composite Materials, Cambridge University Press (year not given)

McCullough, R.L., Concept of Fiber-Resin Composites, Marcel Dekker, Inc., NY, 1971

ABSTRACT: A major basic text on the theory and structural applications of laminated anisotropic plates. Detailed coverage of problems of bending under transverse load, stability, and free-vibrations, as well as laminated beams, expansional strain effects, curved plates, and free-edge effects.

FOREWORD: …provides users with basic knowledge about the design and analysis of composite materials and structures. The six-volume indexed set is an ongoing series to which new volumes will be added as new needs arise and new knowledge is gained about this rapidly growing field of composites…
Volume 1 – Mechanical behavior and properties of composite materials
Volume 2 – Micromechanical materials modeling
Volume 3 – Processing and fabrication technology
Volume 4 – Failure analysis of composite materials
Volume 5 – Design studies
Volume 6 – Test methods
Index to Volumes 1-6

ABSTRACT: Composite materials are increasingly used in aerospace, underwater, and automotive structures. They provide unique advantages over their metallic counterparts, but also create complex challenges to analysts and designers. Practical Analysis of Composite Laminates presents a summary of the equations governing composite laminates and provides practical methods for analyzing most common types of composite structural elements. Experimental results for several types of structures are included, and theoretical and experimental correlations are discussed. The last chapter is devoted to practical analysis using Designing Advanced Composites (DAC), a PC-based software on the subject. This comprehensive text can be used for a graduate course in mechanical engineering, and as a valuable reference for professionals in the field.

SUMMARY: A systematic presentation of energy principles and variational methods. The increasing use of numerical and computational methods in engineering and applied sciences has shed new light on the importance of energy principles and variational methods. Energy Principles and Variational Methods in Applied Mechanics provides a systematic and practical introduction to the use of energy principles, traditional variational methods, and the finite element method to the solution of engineering problems involving bars, beams, torsion, plane elasticity, and plates. Beginning with a review of the basic equations of mechanics and the concepts of work, energy, and topics from variational calculus, this book presents the virtual work and energy principles, energy methods of solid and structural mechanics, Hamilton's principle for dynamical systems, and classical variational methods of approximation. A unified approach, more general than that found in most solid mechanics books, is used to introduce the finite element method. Also discussed are applications to beams and plates. Complete with more than 200 illustrations and tables, Energy Principles and Variational Methods in Applied Mechanics, Second Edition is a valuable book for students of aerospace, civil, mechanical, and applied mechanics; and engineers in design and analysis groups in the aircraft, automobile, and civil engineering structures, as well as shipbuilding industries.

**--------Book**

SUMMARY: Offering a thorough treatment of both contemporary design optimization techniques and the mechanics of composite laminates, Design and Optimization of Laminated Composite Materials broadens engineers' design horizons by providing them with the information they need to take full advantage of this important class of composite materials. Intended to serve as an undergraduate- to graduate-level course text or a professional reference for practicing engineers, it features a rational, integrated presentation, supplemented with case examples, practice exercises, and valuable programming tips. Important features include:
* An integrated approach to the analysis and design of laminated composites
* Selected optimization methods that are suited to the design of laminates with discrete thickness and orientation angles
* Guidelines on getting the most out of numerical and graphical software applications for laminate optimization problems
* A companion Web site containing valuable Mathematica(TM)-based programs and helpful tutorials: www.composite-design.vt.edu

**--------Book**

**--------Book**

SUMMARY: A compact presentation of the foundations, current state of the art, recent developments and research directions of all essential techniques related to the mechanics of composite materials and structures. Special emphasis is placed on classic and recently developed theories of composite laminated beams, plates and shells, micromechanics, impact and damage analysis, mechanics of textile structural composites, high strain rate testing and non-destructive testing of composite materials and structures. Topics of growing importance are addressed, such as: numerical methods and optimisation, identification and damage monitoring. The latest results are presented on the art of modelling smart composites, optimal design with advanced materials, and industrial applications. Each section of the book is written by internationally recognised experts who have dedicated most of their research work to a particular field. Readership: Postgraduate students, researchers and engineers in the field of composites. Undergraduate students will benefit from the treatment of the foundations of the mechanics of composite materials and structures.

**--------Book**

**Composite materials: design and applications**, by Daniel Gay, CRC Press, 2003, 531 pages

COMMENTS: Composite Materials: Design and Applications is an updated translation of the French book Materiaux Composites. It is a comprehensive, well-illustrated reference and text on composite materials and structures. The illustrations are uniquely clear and standardized throughout. This practical book addresses difficult design issues such as sandwich plates, bonded joints, and other details of design. It is a welcome

ABSTRACT: The use of composite materials in engineering structures continues to increase dramatically, and in the seven years since the first edition of this book appeared, advances in materials modeling in general and composite materials and structures in particular have been just as significant. To reflect these developments, renowned author, educator, and researcher J.N. Reddy has thoroughly revised, updated, and enhanced his standard-setting Mechanics of Laminated Composite Plates and Shells: Theory and Analysis. New in the Second Edition: A new chapter dedicated to the theory and analysis of laminated shells. New discussions addressing smart structures and functionally graded materials. Thorough updates to all chapters and a reorganization of chapters that improves the clarity of the presentation. Additional exercises and examples. No other book is as up to date. No other book approaches the subject primarily from the finite element method. And no other book provides such full, self-contained coverage of the theories, analytical solutions, and linear and nonlinear finite element models of plate and shell laminated composite structures.

Mechanics of laminated composite plates and shells, J.N. Reddy, 2004 (pdf from tamu.edu)

ABSTRACT: The calculation of buckling loads is key in designing structural elements and often hinges on numerical methods. However, analytical solutions can serve as critical cross-references that help assess the reliability and accuracy of numerical solutions. The quest for access to closed form analytical solutions that elucidate the intrinsic fundamental and unexpected features of numerical solutions drove the creation of Exact Solutions for Buckling of Structural Members. In researching this book, the authors gathered as many exact buckling solutions as possible, and have presented them in a concise treatment. This book condenses closed form buckling solutions of columns, beams, arches, rings, plates and shells from the vast literature into a single volume. It begins with an introduction to elastic buckling and the importance of elastic buckling load. The following chapters present coverage of flexural buckling solutions for columns under various loads, restraints, and boundary conditions; the exact flexural-torsional buckling solutions of beams; and the buckling solutions of circular arches and rings. Also included in these chapters are discussions of the effect of transverse shear
deformation on the buckling load of columns and the flexural-torsional buckling of columns for thin-walled members with open profiles. The final chapters discuss the elastic buckling of plates under inplane loads and buckling solutions for cylindrical and spherical shells. With coverage of a wide range of buckling load problems, this innovative reference provides engineers and researchers benchmarks for assessing the validity, convergence, and accuracy of solutions obtained by numerical methods.

**Flexural-torsional buckling of structures** by N. S. Trahair, CRC Press, 1993, 360 pages

ABSTRACT: Flexural-Torsional Buckling of Structures provides an up-to-date, comprehensive treatment of flexural-torsional buckling and demonstrates how to design against this mode of failure. The author first explains the fundamentals of this type of buckling behavior and then summarizes results that will be of use to designers and researchers in either equation or graphical form. This approach makes the book an ideal text/reference for students in structural engineering as well as for practicing civil engineers, structural engineers, and constructional steel researchers and designers. The book begins by introducing the modern development of the theory of flexural-torsional buckling through discussions on the general concepts of equilibrium, total potential, virtual work, and buckling. It then continues with in-depth coverage of hand methods for solving buckling problems, the analysis of flexural-torsional buckling using the finite element method, and the buckling of different types of structural elements and frames composed of various elastic materials. Other topics addressed include the design and inelastic buckling of steel members. The book's final chapter considers a collection of special topics.

ABSTRACT: Shell structures are found abundantly in engineering designs and are routinely analysed with finite element methods. The objective of this book is to present, in a unified manner, modern finite element
procedures for general shell analysis. The first chapters introduce the basic concepts for the analysis of shells, explain the mathematical preliminaries, and discuss the mathematical models of plates and shells including their asymptotic properties. The following chapters deal with finite element discretization methods for plates and shells. At the end of the book, applications of these methods in modern engineering practice are described and an overview of nonlinear shell analysis is given.

Bathe, K., 1996, **Finite Element Procedures**, Prentice-Hall, Englewood, New Jersey

ABSTRACT: Elastic shells are pervasive in everyday life. Examples of these thin-walled structures range from automobile hoods to basketballs, veins and arteries, and soft drink cans. This book explains shell theory, with numerous examples and applications. This second edition not only brings all the material of the first edition entirely up to date; it also adds two entirely new chapters on general shell theory and general membrane theory. Aerospace, mechanical, and civil engineers, as well as applied mathematicians, will find this book a clearly written and thorough information source on shell theory.

**Theory of Shell Structures**, By C. R. Calladine Print Publication Year: 1983 Online Publication Date: February 2010
Introduction: In most of the chapters of this book we have assumed that the material from which a shell is constructed behaves under stress in a linear-elastic manner. The materials which are used in structural engineering generally have a linear-elastic range, but behave inelastically when a certain level of stress is exceeded. Moreover at sufficiently high temperatures irreversible creep may be the most significant phenomenon. It is obvious that there are some circumstances in which it is necessary for the designer to understand the behaviour of shells in the inelastic range. This subject is a large one, and in this chapter we shall give an introduction to part of it. The aim of the present chapter is to give a glimpse, mainly through a few specific examples, of the ways in which the structural analyst may tackle problems connected with inelastic behaviour of shells. In general our plan will be to set up the simplest problems which illustrate various important points. But first it is necessary to discuss some general questions in connection with the scope of plastic theory, and the circumstances in which it is valid.
SUMMARY: Shells are basic structural elements of modern technology. Examples of shell structures include automobile bodies, domes, water and oil tanks, pipelines, silos, ship hulls, aircraft fuselages, turbine blades, loudspeaker cones, but also balloons, parachutes, biological membranes, a human skin, a bottle of wine or a beer can. This volume contains full texts of over 100 papers presented by specialists from over 20 countries at the 8th Conference "Shell Structures: Theory and Applications", 12-14 October, 2005 in Jurata (Poland). The aim of the meeting was to bring together scientists, designers, engineers and other specialists in shell structures in order to discuss important results and new ideas in this field. The goal is to pursue more accurate theoretical models, to develop more powerful and versatile methods of analysis, and to disseminate expertise in design and maintenance of shell structures. Among the authors there are many distinguished specialists of shell structures, including the authors of general lectures: I.V. Andrianov (Ukraine), V.A. Eremeyev (Russia), A. Ibrahimbegovic (France), P. Klosowski (Poland), B.H. Kröplin (Germany), E. Ramm (Germany), J.M. Rotter (UK) and D. Steigmann (USA). The subject area of the papers covers various theoretical models and numerical analyses of strength, dynamics, stability, optimization etc. of different types of shell structures, their design and maintenance, as well as modelling of some surface-related mechanical phenomena.

SUMMARY: Shells are basic structural elements of modern technology and everyday life. Examples of shell structures in technology include automobile bodies, domes, water and oil tanks, pipelines, silos, ship hulls, aircraft fuselages, turbine blades and nanotubes. Loudspeaker cones, balloons, parachutes, biological membranes, a human skin, a bottle of wine, and a beer can are examples of shells in everyday life. Shell Structures. Theory and Applications, Volume 2 contains 77 contributions from over 17 countries, reflecting a wide spectrum of scientific and engineering problems of shell structures. The papers are divided into six broad groups: 1. General lectures 2. Theoretical modeling 3. Stability 4. Dynamics 5. Numerical analysis 6. Engineering design. Shell Structures. Theory and Applications, Volume 2 will be of interest to academics, researchers,
designers and engineers dealing with theoretical modelling, computerized analyses and engineering design of thin-walled structures and shell structural elements.

Petr E. Tovstik and Andrei L. Smirnov (Department of Theoretical and Applied Mechanics of the Faculty of Mathematics and Mechanics, St. Petersburg State University, Russia), “**Asymptotic Methods in the Buckling Theory of Elastic Shells**” (360 pages, 2011 ebook), in Series on Stability Vibration and Control of Systems, Series A - Vol. 4
ABSTRACT: This book contains solutions to the most typical problems of thin elastic shells buckling under conservative loads. The linear problems of bifurcation of shell equilibrium are considered using a two-dimensional theory of the Kirchhoff–Love type. The explicit approximate formulas obtained by means of the asymptotic method permit one to estimate the critical loads and find the buckling modes. The solutions to some of the buckling problems are obtained for the first time in the form of explicit formulas. Special attention is
devoted to the study of the shells of negative Gaussian curvature, the buckling of which has some specific features. The buckling modes localized near the weakest lines or points on the neutral surface are constructed, including the buckling modes localized near the weakly supported shell edge. The relations between the buckling modes and bending of the neutral surface are analyzed. Some of the applied asymptotic methods are standard; the others are new and are used for the first time in this book to study thin shell buckling. The solutions obtained in the form of simple approximate formulas complement the numerical results, and permit one to clarify the physics of buckling.

Buckling of thin metal shells, Edited by J. G. Teng, J. Michael Rotter, Spon Press, 11 New Fetter Lane, London EC4P 4EE, 2004 (520 pages)
DESCRIPTION: Thin-walled metal shell structures are highly efficient in their use of material, but they are particularly sensitive to failure by buckling. Many different forms of buckling can occur for different geometries and different loading conditions. Because this field of knowledge is both complex and industrially important, it is of great interest and concern in a wide range of industries. This book presents a compilation and synthesis of a wealth of research, experience and knowledge of the subject. Information that was previously
widely scattered throughout the literature is assembled in a concise and convenient form that is easy to understand, and state-of-the-art research findings are thoroughly examined. This book is useful for those involved in the structural design of silos, tanks, pipelines, biodigestors, chimneys, towers, offshore platforms, aircraft and spacecraft.

ABSTRACT: The increasing use of composite materials requires a better understanding of the behavior of laminated plates and shells. Large displacements and rotations, as well as shear deformations, must be included in the analysis. Since linear theories of shells and plates are no longer adequate for the analysis and design of composite structures, more refined theories are now used for such structures. This text develops, in a systematic manner, the overall concepts of the nonlinear analysis of shell structures. The authors start with a survey of theories for the analysis of plates and shells with small deflections and then lead to the theory of shells undergoing large deflections and rotations applicable to elastic laminated anisotropic materials. Subsequent chapters are devoted to the finite element solutions and include test case comparisons. The book is intended for graduate engineering students and stress analysts in aerospace, civil, or mechanical engineering.

-----Book

PARTIAL ABSTRACT: This book originally appeared as a text prepared for the Defense Nuclear Agency to summarize research on dynamic pulse buckling by the authors and their colleagues at SRI International during the period from 1960 to 1980. The objective of the book was to gather into a cohesive whole material that had been published in reports and the open literature during the two-decade period. In the process of knitting this material together, a substantial amount of new work was done. The book therefore contains many new results never published in the open literature….

-----Book
**Finite element software for plates and shells**, by Ernest Hinton, D. R. J. Owen, Pineridge Press, 1984
ABSTRACT OF CHAPTER 7, “PLASTIC BUCKLING”, by Jagabandhu Chakrabarty (pp. 479-559)

In a typical boundary value problem involving prescribed nominal traction rates on a part $S_F$ of the boundary surface, and prescribed velocities on the remainder $S_v$, more than one mode of deformation may be possible when the applied load reaches a critical value. The lack of uniqueness of the deformation mode under given boundary conditions is commonly referred to as bifurcation, the current shape and mechanical state of the body being supposed to be given or previously determined. For a linear solid, in which the strain rate is a unique linear function of the stress rate during both loading and unloading, a bifurcation mode corresponds to an eigensolution of the field equations and represents a mode quasi-statically possible under constant loads on $S_F$ and rigid constraints on $S_v$. In dealing with the conventional elastic/plastic solid, which is bilinear in the sense that the strain rate is related to the stress rate by separate linear functions for loading and unloading, it is convenient to introduce a linear comparison solid with identical boundary conditions (Section 1.5). While bifurcation in the linearized solid can occur under any given traction rates on $S_F$ and velocities on $S_v$ when the load becomes critical, bifurcation in the actual elastic/plastic solid would occur only under those traction rates for which there is no instantaneous unloading of the material that is currently plastic. The incremental theory of plasticity will be almost exclusively used in this chapter for the estimation of the critical load.

Static and dynamic analyses of plates and shells: theory, software and applications, by Hou-Cheng Huang, Springer-Verlag, 1989
ABSTRACT: This book illustrates the element technology of plates and shells and compares and contrasts the behaviour of current plate and shell elements for thick and thin shell theories as well as for static and transient dynamic analyses. It also highlights the locking phenomenon experienced by most of the currently available elements and introduces a strategy for avoiding this phenomenon. In addition, the book provides the necessary benchmark tests for plate and shell elements. The book will be useful for undergraduates since all fundamental theories are included. It should also be useful for structural engineers in order to understand shell stress analyses. They would be particularly interested in the shear forces in plate and shell structures where most elements are seen to produce poor results. For postgraduates and researchers in this field, the book will be most helpful. Many research workers have been studying shell element technology for two decades. Consequently, plate and shell element design is still an active area. Two associated programmes are provided with the book. One is for static analysis and the other for dynamic analysis. The programmes can be compiled and run on either a mini or a mainframe computer via a terminal.

Theory And Design Of Plate And Shell Structures by Maan H. Jawad
Book Summary of Theory And Design Of Plate And Shell Structures
This is the first book to integrate the theory, design, and stability analysis of plates and shells in one comprehensive volume. With authoritative accounts of diverse aspects of plates and shells, this volume facilitates the study and design of structures that incorporate both plate and shell components. Drawing on his extensive experience in plate and shell theory and design, the author: --introduces the principles and applications of bending of plates; membrane theory and bending of shells; and stability of plates and shells; --explains the crucial elements of roof structure analysis and finite element formulations; --explores topics of current interest, such as plastic design of plates and approximate solution of membrane stress in shells of revolution and in buckling of shells; --describes how to select design approaches according to the functional and safety requirements of specific structures. Each chapter demonstrates the principles, practical applications, and design of a plate or shell component using real-life examples, providing the reader with an in-depth, unified understanding of the theory and function of the component. Chapters are written to be as independent of each other as possible to allow for selective reading on either plates or shells. In addition, the text is conveniently supplemented by appendices of Fourier Series and Bessel Functions. Integrating the fundamental and applied aspects of plate and shell theory, this volume serves as an essential text for graduate students and as an easy-to-use reference for engineers in mechanical, civil, and aeronautical engineering. Mann H. Jawad is Chief Engineer at the Nooter Corporation in St. Louis, Missouri

------

DESCRIPTION: This exciting text is written primarily for professional engineers interested in designing plate and shell structures. It covers basic aspects of theories and gives examples for the design of components due to internal and external loads as well as other loads such as wind and dead loads. Various derivations are kept relatively simple and the resultant equations are simplified to a level where the engineer may apply them directly to design problems. More elaborate derivations and more general equations may be found in the literature for those interested in a more in-depth knowledge of the theories of plates and shells. 

COMPLETE CONTENTS
* Bending of simply supported rectangular plates
* Bending of various rectangular plates
* Bending of circular plates
* Plates of various shapes and properties
* Approximate analysis of plates
* Buckling of plates
* Vibration of plates
* Membrane theory of shells of revolution
* Various applications of the membrane theory
* Bending of thin cylindrical shells due to axisymmetric loads, Various structures
* Buckling of cylindrical shells
* Buckling of shells of revolution
* Vibration of shells
* Basic finite element equations.

An Introduction to Modelling Buckling and Collapse by B. G. Falzon & M. H. Hitchings
First Published - September 2006, Softback, 136 Pages
DESCRIPTION:
The term ‘collapse’ is often used to refer to the sudden loss of structural integrity and does not distinguish between the two major categories leading to structural failure: (a) material failure or (b) structural instability due to loss of structural stiffness within the elastic limit of the material. The term ‘buckling’ is often reserved specifically for the latter category. At an elementary level, predicting material failure may be accomplished using linear finite element analysis. The strains and corresponding stresses obtained from this analysis may be compared to design stress (or strain) allowables anywhere within the structure. If the finite element solution indicates regions where these allowables are exceeded, it is assumed that material failure has occurred. Design allowables are based on experimentally-derived material strengths and usually include a safety margin. This type of analysis will give an adequate prediction for statically determinate metallic structures undergoing small deformations.

If the structure is statically indeterminate, as indeed the majority of practical structures are, the analyst may want to assess the evolution of material failure. The load at which material failure initiates may be significantly lower than that which leads to eventual collapse. The analyst may also want to know the nature of this failure progression, that is, is it gradual or does it occur rapidly? Material failure may be the result of plasticity in
metallic structures or fracture, which is a more prevalent form of failure in brittle materials such as ceramics or carbon-fibre reinforced plastics. The structure may also undergo large deformations before or during material failure and it is therefore apparent that the presence of geometric and material non-linearities requires more sophisticated finite element solution schemes.

Buckling refers to the loss of stability of a structure and in its simplest form, is independent of material strength where it is assumed that this loss of stability occurs within the elastic range of the material. It is primarily characterised by a loss of structural stiffness and cannot be modelled using basic linear finite element analysis. Slender or thin-walled structures under compressive loading are susceptible to buckling. Buckling may also be stable or unstable and different geometries lead to different forms of buckling stability. A distinction is also made between classical buckling and other forms of structural instability. Without resorting to formal definitions and distinctions at this stage, one physical manifestation of these differences is that classical buckling results in the structure deforming primarily in a direction orthogonal to that of the applied loading causing this instability.

Another form of structural instability, termed snap buckling, is where the deformation is primarily in the direction of the applied loading.

Material failure and buckling may both occur in sequence leading to structural collapse. A thin-walled or slender structure may initially buckle elastically but the resulting high deformations may cause localised material failure. A thicker-walled or less slender structure under high compressive loading may exhibit localised inelastic behaviour, such as plasticity, which lowers the stiffness leading to buckling.

Scope
This book provides an introduction to the various mechanisms which may lead to structural buckling or collapse and the strategies employed in modelling this behaviour using finite element analysis. While the use of some jargon is unavoidable, every effort has been made to ensure that definitions are given when required, either within the text or as an entry in the Glossary at the end of this book. It is also the authors’ view that the introduction of mathematical equations is central to giving the analyst further insight into the suitability of the various numerical strategies available in most finite element systems. If the reader is particularly averse to the mathematical treatment given herein, he or she may skip over these and still obtain useful and practical information on modelling buckling and collapsing structures.

The development of new finite element methodologies and formulations, to model highly non-linear behaviour such as buckling and collapse, continues to advance at a rapid pace. The majority of the methodologies and modelling strategies presented in this book may be found in current commercial finite element packages. To give this book relevance beyond the immediate time, recent developments which are still at the research stage are also discussed. While these may not be available commercially at the time of writing, there is enough information given for the interested reader to implement these schemes in non-commercial (research) codes or, if possible, as user subroutines in commercial finite element packages.

7.2. Fracture Mechanics Basics
7.3. Example 7A - Stress Intensity Factor Calculation
7.4. Quarter-Point Isoparametric Elements
7.5. Virtual Crack Closure Technique
7.6. Interface Elements
7.7. Example 7B – VCCT Applied to Skin-Stiffener Debonding Problem
7.8. Example 7C – Mixed-Mode Multiple Delamination Using Interface Elements
8. Practical Guide to Selecting a Solution Scheme
9. Concluding Remarks

Thermal Stress Analysis of Beams, Plates and Shells presents classic and advanced thermal stress topics in a cutting edge review of this critical area. Tackling subjects with little coverage in existing resources, the book considers complex problems, such as multi-layered cases, using modern advanced computational and vibrational methods.

Authors Carrera and Fazzolari begin with a review of the fundamentals of thermoelasticity and thermal stress analysis relating to advanced structures and the basic mechanics of beams, plates and shells, making the book a self-contained reference. They move on to consider more challenging topics, including:

Multilayered, anisotropic thermal stress structures
Static and dynamic responses of coupled and uncoupled thermoelastic problems
Thermal buckling and post-buckling behavior of thermally loaded structures
Thermal effects on panel flutter phenomena
Static and dynamic thermal stress analysis of functionally graded material (FGM) structures

With practical advice on advanced computational methods, and sample problems throughout that cover both metallic and composite structures and account for mesh and meshless methods, Thermal Stress Analysis of Beams, Plates and Shells is a valuable resource for those working on thermal stress problems within mechanical, civil and aerospace engineering settings.

Contents:
1. Introduction
2. Solution of sample problems in classical thermoelasticity
3. Thermoelasticity, coupled and uncoupled variational formulations
4. Fundamental of mechanics of beams, plates and shells
5. Multilayered, anisotropic thermal stress structures
6. Advanced theories for multilayered beams, plates and shells
7. Through-the-thickness thermal fields in one-layer and multilayered structures
8. Computational methods for thermal stress analysis
9. Static response of uncoupled thermoelastic problems
10. Dynamic response of uncoupled thermoelastic problems
11. Static and dynamic responses of coupled thermoelastic problems
12. Thermal buckling
13. Post buckling behavior of thermally loaded structures
14. Thermal effect on flutter of panels
15. Thermal stresses in functionally graded materials

--------Books (monographs) in Polish by Jan Awrejcewicz, et al
SUMMARY: In this monograph both theoretical and experimental approaches devoted to plates and shells analysis are described. A special emphasis is put on the theoretical-experimental method applied to analysis of multi-component non-homogeneity and the methods using laser technique. It has been shown, how to use
the regression technique during estimation of the function characterizing non-homogeneities. In addition, a hologram technique used to define the frequencies and corresponding modes is presented. The following non-homogeneity factors are used: holes and thickness variations, shells with various geometry (circular and rectangular) and the various boundary conditions. In the first case the Argyris element with 12 degrees-of-freedom is used to analyse plates with one and two non-homogeneity factors. In the second case different thickness plates and shells are analysed using sixth order approximations. Analysis of plates and shells vibrations with one-component non-homogeneity is carried out in Chapter 3. Among others, the first 6 frequencies and corresponding modes are estimated. The frequency spectra dependence on the non-homogeneity components is outlined. In Section 3.2 the experimental rigs are described, whereas in Section 3.3 the methods devoted to experimental investigations are outlined. Among others, the influence of non-homogeneous boundary conditions and various holes is investigated. Chapter 4 is devoted to analysis of the influence of holes (situated on the plates and shells edges) on the vibrations. Many experimental results are reported in tables and figures. Chapter 5 presents computational results of the plates with holes using FEM. The numerical results are compared with experimental ones. In Chapter 6 plates and shells with different thickness distribution are analysed using the Bubnov-Galerkin method with various approximations. Chapter 7 is devoted to experimental investigations of small diameters plates and shells used in electronic techniques. The eigenfrequencies and corresponding modes are found. The obtained results are compared using theoretical-experimental and experimental methods.

**SUMMARY:** This monograph is devoted to analysis of dynamical behaviour of shells with thermal excitations and consists of four parts. A state-of-art of the subject is reviewed in Introduction, where a special attention is paid to East European research. Many important results which are not widely known are outlined. It has been shown among others, that the problems of dynamical stability of shells subjected to thermal loads action and accounting nonlinear temperature distribution along their thickness are rarely discussed in the existing literature. In Chapter 1 the fundamental dependencies and computational algorithms are formulated. The general considerations yield further considered differential equations, initial and boundary conditions of the thermoelasticity. In the next step the finite difference method is applied to solve the obtained partial and nonlinear differential equations including thermal and mechanical loads. Then, using both analytical and numerical (Bubnov-Galerkin approach) methods, the applied finite difference approach is verified. The relaxation technique is further used and both static and dynamic loads are analyzed and many practically useful conclusions are given. In Chapter 2 stability of thin shells subjected to an action of transversal mechanical and thermal loads is analysed. First of all, the influence of heat stream magnitude on shells stability simultaneously thermally and transversally loaded is studied. Than, the analysis is extended into the case of sinusoidal transversal load action. Finally, the influence of thermal and mechanical material characteristics depending on the temperature on stability of thin shallow shells is reported. Chapter 3 is oriented on stability investigation of thin shells subjected to longitudinal mechanical and heat stream actions. First, the influence of boundary conditions and surrounding medium on the critical compressing load is investigated. Then the stability of a shell under an action of a constant compressing load and a heat stream is analysed. In Chapter 4 dynamical stability of thin shells under convectional heat transfer is studied. Firstly, the problem is mathematically formulated and then the influence of boundary conditions and thermal loading on the stress-strain shells states are investigated, among others.

SUMMARY: In this monograph dynamical problems of thermoelasticity of thin cylindrical shells thermally excited are analysed and the computational algorithms are proposed and illustrated. The book is oriented on students of mechanical and civil engineering, Ph.D. students, researchers and engineers working in the field of dynamics of plates and shells thermally excited. A state-of-the-art of the considered subject is reviewed in the Introduction, where a special emphasis is put on the Central and Eastern European Countries' achievements. The literature overview led to the following conclusions: (i) the influence of geometric parameters and the boundary conditions on the cylindrical shells with non-homogeneous thermoelastic load is not fully investigated; (ii) a buckling of thin cylindrical shell in conditions of both static and thermal loads is not satisfactorily analysed; (iii) there is a lack of satisfactory theoretical model within mechanical and thermal loads conditions. In Chapter 1 dynamical problem of thermoelasticity of thin cylindrical shells is addressed. First of all, fundamental relations, variational coupled thermoelastic equations and hybrid variational equations governing dynamics of composite orthotropic and thermosensitive shallow shells are derived. Then a rigorous mathematical discussion on existence of a solution to the formulated problem is carried out. The computational algorithms are reported in Chapter 2. First, the difference equations are formulated, and then a solution to the biharmonic equation with respect to the stress function F is given. Then, a discussion on the reliability of the obtained results follows. It includes a comparison of results with other researchers as well as with the experimental results. The application of the relaxation method in the statical and dynamical problems is addressed in Section 2.4. In Chapter 3 dynamical stability of thin shells with non-uniform excitation is discussed and illustrated. First, dynamical stability criterions are overviewed, and then a stability loss of shells under non-uniform load action is investigated. Many computational results with the associated figures are given. Dynamical stability loss and behaviour of thermosensitive shells in condition of non-uniform thermal load is studied in Chapter 4. In section 4.1 the singularities associated with thermal field computations are illustrated, whereas in section 4.2 an influence of geometrical parameters and loads duration on a thermosensitive shell dynamics is reported. The section 4.3 is devoted to analysis of dynamical stability loss of shells with imperfections under action of combined thermal and mechanical loads.

Asymptotical Methods and Their Applications in Theory of Shells, by Jan Awrejcewicz and Igor V. Andrianov, WNT, Warsaw, 2000, 184 pages (in Polish)
SUMMARY: This monograph is devoted to the new challenging applications of asymptotic approaches with a special emphasis on the shells theory. In many cases asymptotic analysis does not only give the qualitative and quantitative results but sometimes also yields the relations between various physical theories. For example, many new results in the fields of statics and dynamics of thin elastic cylindrical shells are obtained. In Chapter 1 a brief history and an overview of the existing asymptotical approaches are given. The updated state-of-the-art and the perspectives of the asymptotic approaches are outlined. The asymptotic series convergence, Padé approximations, advantages and disadvantages of the asymptotic techniques are illustrated and discussed. One of the most important problems occurring during the asymptotic analysis is related to the definition of "small" (perturbation) parameter. One would expect to have a possibly the largest value of the "small" parameter. An estimation of reliability of the obtained results does not belong to easy tasks, since the majorant inequalities should be used. Hence, very often the results obtained are verified numerically. Nowadays, the asymptotic methods possess large applications, also in mechanics of continuous systems like beams, plates, shells, etc. The analysis of thin-walled structures is carried out in Chapter 2. First, in Section 2.1 the introduction to the considered problem is given. Analysis of the boundary value problems in theory of smooth cylindrical shells is carried out in Section 2.2. The fundamental relations are formulated and asymptotic boundary value problems are outlined. Then the fundamental boundary value problems of the statics are formulated and the limiting relations of higher order approximations are derived. The Green function approach is introduced. A comparison of the obtained results with other methods is carried out. Finally, the dynamical boundary conditions are
analysed. Section 2.3 is devoted to the analysis of boundary value problems of theory of orthotropically designed cylindrical shells. This section is organized in a similar way of the previous one.

SUMMARY: This monograph can be treated as an attempt to original analysis of the plates and shells role in our nature, mechanics and biomechanics. In the Introduction the fundamental background of elasticity of deformable bodies, stress-strain states, Hooke's law, Young's modulus and Poisson's coefficients are given. In Chapter 2 the occurrence of shells and plates as the elements of our Earth surface, buildings or internal human organs are discussed and illustrated. A lot of interesting information not known to a reader so far is reported. In Chapter 3 a historical background of the plates and shells theory is given. Chapter 4 is devoted to the overview of the historical development of plates and shells with the emphasis on asymptotic and numerical methods development and their impact on the shell theory. After a brief introduction, a general description of an averaging approach in the shells theory is given. It is shown that sometimes what seems to be bad can be usefully applied. This sentence is supplemented by the appropriate examples. Then today's asymptotology and the computer-oriented methods are compared and discussed. In Chapter 5 the plates and shells theory precursors are described with their short biographies. It includes, among others, the biographies of Johann I Bernoulli, Jacob I Bernoulli, Daniel I Bernoulli, Enrico Betti, Augustin Louis Cauchy, Ernst Florens Chladni, Jean D'Alembert, Adhemar Jean de Saint-Venant, Leonard Euler, Marie-Sophie Germain, Robert Hooke, Edward Hu Law, Gustav Robert Kirchhoff, Werner Tjardus Koiter, Joseph Louise Lagrange, Gabriel LamÈ, Pierre Simon Laplace, Aurie Anatolij Isakowicz, Claude Navier, Witold Nowacki, Walentin Walentynowicz Nowo_li_Bow, Denis SimÈon Poisson, Lord Rayleigh, Eric Reissner, Stepan Prokofiewicz Timoszenko, W_Basow Wasilij Zacharowicz. Chapter 6 includes today's state-of-the-art and perspectives of theory and practice development in the field of plates and shells dynamics. In Chapter 7 some interesting examples of nonlinear dynamics of plates and shells are outlined. Among others, chaotic dynamics and solitons are discussed and reported. Chapter 8 consists of historical as well as new development directions of plates and shells theory, their physical behaviour and mathematical models and it includes the methods of analysis of plates and shells. The Chapter 9 written by Professor M. Kote_Bko and J. Rhodes is devoted to thin walled profile materials, plastic mechanisms of their damage and the numerical methods used for their analysis.

SUMMARY: A characteristic feature of this monograph is focused on the emphasis put on the achievements of Russian scientists in the field of plates and shells dynamics. The latter results are not widely distributed among the students and researchers interested in this branch of mechanics. In the Introduction a brief bibliographical review devoted to plates and shells with complicated shapes and non-homogeneous surfaces is given. It is pointed out, among others, that only a small amount of papers is focused on statical and dynamical analysis of sectorial shells within the geometrically nonlinear background. In Chapter 1 a theory of shallow sectorial shells is introduced. First of all, the fundamental relations, differential equations, initial and boundary conditions are outlined. Then in Section 1.2 the algorithm for solution of nonlinear problems of shallow sectorial shells in a thermal field is proposed. In fact, the modified version of the finite difference method is used, including Gauss and relaxation approaches. A verification of the proposed algorithms is carried out via comparison with available analytical or obtained by other authors numerical results. The comparison is carried out either via the data included in the tables or drawings of deflections, stresses or bending moments of the selected points of the investigated shells. In Chapter 2 a stability of sectorial shells with finite deflections is described. Firstly, the influence of the sectorial shell angle on the dynamical stability is given, which is illustrated via solution of five
different problems (Section 2.1). In Section 2.2 an application of the "set up" approach is applied to determine the critical loads. The approach is illustrated via five different examples. In Section 2.3 a shell stability subjected to heat impact action is analysed, whereas in Section 2.4 the influence on stability of a local surface load is investigated. Many useful conclusions are derived allowing for a direct application for engineers working in the field of shells dynamics. The monograph is oriented on students and Ph.D. students of mechanical and civil engineering faculties as well as the students of applied mathematics.

**SUMMARY:** This monograph belongs to the series yielded as a result of cooperation between the Technical University of Lodz (Poland) and The National University of Saratov (Russia) and devoted to the analysis of plates and shells. The majority of the books from this series has been published by Wydawnictwo Naukowo-Techniczne - Fundacja "Księga Naukowo-Techniczna". In Chapter 1 of this monograph, a general three-dimensional problem of thermoelasticity of a parallelepiped is formulated. Among others, a rigorous mathematical approach to an error estimation analysis and stability of the used difference schemes is addressed. Chapter 2 is devoted to description of various methods used to solve elliptic, parabolic and hyperbolic equations. In addition, a reliability of the obtained results is illustrated and discussed and also some numerical examples are given. Chapter 3 includes numerical analysis of some chosen linear problems of three-dimensional theory of plates. The following problems are considered: static and dynamic, non-stationary heat problems with sources situated inside a plate, solutions to the problems describing non-isotermic processes in statics of plates, influence of internal heat sources on a stress-strain state of a plate and influence of coupling between deformation and temperature on a plate behaviour. Chapter 4 is focused on temperature and deformation fields analysis including physical type nonlinearities. After derivation of differential equations and difference approximation within theory of small elastic-plastic deformations, influence of coupling between temperature and deformation on the stress-strain state is carried out. The monograph is meant for students, researchers within the fields of mechanics, physics and applied mathematics dealing both with theory of plates and analysis of partial differential and difference equations.

**Chaotic Dynamics of Beams, Plates and Shells**, by J. Awrejcewicz and V.A. Krysko, WNT, Warsaw (date not given), 342 pages, ISBN 83-204-3113-1 (in Polish)

**SUMMARY:** This monograph gives theoretical background, modeling and numerical techniques devoted to analysis of regular and chaotic dynamics of continuous mechanical systems represented by beams, plates and shells. The authors present novel approaches to analysis and control of the mentioned continuous objects from the field of nonlinear mechanics. The book is oriented on students, engineers and scientific staff in the area of dynamics and static's of continuous systems, bifurcations and chaos as well as modeling and various numerical methods.

Section 6: Some Early Work on Buckling of Plates and Shells

End of the first section that lists books (Section 6)

End of Section 6

Section 7: Some Early Work on Buckling of Plates and Shells:

“The discovery of the shell as a loadbearing structure is a work of reinforced concrete and started around 1900 with the erection of water and gas tanks plus thin-wall domes. By the end of the accumulation phase of...
structural theory (1900–25) the Zeiss-Dywidag shell by Bauersfeld and Dischinger (see section 8.2.3) had appeared. This was also the period of the technicisation of shell theory, which had evolved in the tradition of the mathematical elastic theory. And by the middle of the invention phase of structural theory (1925–50) the new language of reinforced concrete had been completed by the shell constructions of Dischinger, Rüsch and Finsterwalder, which found their adequate engineering science expression in structural shell theory.

“In fact, Navier had investigated rotational shells in the membrane stress condition in his Résumé des Leçons [Navier, 1826], i.e. shells in which the element axial forces $N_\theta$ and $N_\phi$ plus the element thrust forces $T_\theta$ and $T_\phi$ act at their midsurface, i.e. where the element shear forces $Q_\theta$ and $Q_\phi$, the element bending moments $M_\theta$ and $M_\phi$ plus the element torsion moments $D_\theta$ and $D_\phi$ vanish (Fig. 9-31; see below).

“Lamé and Clapeyron calculated the stresses and deformations in a spherical shell subjected to internal or external pressure [Clapeyron & Lamé, 1833], and in 1854 the latter managed a complete solution to the deformation problem of spherical shells subjected to any distributed loads [Lamé, 1854]. Aron was the first person to consider all moments and formulated the bending theory of any curved elastic shell for the static and dynamic cases [Aron, 1874]. Unfortunately, Aron’s bending theory for shells was not adopted. It was not until 14 years later that Love, working independently of Aron, set up a bending theory for shells [Love, 1888], which he presented in his famous textbook A treatise on the mathematical theory of elasticity [Love, 1892/93]. Rayleigh, too, published separate contributions on shell theory in 1881, 1888 and 1889, and collected these together in a separate chapter in the second edition of the first volume of his The Theory of Sound [Rayleigh, 1894]. A generalisation of the bending theory for shells that did not use the Bernoulli hypothesis of plane sections remaining plane was provided by the Cosserat brothers [E. & F. Cosserat, 1909]. And that concluded the constitution phase of mathematical shell theory.

“Only by using the symbolic notation of H. Lamb in the second edition of his textbook [Love, 1906 & 1907] did Love manage to bring shell theory to the attention of engineering researchers. Nevertheless, a reviewer of the German edition of Love’s book writes [Love, 1907]: “This book is written by an expert for mathematicians and physicists ... A study of this book will not benefit the practising engineer because apart from a few cases the golden bridge leading from vague theory to practice is missing. However, the enthusiastic researcher who senses the familiar results of elastic theory on their theoretical foundations will derive much and new inspiration from this work” [Schönhöfer, 1907, p. 296].

“Practising engineers initially approached shell theory cautiously via the analysis of the simplest shell form, the single-curvature, fixed cylindrical shell; but the representatives of fundamental engineering science disciplines such as applied mechanics and theory of structures were no different. Using this structural model, engineers attempted to size vessels of steel and later reinforced concrete – the works of E. Winkler (1860), F. Grashof (1878), G. A. Wayss (1887), V. G. Shukhov (1888) (see [Ramm, 1990]), R. Maillart (1903) (see [Schöne, 1999]), C. Runge (1904), Panetti (1906), H. Müller-Breslau (1908), H. Reissner (1908), K. Federhofer (1909 & 1910), T. Pöschl and K. v. Terzaghi (1913), A. and L. Föppl (1920) to name just some. In 1923 V. Lewe summarised the methods for the structural calculation of tanks for fluids in a longer article for the Handbuch für Eisenbetonbau (reinforced concrete manual) [Lewe, 1923].”

ABSTRACT: This paper develops a new method for determining the buckling stresses of cylindrical shells under various loading conditions. In part I, the equation for the equilibrium of cylindrical shells introduced by Donnell in NACA report no. 479 to find the critical stresses of cylinders in torsion is applied to find critical stresses for cylinders with simply supported edges under other loading conditions. In part II, a modified form of Donnell's equation for the equilibrium of thin cylindrical shells is derived which is equivalent to Donnell's equation but has certain advantages in physical interpretation and in ease of solution, particularly in the case of shells having clamped edges. The question of implicit boundary conditions is also considered.

ABSTRACT: This paper discusses the collapse by instability of thin-walled cylindrical vessels subjected to external pressure. The most important of the theoretical and empirical formulas that apply to this subject are presented in a common notation. A new and simple instability formula is developed. Three classes of tubes are considered: Tubes of infinite length; tubes of finite length with uniform radial pressure only; and tubes of finite length with both uniform radial and axial pressure. Collapsing pressures calculated by the various formulas are presented in tabular form as a means of comparing the formulas. The formulas are discussed briefly and checked against the results of tests conducted at the U. S. Experimental Model Basin for the Bureau of Construction and Repair, Navy Department. This paper is a sequel to one previously published as a part of the work of the A.S.M.E. Special Research Committee on the Strength of Vessels Under External Pressure.

References listed at the end of the paper:
ABSTRACT: The first section of this paper describes a series of tests of the strength of thin-walled cylinders under a combination of torsion and axial compression or tension. Curves are obtained showing the strength of each of the several types of cylinders tested, under all possible combinations of these loads. All the curves obtained seem to have the same general form and the results suggest the possibility of finding a simple law by means of which a designer could determine the buckling strength of a structure under any combination of shear and normal stress, if he knows its strength under pure shear and under pure compressive stress. The second section describes tests made to investigate the independence of different possible types of buckling of a structure. A set of L-section struts, identical except for the widths of the sides, were tested in compression. With small widths the struts buckle as Euler columns but with the wider widths buckling of the sides, as plates hinged on three edges, occurs first. Great care was taken to eliminate the effect of initial eccentricities. The results check the well-known theories for these two types of buckling and indicate that, for practical purposes, the two types can be considered independently of each other. The results also illustrate how enormously the strength-weight ratio of thin wall construction may be affected by details of design.

ABSTRACT: In two previous papers (von Karman and Hsue-Shen, 1939; von Karman et al., 1940) the authors discussed in detail the inadequacy of the classical theory of thin shells in explaining the buckling phenomenon of cylindrical and spherical shells. It was shown that not only the calculated buckling load is 3 to 5 times higher than that found by experiments, but the observed wave pattern of the buckled shell is also different from that predicted. Furthermore, it was pointed out that the different explanations for this discrepancy advanced by Donnell (1934) and Fluegge (1932) are untenable when certain conclusions drawn from these explanations are compared with the experimental facts. By a theoretical investigation on spherical shells I the authors were led to the belief that in general the buckling phenomenon of curved shells can only be explained by means of a nonlinear large deflection theory. This point of view was substantiated by model experiments on slender columns with nonlinear elastic support (von Karman et al., 1940). The nonlinear characteristics of such structures cause the load necessary to keep the shell in equilibrium to drop very rapidly with increase in wave
amplitude once the structure started to buckle. Thus, first of all, a part of the elastic energy stored in the shell is released once the buckling has started; this explains the observed rapidity of the buckling process. Furthermore, as it was shown in one of the previous papers (von Karman et al., 1940) the buckling load itself can be materially reduced by slight imperfections in the test specimen and vibrations during the testing process. In this paper, the same ideas are applied to the case of a thin uniform cylindrical shell under axial compression. First it is shown by an approximate calculation that again the load sustained by the shell drops with increasing deflection. Then the results of this calculation are used for a more detailed discussion of the buckling process as observed in an actual testing machine.

ABSTRACT: Compressive tests were made of two series of stiffened circular cylindrical shells under axial load. All the shells were 16 inches in diameter by 24 inches in length and were made of aluminum-alloy sheet curved to the proper radius and welded with one longitudinal weld. The ratios of diameter to thickness of shell wall in the two series of specimens were 258 and 572. Strains were measured with Huggenberger tensometers at a number of gage lines on the stiffeners and shell. The results of these tests indicate that a spacing of circumferential stiffeners equal to 0.67 times the radius is too great to strengthen the shell wall appreciably. The results are not inclusive enough to show the optimum in stiffeners. Plain cylinders without stiffeners developed ultimate strengths approximately half as great as the buckling strengths computed by the equation resulting from the classical theory and slightly greater than those computed by Donnell's large deflection theory.

Abstract: A general theory of elastic stability is presented. In contrast to previous works in the field, the present analysis is augmented by an investigation of the behavior of the buckled structure in the immediate neighborhood of the bifurcation point. This investigation explains why some structures, e.g., a flat plate supported along its edges and subjected to thrust in its plane, are capable of carrying loads considerably above the buckling load, while other structures, e.g., an axially loaded cylindrical shell, collapse at loads far below the theoretical critical load.

ABSTRACT: Until recently the famous principle of minimum complementary energy of the classical linear theory of elasticity has defied all attempts at an effective generalization to the nonlinear case where the strain-displacement relations are no longer linear. L. M. Zubov [4] has now taken a significant step towards the solution of this problem in the form of his principle of stationary complementary energy, expressed in terms of the Piola stress tensor. Zubov’s argument, however, is open to criticism at several points. The present paper aims at the removal of these weak points and at a simpler derivation of Zubov’s theorem. The theory is illustrated by some simple examples.

ABSTRACT: Mode interaction is an important and often dangerous phenomenon in the buckling of stiffened plate and shell structure with nearly equal critical loads for the long wave overall mode and the short wave local or panel mode. An approximate general theory is derived on the basis of amplitude modulation of the short wave mode due to its interaction with the long wave mode. The method of analysis is a generalization of previous work on mode interaction in stiffened flat plates and built-up columns. The interaction is shown to have always a detrimental effect on the load carrying capacity of the structure, in particular in the presence of unavoidable imperfections. A few numerical examples illustrate the theory, and some recommendations are formulated for a systematic numerical evaluation.
ABSTRACT: Elastic stability is perhaps the oldest topic in finite elasticity theory. Stability in the sense of Lyapunov is essentially a dynamic concept. Dynamics of continuous media find their proper place under the wings of thermodynamics. The thermodynamic foundation of the theory of elastic stability is now fairly secure, thanks to Duhem and Ericksen. Some subtle mathematical difficulties are still connected with questions of Fréchet differentiability of the elastic energy functional. Applications to specific problems of buckling of structures have preceded the complete development of the theory of elastic stability. This situation is indeed quite common in engineering science. The significance of post-buckling behaviour has been recognized much later. This essentially nonlinear aspect, so characteristic for finite elasticity theory, will be reviewed in some detail.

ABSTRACT: The energy approach to elastic stability is employed to describe characteristic differences in buckling behaviour between bars in compression, plates loaded in their plane, and shells, in particular in the absence of inextensional deformation. The initial stage of post-buckling behaviour of shells is discussed from the standpoint of shallow shell theory and it is applied to more or less localized buckling patterns.

ABSTRACT: Amplitude modulation of short-wave local buckling modes has proved to be a useful tool in the approximate analysis of a number of buckling problems for plates and shells. This concept seems to have been applied first in a modification of Hutchinson's analysis of a complete spherical shell under external pressure. More or less localized imperfections and the associated buckling analysis have improved the understanding of the effect of a local dent. Finally, the nonlinear interaction between local sheet buckling and overall bucking of stiffened plate and shell structures may be described effectively as a modulation of the amplitude of the local short-wave mode due to the long-wave overall mode.
SUMMARY: The theorem of stationary complementary energy is applied to buckling problems for structures of a semi-linear material in cases of an irrotational linear prebuckling state.

N.J. Hoff and S.E. Mautner, “The buckling of sandwich panels”, Journal Aeronaut Sci, 1945

ABSTRACT: Ten 24S-T alclad cylinders of 20-inch diameter, 45- or 58-inch length, and 0.012-inch wall thickness, reinforced with 24S-T aluminum alloy stringers and rings were tested in pure bending. In the middle of the compression side of the cylinders there was a cutout extending over 19 inches in the longitudinal direction, and over an angle of 45 degrees, 90 degrees, or 135 degrees in the circumferential direction. The strain in the stringers and in the sheet covering was measured with metal electric strain gages. The stress distribution in the cylinders deviate considerably from the linear law valid for cylinders without a cutout. The maximum strain measured was about four-thirds of the value calculated from the Mc/I formula when I was taken as the moment of inertia of the cross section of the portion of the cylinder where the cutout was situated. A diagram is presented containing the strain factors defined as the ratios of measured strain to strain calculated with the Mc/I formula. All the 10 cylinders tested failed in general instability. Two symmetric and one antisymmetric pattern of buckling were observed and the buckling load appeared to be independent of the method of manufacture and the length of the cylinder. The buckling load of the cylinders having cutouts extending over 45 degrees, 90 degrees, and 135 degrees was 66, 47, and 31 percent, respectively, of the buckling load of the cylinder without a cutout.

ABSTRACT: Determinations were made under comparison, particularly in that region of loading where the panels are in a buckled state. Cylinders were built and reinforced with a number of stringers and rings. Tests were made by measuring the twist angle of the cylinder caused by known amount of torque while the cylinder
was subject to uniform axial compression. Shearing rigidity of a panel decreases when increasing amounts of compressive loads are applied to the panel in the axial direction.

ABSTRACT: Empirical design curves are presented for the critical stress of thin-wall cylinders loaded in axial compression. These curves are plotted in terms of the nondimensional parameters of small-deflection theory and are compared with theoretical curves derived for the buckling of cylinders with simply supported and clamped edges. An empirical equation is given for the buckling of cylinders having a length-radius ratio greater than about 0.75.

SUMMARY: Empirical design curves are presented for the critical stress of thin-walled cylinders loaded in axial compression. These curves are plotted in terms of the nondimensional parameters of small-deflection theory and are compared with theoretical curves derived for the buckling of cylinders with simply supported
and clamped edges. An empirical equation is given for the buckling of cylinders having a length-radius ratio greater than about 0.75. The test data obtained from various sources follow the general trend of the theoretical curve for cylinders with clamped edges, agreeing closely with the theory in the case of short cylinders, but failing considerably below the theoretical results for long cylinders. The discrepancy in the case of long cylinders increases with increasing values of the ratio of radius to wall thickness. Plotting curves for different values of this ratio reduces the scatter in the test data and a certain degree of correlation with theory is achieved. Advantage is taken of this correlation to obtain estimated design curves for cylinders with simply supported edges, for which little experimental information is available.

ABSTRACT: The results of torsion tests performed by the Forest Products Laboratory upon stiffened thin walled plywood cylinders showed that the buckling stress of the portion the shell between the stiffeners is about 85 percent of the buckling stress of an unstiffened cylinder of the same curvature and thickness The cylinders tested were about 0.04 inch thick and were curved with a 9-inch radius and had from 11 to 28 longitudinal stiffeners from 1/32 to 1/2 inch thick glued to the inner surface The theoretical buckling torque of an unstiffened cylinder of the same weight and curvature as a stiffened cylinder was found to be greater than that for the stiffened cylinder. At the time this work was begun in July 1943 it was thought that more information on the behavior of longitudinally stiffened shells was needed for the design of aircraft structures. Previous work of the Forest Products Laboratory on unstiffened shells showed that plywood is particularly useful for the experimental determination of the buckling stress of shell structures, ...

PARTIAL ABSTRACT: Eighteen 24S-T alclad cylinders of 20-inch diameter, with skin thickness varying between 0.012 inch and 0.025 inch and length varying between 40.5 inches and 64 inches, were tested in pure bending. ABSTRACT: The present paper deals with the buckling of a circular cylindrical shell under axial compression from the viewpoint of energy and the characteristics of deformation. It is shown first, both theoretically and experimentally, that the reason why the buckling of a cylindrical shell is quite different from that of a flat plate is attributable to the existence of a nearly developable surface far apart from the original cylindrical surface. Based upon this result, the experimental fact that the buckling is really not general but local, that is, that the buckled region is limited axially to a range of 1.5 times the wave length of the lobe, is explained by the theoretical result that the minimum buckling load is smaller in the local buckling than in the general buckling case. The occurrence of local buckling is affirmed also from the viewpoint of the energy barrier to be jumped over during buckling, and from a comparison of the theoretical post-buckling state with the experimental results. Finally, the local buckling with the load applied by a spring is analyzed, and it is proved that the minimum buckling load increased with an increase of rigidity of the spring.

ABSTRACT: The critical stress for torsional buckling of circular cylindrical shells obtained from the linear theory with small deformation is considerably greater than for the experimental stress. The present paper clarifies the cause of this discrepancy between theory and experiments on the assumption that the torsional buckling, as well as the compressive buckling, is a Durchschlag phenomenon. Based on the experimental fact that the buckled surface is approximately developable (the mean surface being drum-shaped), the equilibrium state after buckling was calculated by means of the minimum principle of potential energy, and, for the case of buckling under constant load, the lower buckling stress was obtained, which is considerably smaller than the upper buckling stress and which explains the experimental results approximately. In the case of buckling under constant angle of torsion there exists no lower stress.

ABSTRACT: A strain-energy solution of the buckling of a circular cylindrical shell reinforced by evenly spaced circular ring frames of equal strength under hydrostatic pressure was obtained in Part I. The buckled shape was assumed to be sinusoidal with inflection points at the location of the ring frames. For several geometrical configurations the critical pressure was found to be from two to three times that given by the von Mises solution. The assumed buckled shape used in Report I was modified to permit the inflection points of the deformed shape to occur between ring frames. For the geometrical configurations calculated in Report I, the
Critical pressure was found to be about one and one-third times that given by the von Mises solution. This represents a marked improvement over the solution obtained in Report I.

ABSTRACT: A solution is presented for the problem of the compressive buckling of simply supported, flat, rectangular, solid-core sandwich plates stressed either in the elastic range or in the plastic range. Charts for the analysis of long sandwich plates are presented for plates having face materials of 24S-TS aluminum alloy, 75S-T6 Alclad aluminum alloy, and stainless steel. A comparison of computed and experimental buckling stresses of square solid-core sandwich plates indicates fair agreement between theory and experiment.

1949

ABSTRACT: Charts are presented for the analysis of the stability under compression of simply supported rectangular plates with one, two, three and an infinite number of identical equally spaced longitudinal stiffeners that have zero torsional stiffness.

SUMMARY: A small-deflection theory that takes into account deformations due to transverse shear is presented for the elastic-behavior analysis of orthotropic plates of constant cylindrical curvature with considerations of buckling included. The theory is applicable primarily to sandwich construction.

ABSTRACT: A detailed investigation is presented of yield or loading criteria, for work hardening materials,
which lead to constant strain ratios under increasing stress when stress ratios are maintained constant. The
experimenter is given a choice of incremental stress-strain theories with which results of simple or complicated
combined loading tests may be correlated. These theories are dealt with in order of increasing complexity and,
at the same time, increasing capacity to represent experimentally established phenomena. The objective is the
use of the mathematically simplest theory which will provide the desired flexibility in the analysis of
experimental data. Loading functions of isotropic as well as anisotropic types are examined, among them those
depending explicitly on stress alone and those depending on both stress and plastic strain. In the latter cases
only those functions are investigated in which plastic strain appears to the first order. The predicted results of
some basic tests are examined for several loading criteria.

instability problem of monocoque cylinders”, NACA Technical note, April 1951,
proxy Url: http://handle.dtic.mil/100.2/ADA382028

ABSTRACT: Two closely related numerical methods which employ operations tables have been developed and
used in the calculation of the buckling load of a monocoque cylinder subjected to pure bending. They are based
on the assumption of a simplified structure which includes only the most highly compressed portion of the
cylinder. The first method makes use of a 10-row determinant, whereas the second method requires the solution
of a single 10-row determinant. The buckling loads of three cylinders with widely different characteristics were
calculated by these methods. Reasonable agreement with experiment was obtained. A procedure similar to the
first method was developed for the calculation of the buckling load of a cylinder with a cutout. A limited
experimental check was obtained.

for buckling of infinitely long flat plates”, NACA TN 2536, 1951

SUMMARY: In the first six paragraphs the energetic criterion of elastic stability is discussed and the differential equation for the critical vector of displacement in orthogonal curvilinear coordinates is derived. Together with this equation, the boundary condition on those parts of the boundary is given, where the displacements are free. In the last two paragraphs the corresponding basic expressions for thin shells are determined, under the assumption that plane sections remain plane and that surface forces behave as hydrostatic pressure, when the body is passing over from its critical position of equilibrium to a neighbouring one. PARTIAL SUMMARY: When a low arch (a thin curved beam of small curvature) is subjected to a lateral loading acting toward the center of curvature, the axial thrust induced by the bending of the arch may cause the arch to buckle so that the curvature becomes suddenly reversed. The critical lateral loading depends on the dimensions and rigidity of the arch, the elasticity of the end fixation, the type of load distribution, and the initial curvature of the arch. A general solution of the problem is given in this paper, using the classical buckling criterion which is based on theability with respect to infinitesimal displacements about the equilibrium positions….

ABSTRACT: A method is presented which permits the determination of the frequencies of vibrations of infinitely long thin cylindrical shells in an acoustic medium. Expressions are obtained for the displacements of the shell and for the pressures in the medium in the case of forced vibrations due to sinusoidally distributed radial forces. The results indicate that there is a low-frequency range, where no radiation takes place, and a high-frequency range where the external force provides energy which is radiated. Resonance occurs in the low-frequency range only; in the high-frequency range it is prevented by the damping due to radiation. Free and forced vibrations of steel shells submerged in water are discussed; with limitations, the theory may be applied approximately to stiffened shells. The method requires only a minor modification to account for the effect of static pressure in the surrounding medium. The treatment of transient problems is also considered. If high-frequency terms occur in the force, or shock effects are wanted within a short time after the application of the force, a treatment using solely modes of vibration of the submerged structure would be incomplete, as additional terms occur in the solution. As an alternative approach, the modes of free vibration of the structure may be used as generalized coordinates which fully describe the response of the structure but leave the medium to be treated, by means of the differential equations for the potential or in any other way desired.

SUMMARY: The value of the compressive stress at which a thin circular cylindrical shell becomes unstable was worked out theoretically by Southwell. Subsequent experimental results, however, indicated that this result was appreciably too high, and von Karman and Tsien have shown that a thin cylindrical shell can be maintained in a buckled state by a compressive load considerably smaller than that previously predicted by theory. The present paper is an extension of the work of von Karman and Tsien, and shows that the smallest load which will keep a thin circular cylindrical shell in a buckled condition is about one third of that given by Southwell.

ABSTRACT: The various methods of structural analysis are reviewed, and the basic elastic buckling problem of the Euler strut is discussed. Simple models are used to show the important differences between buckling in the plastic range and classical elastic instability. Nonlinear behavior is shown often to be the key to a physically valid solution. The nonconservative nature of plastic deformation alone or in combination with nonlinearity requires concepts not to be found in classical approaches. However, the classical linearized condition of neutral equilibrium is not relevant in inelastic buckling. Analyses of the models suggest that the same information is
obtained from essentially static systems by assuming initial geometrical imperfections as by assuming dynamic disturbances. Both approaches are helpful in understanding the physical phenomena.

ABSTRACT: Descriptions are given of the test model, apparatus, and procedure. A study of the circularity plot at each station indicated (1) a fairly uniform inward radial displacement around the periphery of the model at each ring, and (2) radial displacements which were exaggerations of the initial no-load contours for those stations located midway between rings in the 4 equal bays of the model. The lobes in adjacent bays were staggered; virtually no rotation of the generator occurred at the 2 frames bounding a lobe. This mode of deformation differed from the von Mises assumption of no rotational restraint at the edge of a finite cylinder but was in agreement with 1 of the analyses of Salerno and Levine (PIBAL report 182, 1951). The von Mises theory yielded a minimum value of 123 psi for a buckled configuration of 16 lobes; the experimentally determined buckling pressure for model BR-5 was 80 psi with a buckled configuration of 14 lobes. Permanent set was evident in the regions of the first 3 lobes in the model after removal of the 80-psi pressure. The deviation of the experimental from the theoretical results was attributed to initial out-of-roundness and residual welding stresses.

ABSTRACT: During the past several years, investigation has been carried out at the Daniel Guggenheim School of Aeronautics, New York University, to study the buckling behavior of sandwich structures. The main effort has been directed towards the determination of the buckling loads of circular sandwich cylinders under different loading conditions. It was found that for cylinders with weak cores, linear theory predicts buckling loads which agree with experimental results. This is contrary to the case of homogeneous cylinders, where linear theory predicts buckling loads much higher than those observed in experiments. The reason for this has been explained in Reference 11. In this report, the theory of buckling of sandwich cylinders under axial compression, torsion, and bending, and combined loads is developed in a unified manner; and the principal experimental results are presented. The interrelationship obtained between the critical loads is plotted in the form of non-dimensional interaction curves.

M.L. Baron, „shell to a transverse shock wave”, Columbia University Technical Report No. 10, December 1953

ABSTRACT: We consider a thin homogeneous shell subjected to an arbitrary load causing loss of stability. We assume that the shell has some initial irregularities in its middle surface which can be described in terms of certain initial displacements. When the load is applied, these initial irregularities begin to develop due to creep and cause a redistribution of stresses over both the thickness and the entire area of the shell. This process of stress redistribution may be so considerable that at a certain moment the equilibrium state of the shell may become unstable in Euler's sense, i.e., at a certain moment several modes of equilibrium may be possible, transition to any one of these being instantaneous. We shall call this moment the “critical moment” of loss of stability of the shell. The deviation of the subcritical stress and strain state of an actual shell from the basic state corresponding to a perfectly smooth shell can be described by a system of equations in the stress and deflection functions, assuming that the quantities characterizing these deviations satisfy linearized creep relations analogous to the relations for viscoelastic bodies. This system of equations must be combined with a system of stability equations which takes into account the stresses and strains defined by the system of equations of the subcritical state.

ABSTRACT: Non-linear differential equations have been developed for the calculation of the deflections and buckling loads of Sandwich plates subjected to transverse loads and edgewise shears and compressions. The Sandwich plate consists of two thin metal face sheets bonded to a light slab-the core. The core is taken to have zero moduli as deformations in its own plane. This appears to give an adequate representation of behavior of
many core materials. Some previous theories are shown to be special cases of this more general theory. The essence of non-linearity are shown through the discussion of core properties and action of interface-and-core forces. The restriction of some special forms of displacements of practical interest has been studied and the existence of nonlinear element in the bending problem is clarified. The relative merit of using large bending deflection theory instead of the small bending deflection theory in the faces is given.

ABSTRACT: In the large deflexion of thin plates with free edges, boundary layers develop along those edges under certain conditions. The non-linear effects of membrane stress are confined to the boundary layers and elsewhere the equations are linear. Boundary layer equations are derived and integrated, and are then applied to some specific problems.

ABSTRACT: The magnitude of the uniformly distributed axial compressive load under which a thin-walled circular cylindrical shell buckles by developing bulges over its surface was calculated independently by Lorenz [1, 2], Timoshenko [3] and Southwell [4] over fifty years ago. Unfortunately, experimental results obtained both earlier, and particularly during the last thirty years, have fallen far short of the classical critical stress values. In a report presenting original test results and comparing them with data published by other investigators, Harris, Suer, Skene and Benjamin [5] showed in 1957 that the experimental buckling stress ranges between 20 and 60 percent of the classical value when the radius-to-thickness ratio $a/h$ of the shell is between 250 and 750. The maximal value given in the paper amounts to 82 percent, and the minimal value to 10 percent of the classical critical stress; the value of 10 percent was obtained with a specimen whose $a/h$ ratio was 2500.

H.L. Langhaar and A.P. Boresi (Dept. of Theoretical and Applied Mechanics, Illinois University at Urbana), “Buckling and post-buckling behavior of a cylindrical shell subjected to external pressure”, April 1956, DTIC Accession Number : AD0094524, http://hdl.handle.net/2142/18754

ABSTRACT: In an earlier report (TAM Report No. 80), the authors considered the buckling and post-buckling behavior of an ideal elastic cylindrical shell loaded by uniform external pressure on its lateral surface, and by an axial compressive force. Assumptions were introduced which reduced the shell to a system with one degree of freedom. The present investigation is a generalization and a refinement of this theory. The shell is treated as a system with 21 degrees of freedom. By the imposition of constraints on the 21 generalized coordinates, various end conditions can be realized; for example, simply supported ends with flexible end plates (no axial constraint), simply supported ends with rigid end plates, and clamped ends. Also, effects of reinforcing rings have been incorporated in a more general way than in TAM Report No. 80. The restrictive assumption that the centroidal axis of a ring coincides with the middle surface of the shell has been eliminated. A pressure-deflection curve for an ideal cylindrical shell that is loaded by external pressure has the general form shown in Figure 1. The falling part of the curve (dotted in the figure) represents unstable equilibrium configurations. Also, the continuation of line OE (dotted) represents unstable unbuckled configurations. Actually, the shell snaps from some configuration A to another configuration B, as indicated by the dashed line in Figure 1. Theoretically, point A coincides with the maximum point E on the curve, but initial imperfections and accidental disturbances prevent the shell from reaching this point. Point E is the buckling pressure of the classical infinitesimal theory (called the "Euler critical pressure", since Euler applied the infinitesimal theory to columns). To some extent, point A is indeterminate, but it is presumably higher than the minimum point C unless the shell has excessive initial dents or lopsidedness. In TAM Report No. 80, a hypothesis of Tsien was used to locate point A. In the present investigation, point A is not considered. Rather, attention is focused on the development of a theory that will determine the entire load-deflection curve. For short thick shells, such as the inter-ring bays of a submarine hull, the Euler critical pressures, determined by TAM Report No. 80, are too high, presumably because the assumption that the shell buckles without incremental hoop strain is inadmissible in this range. The present report corrects this error. Numerical data on the Euler critical pressures of shells with simply supported ends and flexible end plates have been obtained with the aid of the Illiac, an electronic digital computer. The data are tabulated at the end of this report. For short shells without rings, the buckling pressures
are appreciably lower than those determined by von Mises' theory. The numerical data for the Euler buckling pressures of shells with uniformly spaced reinforcing rings are sufficiently extensive to permit interpolation to estimate effects of various ring sizes. Some exploratory numerical investigations of post-buckling behavior have been conducted with the Illiac. It is not feasible, at the present time, to handle nonlinear equilibrium problems for systems with 18 degrees of freedom. Consequently, for the numerical work, some higher harmonics were discarded so that the system was reduced to 7 degrees of freedom. Even then, the numerical problem is formidable. The calculations were confined principally to the determination of the minimum point C on the post-buckling curve (Figure 1). The pressure at point C is the minimum pressure at which a buckled form can exist. It is found that the ordinate of point C, determined by TAM report No. 80, is somewhat too high. The two theories are compared by a table and curves at the end of this report.

Henry L. Langhaar and Arthur P. Boresi, “Snap-through and post-buckling behavior of cylindrical shells under the action of external pressure”, University of Illinois Bulletin in cooperation with the Office of Naval Research, Engineering Experiment Station Bulletin No. 443, 1957

ABSTRACT: This report treats the buckling and post-buckling behavior of a cylindrical shell that is subjected to uniform external pressure p on its lateral surface, and an axial compressive force F. The force F varies with the pressure p in such a way that F = (lambda)a^2(p), in which a is the mean radius of the shell and lambda is a dimensionless constant. If the shell is immersed in a fluid at constant pressure p and if the force F results only from the pressure p on the ends, lambda = pi. The ends of the shell are assumed to provide simple support to the cylindrical wall. Accordingly, the radial and circumferential displacement components of the middle surface of the wall vanish at the ends. If the ends of the shell are free to warp, no other constraint is imposed on the deformation. If the ends of the shell are rigid, the axial displacement is constant at either end. Both of these cases were investigated. For generality, the shell was considered to be reinforced by several rings or hoops. Only geometrically perfect shells were studied; that is, initial dents and out-of-roundness were not taken into account. Only shells with a linear stress-strain relation were considered. If the axial force F is not too great, the shell assumes a fluted form when it buckles. This form is illustrated by Fig. B, which is a photograph of some of Sturm's test specimens (7). The number of flutes in the buckled form is influenced strongly by the ratio L/a, in which L is the length of the shell. Fig. C illustrates several forms of cross sections of cylindrical shells that have been buckled by external pressure. When the axial force F predominates, the buckled shell assumes a form in which diamond-shaped facets occur (1. Art. 85). This type of buckling was not considered in the present study; the axial force F was assumed to be so small that the fluted pattern occurs. The admissible range of F was not determined, but the fluted pattern usually occurs if lambda does not exceed pi.

ABSTRACT: Equations for the large deflection of thin plate established by Th. von Karman has been well known for many years. But so far there have been only a few iproblems studied with numerical certainty. S. Way was the first to apply these equations to solve the problem of a clamped plate under uniform pressure by the method of power series. After this, S. Levy found the solution of the simply supported rectangular plate under uniform load by the method of double trigonometric series. Both methods are too labourious to be applicable to other more important cases. Lately, Chien Wei-zang treated Way's problem again by means of the perturbation method and obtained excellent results. By the method as given by Chien Wei-zang, Yeh Kai-yuan worked out the problem of circular plate with a central hole under central concentrated load. In this paper, more results are given for various circular plates under various edge conditions. These include uniformly loaded circular plate under various edge conditions (section 2) and central concentrated loaded circular plate under various edge conditions (section 3). Such edge conditions are: (1) simply supported, (2) simply hinged, (3) rigidly clamped, (4) clamped but free to slip, (5) edge clamped but with possible slipping in horizontal direction, (6) edge simply supported but elastically fastened, and (7) edge clamped in elastic wall. All these results are presented in such a form that direct application in design problem is possible. In particular cases,
under edge conditions (1) to (4), as \( \sqrt{=} = 0.3 \), design formulae and curves for central deflection, radial tensile stress and radial bending stress are presented.

ABSTRACT: This report is one of a series issued in cooperation with the Army-Navy-Civil Committee on aircraft design criteria under the supervision of the Aeronautical Board. Reviewed and reaffirmed March 1956. Original report issued March 1948.

ABSTRACT: A problem of creep stability of columns and plates is considered. In an analysis use is made of two forms of the creep theory based on the strain hardening hypothesis. For a uniformly compressed plate a comparison is made between the results according to the flow theory and strain theory.

ABSTRACT: Available theories and test data on buckling of curved plates and shells are reviewed. The test data for torsion and external-pressure loadings are correlated in terms of linear buckling theories for both the elastic and inelastic ranges. The cases which exhibit a marked disagreement between linear theory and test data have been analyzed by a unified semi-empirical approach which is satisfactory for analysis and design purposes.

ABSTRACT: This report presents a theoretical analysis is presented for the behavior of long, circular, cylindrical shells of sandwich construction under axial compressive loads. The analysis is designed to evaluate the effects of the relatively low shearing moduli of sandwich cores on buckling stresses. Families of curves are presented for use in designing shells of sandwich construction having isotopic facings and orthotropic or isotropic cores. The results of the theoretical analysis were compared with those obtained from tests on a series of curved panels. It was found that the theory applied reasonable well to curved plates of sizes sufficient to include at least one ideal buckle. Application of the theory thus is not limited to long, complete cylinders.

ABSTRACT: The elastic stability of a thin-walled circular cylindrical shell is investigated by means of the small-deflection theory when the shell is subjected to such nonuniform heating as causes a uniform axial compressive stress to arise in a band of width 2b while the rest of the shell is free of stress. The critical value of the compressive axial stress is found to be equal to the critical stress of the same circular cylindrical shell when subjected to uniform axial compression provided the band is not extremely narrow. In the latter case the critical stress of the band is higher than that of the uniformly compressed shell.
ABSTRACT: By finite element elastic-plastic analysis it has been possible to obtain detailed information on the deformation process in the vicinity of a growing crack in sheet metal. It is found that the crack grows when the value of the crack tip opening angle exceeds some critical value. Particular attention is given to the closure behaviour if the loading forces are reduced. The results obtained are compared with experimental data. A flat triangular element with initial curvature can be looked upon as a doubly curved shell element. Thus a shell element is developed with nodal displacements in the three corner points and in the three midside points and with two parameters for rotations about each side. Element properties can be derived from quadratic displacement functions, linearly varying bending moments and linearly varying membrane deformations, the latter as an interpolation between the values in the corners. These corner values are determined by the appropriate nonlinear expressions in the displacements. On the basis of shell theory and the principle of minimum potential energy the merits of this particular finite element were thoroughly investigated. In view of its accuracy in linear problems, and since rigid body motions are fully represented, the element will also be very suitable for geometrically nonlinear problems. Though for the derivation of the features and properties of the finite elements the continuum theory will be used, in the analysis of a structure finite elements may be looked upon as models of mechanical behaviour in their own right. This approach proved to be particularly useful in the kinematic and dynamic analysis of mechanisms. Examples will be given of the kinematic description of some special elements, such as gears. Also for stability analysis the discrete approach was found to be fruitful of results. With properly chosen deformation parameters as generalized strains the buckling and postbuckling behaviour, as well as the nonlinear behaviour in general with small but finite rotations, can be analysed for struts, plates and shells, whilst the physical linearity on the level of the finite elements is retained. An effective elastic analysis of nonlinear problems is obtained in terms of perturbation equations for the participation factors of eigenvectors. These equations, limited in number, can be solved by a special method that was devised for the
computation of critical equilibrium states of nonlinear elastic systems. In this method difficulties due to matrix singularity in the incremental equations are overcome by the introduction of the path length as independent variable.

ABSTRACT: The stability of elastic-plastic sandwich shells of an arbitrary shape is investigated on the assumption that, at the moment of buckling, the load-carrying faces are in a fully plastic state and the core remains elastic. The equations are obtained on the basis of both the deformation theory and the plastic flow theory. The flexural stiffness of the faces is taken into account. The equations obtained permit the prediction of the critical loads of columns, plates, and shells of arbitrary form.

ABSTRACT: We consider in this report the determination of the upper limit of critical loads in the case of simultaneous action of a compressive force, uniformly distributed over plane cross sections, and of isotropic external normal pressure on cylindrical or conical shells of circular cross section. As a starting point we use the differential equations for neutral equilibrium of conical shells which have been used for the solution of the problem of stability of conical shells under torsion and under axial compression. Upon solution of the problem it is possible to satisfy all boundary conditions, in contrast to the report (ref. 3) where no attention is paid to the fulfillment of the boundary conditions and to the report (ref. 4) where only part of the boundary conditions are satisfied by solution of the problem according to Galerkins’s method. Approximate formulas are used for the determination of the critical external normal pressure with simultaneous action of longitudinal compression. Let us note that the formulas suggested in reference 5 are not well founded and may lead, in a number of cases, to a substantial mistake in the magnitude of the critical load.

ABSTRACT: A novel approximate theoretical solution is presented in this paper for the boundary disturbance of thin elastic shells of revolution with a nearly spherical middle surface and constant thickness. The indicated solution is a procedure of successive corrections, which was originally used by S. D. Poisson in handling non-linear differential equations and introduced into thin shell analysis by E. F. Burmistrov.

W.P. Vafakos, “Study of thermal stresses and buckling criteria of thin-walled circular conical shells”, Wright Air Development Center, 1958

ABSTRACT: A method is presented for obtaining nonlinear integro-differential equations equivalent to the differential equations of the nonlinear theory of depressed shells. It is shown that in a number of cases the integral equations obtained lead to the same results as the nonlinear differential equations.

ABSTRACT: This paper describes a practical, graphical and numerical procedure for the determination of the collapse time of pin-ended aluminum alloy columns subject to creep. A “critical deflection” is found at which the bending rigidity of the column is reduced to such an extent that the column becomes unstable under the constant load applied to it. To eliminate some of the unessential complexities of the problem, the analysis is carried out on the assumption that the actual column can be replaced by an idealized two-flange column which deflects sinusoidally up to failure. The flexural stiffness is taken as constant along the length of the column and equal to the mid-point stiffness, which is determined from the stress-strain curve of the material. The corresponding “critical time” is then calculated by using the creep-strain vs. time curves of the material. The method gives good agreement with experimental results obtained at the Polytechnic Institute of Brooklyn and at the Battelle Memorial Institute.

D.O. Brush, “Buckling of a cylindrical shell under a circumferential band load”, J. Aerospace Sci., 1959

ABSTRACT: The results of an extensive experimental program on the stability of cylindrical and conical shells under various loading conditions are presented and discussed. Loading conditions for both cylinders and cones include axial compression, axial compression with internal or external pressure, bending with and without internal pressure, axial compression combined with both bending and internal pressure, and a limited amount of data on torsion of conical shells. Where feasible, values suitable for design are recommended and areas needing additional theoretical and experimental study are indicated.

ABSTRACT: The results of an investigation to determine the influence of small deflections on the stability of internally pressurized conical shells under axial compression is presented. The critical axial load is found to depend on a geometry parameter for the small end of the cone, the internal pressure, and, unlike results for cylindrical shells, the end fixity of the shell. Experimentally obtained data are in qualitative agreement with theory but differ quantitatively, probably because of yielding of the low melting temperature alloy used to clamp the ends of the shells and yielding of the shell material.

ABSTRACT: Simplified differential equations governing the deformations of thin circular conical shells subjected to arbitrary loads and arbitrary temperature distributions are derived by the principle of the minimum total energy. The equations reduce to Donnell's expressions when the cone angle approaches zero. The same method of solution with slightly relaxed boundary conditions for the non-dimensional displacement along a generator, and the non-dimensional circumferential displacement, is then applied to the thermal buckling problem of truncated conical shells subjected to axisymmetrical temperature distributions. A typical example is analyzed. The equations are also extended to include problems of elastic stability
PARTIAL INTRODUCTION: During the next decades more and more shell-type structures in various areas of technology will be made out of composite materials. This refers also to toroidal shells encountered in spacecraft, in submarine structures, as well as in other areas of technology. In this connection it is important to investigate the stability of toroidal shells made out of composite materials having different elastic characteristics in various directions. To solve this problem we shall make use of the finite element method as the most suitable for computer implementation…

ABSTRACT: The structural design of a long range ballistic missile or a space rocket vehicle is an intriguing problem. It is hardly necessary to stress the importance of achieving as light a structure as possible, since any unnecessary increase of structural weight can severely affect its performance or result in a profound increase of its total weight. There is a dearth of published information on this subject, presumably because of security restrictions. Among the papers available, only Sechler dwells on the structural design consideration in any detail. We have therefore very few specific facts to guide us, and can only relate the problem to our aircraft design experience with commonsense.

ABSTRACT: The present article reviews some recent developments in nonlinear elastic membrane theory with special emphasis on axisymmetric deformation of flat circular and annular membranes subjected to a vertical surface load and with prescribed radial stresses or radial displacements at the edges. The nonlinear Föppl
membrane theory of small finite deflections as well as a simplified version of Reissner's finite-rotation theory is employed, assuming linear stress-strain relations. The main analytical techniques are reported which have been applied recently in order to determine the ranges of those boundary parameters for which solutions of the relevant nonlinear boundary value problems exist, and ranges of parameters for which the principal stresses are nonnegative everywhere. Concerning plane membranes, it is shown how the mathematical theory of existence and uniqueness was nearly completed in recent works in contrast to curved membranes where references can be given to rather few results.

ABSTRACT: The objective of this investigation was to determine the polstbuckling strength of thin web plate girders. The design of transversely stiffened plate girders presently is limited to girders whose web depth to web thickness ratios do not exceed the value of 170. This limit was derived from the web buckling theory. But in discussing the application of the theoretical buckling formulae, Ref. 253, p. 415, Timoshenko suggests using a factor of safety of only 1.5…

Most of the references listed at the end of the report. (Most of these early papers are in German. I included the German titles only in the first few of the 272 references. In the many other references I give the titles in English only, even though the paper by Basler, et al. gives the titles first in German and then in English. I had to type all these references because I could not cut-and-paste. Therefore, please excuse typos. I skipped a few references either because they did not apply to buckling or because they were similar to a previous reference. I typed “etc.” on a line by itself indicating a skipped reference or skipped references.)

The theory of thin shells is examined and some simplified general expressions are presented. These reduce to Donnell's expressions in the case of circular cylindrical shells. An appropriate variational principle is formulated and the similarity to shallow-shell theory is shown. These results and those of the more exact Flugge shell theory are applied to the problem of free vibration of conical shells. Approximate solutions are obtained by variational methods using the various theories and various displacement and stress functions. Comparison of the results indicates that the method which utilizes a logarithmic transformation of the axial coordinate in conjunction with appropriate displacement expansion modes satisfying the geometrical boundary conditions yields results valid for both the membrane and bending cases and is capable of being used to obtain higher approximations. The results reveal that the influence of taper on membrane and bending frequencies of circular cylinders is opposite in nature, the former being increased, the latter-decreased by the taper. The general problem of panel and shell flutter is reviewed and a physical explanation of the phenomenon is offered. A general formulation is given, followed by a method of solution which is named here after Movchan and Houbolt, who apparently developed it independently. The Galerkin method is examined and its characteristics for this problem are discussed. This method is then applied in the solution of the flutter problem of cylindrical and conical shells. Extensive calculations indicate that by taking account of the previously neglected axial bending stiffness of the shell, the nature of the flutter mode is revealed and minimum flutter speeds are obtained, which are much lower than those obtained previously using 'medium shell' theory. The effect of large thermal stresses on the frequencies of plates under generalized support conditions is investigated. It is shown that whereas before buckling occurs the effect of a rising temperature is to decrease the frequencies, the opposite effect is true after buckling has taken place.
The role of the support conditions is stressed.

ABSTRACT: The stability under axial compression and lateral pressure of a finite circular-cylindrical shell with an elastic core is treated by means of Donnell’s equations. For lateral pressure it is found that a previous solution treating the cylinder as a ring or a long cylinder is adequate for a wide range of combinations of length-radius ratio, radius-thickness ratio, and ratio of moduli of core and cylinder. Results for axial compression are included for completeness and to correct a previous analysis of the same problem.

D. O. Brush and B. O. Almroth (Lockheed Missiles and Space Co., Palo Alto, California, USA), “Buckling of core-stabilized cylinders under axially-symmetrical external loads”, (publisher or report number not given), January 1962, DTIC Accession Number: AD0610266
ABSTRACT: An equation is derived for the elastic stability of a circular cylindrical shell which is filled with a soft elastic core and is subjected to general axially-symmetrical lateral pressure combined with a central axial force. Numerical results are given for three lateral pressure distributions of interest in rocket motor case analysis: Uniform pressure, linearly varying pressure, and a circumferential band of pressure located at an arbitrary distance from one end of the cylinder. Comparison is made with results of previous theoretical and experimental investigations, where available.

ABSTRACT: A buckling analysis is presented for a circular cylindrical shell subjected to nonuniform external pressure. The general approach is not restricted with respect to the distribution of the lateral pressure. However, the final formulation is specialized for the case in which the pressure distribution is of the form \( p = p_0 + p_1 \cos(\phi) \) within a centrally located circumferential band. In the buckling analysis the stability criterion is based on the principle of minimum potential energy, and the Rayleigh-Ritz procedure is used to expand the displacement components in trigonometric series. Buckling pressures are computed in terms of nondimensional parameters and are presented in graphical form.

ABSTRACT: The postbuckling behavior of a circular cylindrical shell subjected to axial compression is considered. Because of numerical difficulties, previous analyses of this problem have been severely restricted and do not yield quantitatively satisfactory results. The most accurate such analysis gives a minimum postbuckling load that is approximately three times higher than corresponding test values. In the present analysis, the number of free constants in the displacement function has been considerably increased, and the computed minimum postbuckling load is in close agreement with available test results. Additional tests are suggested to support the establishment of a buckling criterion which, together with the presently computed postbuckling curve, could serve as a sound basis for the design of cylinders under axial compression.

W.F. Thielemann, “New developments in the nonlinear theories of the buckling of thin cylindrical shells”, Aeronautics and Astronautics, 1960

ABSTRACT: The correct solution of the problem of hazardous loads may be obtained only by means of statistical methods. The considerable discrepancy between the experimental values of the critical loads is explained by the fact that the value of the latter is very sensitive to initial deformations, defects in the
preparation and attachment, and to non-uniformities of loading, etc. In turn, the factors mentioned have an accidental character and are subject to some statistical laws. Knowing the laws of the distribution of these accidental factors, one can establish laws of the distribution of the parameters characteristic of the deformed state of the shell. The problem of the engineering calculation of the shell is then reduced to the determination of the load values at which the probability of 'buckling' (or of the hazardous state determined in any arbitrary sense) does not exceed some previously established value for a given construction. The statistical approach serves also as a basis for the correct interpretation of the experimental results and of the tabulation of the results of different authors.

ABSTRACT: The collapse of a cylindrical shell due to tight fiber windings is investigated theoretically and experimentally. Buckling in the infinitesimal sense of Euler appears to be possible, if the fibers are not bonded well to the shell. Perhaps more significant than the Euler critical load is a dangerous snap-through condition that may develop.

CONTENTS: Stresses Due To Impact; Impact By an Infinite Mabs: Initiation of instability, Critical length for inextensional buckling, Postbuckling behavior, Secondary buckling, Effect of internal pressure; Impact By a Finite Mass: Instability, Postbuckling behaviour, Secondary buckling; and Experimental buckling behavior: Buckling at the impacted end, Inextensional nature of buckling, and Change of buckle pattern during postbuckling.

ABSTRACT: Experimental and theoretical studies of the buckling and collapse of circular cylindrical and conical shells under longitudinal impact are described. Various conditions of loading were investigated such as impact with rigid, fluid, and granular media, and such effects as initial geometrical imperfections, edge support, and loading asymmetry were included. In addition, the effect of axial impact at velocities up to 391 ft/sec on the buckling of thin cylindrical shells was studied experimentally. Finally, three problems, relating to the experiments were studied theoretically: (1) the dynamic buckling of a circular cylindrical shell subject to an axial loading which varies linearly with time, using the nonlinear theory, (2) dynamic buckling of a circular cylindrical shell subject to a constant velocity end displacement, including the effects of plasticity and incorporating extremely large deflections, and (3) the inextensional shortening and collapse modes of conical shells for the complete range of end shortening.

Coppa, “Measurement of initial geometrical imperfections of cylindrical shells” (Imperfection maps of cylindrical shell surface measured with apparatus consisting of reference surface, rotating mounting plate, oscillograph, low pressure displacement transducer, etc), AIAA Journal, Vol. 4, January 1966, pp. 172-175

PARTIAL ABSTRACT: Experimentally observed effects of edge conditions on the buckling behavior of cylindrical shells under axial compression impact are presented. Three effects are discussed, namely, those due to (1) inward radial displacement restraint of the shell wall, (2) asymmetry of the applied loading resulting from obliquity between the impact plate and the end cross section plane of the shell, and (3) impact velocity…

Joseph Kempner, “Unified thin-shell theory”, Polytechnic Institute of Brooklyn, NY, March 1960, DTIC Accession Number : AD0689144
ABSTRACT: Structural components which have one dimension very much smaller than the other characteristic dimensions are widely used in many fields of engineering. Such plate and shell structures have received wide attention in the literature. Quite often a complex reinforced shell can be represented by an equivalent unreinforced anisotropic shell which under appropriate conditions can be considered to be of an orthotropic material. With very few exceptions, problems involving small deformations, large deformations, and buckling are treated separately with the interrelation of these three areas of theory not clearly revealed. It is the purpose of these notes to present in a concise manner a theory of thin-shells which, while revealing the essential unity of the whole of shell theory, still retains much of the simplicity afforded by the acceptance of the usual
assumptions. The general mathematical approach described by Novozhilov for problems of nonlinear elasticity is applied in the present development.

ABSTRACT: The studies briefly described stem from continuing investigations of plates and shells under external loading and elevated temperatures, and include problems of special interest to designers of missiles and aircraft. Chapter 1 presents the results of investigations of the effects of creep in structures, with particular emphasis on the bending of circular plates. Chapter 2 outlines the work performed on heat conduction problems using Biot's variational method. Chapter 3 discusses the problem of the buckling (small-deflection theory) and postbuckling (large-deflection theory) of noncircular (oval) cylindrical shells under axial compression. Chapter 4 describes work on the analysis of the effects of concentrated loads applied to reinforcing frames of finite and infinitely long circular cylindrical shells. Chapter 5 discusses the results obtained from the analysis of the dynamic response of plastic spherical shells.

ABSTRACT: The effects of initial imperfections and residual welding and rolling stresses on the yield strength of a stiffened cylinder were investigated by tests of a machined and stress-relieved model, Model BR-7M, identical in geometry and of the same material as a previously tested fabricated model, Model BR-7. The experimental collapse pressure of 1502 psi agreed well with collapse pressures computed from theories which account for the plastic reserve strength. The pressure at which yielding began agreed more closely with that calculated by the maximum-shear-stress or the Hencky-Von Mises criterion than with that calculated by the maximum principal-stress criterion. The data also indicated that the mathematical form of the deflection function of the shell did not change appreciably in the elastic-plastic range. Comparison of the collapse pressures of the machined and welded models indicated that, for the geometry tested, the residual welding and rolling stresses do not adversely affect the collapse pressure.

ABSTRACT: An approximate theory for the process is derived, leading to a solution of the type $P = Ct^{1.5} \sqrt{D}$, where $P$ is the collapse load, $t$ the shell thickness, $D$ the shell diameter, and $C$ a constant for any given material. Good agreement is exhibited between this relationship and experimental results.

ABSTRACT: The dynamic stability of a thin, perfectly conducting cylindrical shell in axial and azimuthal magnetic fields is investigated by means of the method of normal modes. It is found that in cases where a growth of a surface perturbation is indicated, the $e$-folding time corresponds to the time required for the shell to collapse radially. Where stability is predicted, an initial surface perturbation can be shown to execute an oscillatory and damped motion.

ABSTRACT: A historic review of the development of our ideas on buckling is presented. It continues with a report of work on the stability of thin shells now under way at Stanford University. The results obtained so far in this investigation can be presented under three headings: First, a new solution is found to the classical small-deflection equations of the stability of thin-walled circular cylindrical shells. The second part deals with the large displacements developing when the thin circular cylindrical shell suddenly snaps through into a polyhedral buckled shape often designated as the diamond shape. In the final part the transmission of the axial load through the fully buckled circular cylindrical shell is studied.

ABSTRACT: The bending by uniform lateral loading, buckling by two-dimensional hydrostatic pressure, and the flexural vibrations of simply supported polygonal plates are investigated. The method of meeting the boundary conditions at discrete points, together with the Marcus membrane analog [1], is found to be very advantageous. Numerical examples include the calculation of the deflections and moments, and buckling loads of triangular square, and hexagonal plates. A special technique is then given, whereby the boundary conditions are exactly satisfied along one edge, and an example of the buckling of an isosceles, right-angled triangle plate is analyzed. Finally, the frequency equation for the flexural vibrations of simply supported polygonal plates is shown to be the same as that for buckling under hydrostatic pressure, and numerical results can be written by analogy. All numerical results agree well with the exact solutions, where the latter are known.

ABSTRACT: The stability of circular cylindrical shells under pure bending is investigated by means of Batdorf's modified Donnell's equation and the Galerkin method. The results have shown that contrary to the commonly accepted value, the maximum critical bending stress is for all practical purposes equal to the critical compressive stress.

Hiroichi Ohira 1965 Local Buckling of Circular Cylinders of Finite Length due to Axial Compression and the Effects of Edge Constraint, presented at the Fifteenth Japan National Congress for Applied Mechanics, Sept. 8, 1965, and to be published in the Proceedings. (Consise Japanese summary and a set of the figures sent to the author in October 1965.)

ABSTRACT: In this part, a method for measuring plate and shell buckling of fabrics is described. The same instrument can also be used to measure extension-compression in the plane of the fabric. The instrument consists of an attachment to the Instron Tensile Tester, and complete load-deformation curves are obtained.

ABSTRACT: Thermal stress distributions in uniform circular cylindrical shells due to axial temperature distributions are investigated. The discontinuity effect due to the presence of a cooler stiffening bulkhead is considered, and the possibility of thermal buckling of the shell due to the circumferential discontinuity stress is examined. The buckling analysis is based on Donnell's shell equation, and particular attention is given to shells having clamped edges. An experimental investigation of this buckling problem is discussed, and the results obtained are seen to agree reasonably well with theory.
ABSTRACT: Load-deformation curves obtained by the methods for shearing and buckling described in Part I and II are analyzed and discussed. Parameters obtained from these curves are given for 66 commercial fabrics covering an extreme range. Different fabrics show widely different values for the parameters obtained from both shearing and buckling curves. It is further shown that there exist close relationships between simple deformations like shearing and plane buckling and complex deformations like buckling of corrugated fabric shells. The formability of a fabric is defined as the maximum compression a fabric can take up before it buckles, given a certain geometric arrangement. The formability determines the tailorability and the crease pattern of fabrics. The formability is dependent on fabric direction, and it is shown that the integrated formability should be related to the product of buckling load and shear angle. A theoretical analysis of formability is given, and it is shown that it can be expressed as the product of an anisotropy ratio and the square of the fabric thickness. It is further shown that the shell buckling load depends on both the plane buckling load and the shear angle, in such a way that increasing shear angle leads to decreasing shell buckling load. It is shown that combination of high formability and low shell buckling load generally is attained by combining relatively high thickness with low bending modulus. It is also shown that wool fabrics generally have this combination of properties. A fabric map is given for all the commercial fabrics. Each fabric has a certain position on the map dependent on bending stiffness (which is closely related to buckling load) and shear angle. Attention is given to the relation between creasing behavior of fabrics and fabric properties. There is a certain relation between crease recovery angle and formability and a good relation between this angle and the noncyclical energy loss in shell buckling. The hypothesis that recovery properties depend mainly on the interaction within the fabric between frictional forces and elastic forces of the fibers is put forward. The energy loss following any fabric deformation depends mainly on friction. The permanent deformation is probably due to the fact that the elastic forces of the fibers cannot overcome the friction. By means of a rheological model it is shown how friction and fiber stiffness may interact in a fabric. It is shown that the stiffness value should be that obtained at infinitely slow loading of the fiber.

ABSTRACT: An experimental and theoretical investigation of the effect of a specific type of initial imperfection on the buckling load of a circular cylindrical shell under axial compression loading was carried out. The imperfection studied was axially symmetric in shape and had the form of a half sine wave in the length direction. Both inward and outward bowing imperfections were considered. The experiments were carried out with shells fabricated by a copper electroforming process. The shells had no longitudinal seams and had unintended imperfections of the order of the wall thickness. The buckling stress for the intended imperfection studied was only slightly influenced over a considerable range of imperfection amplitudes. The theoretical solution located the bifurcation points of the prebuckled axially symmetric state. The solution showed that outward bowing shells should have the same buckling stress as a perfect cylindrical shell and inward bowing shells should have a lower buckling stress than the perfect cylinder.

L.H.N. Lee, “Effects of modes of initial imperfections on stability of cylindrical shells under axial compression”, 1962, pp. 143-161 (publisher not given in the ProQuest-CSA file)

ABSTRACT: This paper presents a theoretical solution to the problem of determining the buckling characteristics of an axially compressed, long, cylindrical shell which contains a solid or elastic core with a modulus lower than that of the shell. The buckling mode is assumed to be sinusoidal in both the axial and circumferential directions, with the bellows mode taken as a special case. Numerical results are obtained for the buckling characteristics of cylinders with solid cores. These results are found similar to those of P. Seide, who considered the bellows buckling mode.

DOI: 10.1115/1.3640658

ABSTRACT: A theoretical study is made on the local ovaling of a relatively thick tube of low modulus caused by bending. Use is made of modified Donnell’s large-deflection theory [3] and the principle of minimum potential energy in the solution. It is found that tubes with small radius-thickness ratio tend to buckle by local ovaling rather than by the small wave pattern since the former yields lower buckling moment than the latter.

ABSTRACT: The investigation of the behavior of a uniformly thick, thin spherical shell subjected to uniform external pressure in the buckling and post-buckling regions is undertaken both from a theoretical and from an experimental point of view. A perturbation scheme similar to one developed by Koiter is applied to the nonlinear buckling problem of a complete spherical shell. The nonhomogeneous linear differential equations which result are solved, with the aid of the high speed digital computer, in a finite series of Legendre polynomials. In the neighborhood of the linear buckling load, the shell is shown to be unstable both for the case of the linear buckling mode's being an odd function about the equator and for its being an even function. Four hemispherical shells made of materials with low Young's moduli (less than 1000 psi) were observed in the laboratory in several prebuckling and post-buckling states. Use of photographic methods for the measurement of the radial and tangential displacements of points marked along the meridians of the shells shows a region of small but very definite outward radial displacements adjacent to the main buckling dimple. Furthermore, the displacements observed were symmetric about the polar axis. The experimental buckling pressures observed for the four shells tend to indicate that the critical pressure calculated according to the linear theory may be the correct one, i.e., the buckling pressures varied from about half to over three quarters of the linear buckling load.

ABSTRACT: (none given)

ABSTRACT: The most rigorous theory of the creep buckling of initially imperfect columns (due to Hoff and Fraeijs de Veubeke) is examined for possible simplifications. It is found that the influence of plasticity on the life of a column can be ignored under certain conditions characterized by the proportional limit stress, a creep parameter, the applied stress, and the initial curvature. These conditions are conveniently presented in the form of graphs for steady creep as represented by the power and the exponential laws. The simplification possible in the regions so defined permits the application of the early theories such as those due to Kemper, Libove, etc. For steady creep these lead to simple formulae which consist of the life determined according to Gerard’s suggestion multiplied by a correction factor. Some published data are examined in terms of the present ideas and give encouraging agreement with the theoretical results, for values of the correction factor ranging from 0.0074 to 1.25. Information is given on preliminary results of an experimental investigation now in progress at Stanford University.

ABSTRACT: Closed-form solutions are given of the linear Donnell equations defining the buckling of thin-walled circular cylindrical shells subjected to uniform axial compression. In addition to the classical simple support conditions requiring the vanishing of the radial displacement, the axial bending-moment resultant, the axial additional normal-stress resultant, and the circumferential displacement, three other, equally justifiable, simple support conditions are defined and studied in the case of the semi-infinite shell. Two of them yield buckling stresses amounting to about one half the classical critical stress.

ABSTRACT: Elastic stability of clamped shallow spherical shells subjected to a small finite-area load at the apex is studied experimentally. Upper and lower critical buckling loads and prebuckled and postbuckled deflections are found for lambda between 10 and 17. Buckling modes have been observed and defined. Nonaxisymmetric deformations are noted. Shells for lambda less than 8 1/2 exhibit plastic behavior and do not buckle.

ABSTRACT: The accurate calculation of stresses at boundaries and interfaces where FEM analysis may be unreliable is presently undertaken by an error analysis that derives a continuous approximation to discrete finite-element data, which can be differentiated to compute continuous stresses for component-failure predictions. An evaluation is conducted of this approximation in the context of the nonlinear PDEs. A novel interpolation formula which is a simple modification of the double Fourier sine series is used to reduce truncation errors near the rectangular plate boundary by means of an 'extended grid'. Results are presented from a FEM solution, a conventional double-Fourier series' continuous approximation, and a solution applying interpolation on the extended grid, which yields superior convergence properties near the plate boundaries.

ABSTRACT: The effect of axial elastic restraint on the instability of a circular cylindrical shell under uniform axial compression is analysed by a Rayleigh-Ritz approach within the bounds of linear theory. The effect is calculated for a wide range of parameters, and design curves are presented for the percentage increase in critical load.

ABSTRACT: The analysis of the general instability of stiffened cylindrical shells under hydrostatic pressure carried out earlier is continued in order to study the inversion of the eccentricity effect. 250 typical shells of varying geometries are considered. The results show that the inversion of the eccentricity effect is practically independent of the geometry of the rings but depends very strongly on the shell geometry parameter Z. A range of inversion is found. A detailed physical explanation of the causes of the eccentricity effect and its inversion is proposed.

ABSTRACT: The effect of stiffener eccentricity on the critical load is studied for cylindrical shells under axial compression. Classical simple support and classical clamped end conditions are considered. A detailed physical explanation of the causes of the eccentricity effect is proposed and verified by computations for 350 typical shells. As in the case of buckling under hydrostatic pressure and torsion, the behavior of the eccentricity effect in the case of axial compression also depends very strongly on the geometry of the shell, represented by the Batdorf parameter. On the other hand the geometry of the stiffeners influences only its magnitude. At very low Z, inversion of the eccentricity effect occurs, but for practical dimensions outside stringers always stiffen the shell more than inside ones. The eccentricity effect has a pronounced maximum at practical values of Z. The behavior of the eccentricity effect is very similar for clamped and for simply supported shells. The effects of eccentricity of ring stiffeners are also considered.

ABSTRACT: Theoretical and experimental research on the buckling of stiffened and unstiffened conical and cylindrical shells, carried out over a period of 3 years, is summarized. The topics of earlier work are outlined and the more recent topics are summarized. These include: discreteness effect in stringer-stiffened shells and the effect of elastic restraint on panels and sub-shells; the influence of inplane boundary conditions for ring-stiffened cylindrical shells; extensive tests on stringer-stiffened cylindrical shells under axial compression and ring stiffened conical shells under torsion; and also thermal buckling of cylindrical shells.

ABSTRACT: The work is a further step towards optimization of stiffened cylindrical shells. Rings and stringers of non-uniform cross-section are analysed as a means of obtaining higher structural efficiencies. For lateral pressure loading, rings with non-uniform height or width are compared. The gain in general instability pressure
relative to the uniformly stiffened shell of the same weight amounts to 70-80%. For prescribed loading, 10-20% weight savings are obtained. For axially compressed cylinders, stringers with sinusoidal and linear height variation are studied and compared. Gains in load and weight savings of 30% and 10%, respectively, are obtained, and the sinusoidal variation is found to be superior to the linear variation. Finally, cylinders under hydrostatic pressure stiffened by a combination of uniform stringers and non-uniform rings are analysed. Different configurations are checked in order to obtain the highest possible efficiencies.

ABSTRACT: An experimental and theoretical study of the buckling of closely stiffened cylindrical and conical shells under axial compression has been undertaken to determine the influence of the stiffener geometry and spacing on the applicability of linear theory. Tests on integrally ring-stiffened cylinders, in which the spacing, cross-sectional area and eccentricity of the stiffeners are varied are described. The bounds of general instability are first determined by an elementary analysis of sub-shells and panels between stiffeners, in conjunction with “smeared” stiffener theory…

ABSTRACT: An experimental program was conducted in order to determine the family of interaction curves for the buckling of unstiffened conical shells under combined axial compression, torsion, and external or internal pressure. Careful experimental technique permitted many repeated buckling tests on the same aluminum alloy shell without noticeable damage and yielded reliable interaction curves. Results of combined-loading tests are presented and compared with linear theory. Test results show that the interaction curve for compression-torsion-pressure loading is defined by superposition of compression-pressure, torsion-pressure and compression-torsion behavior.

ABSTRACT: The buckling of ring-stiffened cylinders is studied by a 'discrete' approach, in which the rings are considered as linear discontinuities represented by the Dirac delta function. The analysis is a linear Donnell type theory that takes account of the eccentricity of stiffeners. Buckling loads under hydrostatic pressure, lateral pressure and axial compression are compared with those obtained by 'smeared-stiffener' theory for an extensive range of geometries. The discreteness effect depends very strongly on the geometry of the shell and the eccentricity of the rings. Significant discreteness effects are found for hydrostatic pressure loading.

ABSTRACT: The stability of simply supported conical shells under axial compression is investigated for 4 different sets of in-plane boundary conditions with a linear Donnell-type theory. The first two stability equations are solved by the assumed displacement, while the third is solved by a Galerkin procedure. The boundary conditions are satisfied with 4 unknown coefficients in the expression for u and v. Both circumferential and axial restraints are found to be of primary importance. Buckling loads about half the “classical” ones are obtained for all but the stiffest simple supports SS4 (v = u = 0). Except for short shells, the effects do not depend on the length of the shell. The physical reason for the low buckling loads in the SS3 case is explained and the essential difference between cylinder and cone in this case is discussed. Buckling under combined axial compression and external or internal pressure is studied and interaction curves have been calculated for the 4 sets of in-plane boundary conditions.

Main purpose of test program is to make a close study of the influence of stiffener geometry and spacing on the applicability of the linear theory

ABSTRACT: The buckling of integrally external ringstiffened conical shells under axial compression was investigated experimentally. Experimental results were compared with theory to find the effect of the stiffener parameters (e/2h), (A2/a0h) and (I22/a0h^3) as well as of shell geometry. Agreement between classical linear theory and experiments was found to be governed primarily by the area parameter (A2/a0h), and correlation with theory was significantly affected in the range 0.1<(A2/a0h)<0.5 of that parameter. Beyond this region there is practically no improvement with increase in ring area, whereas the weight of the shell continues to increase linearly. An approximate formula is proposed for calculation of critical loads and found to yield results very close to the more exact critical values calculated by linear theory. A modified “Southwell plot” method was applied and both the intercept method and slope method were used. Critical loads computed from the strain records were found to be below the classical linear-theory predictions and closer to experimental ones.

Taylor's series is preferable. For assumptions of Koiter's theory. It is shown that a strain large reduction of the classical buckling load. The non-investigated. It seems that a slight non-
displacement relationship which in fact represents a slightly non-linear stress-strain constitutive relationship is investigated. It seems that a slight non-linearity in the stress-strain curve may lead in some cases to unexpected large reduction of the classical buckling load. The non-linear constitutive law is not consistent with the basic assumptions of Koiter's theory. It is shown that a strain-displacement relationship obtained by the use of Taylor's series is preferable. For complicated structures calculation errors are unavoidable. A straight forward
application of Koiter's theory for such structures would lead to incorrect interpretation. A method to avoid such a difficulty is proposed and both analytically and numerically described.

Abstract: Axial buckling tests on machined integrally stiffened cylindrical shells were carried out. Complete mappings of the shell imperfections and the prebuckling growth were obtained. The lightly ring-stiffened shells behaved in a manner similar to the isotropic shells that were previously tested. For these shells, the predominant prebuckling deformation consisted of a half-wave in the axial direction with several circumferential waves. The similarity of the lightly ring-stiffened shells and the isotropic ones suggests that the uniqueness of the buckling mode for stiffened shells may not greatly influence the prebuckling behavior. The heavily ring-stiffened shells showed a sizable amount of short wave length axisymmetric growth before buckling. Buckling in all cases resulted in an asymmetric pattern. The stringer-stiffened shells showed a prebuckling behavior also similar to the isotropic results. However, the buckling pattern consisted of longer axial wave lengths. Correlation of the experimentally obtained buckling loads with linear buckling theory showed good agreement in most cases.

ABSTRACT: A review of the existing knowledge of buckling of shells. Note is taken of the lack of information concerned with concrete shells as against that available for plastic and metal shells. Reported work in metal and plastic shells in the areas of elastic, inelastic, and large deflection theory of buckling is applied to concrete shells. Cylindrical shells are discussed under conditions of axial load, radial pressure load, torsional load, and bending. Spherical shells under radial pressure and curved plates under bending are also covered.

SUMMARY: The development of finite element calculational procedures for thin shell instability analysis has involved the definition of appropriate element representations (i.e. the geometric form of the element and the approximation of displacement and/or stress), constitutive expressions, and computational algorithms. Among these, the status of thin shell finite element representations remains unsettled. This paper therefore emphasizes recent developments in the basic aspects of thin shell finite element analysis and discusses one simplified approach in more detail. Formulative and computational procedures for elastic instability analysis are then summarized and numerical results are shown for the simplified shell element formulation.

ABSTRACT: Stiffness equations are formulated in representation of the elastic instability behavior of a doubly-curved thin shell element. The element is in the form of a shell of translation of constant thickness and constant principal radii of curvature. The derived relationships are expressed in curvilinear coordinates. An approximate method of eliminating unwanted degrees of freedom from the statement of the buckling eigenvalue problem is applied. Illustrative examples cover the utilization of the element in plate, cylinder, and doubly curved shell elastic instability problems with known solutions. Related comparisons assess the accuracy of the basic formulation, the approximate reduction procedure, and the ability of the present formulation to deal with special features of cylinder buckling.

R.C. Tennyson, (University of Toronto), “An experimental investigation of the buckling of circular cylindrical shells in axial compression using the photoelastic technique (Photoelastic analysis of circular cylinder shell buckling in axial compression)”, 1964 (no publisher given)

ABSTRACT: A novel method for fabricating “near-perfect” circular cylinders of photoelastic plastic is presented. The spin-casting technique was found to yield circular cylinders having thickness variations as low
as plus or minus 0.0006 in., and capable of maintaining this tolerance on shells with radius-to-thickness ratios in the range of 100 < R/t < 600. The cylinders generally were found to buckle within 10 per cent of the classical computed load, and within only a few per cent of the reduced value taking into account the clamped end constraints. This represents an increase over previous experimental data. Buckling was completely elastic, and, as a result, repeatability of the buckling load and buckling process was observed for as many as 20 tests on any one shell. Experimental evidence of the unstable states occupied by the shell during the buckling process was found by photographing the change in the 45-degree isoclinics with wave shape. Shell alignment, end constraints, and the method of applying a uniform compressive end load on the cylinder are also discussed. Although no new techniques were employed, the methods used were found reliable and accurate.

R.C. Tennyson and S.W. Welles (Institute for Aerospace Studies, University of Toronto, Ontario, Canada), “Analysis of the buckling process of circular cylindrical shells under axial compression”, February 1968, DTIC Accession Number: AD0665531

ABSTRACT: Geometrically 'near-perfect' circular cylindrical photoelastic shells having radius-to-thickness ratios of the order 100 - 440 were tested in pure axial compression. The critical buckling loads were found to agree within 10 - 14% of the classical value, or within a few percent of the reduced buckling load taking into account the clamped end constraint. High speed photographs of the buckling process were obtained using two cameras viewing the change in the 45 deg isoclinics over the entire cylinder's length and over 60% of the cylinder's perimeter. A theoretical analysis of the inception of buckling using Koiter's mode shapes demonstrated that the classical buckling mode was observed in the experiments for the first time. Further investigation of the nonlinear postbuckling mode shapes just after initial buckling predicted the wave forms observed. It was also determined that the shallow shell equations used to describe the large-deflection postbuckling behaviour do not predict isoclinic patterns which are observed in the later stages of buckling.

ABSTRACT: The effects of unreinforced circular cutouts on the buckling behavior of circular cylindrical shells subjected to axial compression have been investigated. In addition, the membrane stress distribution and isoclinic patterns were determined around the edge of the cutout, using photoelastic shells, and the results compared with recent theory. The membrane stress concentration factors were found to increase rapidly with increasing values in the curvature parameter β. Large reductions in the critical buckling loads occurred for relatively small cutouts (e.g., a 50 percent reduction in the collapse load was found for a/R = 0.10). As a result of the investigation, design information is provided for determining the effect of a/R on the critical buckling load of a circular cylindrical shell.

speed photographic recording of photoelastic isoclinic pattern changes), SPIE JOURNAL. Vol. 8, pp. 167-174. 1970

ABSTRACT: A survey of recent work by the author on the interaction of highly controlled buckling experiments with various aspects of cylindrical shell theory for both homogeneous isotropic and laminated anisotropic structures is presented. Emphasis is placed on the necessity of utilizing accurately manufactured test models for validation of elastic buckling theory. The areas examined include: dynamic buckling under transient axial impulsive loading; static buckling of isotropic and laminated anisotropic (composite) cylinders due to combined axial compression, hydrostatic pressure and torsion loading; the effect of cylinder length on buckling behavior for both single and combined loading cases. Of particular interest is the buckling of cylinders under multiple loading where it was found that as L-squared/Rt was decreased, the interactive curve changed from 'concave' to 'convex'. The analytical models used in these studies include the effect of boundary conditions and associated nonlinear prebuckling deformations. In most instances, results are shown for both perfect and imperfect shells to demonstrate the comparative agreement one can achieve between theory and experiment.

ABSTRACT: This report presents theoretical and experimental data on the buckling of short, homogeneous, isotropic circular cylinders subjected to simultaneous loading of axial compression and hydrostatic pressure. Of major significance is the drastic change from “concave” to “convex” interactive behavior as the Z parameter is decreased. This phenomenon is demonstrated for both clamped and simply supported boundary conditions.

ABSTRACT: Classical small deflection theory is used to derive buckling coefficients for cylinders of sandwich construction under axial compression. The core is assumed to be orthotropic, but the results do not differ much from isotropic core unless the core shear modulus is much smaller circumferentially than axially. The buckling coefficients for isotropic core and orthotropic core stiffened circumferentially are the same and are presented in a particularly simple formula…..

References listed at the end of the report:

PARTIAL INTRODUCTION: The difficulties inherent in the theory of the buckling of thin shells are most pronounced when a cylindrical shell under axial compression is considered. This problem was first attacked in the early 1900's by Lorentz, Southwell, Timoshenko, Flugge and Donnell. They neglected all terms higher than second order in the potential energy and solved the resulting linear equilibrium equations for the classical or linear buckling load (also called the Euler load). The theoretical results of the classical theory did not, however, agree well with the early experiments of Lundquist and Donnell. Significant disparities occur not only in the buckling load, which the theory predicts three to four times too high, but also in the wave form. In addition, the classical theory yields a wave pattern which envelops the entire surface of the shell and, is not in accord with the observed behavior of local instabilities. Lastly, the scatter of experimental points and the definite tendency for a shell to buckle radially inward, rather than, as predicted by the theory, both inward and outward, are two additional characteristics not described by the classical theory. Numerous attempts have been made to reconcile these discrepancies between the experiments and the classical theory. In one of the first, Flugge (16) adjusted the theoretical boundary conditions to coincide with those actually realized in the laboratory, but found only a negligible influence on the buckling loads of most cylinders. In contrast, a recent investigation by Stein (7) shows a significant drop in...

ABSTRACT: Experimental verification has been made of the previously developed theoretical analysis, and corresponding design data sheet, which permits the prediction of critical shear buckling stresses for square panels of orthotropic material with clamped edges for any angle that the principal axis of elasticity makes with the reference edge. The theory correctly predicts low values of buckling stress for a 135-degree angle for materials in which the elastic constants in the two principal directions are widely different. Experiments with a woven roving laminate, in which the ratio of moduli in the principal directions is 2:1, show buckling stresses 15 percent lower than the predicted values. The differences are accounted for by the knowledge that theory predictions are about 5 percent high and by variations in properties and dimensions of actual materials which preclude the development of full buckling strength. A recommendation is made to utilize the data sheet with due consideration given to these differences.

ABSTRACT: The purpose of this program is to develop and prove out a theoretical method for accurately predicting the critical buckling strength of externally pressurized cylinders made from orthotropic materials and to find the optimum construction of filament reinforced plastic (FRP) cylinders under such loading. A description of the program and its significance to the overall BuShips Deep Submergence program and a summary of the work accomplished to date are given. Theoretical analytical expressions for predicting elastic buckling collapse and elastic constants of FRP cylinders are presented and discussed. Results of initial buckling and discontinuity stress analysis of proposed test cylinders are presented.

ABSTRACT: This paper shows that when very thin cylindrical shells are subjected to an external impulsive pressure, the interaction between the radial, purely extensional mode and the flexural modes is sufficient to precipitate permanent wrinkles. The theory predicts that these wrinkles occur at a wavelength which depends on the magnitude of the pressure pulse as well as on the cylinder parameters; experiments on cylindrical shells and thin strips confirm this prediction. Framing camera photographs showing the formation of wrinkles of this type are also presented.

ABSTRACT: Stiffening by means of an elastic core is demonstrated to increase significantly the resistance of a cylindrical shell to buckling from an external impulsive pressure. Both theory and experiments show that the elastic core constrains the shell to absorb more energy by membrane plastic flow. Inclusion in the theory of a continuously changing tangent modulus of the shell material leads to a critical core modulus which depends on the hoop strain and explains the increased wave numbers observed in the experiments with stiff cores.

ABSTRACT: Buckling of thin cylindrical shells from axial impact is studied under the assumption that initial imperfections can be approximated by “white noise.” Linear small-deflection theory is used to calculate the resulting growth of the normal modes, and a statistical analysis gives the expected values for the “preferred” axial and circumferential wave-lengths. Very high-speed photographs (240,000 frames/sec) of shells buckling under axial impact show excellent agreement with the theory and demonstrate that large-deflection buckling follows the pattern established by the early linear motion.

ABSTRACT: A theory of dynamic pulse buckling is developed for cylindrical shells subjected to symmetric lateral pressure pulses of duration ranging from an ideal impulse to durations so long that the pulse is a step load. To cover this range three theoretical models are used: a tangent modulus model for impulsive loads that produce plastic flow buckling, a strain reversal model for loads of intermediate duration which produce complicated elastic-plastic buckling, and an elastic model for long loads that produce elastic buckling. Peak pressure and impulse are identified as the most significan load parameters, and critical curves for buckling are generated in the pressure-impulse plane based on an amplification of shell imperfections. It is shown that these curves, from the symmetric load theory, can be used to give reasonable estimates for critical loads for smoothly varying asymmetric loads, such as from a lateral blast wave. Simple formulas are given for the critical curves in terms of the shell elastic and plastic material properties, radius-to-thickness ratio, and length-to-diameter ratio. The curves agree well with experimental results over the entire range of pressure and impulse.

ABSTRACT: The formation of small, flexural wrinkles in the walls of a sandwich shell under uniform radial impulse is examined. A buckling criterion based on the magnifications of initial wall imperfections is used to evaluate threshold impulses. Using a given weight of material, this criterion is used to determine the optimum ratios of the inner and outer wall thicknesses for various core thicknesses. It is shown that the optimum shell for a given weight of material and outer diameter is a single-wall shell. The loss in efficiency obtained by using typical sandwich shells is about 30 percent. These results are supported by experimental evidence.

ABSTRACT: A great deal of work has been done on buckling of cylindrical shells under dynamic axial loads. The motivation for much of this work stems from the design of missiles to sustain the sudden application of thrust from rocket engine ignition. The thrust-time history is idealized as a step or a linear ramp increase to a constant operating thrust. The concern is that the dynamic buckling load may be smaller than the buckling load for a slowly applied thrust. Other applications occur in transportation accidents, where the loading is from impact and often exceeds the static buckling load.

ABSTRACT: A theory is postulated to explain the plastic buckling of cylindrical shells caused by uniform radially inward impulses. Experimental results are presented which show that the number of buckles increases with the shell length. A simple formula is derived which predicts preferred mode numbers in agreement with the experimental results for shells with lengths up to about 1 1/2 dia. For longer shells, mode numbers may be obtained by numerical integration of the equation of motion. The increase in mode number with shell length is attributed to the relative effects of the “directional” and hardening contributions to the reactive bending moment, the former stemming from yielding in a biaxial plastic state of stress. In short shells (length < dia), it is shown that the directional moment dominates, whereas in long shells (length > 3 dia) the hardening moment dominates. The mode prediction formula just mentioned applies whenever the directional moment dominates and the difficulty in treating cases where the hardening moment is significant is indicated. Again, for the former case, a simple threshold impulse formula is derived conforming to the experiments.
ABSTRACT: An experimental and theoretical investigation of dynamic buckling of thin cylindrical shells under oscillating stress waves following axial impact shows that hoop breathing response induced by the Poisson effect plays a strong role in initiating buckling, and that the stress oscillations allow buckling initially localized near the impacted end to propagate up the shell toward the free end. As a result of this energy spreading, the total compressive impulse of multipulse loading can be substantially larger than the critical impulse for a single pulse. The radial deformation of breathing provides a deterministic mechanism for initiation of symmetric buckling, which dominates early response for superclassical impact loads. For subclassical impact loads, the circumferential stress resultant from the Poisson effect excites hyperbolic growth of a large group of asymmetric modes; a continuous range of impact loads extending to values below the static classical buckling load therefore result in dynamic buckling within the scope of classical buckling theory with inertia terms added.

ABSTRACT: Comparisons between an unknown-but-bounded imperfection model and a random imperfection model show that for simple pointwise failure measures, at least, the two models give the same expressions for their measures of response, but each measure has a distinctly different interpretation. The former gives the maximum possible response for any imperfection within a specified bound. The latter gives the standard deviation of response, which, together with the statistical distribution, can be used to specify the maximum response at a specified confidence level. However, since the statistical distributions of imperfections, and hence of the response are often unknown, confidence levels are difficult to define, especially in the tail of the distribution at high confidence levels. The unknown-but-bounded model requires less information about the imperfections to come to a well-defined bound on response. It is further shown that, while the maximum possible response might seem to be a severe failure avoidance criterion, it can be less constricting than having to impose artificially high confidence levels with poorly known statistical distributions.

ABSTRACT: The theoretical basis of two related but distinctly different dynamic buckling criteria are summarized with the objective of demonstrating the range of applicability of each, so that together they cover the entire range of dynamic pulse loads from nearly impulsive loads to step loads of infinite duration. The example chosen is a cylindrical shell under elastic axial loads but the approach is applicable more generally. A critical amplification-of-imperfections criterion with a linear shell theory is shown to be applicable for short duration loads, for which a threshold nonlinear divergence criterion gives loads an order of magnitude too conservative. Conversely, the linear theory is inapplicable for long duration loads, for which critical loads are lower than the linear static buckling load because of imperfection sensitivity. In this range the threshold
nonlinear divergence criterion is used. For loads of intermediate duration, an extended critical amplification criterion is used with equations that conservatively assume zero static buckling load but give an unchanged formula for critical load amplitude-duration combinations.

ABSTRACT: Convex and probabilistic model solutions are obtained for multimode dynamic buckling of cylindrical shells with uncertain imperfections under symmetric radial impulse loads. It is found that the maximum possible buckling deformations for any imperfection within uniform bounds can be made comparable to the buckling deformations from the probabilistic models at a reliability of about 99.5 percent. Numerical evaluation and interpretation of the convex model is much simpler than for the probabilistic models, and the convex model solution provides means for quality control of each and every shell by simply recording the values of the bounds from appropriately filtered imperfection measurements.

ABSTRACT: Elastic moduli for filament wound cylinders having a wall configuration composed of several alternating helically and circumferentially wrapped layers are determined experimentally. The moduli were determined from measurements made on several glass epoxy cylinders and tubes loaded in pressure, torsion, or compression. Computations of elastic constants were made for the test specimens as well as for hypothetical boron epoxy cylinders to demonstrate the importance of the matrix in determining extensional stiffness. A comparison of calculations and experiment indicates that moduli measured in regions where the cylinder matrix behaves linearly are in reasonable agreement with computed values.

ABSTRACT: Results of compression tests conducted on 51 multilayered glass-epoxy cylinders are presented. Tests were conducted at both room temperature and elevated temperatures on cylinders having various helical wrap angles, matrix materials, and diameters. Experimental results indicate that, in some of the cylinders, failures were induced by buckling whereas, in others, failures were induced by thermal degradation and/or nonlinearity in the stiffness of the matrix material in the cylinder wall. The data obtained from the unheated cylinders are compared with buckling predictions based on linear anisotropic shell theory and with material strength predictions based on anisotropic yield criteria. The comparison indicated that agreement obtained between buckling tests and theoretical predictions was comparable to that obtained in previous experience with metal cylinders and that strength predictions were overly conservative. The results suggest that the compressive strength of a filament-wound cylinder can be limited by its material strength and that more refined material strength analyses are needed for multilayered fibrous composites loaded in axial compression.

ABSTRACT: A theory for thermal buckling of an orthotropic, multilayered, stiffened cylindrical shell is presented. The theory includes the effects of eccentricity of layers and stiffening, and deformations prior to buckling. It is sufficiently general to account for discrete rings and averaged properties of longitudinal stiffening, as well as arbitrary temperature distributions through the thickness of the shell and depth of the stiffeners. Two computer programs are described corresponding to solutions for buckling obtained by using finite differences and determinant plotting or modal iteration. Computed results for thermal buckling of unstiffened and ring-stiffened shells are presented and are in reasonable agreement with published results. The interaction of thermal loading and axial compression in two large-diameter stiffened shells representative of a launch vehicle interstage and a preliminary supersonic transport fuselage design is investigated. Results indicate that buckling can occur in both structures at a realistic temperature under thermal loading alone.

ABSTRACT: A theoretical study of buckling of clamped shallow spherical shells under uniform external pressure is presented. For sufficiently large deflection, deformations of such shells are not proportional to the applied pressure. The shell deforms axisymmetrically under sufficiently low pressure. The problem of axisymmetrical snapping has been solved by different numerical methods and the results agree with each other. The buckling pressures obtained in such a manner are too high as compared with experimental results obtained in References. Initial imperfections of the shell and unsymmetrical buckling are presumed to be the sources of this discrepancy between axisymmetrical buckling theory and experiment.

ABSTRACT: For a viscoelastic clamped shallow spherical shell, the vertical deflection due to uniformly distributed external pressure is a function of time. When time reaches a critical value, the shell may snap through suddenly. This critical time depends on the magnitude of the applied pressure as well as the shell geometry. The governing equations for large deformations of viscoelastic shells can be derived by applying the correspondence principle to the equivalent equations in the elastic case. The critical times for various shells under different pressures are evaluated numerically. If the deflection volume of the shell is a constant throughout the deformation process, the external pressure decreases due to relaxation of stresses in the viscoelastic shell. This decreasing external pressure is also calculated in this paper.

ABSTRACT: The serious discrepancy between theoretical and experimental results for the buckling load of axially compressed cylindrical shells is well known. This paper presents results of a test program specifically designed to throw some light on the causes of the discrepancy. Ten nominally identical nickel cylinders were fabricated by electrodeposition and tested under both dead-weight and controlled end-shortening conditions. The test results indicate the following: the buckling load under usual laboratory conditions depends on the properties of the test specimen itself rather than on the testing environment, the buckling loads under dead-weight and controlled end-shortening conditions are the same, a sharp puff of air during loading can cause buckling at a considerably reduced load level, minimization of initial imperfections in the test specimens greatly increases the buckling load, and the magnitude of the minimum postbuckling equilibrium load is relatively insensitive to initial imperfections

OUTLINE: Contents: The elastic law; Equations of equilibrium; Shells of revolution under axially symmetric loads; Toroidal shell under external pressure-theoretical analysis; Toroidal shell under external pressure-numerical results; Free vibrations of prestressed shells of revolution.

BRIEF SUMMARY: Report tests "conducted on nominal 8.0-in.-OD by 0.25-in.-wall and 4.0-in.-OD by 0.12-in.-wall specimens made from commercial pipe and tubing" (p. 1).

ABSTRACT: An experimental investigation was carried out to determine the critical buckling loads of several shallow spherical sandwich shells. A cold-forming process simultaneously using pressure and vacuum was employed to manufacture the nearly perfect spherical facing layers from 5052 aluminum-alloy sheets of 0.006 and of 0.008-in. thicknesses. Eight shallow spherical-shell specimens of 20-in. base diameter and of 20 and 30-
in. radii with 1/8 and 1/4-in. thickness of “Flexcore” have been tested in a 300-psi autoclave specifically designed for these experiments. The pressure on shells was developed by the differential pressure between the inner and the outer chambers separated by the shell being tested. When the inner chamber was maintained at atmospheric pressure and gas pressure was applied in the outer chamber, the testing procedure was termed “soft.” Alternatively, the inner chamber would be filled with fluid with the outer chamber remaining filled with gas. By initially pressurizing both chambers equally, a load on the shell could be developed by the differential pressure due to controlled bleeding of the fluid inside the inner chamber, while the gas in the outer chamber was maintained at the initial pressure. This is an accurate volume-control experiment and this testing procedure was termed “hard.” In the latter case, it was possible to monitor the displacements of the shell for each load increment with a nest of clip gages of an unique design. It was found that there is no substantial difference in the buckling loads between the hard and “soft” systems. All shells buckled in the plastic range. A reasonably good correlation is obtained with a linear theory using the double modulus for the sandwich segments.

ABSTRACT: An extension of the Donnell and Wan analysis for the buckling of a shell with initial imperfections is presented for a mode of arbitrary profile. Results for a mode with 26 arbitrary parameters are given with charts of the stress strain characteristics for cylinders with initial displacements of between one eighth and five times the skin thickness of the cylinder. A direct optimisation of the energy function is used. Almroth's minimum post buckled stress for the ideal cylinder (0.0656 Et/R) is lowered to 0.0518 Et/R and a critical assessment of the value of such figures provided.

ABSTRACT: The theoretical estimation of the buckling strength of a cylinder loaded in axial compression is improved by the use of a more representative deflected form of the buckled cylinder than has previously been used. Kempner’s buckling strength for dead-weight loading is reduced by 18 per cent. The presentation of the magnitude and distribution of the constraint system required to maintain the mode is novel and instructive. References listed at the end of the paper:

ABSTRACT: Calculations are presented from an analytical investigation on the influence of ring stiffeners on the instability modes of orthotropic cylinders subject to compressive or bending loads. The analysis is performed by employing small-deflection theory and by modifying the equilibrium equations to include the effects of discrete ring stiffeners characterized by a bending stiffness that restrains radial deformation of the shell. These calculations indicate that the ring bending stiffness necessary to cause panel instability can be adequately determined by use of an analysis which does not include the discreteness of the rings. Comparison of the results of the calculations with an empirical ring design criterion in common use indicates that the empirical formula can be either very conservative or very nonconservative depending on the cylinder geometry.

ABSTRACT: A small-deflection theory for buckling of stiffened orthotropic cylinders which includes eccentricity (one-sided) effects in the stiffeners is derived from energy principles. Buckling solutions
corresponding to classical simple-support boundary conditions are obtained for both orthotropic and isotropic stiffened cylinders subjected to any combination of axial and circumferential loading. Comparable solutions for stiffened flat plates are also given. Sample calculations of predicted compressive buckling loads obtained from the solutions are compared with existing solutions for ring-stiffened corrugated cylinders, ring-and-stringer-stiffened cylinders, and longitudinally (stringer) stiffened cylinders. The calculations demonstrate that eccentricity effects are large even with very large diameter cylinders of practical proportions and should be accounted for in any buckling analysis.

ABSTRACT: The stability of stiffened orthotropic cylinders which include the effects of eccentric stiffeners and are loaded with pure bending or any combination of bending and compression is investigated analytically by means of a small deflection theory. Solutions to the buckling equations are obtained for simple support boundary conditions by use of the Galerkin method. The pure bending buckling loads are compared with existing pure compression buckling loads for three contemporary cylinder configurations. Also shown are predicted buckling modes and typical interaction curves between bending and compression. The results show that eccentricity effects are substantial and that the maximum pure bending load may be as much as 40 percent greater than the pure compression load.

ABSTRACT: Buckling experiments were performed on a series of model torispherical bulkheads loaded by internal fluid pressure. Models were rigid polyvinyl chloride with a base diameter of 10.52 in. Parameters examined included thickness, central angle and toroidal radius. Initial data obtained show the critical buckling pressure to vary as a power of the thickness and almost linearly with central angle. The buckling pressure was found also to be very sensitive to change in toroidal radius. The use of rigid polyvinyl chloride as a model material permitted economical fabrication of test bulkheads with very uniform thickness and uniform material properties throughout.

ABSTRACT: Measurements were made of the dynamic buckling displacements of the surfaces of spherical caps during buckling under uniform external pressure. Relationships between shell geometry and the magnitude of the surface displacements, velocities and accelerations during buckling were obtained. The use of a displacement transducer whose sensing element is a photovoltaic cell is described.

PARTIAL INTRODUCTION: The problems of determining theoretically the conditions under which a thin circular shell under axial compression becomes unstable, and of determining the postbuckling behavior of the shell have been of interest to engineers and scientists for nearly sixty years. The first theoretical work on this problem was done by such noted investigators as Lorentz (1), Timoshenko (2) Southwell (3), and Flugge(4). They found what might be called the classical or Euler buckling load. This is the load at which an equilibrium configuration differing from the initial configuration by an infinitesimal displacement can be found. In other words, it is the load at which a bifurcation in the load-axial deflection curve exists. When a cylindrical shell buckles, the change in the potential energy of the shell can be expressed as a sum of second, third, and fourth order terms in the radial displacement, wr. The equilibrium equation in the radial direction can be found by setting the first variation of this additional potential energy equal to zero. If only the second order terms are used, the resulting equilibrium equation is linear. The resulting system is homogeneous, and the lowest value of axial load for which a nontrivial solution exists is the Euler load… References listed at the end of the dissertation:

ABSTRACT: Energy expressions and related differential equations for non-circular cylindrical shells, analogous to the corresponding relations presented by Donnell for thin-walled circular cylindrical shells, are summarized. Appropriate energy expressions are then applied to the classical buckling and to the nonlinear postbuckling problems of an axially compressed oval cylinder whose cross section is characterized by a simplified form of an expression proposed by Marguerre. In the case of classical buckling, the results show, for a range of major-to-minor axis ratio of the cross section lying between 1 (the circular cylinder) and 2.06, that the out-of-roundness has a marked effect on the critical load, and that introduction of the maximum radius of curvature into the formula for the classical buckling stress of a circular cylinder leads to good results for thin-walled shells of moderate eccentricity of the cross section. The postbuckling behavior is investigated through the application of the principle of stationary potential energy together with an approximate deflection function. The latter represents a modification of the expression applied earlier by the authors. The new results show that, in addition to the previously observed relative minimum postbuckling load, a relative maximum postbuckling load can exist. Furthermore, for controlled end-displacement loading, the large-deflection load vs end-shortening curve can correspond to stable equilibrium configurations throughout the entire loading range, whereas for dead-weight loading the region of the curve between the maximum and the minimum loads represents unstable configurations.

ABSTRACT: Buckling and initial postbuckling of an oval cylindrical shell under pure bending and under combined uniform axial compression and bending is investigated. The first- and second-order stability equations are developed from the Donnell-type equations that are shown to be appropriate. The solution of these two sets of equations determines, respectively, the buckling characteristics and a “sensitivity parameter.” The buckling loads are found to be in good agreement with the engineering approximation based on the assumption that buckling occurs when the local axial stress equals that corresponding to the classical buckling stress of a locally equivalent circular cylindrical shell under uniform axial compression. Results also show that an oval cylinder can be stronger or weaker than the equivalent circular cylinder, depending on the orientation of the couples. However, in any case the oval shell is always found to be sensitive to imperfections; the greater the load-carrying capacity, the greater the sensitivity. Furthermore, in contrast to the behavior of the circular and weak oval cylinders, buckling of the strong oval cylinder need not initiate at the position of maximum compressive stress.

ABSTRACT: The serious discrepancy between theoretical and experimental results for the buckling load of axially compressed cylindrical shells is well known. This paper presents results of a test program specifically designed to throw some light on the causes of the discrepancy. Ten nominally identical nickel cylinders were fabricated by electrodeposition and tested under both dead-weight and controlled end-shortening conditions. The test results indicate the following: the buckling load under usual laboratory conditions depends on the properties of the test specimen itself rather than on the testing environment, the buckling loads under dead-weight and controlled end-shortening conditions are the same, a sharp puff of air during loading can cause buckling at a considerably reduced load level, minimization of initial imperfections in the test specimens greatly increases the buckling load, and the magnitude of the minimum postbuckling equilibrium load is relatively insensitive to initial imperfections.

ABSTRACT: Recent investigations by Stein and by Fischer on the influence of edge conditions on the critical load of cylindrical shells are here extended to cover six additional combinations of boundary conditions. The results show that drastic reductions of the critical load for cylinders with lateral support of the edges are obtained only if the edges are free in the tangential direction. For other boundary conditions, this reduction is never more than about 20 percent. Consequently, the results of this investigation alone cannot explain the well-known discrepancy between theory and test data. However, the importance of the choice of boundary conditions for practical analysis is clearly demonstrated.

ABSTRACT: Recent investigations on the influence of edge conditions on the critical axial load of cylindrical shells are extended here to include cylinders with elastic edge restraint. It is shown that weak edge conditions are unlikely to affect the critical load significantly in experiments or in practice. Also the effects of symmetric initial imperfections were investigated. The critical load for cylinders with initial imperfections in the form of a cosine function was found to be somewhat lower than was indicated in a previous analysis by Koiter. The analysis also disclosed that very short cylinders would not be sensitive to the types of imperfections which were considered. A few tests were performed and their results tend to support this conclusion.

ABSTRACT: Axial compression tests were performed on eleven thin-walled aluminum cylinders with rectangular cutouts. Various types of cutout reinforcement were installed on seven of the test specimens. The test results are compared with the cylinder buckling loads prior to installation of the cutouts, and correlated with computer-predicted failure loads. The latter were based on the use of the STAGS computer program. For thin cylinders such as these, the test and computer-based analysis shows that for small to moderate size cutouts, reinforcement of the cutout is of no benefit unless the cylinder is of extremely high (geometrical) quality. For cylinder quality and cutout size where reinforcement is beneficial, the relative merits of the various reinforcement configurations are discussed and an empirical basis for design is proposed.

ABSTRACT: (shells, failure, structural properties, numerical analysis, buckling, plastic properties, tensor analysis, computer programming newton-raphson method, collapse, plates, finite difference theory, stags computer program, structural analysis. The report presents a theory for nonlinear collapse analysis of shells with general shape. The theory combines energy principals and finite difference methods to obtain a system of nonlinear equations; these are solved by a modified Newton-Raphson technique. For greater economy and flexibility in the analysis a capability is provided for use of variable spacing finite difference grids. Inelastic material behavior, as predicted by the White-Besseling Theory, is incorporated into the analysis. A computer code, STAGS, based on the theory has been written and used to solve a number of sample problems. Results for these problems are presented.

ABSTRACT: Some examples in which the high-speed computer has been used to improve the static stability analysis capability for general shells are examined. The fundamental concepts of static stability are reviewed with emphasis on the differences between linear bifurcation buckling and nonlinear collapse. The analysis is
limited to the stability of conservative systems. Three examples are considered. The problem of cylinders subjected to bending loads is used as an example to illustrate that a simple structure can have a sufficiently complicated nonlinear behavior to require a computer analysis for accurate results. An analysis of the problems involved in the modeling of stiffening elements in plate and shell structures illustrates the necessity that the analyst recognizes all important deformation modes. The stability analysis of the Skylab structure indicates the size of problems that can be solved with current state-of-the-art capability.

ABSTRACT: An efficient and general computer program for structural analysis allows the user to choose between a number of different procedures. New methods for computerized structural analysis are still being improved at a rapid pace. Consequently only a very few structural analysts can be expected to be well acquainted with all aspects of the technology, and will often find it difficult to use the sophisticated programs that presently are available. If dynamic loading or possible stability failure must be considered, the computer programs are becoming increasingly difficult to use. The trends in future computer programming for structural analysis must include efforts to facilitate the user's burden without significant loss of efficiency. This paper contains a discussion of the difficulties involved in modeling and in the choice of solution procedures. Special emphasis is placed on the possibility of designing computer programs so that sound selection of procedures can be made automatically if the user declines to state a preference.

ABSTRACT: An evaluation is undertaken of currently used discretization procedures in numerical analysis of structures. Emphasis is on the nonlinear behavior of thin shells and plates. It is found that the computer economy is extremely sensitive to the choice of element configuration. A proper balance between the order of the approximations of inplane and lateral displacements is important. The best finite element procedures are superior to finite differences for bifurcation buckling and for moderate nonlinearity. However, for shell collapse analysis the finite differences approach is quite superior to the finite elements. Suggestions are made for improvement of finite element technology for structures undergoing large rotations.

ABSTRACT: Composite materials have favorable stiffness/weight and strength/ weight ratios. Since the technology is relatively new and use of such materials introduces special problems, there has been some reluctance among designers to adopt composites in primary structures, particularly for buckling critical components. The purpose of the review of the literature presented in this report is to illustrate the special problems connected with use of composites. The body of the report summarizes the conclusions the author felt could be based on the available material. The Appendix contains an annotated bibliography, listing 95 references on the subject.

**Also from the 1981 Almroth Report:**

**References listed in Section A of the Appendix, A. General Theory:**

The publications in Section A discuss the bifurcation buckling analysis based on a first order shell theory, i.e., the influence of transverse shear deformations is not included.

Almroth’s comments: This paper does not discuss the buckling. However, it appears to represent the first recognition of the importance of the membrane-bending coupling. It is indicated that the plate bending stiffness due to this effect can be considerably reduced.
Almroth’s comments: The paper derives the general theory of buckling of laminated plates. Many of the applications to practical cases presented subsequently were based on these equations.

Almroth’s comments: A completely general set of buckling equations for cylindrical shells is derived. An analytic solution for special boundary conditions is presented.

Almroth’s comments: The theory of Reference A-2 is applied in a study of the buckling of cylindrical shells. The results indicate a deleterious effect of the membrane bending coupling.

Almroth’s comments: The paper shows by use of theory as well as experiment that if both ends of an anisotropic cylinder are restrained from rotation, an applied axial extension results in the development of inplane shear in the shell wall and eventually in buckling.

Almroth’s comments: The stability equations, including "smeared stiffeners" are derived and applied to one example. The author warns that the coupling between membrane and bending effects should not be overlooked.

Almroth’s comments: The paper presents an approximate method to account for membrane bending coupling by reducing the bending stiffness in an orthotropic analysis.

Almroth’s comments: A Fourier series solution, including membrane bending coupling, is derived. It is shown that this coupling is important if the plies are few but that the deleterious effect can be practically eliminated in plates with many plies (six or more). For crossplies (theta = 0deg., 90deg.) the reduced stiffness method presented in Reference A-7 gives a good approximation.

Almroth’s comments: Nonlinear equations including the effect of coupling between membrane and bending action. Subsequently, the equations are linearized and used in a bifurcation buckling analysis of angle-ply plates. The number of plies and the fiber orientation are varied. With only two layers, theta = 45deg. and EI/E2 = 40, the coupling effect reduces the buckling load by a factor of about three.
Almroth’s comments: A Galerkin solution is presented to the buckling problem for anisotropic plates with simple support and under different types of loading. Effects of membrane bending coupling are included and the reduced stiffness method of Reference A-7 is found to be a good approximation.

Almroth’s comments: The theory neglects anisotropy as well as membrane bending coupling.

Almroth’s comments: The paper summarizes some of the work on buckling and vibrations of composite material plates. A warning is issued that the reduced bending stiffness approach (Reference A-7) may not always be accurate.

Almroth’s comments: The stress-strain curve for the material is assumed to be bilinear with the discontinuity at the origin. An interaction curve for axial load and lateral pressure buckling is computed for a material with the tension modulus twice as large as the compression modulus. Further results on this topic are presented in Reference A-26.

Almroth’s comments: Aluminum cylindrical shells with T-stiffeners are reinforced with strips of boron-epoxy. It is shown that 10% of the composite material by volume can increase the buckling load by as much as 80% for elliptical cylinders under external pressure. A couple of experiments verify the analytical results.

Almroth’s comments: Theoretical results are presented for the buckling of single-ply rectangular plates. Buckling loads are given as functions of the fiber orientation.

Almroth’s comments: Toroidal shell segments are analyzed. The effects of membrane bending coupling are demonstrated.

Almroth’s comments: Essentially the same as Reference A-14. A computer program listing is added.

Almroth’s comments: The author observes that the stress-strain curve for shear in single laminates may be highly nonlinear. This may reflect the time dependence of the deformation of the matrix. The results indicate
that inclusion of this effect might reduce the buckling load by some 5%. The effect may be of importance when composites are used at elevated temperatures.

Almroth’s comments: The paper considers two different stacking sequences for the wall of cylindrical, barrel shaped, "inversely barrel shaped", and spherical shells. The stacking sequence that gives the highest buckling loads for cylinders and spheres is found to be the least efficient for barrel shaped shells.

Almroth’s comments: The computer program BUCLISP 2 for buckling of panels and including composite material is described. The program applies to cases in which it can be assumed that the buckling mode in the direction of the stiffeners is sinusoidal. Some numerical results are presented. These include some comparisons to analytical solutions. Special problems considered are comparison between bonded and riveted structures and the effects of boron fiber reinforcement of titanium panels.

Almroth’s comments: This is an excerpt from Reference A-20.

Almroth’s comments: Circular plates, materially orthotropic with respect to the polar coordinates, are subjected to axisymmetric loading. Buckling loads are presented for a few cases demonstrating some sensitivity to the fiber orientation.

Almroth’s comments: This very brief note shows how natural frequencies for 45-degree angle-ply and cross-ply plates vary as the buckling load is approached.

Almroth’s comments: The effect of membrane bending coupling is illustrated by use of a few examples.

Almroth’s comments: Some numerical results from BUCLAP2 on the buckling of long laminated plates are presented. A warning is included that the "reduced bending stiffness method" (Reference A-7) does not always give good results.

Almroth’s comments: A buckling criterion is derived for shells with different moduli in tension and
compression. The effect of this difference is significant only if the ratio between the moduli is larger, say 2 or so, than it is for most composites. The effect is illustrated on interaction curves where discontinuities occur as the stress in one direction changes sign. Presumably the modulus in any given direction also depends on the stress in the other direction. If such an effect could be included, the interaction curves may be somewhat smoother.

Almroth’s comments: A discussion is presented on the critical buckling loads for typical tubular stress specimen for assessment of strength and stiffness.

Almroth’s comments: The paper elaborates on the applicability of bifurcation theory in view of the lateral displacements caused by membrane bending coupling effects. The bifurcation buckling load is a meaningful parameter only if prebuckling bending is insignificant. It is claimed that the "reduced bending stiffness method" (Reference A-7) is applicable only if the principal directions of the laminates are parallel to the plate edges.

Almroth’s comments: The need to include membrane bending coupling effects in buckling and vibration analyses is demonstrated.

Almroth’s comments: The paper considers optimum fiber orientation for angle plies with 20 layers. Plates with different aspect ratios are included.

Almroth’s comments: A large number of numerical results are presented for rectangular orthotropic panels in shear. The variation of shear and compression buckling loads with the fiber orientation is presented for plates of different aspect ratios.

Almroth’s comments: A buckling analysis based on a sinusoidal mode is presented. It is pointed out that constraint on transverse displacement can severely reduce the buckling load.

Almroth’s comments: The paper reviews the literature on the problem of buckling of cylindrical shells under different loading conditions. The special problems of nonlinear stress/strain behavior, different moduli in
tension and compression and the effects of shape imperfections are discussed. In addition to the review, a series of torsion tests are reported with the experimental results ranging from 0.79 to 1.17 times the analytical. The conclusion is that a moderate reduction factor is sufficient in the case of torsion. In the case of axial compression, a more severe reduction is needed. The authors suggest that many more tests are needed.

Almroth’s comments: A Galerkin solution based on beam functions is presented for bifurcation buckling and flutter. The emphasis in the paper is on the effects of anisotropy and fiber-orientation. Both for shear and axial compression, the optimum angle-ply corresponds to a fiber orientation of about 45 degrees.

Almroth’s comments: A two-term Galerkin solution is used for analysis of critical axial compression of orthotropic plates. Results are given for different degrees of rotational constraint along the edges.

Almroth’s comments: Local and general instability failures are considered for a compression member in a lightweight satellite structure of composite material. Results of two crippling tests show good agreement with analysis.

References listed in Section B of the Appendix of Almroth’s 1981 report, B. EFFECTS OF TRANSVERSE SHEAR:
The following publications are concerned with the deleterious effects of transverse shear deformation on the buckling load of shells and plates. While the first two are concerned with the theory in general, the remaining papers apply specifically to composite material.

Almroth’s comments: The effect of transverse shear is introduced in the plate bending theory. The shear stress distribution through the thickness is assumed to vary in a way that is consistent with a linear normal stress distribution.

Almroth’s comments: The influence of transverse shear deformation is introduced in a way that is similar to the procedure in Reference B-1.

Almroth’s comments: A laminated shell is modeled by representation of bond layers with a set of springs. The springs can deform in the lateral direction and also undergo slip to represent the shear deformation. A few numerical results are given.

Almroth’s comments: The paper considers the effect on the buckling of isotropic plates of the transverse shear deformation. Results are given for simply supported plates of different aspect ratios.

Almroth’s comments: Shear deformations in the bond layer between different laminates are included in an analysis of bending and buckling of laminated beams.

Almroth’s comments: Equations for vibration and buckling are derived for plates consisting of isotropic lamina. Some results are given for three-ply laminates. If the shear modulus is the same in all lamina and h/b = 0.1, the error due to neglect of transverse shear is about 7%. If the shear stiffness in the middle layer is reduced by a factor of 15, the error is 35%.

Almroth’s comments: The theory of Reference B-6 is extended to orthotropic laminates. It is shown by comparison to 3-dimensional analysis that the second order shell theories by Reissner and Mindlin (References B-1 and B-2) give good results for very thick plates.

Almroth’s comments: The effect of transverse shear on the buckling of composite material columns is studied. Results are shown in the range of 20 < EI/G < 50.

Almroth’s comments: A theory is derived for buckling of laminated shells in which the transverse shear deformation is included and the corresponding modulus can vary from layer to layer. Buckling loads are presented as functions of G/E in the range of 0.01 - 1.0.

Almroth’s comments: Mindlin's second order theory (Ref. B-2) is used in analysis of plates of width b loaded in the axial direction. The aspect ratio a/b and the parameter S is approximately equal to (EI/GT)x(h/b)^2 are varied in a parametric study.

Almroth’s comments: A second order theory (Reissner-Mindlin) is derived. Results from this theory are compared to results from three-dimensional theory. It is found that the plate theory can give good approximations for plates with b/h = 0.3. It is also found that the correction for shear deformation varies with the number of layers. With moduli typical for glass/epoxy composites (EI/E2 = 30 and the transverse shear moduli 0.5 and 0.6 times E2 ) it is found that the effect should be included if h/b > 0.05.
Almroth’s comments: For the purpose of examining the effects of transverse shear, it adds little to the results of Reference B-11.

Almroth’s comments: The paper is primarily concerned with computer economy. In regard to the effects of transverse shear deformation, it is noted that this effect in the postbuckling range is similar to its effect on the buckling load. That is, it should be included for a typical (simply supported plate) if h/b > 0.05.

References listed in Section C of the Appendix of Almroth’s 1981 report, C. IMPERFECTION SENSITIVITY AND POSTBUCKLING STRENGTH
The following publications discuss the imperfection sensitivity of the buckling load and possible postbuckling strength for plates and shells in compression. Except for the first three papers on the general theory, they consider the special problems connected with use of composite materials.

Almroth’s comments: An analysis is presented of buckling and postbuckling behavior of simply supported cylindrical shells of composite material. A Donnell type theory including the effects of anisotropy is used. The deformation pattern in the postbuckling range is represented by a four term series. Numerical results are obtained for a number of different three-layered shells. The maximum efficiency is obtained with the combinations theta = (0deg., 70deg., -70deg.) and (90deg., 20deg., -20deg.).

Almroth’s comments: A nonlinear analysis is formulated for anisotropic shells with imperfections under torsional loading. The numerical results indicate moderate imperfection sensitivity.

ABSTRACT: A perturbation technique is employed to determine the critical buckling stress of a simply supported rectangular plate of variable thickness. The differential equation is derived for a general thickness
variation. The problem of bending, vibration, buckling, and that of dynamic stability of a variable thickness plate can be deduced from this equation. The problem of buckling of a rectangular plate with simply supported edges and having general variation in thickness in one direction is considered in detail. The solution is presented in a form such as can be easily adopted for computing critical buckling stress, once the thickness variation is known. The numerical values obtained from the present analysis are in excellent agreement with the published results.

Almroth’s comments: The same deformation mode as in Reference C-3 is here applied in a nonlinear analysis of axially compressed cylinders with geometric imperfections. Shells with close to optimum fiber orientation appear to be the more sensitive, but within the range under investigation the optimum orientation remains unchanged.

Almroth’s comments: The paper contains a summary of the results presented in Reference C-3.

Almroth’s comments: The analysis of Reference C-3 is extended through the addition of an internal pressure. It is shown that the internal pressure has a beneficial effect on the imperfection sensitivity. For the cases investigated, the Donnell and Sanders equations give essentially the same results.

ABSTRACT: In recent years orthotopic cylindrical shells such as stiffened or fiber reinforced cylinders have been used extensively in aerospace structures. These structures are often subjected to axial compression and internal pressure. The thin cylindrical shells are known to be imperfection sensitive, and their buckling loads are substantially reduced by the presence of small initial deviations from the circular shape of the shell. The behavior of imperfect cylindrical shells has been studied by various investigators [1–5]. Both isotropic and anisotropic shells have been considered in these structures. In most of these investigations Karman-Donnell strain-displacement equations were used.

References listed at the end of the paper:

Almroth’s comments: The paper presents some of the results in Reference C-6 in a more readily available source.

Almroth’s comments: It is concluded in the paper that composite shells may be somewhat less sensitive to imperfections than the isotropic shells are. Consistently with this observation it is found that boron-epoxy shells are less sensitive than glass-epoxy shells.

Almroth’s comments: A method is presented to determine the “knockdown factor” for different types of cylinders based on their relative sensitivity to axisymmetric imperfections (Koiter's special theory). For composite material cylinders (filament wound), it appears that the method gives results that are only slightly less conservative than those obtained through application of the same knockdown factor as for an isotropic cylinder with the same "effective thickness."

Almroth’s comments: In this paper the authors base their analysis on Koiter's general theory. In comparison to Reference C-6, shells with larger imperfection amplitude are included in the study. With an imperfection of about the size of the shell thickness, the advantage of using a fiber orientation close to optimum is totally eliminated.

Almroth’s comments: The effect of axisymmetric imperfections is studied by use of Koiter's special theory. The numerical study is restricted to the three-layered combinations (theta, 0deg., -theta) and (theta, -theta, 0deg.), of which the latter appear to be the most efficient. As in Reference C-9, it is shown that shells with optimum fiber orientation are the most sensitive to imperfections and that a moderate imperfection amplitude is sufficient to wash out the advantages of an optimum design.

Almroth’s comments: A buckling and postbuckling analysis based on a double Fourier-series approach is presented for flat plates. Some plots are given that indicate outer surface stresses as functions of applied load.

Almroth’s comments: A number of cylinders were measured to determine initial deviations from true geometry. The axisymmetric part of the imperfections was isolated and Koiter's special theory applied. The same results are also presented in Reference D-2 with some additional detail.

C-17. Kulkarni, S. V., and Frederick, D., Buckling of Partially Debonded Layered Cylindrical Shells,
Almroth’s comments: A local buckling analysis is applied to the two separate branches corresponding to an axisymmetric delamination at midplane.

Almroth’s comments: This represents an extension of the investigation reported in Reference C-15.

Almroth’s comments: In contrast to References C-15 and C-18, this paper considers the case in which the applied shortening is uniform rather than the force intensity. The postbuckling analysis is based on the assumption that the lateral displacement varies sinusoidally in the axial direction (the direction of the load) and can be accurately defined by a 4-term power series in the transverse direction. A couple of test results were included showing good agreement between computed and measured lateral displacements. The agreement on the stress distribution deteriorates with increasing load.

Almroth’s comments: A one term solution is presented for the postbuckling behavior of unsymmetrically stacked cross-plies.

Almroth’s comments: Blade-stiffened composite material panels under axial compression are designed for minimum weight with buckling constraints. The bending stresses due to a bow-type imperfection are included. It is found that the weight efficiency is much better if the imperfection is allowed to affect the optimized design. Authors’ ABSTRACT: A structural synthesis computer code which accounts for first order effects of an initial bow and which can be used for sizing stiffened composite panels having an arbitrary cross section is used to study graphite blade-stiffened panels. The effect of a small initial bow on both the load carrying ability of panels and on the mass of panels designed to carry a specified load is examined. Large reductions in the buckling load caused by a small initial bow emphasize the need for considering a bow when a panel is designed.

Almroth’s comments: In comparison to the results of Reference C-19, an additional term is added to describe the displacement as a function of the axial coordinates. There is no indication of whether this improves correlation with test.

References listed in Section D of the Appendix of Almroth’s 1981 report, D. EXPERIMENTAL VERIFICATION
The papers in the following are mainly devoted to the verification of analytical results by use of experiments.

Almroth’s comments: Filament winding is not representative for modern manufacturing techniques of composite shells. The comparison between test and theory may not be quite the same for modern specimens. From the theoretical part of the paper it is concluded that the best efficiency is obtained if the balance between helical and hoop windings is such that 0.5 < Ex/Ey < 1.0. Four cylinders were tested and the reduction factor, phi, was found to be much the same as for metal cylinders. The results were:

- R/t = 152, 128, 123, 122
- Ex/Ey = 0.62, 0.83, 1.26, 1.93
- phi = 0.655, 0.630, 0.685, 0.688

Almroth’s comments: The cylinders were manufactured through winding. The inplane stiffnesses were determined experimentally through application of lateral pressure, torsion, and tension. The shells were essentially orthotropic. Presumably the number of layers was large enough so the shell wall material could be considered to be homogeneous and orthotropic. Four of the cylinders buckled between 40 and 48 percent of the classical buckling load. This severe reduction was assumed to have been caused by pretest damage at the ends. For the other ten cylinders, the knockdown factor varied from 0.66 (R/t = 238) to 0.85 (R/t = 85). These results are in line with the behavior of isotropic shells.

Almroth’s comments: The cylinders were manufactured through winding. All cylinders had a thickness of 0.035 in. with the three different layups:
- 0deg., 45deg., -45deg., 90deg. (labeled isotropic)
- 0deg., 22.5deg., -22.5deg., 90deg. (labeled orthotropic)
- 30deg., 90deg. (labeled anisotropic)

For each of the three layups and three different radii (3.6, and 12 in.) five cylinders were manufactured so that for all different geometrical configurations test could be performed in, axial compression, torsion, bending, combination of axial load and torsion, combination of axial load and bending. The results of torsion tests can only be explained by the assumption that the theory used underestimates the critical torque approximately by a factor of two. Possibly this is due to inaccuracy in applied boundary conditions. All the configurations give approximately the same theoretical buckling load. There is not a clear trend indicating a variation in the knockdown factor, not even with the radius/thickness ratio. Typical results are (given in a table in Almroth’s report.) With a larger number of specimens it seems that at least a more pronounced tendency would be found towards decreasing knockdown factor with increasing radius.

Almroth’s comments: Experimental buckling loads are determined for a large number of plates, of which the majority were of composite material with graphite, glass or boron fiber reinforcement. In almost all cases the load displacement curve indicates large lateral displacements and the test is interrupted before the theoretical buckling load is approached. This behavior is observed also for metal plates and composites with little or no membrane bending coupling. Therefore, the eccentricity seems to be due to initial curvature or offset in loading rather than to membrane bending coupling.

D-5. Leone, E. M., Oplinger, D. W., and Serpico, J. C., Experimental Studies of the Elastic Stability of Three-

Almroth’s comments: A total of seven cylinders were tested. The material featured graphite fibers in axial and radial directions and quartz filaments for radial reinforcements. The radius-thickness ratio was in the range of 35 to 40. The loading was lateral pressure, hydrostatic pressure, or hydrostatic pressure with the addition of a component of axial compression. With use of experimentally determined inplane shear modulus, predicted lateral pressures agree well with experimental results. The tests including an axial load component seem to fall somewhat below prediction although conservatively a linear interaction curve was used and the selected example indicates that strain reversal may have occurred well below final collapse.

D-6. Ashton, J. E., and Love, T. S., Shear Stability of Laminated Anisotropic Plates. (no publisher or date given)
Almroth’s comments: Shear buckling tests were performed on 14 boron epoxy laminated plates. The load was applied as a diagonal tension on a "rigid picture frame." The corners on the panel were notched so that local failure would be avoided. The critical load is determined by use of the Southwell plot. The load displacement curve is given for one example and indicates a gradual growth of the lateral displacement. As the specimens were symmetric with 16 layers, this is not the result of membrane-bending coupling but rather it must be assumed that the initial geometric deviations were relatively large. As must be expected, the agreement between the Southwell load and analytical (Rayleigh-Ritz) results is good. The failure load (35,800 lb) is given only for one panel (with a buckling load of 29,000 lb). For all panels b/t was about 100.

Almroth’s comments: Both these publications summarize the results of Reference D-4. The article in the AIAA Journal is somewhat more specific about the test setup.

Almroth’s comments: The tests on torsion tubes were intended as fracture tests. However, it is observed in many cases that fracture was preceded by strain reversal. Evaluation of the results seems difficult because the stress-strain curves show considerable nonlinearity at low stress.

Authors’ ABSTRACT: Results are presented from torsion tests conducted on 36 multilayered, filament-wound, glass-epoxy tubes. Configurations with helical windings and with alternating helical and circumferential windings were investigated for various winding angles. Under small loadings, shear moduli deduced from linear shear stress-strain curves were found to be in reasonable agreement with analytical predictions. Under larger loadings, various degrees of nonlinearity in shear stress-strain curves were encountered, depending on the helical winding angle. Experimental torsional strengths were defined by a 0.2-percent offset yield stress or by maximum stress when large nonlinearities did not exist. These strengths were compared with torsional buckling predictions for orthotropic cylinders, and with material strength predictions based on orthotropic yield criteria and elastic stress analysis. Computed elastic buckling stresses were considerably higher than the experimental strengths for most of the test specimens except for those with only 30 deg and 45 deg windings. Experimental torsional strengths were found to correlate with conventional yield predictions if predicted yielding in certain layers were ignored or if unrealistically large transverse tensile and shear strengths of unidirectional laminae were employed in the analysis.

Almroth’s comments: Some 70 flat plates, approximately square with a side of 6-114 in., were tested under axial compression. The plates were manufactured from cloth and very thin, b/t = 175 or so. The report gives the Southwell load for all panels. Excessive scatter probably indicates nonuniform material properties. It is stated that the agreement between the Southwell load and observed strain reversal is poor. The author's conclusion that the strain-reversal technique has no value is dubious. Strain reversal is a definite indication of the development of buckles and as such a physically meaningful parameter. On the other hand, any experimental method (whether in agreement with theory or not) that gives a different result is not applicable to the case in question. It may be noticed that at least some of the panels were tested up to 3 or 4 times the bifurcation buckling load.

Almroth’s comments: An experimental analysis is presented of the postbuckling behavior of shear panels. The panel dimensions were 6x18 in. and the thickness about 0.02 in., i.e., b/t = 300. The panels were tested to failure which occurred at 8 to 10 times the bifurcation buckling load. In a couple of cases, the panels were tested without failure 100 times to a load level corresponding to 5 times the bifurcation load. Subsequently, these panels were tested to failure with no obvious reduction in strength. Generally, failure occurred in one of the corners of the panel before the average shear strain in the panel had reached half of the shear strain corresponding to fracture.

Almroth’s comments: A number of glass-epoxy cylinders were manufactured with considerable care. The initial geometrical imperfections were measured. The axisymmetric part of these imperfections was isolated and expressed in terms of trigonometric series. By use of the classical bifurcation buckling analysis, critical loads were computed and the cylinders subsequently were tested. The agreement between computed and measured buckling loads is fair. For the 14 cylinders tested, predictions range from 0.50 to 0.85 times the critical load for perfect cylinders while the experimental results range from 0.41 to 0.75 times this load. In general, the predictions were 10 to 20% on the high side.

Authors’ ABSTRACT: An analytical solution for the buckling load was obtained by using cylindrical shells. An analytical solution for the buckling load was obtained by using Koiter's theory for axisymmetric and asymmetric imperfections. For axisymmetric imperfections, numerical evaluation were carried out for the case of three-ply composite shells of glass, boron and graphite-epoxy construction. It was found that drastic buckling load reductions occurred comparable to isotropic shells for small values of imperfection amplitudes. For each cylindrical shell, test model fabricated from three ply preimpregnated glass-epoxy, an equivalent imperfection amplitude was computed by using the root mean square imperfection measurements obtained from several generators. Fairly good agreement was found between the analytically predicted and experimental buckling loads.

Almroth’s comments: Four boron-epoxy and four titanium cylinders with boron-epoxy reinforcement were tested in axial compression, all with R/t about 25. Inside and outside strains are recorded as functions of the load for the four composite material cylinders and for one of the titanium cylinders. Only for the titanium cylinder is there some indication of buckling (strain reversal) before failure occurs.

Almroth’s comments: A number of cylindrical panels were tested under axial compression. Some of the test specimens suffered no damage and could be retested under different conditions. Therefore, 72 panels yielded 84 test results. All panels had a length of 13 in., a radius of 12 in., and a width of 9 in. (43 deg.). Panel thickness and layup were varied through the test series. Buckling loads were registered by use of the Moiré grid technique. For flat panels it appears that initial eccentricities or membrane bending coupling would render this technique useless; compare the results of Reference D-4. However, for the cylindrical panels, it appears that the development of the buckling pattern is rapidly accelerated as the critical load is reached and the Moiré technique seems to have been very useful. In some cases, the tests were continued after the Moiré pattern indicated buckling. In no case could the load be significantly increased before snap-through occurred. Typical examples are:

Moiré: 6300, 715, 1290, 5700, 3530
Snap-through: 6340, 725, 1315, 5810, 3685

In nine cases snap-through occurred without previous indication by the Moiré pattern. In five cases the indication by the Moiré pattern was essentially simultaneous with snap-through. In the remaining cases the test was interrupted when the Moiré pattern indicated buckling and the specimens could be used again. (cannot copy and paste more comments with regard to this reference.)

Almroth’s comments: Six cylinders were manufactured for the tests. The laminates were four-ply (±45)s and six-ply (0/±45)s. The outside diameter was 15 in. and the cylinder length 15 in. The ply thickness varied from 0.0053 to 0.0065. Strain reversal was used to indicate buckling and in most cases the test was nondestructive so that a complete or partial interaction curve could be obtained for one specimen. The knockdown factor for axial compression is about 0.65. The analytical solution for torsion buckling appears to be off approximately by a factor of two.

Almroth’s comments: Four graphite-epoxy and four boron-epoxy cylindrical panels were tested in shear. The panels covered each 45 degrees and four panels were mounted together. The shell wall consisted of 8 ply plus-minus 45 deg. laminate. Due to the fact that relatively few laminates were used, the critical torque is about 50% higher in the favorable direction. The panels were 9 in. long and the radius was 12 in. The average thickness was about 0.056 (R/t about 200). The specimens were first tested in the weaker direction. The buckling load was registered by use of a Southwell plot based on bending strain rather than displacement. The critical load so determined varied between 84 and 106 percent of the theoretical load corresponding to clamped edges. In a second test, the torque was applied in the opposite direction. The Southwell load varied between 85% and 95% of the theoretical value for clamped shells. Furthermore, the Southwell loads agreed very well with the load level at which the lateral displacements started to grow rapidly. The tests in this direction were continued to failure which occurred at about 20% above the buckling load. At this load level, the buckle depth was of the same order of size as the shell thickness.

Almroth’s comments: Of 39 cylinders tested, a few were pure metal cylinders, a few composite reinforced metal
cylinders, but the majority were pure composite cylinders. Since many of the cylinders were tested in both directions, a total of 51 test results were available for comparison to theory. Boron-epoxy and graphite-epoxy cylinders were tested with various layups and for two different R/t values (150 and 75) and three different values of L/R (3.2, 6.7, 13.3). Due to the great variety of specimens, duplication is minimal which makes it difficult to discover any clear trends. There is, for example, no indication that the parameters L/R or R/t should have any influence on the knockdown factor phi. It may be noticed, however, that two tests with R/t = 75 and with a favorable layup fractured without any previous indication of buckling at about 60% of the critical load. An optimum layup was determined analytically for shells subjected to torsion in one direction only. For these cylinders (-82.5, 30, 20, -82.5) s, the knockdown factors were relatively low (0.79, 0.88, 0.61, 0.54). For this layup the ratio between critical loads for loading in the two directions is as high as 3.5. For shells with 45deg. windings this ratio is only of the order 1.5 to 2.0. There is no indication among these that the more efficient layups should be more sensitive to imperfections. Generally the torque drops somewhat after buckling or it stays constant. In no case is there any indication of postbuckling strength above the bifurcation load. The strain at fracture is not observed but stress-strain curves are shown for all specimens. In many of these (including some with R/t = 75), strain levels were reached which considerably (5 times or so) exceed the critical strain. The knockdown factor for the 51 experiments varies from 0.54 to 0.95 with an average close to 0.80.

Almroth’s comments: The results of Reference D-16 are presented in a slightly more polished form.

Almroth’s comments: Composite flat plates were tested under different compression. The value of b/t was about 100 for all plates. Most plates have considerable membrane-bending coupling. Load displacement curves are not shown but it can be assumed that the bending of the plate sets in gradually and that the bifurcation buckling load is insignificant as a design parameter. The buckling load is determined by use of the Southwell plot as well as by the dynamic method (extrapolation to zero of natural frequency). The agreement between these two methods is good.

Almroth’s comments: Tests were carried out on three T- and blade-stiffened panels. Buckling and crippling predictions (elastic) based on "elementary methods" were in good agreement with test results. Some of the stress-strain curves for the material (transverse stress and shear) show considerable non-linearity.

Almroth’s comments: Tests were conducted on a number of hat-stiffened graphite-epoxy panels. The panel dimensions correspond to optimum weight configurations. A number of panels (23) of length 16 in. were critical in local buckling. In the experiments local buckling was observed by use of the Moire pattern and by the observation of strain reversal. These two methods agree with one another but the agreement with theory (BUCLASP) is not good. This is assumed to be due to large deviations from nominal thicknesses and to local initial stresses due to the curing process. The experiments were continued to ultimate failure which typically
occurred at about 25% above the experimental buckling load. The authors conclude that "buckled skin concepts" might be possible (but that), the brittle nature of graphite-epoxy composites makes their practicality highly speculative at this time. In addition, six longer panels (60 in.) were tested. These were critical in Euler buckling. The test results in these cases fall between 64 and 90 percent of the critical load. This disagreement appears to be the result of transverse shear effects. The disagreement between experiment and theory reduces a potential 50% weight saving (in comparison to aluminum) to a 32% saving. This estimate does not account for the use of buckled skin concepts for aluminum panels.

Almroth’s comments: A literature review is presented on the subject of buckling of cylindrical shells. Available closed form solutions are summarized. A computer program listing is presented for the buckling of anisotropic cylinders under torsion, external pressure and axial load. A number of numerical results indicate that the shapes of the interaction curves vary considerably with the layup. Two fiberglass cylinders were tested. An inside mandrel was used to arrest the buckles and allow repeated testing on the same specimen. The shape of the interaction curves agrees with theoretical results. For comparison with theory an analysis was carried out including axisymmetric imperfections. These were chosen equal to those on the "worse meridian". The test results in axial compression were some 10% below the bifurcation load for the imperfect cylinder. In both cases, the radius to thickness ratio was 234.

Almroth’s comments: Graphite-epoxy plates with the unloaded edges simply supported and channel sections were tested in axial compression. Results were compared to results of "classical, closed-form orthotropic elastic buckling theory for flat plates." In many cases, the registered buckling load was well below the theoretical values. For the plates with b/t varying from 19 to 45, the ratio between experimental and theoretical results varied between 0.61 and 0.88. For the channels the corresponding ratio varied from 0.77 to 1.10. Ultimate failure for the plates varied from 0.71 to 1.55 times the bifurcation buckling loads. For the channels this range was 1.18 to 3.83.

Almroth’s comments: Three panels, 845 x 115 mm, were tested in shear. The layups were 8-ply (±45)s (t = 1.04 mm), 10-ply (90, 2±45)s (t = 1.30 mm) and 8-ply (2 + 90, 2±45)s (t = 1.04 mm). Buckling at test was observed by use of the Moire pattern. The ratios between test and theory for the three specimens were 0.72, 1.27, and 0.75. The tests were continued to failure. The ultimate load values were 2.73, 1.9 and 2.87 times the bifurcation buckling loads (theoretical). The STAGS computer program and Tsai's fracture criterion were used to determine the ultimate load analytically. The agreement between test and theory on this point was surprisingly good, the ratios between experimental and theoretical results being 0.93, 1.16 and 1.07.

End of Almroth’s 1981 survey

ABSTRACT: In the following paragraphs possible future trends in the nonlinear analysis of structures are contemplated. If any predictions at all are to be made, they must be based on the assumption that research and development in the area will be responsive to the needs of the engineering community, perhaps primarily within the aerospace and nuclear industries. This need is definitely for more efficient general purpose programs derived in such a way that they are reasonably easy to use. Some new technology is presented in the recent literature, in the form of new ideas in discretization procedures and in automation of the methods for solution of nonlinear equation systems. The prediction is simply that these are going to be further developed, thoroughly evaluated and eventually included in commonly available software.

ABSTRACT: Equations are presented for the analysis of simply-supported orthotropic plates subjected to static and dynamic loading conditions. Transient loading conditions considered include sine, rectangular, and triangular pulses, and pulses representative of high explosive blast and nuclear blast. These pulses can be applied as a uniform load over the panel, a concentrated load, a uniform load applied over a small rectangular area, and a cosine loading applied over a small rectangular area. A method for the analysis of low velocity impact is also presented.

M. Mikulas, Jr., et al, “Buckling of a cylindrical shell loaded by a pre-tensioned filament winding”, NASA, 1964

ABSTRACT: Exact solutions are derived of the classical differential equations defining the deformations of axially compressed thin-walled circular cylindrical shells. The end conditions along the circular edges are assumed as the vanishing of (1) the radial displacement; (2) of the longitudinal bending moment; (3) of the variation in the axial normal stress, and (4) of the circumferential membrane shear stress. Under these conditions of simple support the critical value of the uniformly distributed axial normal stress is one-half the classical critical value.

K. Forsberg, “A review of analytical methods used to determine the modal characteristics of cylindrical shells”, NASA CR 613, 1965

doi: 10.1007/BF02327148
ABSTRACT: The results of buckling tests on circular cylinders heated uniformly along axial strips are presented and discussed. Calculations of critical temperature based upon the small-deflection theory for thin circular cylindrical shells are included and a comparison is made between theoretical and experimental results. Cylinders heated along axial strips of given widths have a theoretically predicted behaivor which corresponds
reasonably well to the behavior obtained by experiment. Curves are included showing the variation of critical
temperature with respect to heated axial-strip width.

References listed at the end of the paper:

L. Katz, “Compression tests on integrally stiffened cylinders”, NASA TMX-55315, August 1965

ABSTRACT: The paper presents methods for the analysis of framed structures which behave primarily as shells. Questions of membrane forces, analogous elastic properties, and buckling criteria are treated. The collapse of a 307-ft span reticulated dome in Bucharest in 1963 is investigated, and it is shown that the analyses presented in the paper gives a buckling load which is only approximately one-fifth of the critical load expected by the original designers, but which indeed agrees within 10% with the actual load at failure. Analyses of other important reticulated domes are also given.

ABSTRACT: A state-of-the-art review of the stability of cylindrical shells is presented. The copious theoretical results available in the literature are discussed and compared with available experimental results. Reasons for the well-known discrepancies between theory and experiment are indicated and various design formulas which take these discrepancies into account are given. Most of the available experimental data are for linearly elastic metallic or plastic specimens. The behavior of these can differ markedly from the behavior of reinforced concrete structures which are subject to cracking and material nonlinearity. The applicability of linearly elastic shell data to the buckling analysis of concrete shells is discussed briefly on the basis of a comparison of the few test results for reinforced concrete shells with those for elastic shells.

DOI: 10.1115/1.3627252
ABSTRACT: It is shown in this paper that previous, independent analyses of the phenomena of dynamic elastic instability and dynamic plastic-flow buckling of circular cylindrical shells can be combined in a single approach leading to results consistent with those that follow from these analyses. The response of the shell in both cases is governed by the interaction between the fundamental radial, purely extensional mode of deformation and inextensional flexural modes always present in the response. An analytical procedure is given for the determination of dominant modes in the elastic and plastic phases of the response, and the results of this procedure are verified by comparison with numerical and experimental data.

ABSTRACT: The asymmetric buckling of truncated and complete conical shells under uniform hydrostatic pressure has been studied by many authors. In all of these investigations, membrane theory has been used to define the stress state prior to buckling. In the present paper this problem is studied by means of finite difference analysis, taking into account the large deformation in the prebuckling state. Numerical results are obtained and compared with the results of other investigations.

“Buckling of thin cylindrical shells heated along an axial strip”, Experimental Mechanics, Vol. 5, No. 8, pp 247-256, August 1965
ABSTRACT: The results of buckling tests on circular cylinders heated uniformly along axial strips are presented and discussed. Calculations of critical temperature based upon the small-deflection theory for thin circular cylindrical shells are included and a comparison is made between theoretical and experimental results. Cylinders heated along axial strips of given widths have a theoretically predicted behavior which corresponds reasonably well to the behavior obtained by experiment. Curves are included showing the variation of critical temperature with respect to heated axial-strip width.

ABSTRACT: The plastic buckling of cylindrical shells under axial compression is studied analytically and experimentally. Attention is given to both the nonlinear and nonconservative aspects of the stress-strain relation. The effect of unloading is investigated in an exact manner for a hinge model which is proposed and in both an exact and an approximate manner for a geometrically perfect shell. Thirty tests are reported on cylindrical shells of 2024-T4 aluminum with radius to thickness ratios of 120 through 10 and length to radius ratios of 0.20 to 7. Specimens were prepared with three different types of end conditions and were tested either through a ball and socket arrangement or flat ended between smooth bearing blocks. A simple (j sub 2) incremental theory gives results very close to j sub 2 deformation theory and does predict both buckling strength and the geometry of buckling for thick and moderately thick shells.

ABSTRACT: Axisymmetric plastic buckling of axially compressed cylindrical shells is studied for semi-infinite shells and shells of finite length subject to free-edge boundary conditions. It is shown that the length of the cylinder has a negligible effect on the buckling load. Reductions in buckling stresses from the classical simple-support value are significant, with the amount of reduction dependent on the details of the variation of tangent modulus with stress. Numerical results are presented for cylinders composed of 2024-T4 aluminum and 3003-0 aluminum.

ABSTRACT: The Sanders’ equations for a circular cylindrical elastic shell of constant thickness are reduced to a single, simple, fourth order partial differential equation for the complex-valued function $W+i\sqrt{A/D}F$, where $W$ is the midsurface normal deflection, $F$ is a stress function, and $A/D$ is an elastic constant. Auxiliary equations expressing the tangential midsurface displacements, stress resultants, stress couples, and Kirchhoff edge forces in terms of $W$, $F$, and surface load integrals are also derived. Approximations are introduced only in the stress strain relations, but the resulting errors are shown to be negligible by Koiter’s arguments. Work of previous writers is reviewed and compared with results of the present paper.

ABSTRACT: The intrinsic equations of nonlinear thin shell theory are reduced to a relatively simple set of six equations in six unknowns. Boundary conditions to use in conjunction with the equations are obtained. The equations are compared with those of other authors for some special cases. For easy use, the equations and boundary conditions are given in lines-of-curvature coordinates.

ABSTRACT: Fung and Tong have recently explained the sphering of red blood cells in hypotonic solution by showing that a thin-walled elastic membrane with the right extensional stiffness and surface tension distribution will swell into a sphere under internal pressure. In this report we investigate the stability of the spherical state of Fung and Tong's model by applying the static energy criterion, which requires a determination of the sign of the quadratic terms in the potential energy functional. It turns out that a spherical cell model with radius less than that of the equatorial radius of the original undeformed cell is indeed stable, if and only if the supposedly arbitrary elastic parameters in the model are restricted in their possible range of values.

PARTIAL ABSTRACT: Experimental data on the mode of buckling of circular cylindrical shells under axial compression enables us to draw the conclusion that the number of dents in the peripheral direction, n, depends only on the ratios L/R and R/h, where L, R, and h are respectively the length, radius, and thickness of the shell...

ABSTRACT: A theoretical investigation is made of the axisymmetric snap-through buckling of a shallow conical shell subjected to an idealized impulse applied uniformly over the surface of the shell. The shell is assumed to behave as a single-degree-of-freedom system, and a study is made of the strain energy at maximum displacement: i.e., zero velocity. Under certain conditions this equilibrium position becomes unstable and the shell can snap through (or buckle). Nonlinear strain displacement equations are used and solutions are obtained for clamped and simply supported boundaries at the edge of the shell. Results for the cone are compared with similar results for a shallow spherical cap having the same rise as the cone. This comparison indicates that the spherical shell can resist a larger impulse than the conical shell before buckling.

ABSTRACT: This paper deals with the dynamics and stability of flexible pipes containing flowing fluid, where the flow velocity is either entirely constant, or with a small harmonic component superposed. An extensive historical review of the subject is given. In the case of constant flow velocity, the dynamics of the system is examined in a general way and it is shown that conservative systems are subject not only to buckling
(divergence) at sufficiently high flow velocities, but also to oscillatory instabilities (flutter) at higher flow velocities. Also presented are some new results for cases of systems subjected to internal dissipative forces. In the case of harmonically varying flow velocity, the equation, of motion derived here exposes an error in a previous derivation. Stability, maps are presented for parametric instabilities, computed by Bolotin's method, for pipes with pined or clamped ends, as well as for cantilevered pipes. It is found that the extent of the instability regions increases with flow velocity for clamped-clamped and pinned-pinned pipes, while a more complex behaviour obtains in the case of cantilevered pipes. In all cases, dissipation reduces the extent of, or entirely eliminates, parametric instability zones.

ABSTRACT: Design of efficient cylindrical shells for carrying moderate compressive loads leads to the requirement that they be stiffened. The buckling behavior of such stiffened cylinders differs considerably from that of thin monocoque cylinders in several noteworthy respects: 1) Stiffened cylinders are often effectively "thick," and exhibit large buckle wavelengths. Their strength is consequently influenced little by imperfections and can be predicted accurately by linear buckling analysis. Refined and sophisticated linear analysis thus becomes a powerful design tool. 2) One-sidedness of stringers and rings produces strong interaction between "membrane" and bending forces. Calculations and tests have revealed instances where change of reinforcement from one surface to the other changes buckling strength by a ratio of two or more. 3) Because of the larger, well defined wave form, the strength of stiffened cylinders always depends on the constraint (or lack of it) from adjoining cylinders and domes (or test fixtures), and the resistance to bending moment may appreciably exceed the resistance to uniform load. This paper describes several methods, having varying complexity and versatility, for treating buckling of stiffened cylinders. The determination of the required ring stiffness for preventing general instability is identified as being central to optimum design; commonly used methods of determination are shown to be unreliable. Theoretical and experimental results are compared, and future development is outlined.

G. A. Thurston, “Buckling of imperfect cylinders under axial compression”, NASA, 1966

ABSTRACT: An extension of the finite-element displacement method to the analysis of linear bifurcation buckling of general shells of revolution under static axisymmetric loading is presented. A systematic procedure for the formulation of the problem is based upon the criterion that the condition for neutral stability of a system is the vanishing of the second variation of the total potential energy from the stable equilibrium state to the perturbed bifurcation state; this results in an eigenvalue problem. For solution, the shell is discretized into either a series of conical frusta or of frusta with meridional curvature. The prebuckling equilibrium solution is axisymmetric, but the perturbation-displacement field within each element is represented by Fourier circumferential components of the generalized displacements which are defined at the nodal circles. The present formulation is applied to a number of shells of revolution with and without meridional curvature, and comparisons are made with other theoretical and available experimental results.

ABSTRACT: Dynamic equilibrium equations and boundary conditions are derived from energy principles for eccentrically stiffened cylinders and flat plates. In-plane inertias are neglected and frequency expressions are obtained for simple-support boundary conditions for both the cylinder and the plate. Results in the form of plots of frequencies as a function of mode shape illustrate the effects of eccentricities. It is found that these eccentricities can have a significant effect on natural frequencies and should be investigated in any dynamic analysis of stiffened structural members.

ABSTRACT: Closed-form solutions are given of the linear Donnell equations defining the buckling of thin-walled circular cylindrical shells subjected to uniform axial compression. In addition to the classical simple
support conditions requiring the vanishing of the radial displacement, the axial bending moment resultant, the axial additional stress and the circumferential displacement, three other, equally justifiable, simple support conditions are defined and studied in the case of the semi-infinite shell. Two of them yield buckling stresses amounting to about one-half the classical critical stress.

ABSTRACT: The results of buckling tests on uniformly heated, clamped, thin circular cylindrical shells are presented and discussed. Particular attention is paid to both the actual buckling process and the ensuing postbuckling behavior. Load vs. end-shortening curves are included. The possibility of “snap-through” buckling which occurs at a value of end shortening greater than that corresponding to the maximum supported load is experimentally verified. A comparison of the present experimental results with available theory is made. It is observed that the experimental values of the buckling temperature can be substantially greater than the temperatures calculated by linear theory from the experimental buckling loads; however, the buckling stresses are the same whether the loading is thermal or mechanical.

ABSTRACT: Considered are problems of free and forced vibrations, static and dynamic stability and aeroelasticity of orthotropic shells and plates placed in a variable temperature field. It is assumed that the physical-mechanical characteristics of the material of the shell (plate) depend on the temperature. It is shown that taking into account the dependence of the physical-mechanical properties of the material of the shell (plate) on temperature introduces essential qualitative and quantitative changes in the problem of vibration and stability.

ABSTRACT: The solution for buckling of a stiff elastic layer bonded to an elastic half-space under a transverse compressive plane strain is presented. The results are compared to an approximate solution that models the layer using beam theory. This comparison shows that the beam theory model is adequate until the buckling strain exceeds three percent, which occurs for modulus ratios less than 100. In these cases the beam theory predicts a larger buckling strain than the exact solution. In all cases the wavelength of the buckled shape is accurately predicted by the beam model. A buckling experiment is described and a discussion of buckling-induced delamination is given.

ABSTRACT: The nonlinear analysis of shell structures is studied by both the Eulerian and the Lagrangian approach. Current methods are discussed on the basis of both formulations. It is found that the widely used updated procedure is a combination of both approaches. From the current standpoint it makes use of a mixture of incremental stiffnesses derived by both approaches. The ‘bowing’ effect was found to be the main source of error in this updated procedure, and this effect was shown to be negligible when a large number of elements were used. Case studies investigate various aspects of the nonlinear behavior of arches, axisymmetric shells of revolution, flat plates, and arbitrary shells.

ABSTRACT: In this work a numerical model is developed for the welding and subsequent loading of a fabricated structure. The model treats the weld process as a thermo-mechanical problem. A finite element formulation derived from the uncoupled thermal and mechanical energy balances forms the basis of the model. During the development of the thermal model, two significant problems are discussed. One is the material nonlinearity, which manifests itself in the temperature dependence of the thermal properties, and in the fusion problem, where the material phase change is accompanied by a latent heat effect. This latter is modeled by use of a modified specific heat, since the materials of prime concern are alloys which melt over a finite range of temperature, while the former are introduced through periodic re-evaluation of the properties throughout the analysis. The second problem is that of boundary conditions: The deposition of molten bead on the base is modeled by using the intimate contact boundary condition, which is developed into a set of impulse type equations on the finite element model. Since radiation is a dominant cooldown mechanism, this boundary condition is also included. Thus the first part of work develops a non-linear finite element thermal analyzer capable of modeling all of the above effects. This program is then applied to several problems in order to assess its accuracy. During the second part of the work the mechanical model is described. This is an incremental finite element model in which the basic constitutive descriptions are time independent elastic-plastic behavior with temperature dependent properties, and a creep rate formulation for the time dependent behavior. The development is not based on thermodynamic theories but on direct extension of the classical (isothermal) theories. The model includes finite strain effects during isothermal loading, so that it may be used in the modeling of distortion sensitive structure. The integration of the rate equations is discussed with respect to the introduction of a residual load (total equilibrium) correction; it is shown that such a correction must be introduced very carefully in a completely incremental formulation such as is developed here. Finally the model is compared with simple bead-on-plate weld experiments, performed with high strength steels. It is found that in one case the experimental approximations are well justified by the finite element results, but there is no
agreement with the experimentally measured residual stresses. The suggested explanation for the unique stress patterns observed experimentally is shown to have little effect on the finite element stress predictions, so that it is concluded that the finite element model does not include a significant material behavior in this case. In the second example it is shown that the experimental assumptions were not justified by the results of the present model. In both cases the model predicts the usually expected residual stress patterns. Use of a simple creep formulation is shown to give the same order of residual stress reduction as a result of post weld heat treatment as is measured experimentally.

ABSTRACT: The first part of this paper is in the nature of a progress report on recent developments of analysis methods for filamentary composites. Theoretical predictions of the stiffness and strength properties of a unidirectional composite based on a knowledge of the constituent properties are correlated with experiments for both tensile and compressive loadings. The analysis of multilayer or laminated composites based upon the unidirectional composite properties then requires the rather straight forward use of classical anisotropic shell theory. Some structural aspects of filamentary composites designed for biaxial loads are considered in the second part. In particular, certain design restrictions inherent in the use of such composites become evident when compared to the more familiar isotropic sheet. Some of these restrictions can be overcome by a close matching of filament orientations and stress field. These factors serve to emphasize the overwhelming importance of creative structural concepts in the design of successful filamentary composites.

ABSTRACT: This paper presents an approximate finite deflection analysis of the buckling behaviour of long, slightly curved panels in uniform compression parallel to the generators; the sides, which may be clamped or simply-supported, are either free to move circumferentially or are completely restrained against circumferential movement.

W. H. Horton, S. C. Bailey and A. M. Edwards (Department of Aeronautics and Astronautics, Stanford University, Stanford, California, USA), “Nonsymmetric buckle patterns in progressive plastic buckling” (Experiments conducted by the authors were concerned not only with the method in which a buckle generates
and develops in a thick-walled shell, but also with the influence of geometric and mechanical parameters on this process), Experimental Mechanics, Vol. 6, No. 9, 1966, pp. 433-444, doi: 10.1007/BF02326556

ABSTRACT: This paper presents the results of a series of experiments on the progressive plastic buckling of cylindrical shells under axial compressive load. It shows that, for shell bodies with anR/t less than 100, the normal axisymmetric ring buckling will develop into nonsymmetric patterns. We demonstrate that there exists also a class of shells within this thickness-radius range for which nonsymmetric plastic buckling always occurs without the prior formation of a ring. It appears from the limited number of tests made that, for a particular R, R/t, material and rate of loading, there is a critical value of L, above which there is a high probability of the buckle pattern developing in a nonsymmetric fashion. It seems probable, too, that there are bands of R/t for a particular L/R, R, material and rate of loading for which the buckle number will be constant. The experiments tend to indicate that the postbuckling efficiency of the shell decreases with increasing buckle number.

The nonsymmetric patterns demonstrated appear to be inextensional deformations. They are very similar in character to the Yoshimura pattern which occurs as the limiting case for thin shells in axial compression and, under impact loading. Load-displacement histories are presented for some of the various modes of failure demonstrated.

**ABSTRACT:** The buckling of cylindrical shells with free longitudinal edges subjected to uniform axial compression is examined. The solutions are based on the simplified elastic equations of the small deflection theory known as the Donnell's equations. Results obtained were presented in a number of charts. It was found that in the practical range of thin shell structures, the critical buckling stress of a cylindrical shell may be 1/10, 1/100, or 1/1000 of the buckling value of a corresponding cylindrical tube with the same radius, $R$, thickness, $t$, and length $L$, as the ratio of $t/R$ decreases and the ratio of $L/R$ increases. Although the small deflection theory may give buckling stresses higher than the actual buckling values, it will serve the purpose of establishing the upper bounds of the buckling loads. The study of shells with free longitudinal edges and subjected to uniform axial compression may be regarded as an initial step for studying shell roofs with edge beams and subjected to longitudinal membrane stresses varying from compression to tension.

**ABSTRACT:** An exact solution is derived for the buckling of a circular cylindrical shell with multiple orthotropic layers and eccentric stiffeners under axial compression, lateral pressure, or any combination thereof. Classical stability theory (membrane prebuckled shape) is used for simply supported edge boundary conditions. The present theory enables the study of coupling between bending and extension due to the presence of different layers in the shell and to the presence of eccentric stiffeners. Previous approaches to stiffened multilayered shells are shown to be erratic in the prediction of buckling results due to neglect of coupling between bending and extension.

**ABSTRACT:** A solution for the plastic buckling of eccentrically stiffened cylinders is derived by use of the J2 deformation theory of plasticity for a set of simply supported edge boundary conditions. The uniaxial character of the stiffeners and the stiffener eccentricity (asymmetry about the cylinder middle surface) are explicitly accounted for as is a variable Poisson's ratio in the plastic region. A closed-form stability criterion is obtained for axial compression, lateral pressure, and hydrostatic pressure loadings. The present results are more realistic for most practical stiffened cylinders than an existing solution in which an orthotropic shell model is used. A numerical example is given to illustrate the effect of plastic action on the buckling load of a typical aerospace structure. The FORTRAN IV computer program is described and listed.

**ABSTRACT:** An exact buckling criterion, within the framework of classical buckling theory, is derived for eccentrically stiffened multilayered circular cylindrical shells made of materials that have different orthotropic
moduli in tension and compression. Such behavior is typical of many current composite materials. The buckling criterion is valid for arbitrary combinations of axial and circumferential loading, including axial compression and internal pressure as well as axial tension and lateral pressure. The material model (stress-strain relationship) involves a bilinear stress-strain curve with a discontinuity in slope (modulus) at the origin. A numerical example of buckling of a ring-stiffened two-layered circular cylindrical shell is given to illustrate application of the buckling criterion. A FORTRAN IV computer program, BOMS II, that implements the aforementioned analysis is described and listed.

ABSTRACT: Small geometrical imperfections in some structures can be responsible for large reductions in their static buckling strengths. As is well known, a thin shell is often very imperfection-sensitive in this sense, with a perfect specimen sometimes having a “classical” buckling strength several times higher than that of an imperfect one. Many analytical studies have sought to correlate reductions in buckling strength with assumed initial imperfections of various sizes and shapes. Such studies may eventually provide the quantitative information needed for the establishment of a statistical theory of buckling, which would relate the probability of buckling under a given static load to the spectrum of imperfections (see [1]). But at the present time, the design of shells leans heavily on experiment, and analysis has been mainly useful in identifying imperfection-sensitive structures and in establishing, in a qualitative way, the degree of this sensitivity.

References listed at the end of the paper:

ABSTRACT: The present paper continues an earlier study by the same authors with a view toward presenting a complete picture of the dynamic buckling of some imperfection-sensitive models. The initial study was concerned with buckling of the models, and real structures as well when subject to loads suddenly applied and subsequently held constant. Here, consideration is extended to buckling under loading histories characterized by a finite length of time of load application. The results are presented in a form such that the dynamic buckling load of the initially imperfect model is related to its static buckling load. Thus, explicit dependence on its initial imperfection has been bypassed. In this form the implication of the model results for real structures are most apparent. The application of these results to actual structures is discussed, and several observations on the general character of dynamic buckling are noted. Finally, attention is focused on the cylindrical shell under axial compression. The limited results obtained tend to substantiate the validity of the model results, and we are led to suggest what should be a conservative criterion for this structure for design against dynamic buckling.

ABSTRACT: The initial postbuckling behavior of a shallow section of a spherical shell subject to external pressure is studied within the context of Koiter’s general theory of postbuckling behavior. Imperfections in the shell geometry are shown to have the same severe effect on the buckling strengths of spherical shells as has been demonstrated for axially compressed cylindrical shells. Large reductions in the buckling pressure result from small deviations, relative to the shell thickness, of the shell middle surface from the perfect configuration.

ABSTRACT: The initial post-buckling behavior of double curvature shell segments subject to several loading conditions is determined on the basis of Koiter's general theory of initial post-buckling behavior. Previously, the classical buckling loads associated with these shells were shown to be strongly dependent on the two radii of curvature and their relative magnitudes. Here, the initial post-buckling behavior and associated imperfection sensitivity are also seen to be strongly dependent on the two curvatures.

ABSTRACT: A quantitative study of the imperfection-sensitivity of eccentrically stiffened cylindrical shells is presented. Results are given for both axial and ring stiffened cylinders under axial compression and hydrostatic pressure. In some instances, in particular in the case of axially stiffened cylinders under axial load, the sensitivity to imperfections, as well as the classical buckling load, appears to be strongly dependent on whether the stringers are attached to the outside or inside of the cylinder. Under certain conditions stiffening can significantly reduce or perhaps completely eliminate imperfection-sensitivity, whereas in other cases it may play a much smaller role in lowering the sensitivity.

ABSTRACT: Buckling and initial postbuckling behavior is determined for thin, elastic cylindrical shells of elliptical cross section. This study complements the buckling and advanced postbuckling calculations reported by Kempner and Chen on a similar class of shells. The initial postbuckling analysis indicates that like compressed circular cylinders, the oval cylinders will be highly sensitive to small geometrical imperfections and may buckle at loads well below the predictions for the perfect shell. On the other hand, buckling will not necessarily result in complete collapse. A series of simple tests has been performed which provide qualitative verification of the major features of the theory.

ABSTRACT: The initial postbuckling behavior of axially stiffened cylindrical shells is studied with a view to ascertaining the extent to which various effects such as [indecipherable] eccentricity, load eccentricity, and barreling influence the imperfection sensitivity of these structures to buckling. In most cases, when these effects result in an increase in the buckling load of the perfect structure, they increase its imperfection-sensitivity as well. In some instances, however, barreling can significantly raise the buckling load of the shell while reducing its imperfection-sensitivity. The analysis, which is based on Koiter's general theory of postbuckling behavior and is made within the context of Kármán-Donnell type theory, takes into account nonlinear prebuckling deformations and different boundary conditions.

Steven E. Forman and John W. Hutchinson (Harvard University, Cambridge, Massachusetts, USA), “Buckling
ABSTRACT: Buckling analyses of several reticulated shell structures are carried out using both an approximate equivalent shell analysis and a discrete analysis which is essentially exact. The structures considered are: an infinite reticulated beam under axial compression and resting at equally spaced intervals on elastic springs; a shallow section of a reticulated sphere with an equilateral triangle grid subject to normal loading; and an infinite reticulated cylindrical shell with an equilateral triangle grid subject to axial compression. The discrete analysis is used to evaluate the accuracy of the predictions of the equivalent shell analysis. The buckling load computed on the basis of the equivalent shell analysis is nonconservative when a characteristic wavelength of the buckling deformation is on the order of the member length or the axial load in a member at buckling is on the order of the Euler buckling load of a simply supported column. The effect on the buckling load of reducing the rigidity of the joints is investigated for both the beam-spring model and the reticulated spherical shell. Finally, the importance of the discrete analysis is illustrated by the determination of the optimum properties of a shallow section of a reticulated sphere subject to a prescribed normal loading and designed against buckling.

ABSTRACT: A combined theoretical and experimental investigation has been carried out on the effects of certain types of local axisymmetric imperfections on the buckling of cylindrical shells under axial compression. Buckling loads have been calculated for a variety of "dimple" imperfections. Results have been obtained for constant thickness shells with middle surface variations from the geometry of a perfect cylinder as well as for shells with local axisymmetric thickness variations. Nonlinear prebuckling effects and edge conditions are taken into account. In the experimental program a series of seven photoelastic plastic circular cylindrical shells each containing a local axisymmetric dimple centered at mid-length were tested under pure axial compression. All cylinders were constructed by the spin-casting technique and the local imperfection was cut on both the inner and outer walls using a hydraulic tracer-tool apparatus in conjunction with a metal template. A broad range of imperfection amplitudes and wavelengths was investigated. The experimental results were in good agreement with the theoretical predictions.

ABSTRACT: Aspects of postbuckling behavior are investigated for structures undergoing plastic deformation. The structures singled out are characterized by a highly imperfection-sensitive behavior where buckling takes place in the elastic range. A simple model study is carried out and is followed by an analysis of the plastic buckling of a complete spherical shell under external pressure. In both instances, the bifurcation behavior and subsequent deformation of the perfect structure as well as the influence which geometric imperfections have on buckling are studied.

ABSTRACT: In the first part of the paper a simple model is used to introduce some of the analytical and physical features of post-bifurcation phenomena in continuous elastic-plastic systems. An analysis is presented for the initial post-bifurcation behavior of a class of elastic-plastic solids subject to loads characterized by a single load parameter. Bifurcations which occur at the lowest possible load are singled out for attention. The theory makes connection with Hill's general theory of bifurcation and uniqueness in elastic-plastic solids and Koiter's general approach to the initial post-buckling behavior of conservative elastic systems. Buckling of an axially compressed column in the plastic range is used to illustrate the theory.

ABSTRACT: The effect of small imperfections on the buckling of continuous structures loaded into the plastic range is studied. A simple model study is presented and several additional examples are discussed. The rôle of the load at which elastic unloading first occurs is emphasized, and a general asymptotic analysis is given for the behavior prior to the onset of elastic unloading for a class of elastic-plastic solids subject to loads characterized by a single load parameter. Asymptotic imperfection-sensitivity formulae are obtained whose features are similar to analogous formulae for elastic structures.

ABSTRACT: A method is presented to determine the general instability load of a ring-stiffened corrugated
cylinder under axial compression. This method is developed using linear small deflection theory. The stiffness properties of the rings are uniformly distributed along the cylinder and the eccentricity of the rings with respect to the corrugation centerline is taken into account. Analytical and experimental results are compared. In this comparison good agreement is obtained for cylinders loaded in pure compression. For the cylinders subjected to bending or a combination of bending and compression the analytical calculations are conservative. A computer program for the application of this method has been developed. The program and an explanation of its notation are included in this report.

J.N. Dickson and S.B. Biggers (NASA Langley Research Center, Hampton, Virginia, USA), “POSTOP: Postbuckled open-stiffener optimum panels-theory and capability” (no publisher or date given by ProQuest-CSA)

ABSTRACT: The computer program POSTOP was developed to serve as an aid in the analysis and sizing of stiffened composite panels that are loaded in the postbuckling regime. A comprehensive set of analysis routines was coupled to a widely used optimization program to produce this sizing code. POSTOP is intended for the preliminary design of metal or composite panels with open-section stiffeners, subjected to multiple combined biaxial compression (or tension), shear and normal pressure load cases. Longitudinal compression, however, is assumed to be the dominant loading. Temperature, initial bow eccentricity and load eccentricity effects are included. The panel geometry is assumed to be repetitive over several bays in the longitudinal (stiffener) direction as well as in the transverse direction. Analytical routines are included to compute panel stiffnesses, strains, local and panel buckling loads, and skin/stiffener interface stresses. The resulting program is applicable to stiffened panels as commonly used in fuselage, wing, or empennage structures. The analysis procedures and rationale for the assumptions used therein are described in detail.

ABSTRACT: Stiffness and mass matrices have been developed for rings, which together with similar matrices for shell elements have been applied to ring-reinforced circular cylindrical and conical shells. The finite-element solution, for the general instability and vibration of circular cylinders and cones, has been compared successfully with existing theories and also with experimental results, where the latter have been available. An investigation has been made also of the effects of pressure on the vibration characteristics of a ring-reinforced circular cylinder.

ABSTRACT: Analysis of the simple model proposed yields equilibrium curves in agreement with those obtained by other investigators for axially compressed, thin-walled, circular cylindrical shells. A rigorous calculation of the stability of the equilibrium of the model indicates that the snap-through phenomenon can be entirely absent when an imperfect shell is heated in a perfectly rigid testing machine. When the testing machine is sufficiently elastic, snap through will occur. It may take place at a temperature smaller than, equal-to, or greater than $T = \epsilon_{cr}/\alpha$, where $\epsilon_{cr}$ is the theoretical critical strain of the perfect shell and $\alpha$ is the coefficient of expansion of the material of the shell, but the maximum stress produced in the imperfect shell will always be less than $\epsilon_{cr}E$, where $E$ is Young’s modulus of the material.

ABSTRACT: Earlier numerical solutions of the von Karman-Donnell large-displacement equations for thin circular cylindrical shells have been extended by considering larger numbers of terms in the double Fourier series representing the radial displacements after buckling. In the most comprehensive one of the calculations whose results are presented here a total potential energy expression consisting of about 1100 terms was minimized with respect to 16 unknowns. The results of the computations as well as theoretical considerations indicate that the solution for long shells of the von Karman-Donnell equations with the aid of the von Karman-Tsien Leggett procedure leads in the limit to the trivial solution in which the amplitude of the displacements tends to zero, the number of waves around the circumference tends to infinity and the average axial compressive stress capable of maintaining equilibrium in the post-buckling state tends to zero.

SUMMARY: The, development of our knowledge of the buckling of thin-walled circular cylindrical shells subjected to axial compression is outlined from the beginning of the century until the present, with particular emphasis on advances made in the last twenty-five years. It is shown that practical shells generally buckle under stresses much smaller than the classical critical value derived by Lorenz, Timoshenko, Southwell and Flügge. A first explanation of the reasons for the discrepancy was given by Donnell and the problem was explored in detail by von Kármán, Tsien and their collaborators. More recently, Yoshimura discovered the existence of an inextensional displacement pattern which the wall of the shell can suddenly assume, and Koiter found an explanation of the sensitivity of the buckling stress to small initial deviations from the exact circular cylindrical shape. In the last few years further interesting discoveries were made in Japan and in California regarding the effects of details of the boundary conditions, and many additional numerical results were obtained with the aid of high-speed electronic digital computers. Improvements in experimental techniques have also contributed significantly to a clarification of the problem and to an establishment of the unavoidable deviations from the

ABSTRACT: The creep deformations of a circular cylindrical shell are calculated under the action of uniform axial compression. The edges of the shell of finite length are simply supported and the deformations are assumed to be axially symmetric. Such axisymmetric deformations have been observed to occur when the shell is moderately thin-walled. The solution is obtained in the form of trigonometric series for the stresses and displacements.

ABSTRACT: This paper is not meant to be the definitive publication on the creep buckling of plates and shells; it is rather a progress report on work completed in the relatively near past, mostly by the present author and his collaborators. Results obtained by other researchmen will also be discussed, particularly if there has been some interaction between these men and the present author. Omission of reference to the work of any other investigator should not be interpreted to mean that it is considered to be of an inferior quality; lack of such mention may simply indicate that the present author is unfamiliar with the work, or that he had to leave it out for lack of space.

ABSTRACT: Curvilinearity of the generators forces the structure to behave in a qualitatively different way under the action of axial forces. Firstly, up to loss of stability the individual generators of the system are in a state of longitudinal-transverse bending. Secondly for a shell with negative Gaussian curvature there may be a sharp drop in the critical axial compressive loads even in structures that deviate only slightly from the cylindrical. All this means that shells of revolution with curvilinear generators in axial compression cannot be designed for stability using the formulas derived for cylindrical systems.

ABSTRACT: Complete spherical shells with radius-to-thickness ratios of from 1570 to 2120 were produced by electroforming. For specimens of good quality and for optimum testing conditions, buckling pressures up to 86 percent of the classical value were obtained. The effect of loading-system characteristics was examined by pressurizing spherical shells in rigid and soft systems and no difference in buckling pressure was observed. It was found that buckling behavior is strongly influenced by the nature and severity of flaws or imperfections; i.e., low buckling pressures can be correlated with the presence of severe flaws or nonuniformities.

ABSTRACT: The stability of a long, thin, elastic circular cylindrical shell subjected to axial compression and an axisymmetric load moving with constant velocity along the shell axis is studied. With the aid of the direct method of Liapunov, and employing a nonlinear Donnell-type shell theory, sufficient conditions for local stability of the axisymmetric response are established in a functional space whose metric is defined in an average sense. Numerical results, which are presented for the case of a moving decayed step load, reveal that the sufficient conditions for stability developed here and the sufficient conditions for instability obtained in a previous paper lead to the actual stability transition boundary.

ABSTRACT: (none given)

ABSTRACT: The plastic collapse of thin shells of revolution under axisymmetric loads is considered. A rigid perfectly-plastic material is assumed. Methods of limit analysis are applied to find collapse loads. The Tresca-Mohr yield criterion, as closely approximated by Nakamura [1, 2] is used.

ABSTRACT: A study of the coupling effect of inertia terms and vibration modes on the dynamic stability of simply supported cylinders of finite or infinite length subjected to uniform radial impulsive pressure (as in space reentry or underwater explosion). In the prebuckling stage, the shells exhibit symmetrical motion; during buckling they oscillate, but if the oscillation is bounded rather than uncontrolled, the system is called dynamically stable. The well-known analogy between thermal stress and equivalent loading is used to derive an equivalent thermal stress problem. The coupling of radial and tangential inertia terms does not seem to be pronounced for radial pressure. The consideration of nonlinear terms in the stability equation is essential. Appendices give the derivation of the problem, the two inertia terms, and the nonlinear effect.

of recent shallow shell finite-element analyses”, International Journal of Mechanical Sciences, Vol. 12, No. 10,
ABSTRACT: Recent advances in the analysis of shallow shells by finite-element technique are reviewed and
results obtained using different stiffness matrices compared. The question of including rigid body modes in the
prescribed displacement field is discussed. It is found that the constant strain condition, other than the trivial
one—i.e. rigid body modes—cannot be satisfied in the case of curved plates and shells.

Department of Civil Engineering, Lehigh University, 1962
ABSTRACT: Welded built-up members are being used more frequently in steel construction due to economy,
convenience and aesthetics. The residual stresses produced in the members as a result of the welding play an
important role in the buckling strength of the members. This dissertation presents the results of an investigation
into the elastic, elastic-plastic and plastic buckling of steel plates containing residual stresses. Particular
attention is given to the local buckling of built-up columns of box-shaped cross section. The material of the
members is steel with a stress-strain relationship assumed to be elastic perfectly plastic, and with a Poisson's
ratio of 0.3 in the elastic range and 0.5 in the plastic range. The analysis of the behavior of the plate material in
the plastic range was based on both the secant modulus deformation theory and the flow theory. The theorem of
minimum potential energy was applied to solve the buckling problem. A simplified residual stress distribution
was used in the analysis. Analytical solutions were obtained for the elastic, elastic-plastic and plastic buckling
of a plate simply supported at the loading edges with the other edges elastically restrained or simply supported
or fixed. Numerical examples of the analytical solution were presented for the study on the strength of local
buckling of square built-up columns, that is, case (a) above. This study showed that the first term of the series of
the assumed deflection function was sufficient to investigate the elastic, elastic-plastic and plastic buckling of
the plate with residual stresses. An experimental study was performed on two short columns to check the theory
for the square built-up column of the numerical examples. Good agreement was obtained with the results of the
numerical calculation for elastic buckling and for elastic-plastic buckling, based on the secant modulus
deformation theory. The experiments also showed that the ultimate load was very close to the critical buckling
load for the elastic-plastic buckling, but that the post buckling strength was large for the elastic buckling.

“Experimental investigation of the buckling of plates with residual stresses”, in Test Methods for Compression
ABSTRACT: This is a summary of local buckling tests of plate elements in square columns built up by
welding. The experiments were conducted to verify theories for the elastic and elastic-plastic buckling of plates
with emphasis on the effect of residual stress. This was part of a general study on the strength of welded
columns and the influence of residual stress on plate buckling. Both ASTM A 7 and A 514 steels were used.
The square section simulated plates simply supported at the unloaded edges, and the length of the column was
chosen so that end conditions had no effect either on the residual stress distribution or on the local buckling
strength of the columns. Short columns were tested in the “as-placed” condition in a mechanical-type testing
machine. The transverse deflection (local buckling) of the plates was measured at a number of cross sections by
a 1/10000 in. dial gage fixed to a frame held manually. The “top of the knee” method was used to estimate the
bifurcation load. The experimental results showed good correlation with theoretical predictions including the
effect of residual stress for elastic buckling and for elastic-plastic buckling based on the total strain theory. The
results of experiments indicates that considerable post-buckling strength may be expected for elastic buckling of
plates, although not for elastic-plastic buckling.

“Determination of plastic buckling load for axially compressed plates from experimental data”, in Test Methods
PARTIAL ABSTRACT: Many papers have been published on the instability of plates in the plastic range.
However, it has been a difficult problem for researchers to determine the buckling load of a plate from
experimental data. Several approaches have been used. The critical buckling load for applied average strain has
been assumed to be equal to the maximum load (or the corresponding strain) carried by the plate. Another
approach is to take the point of a rapid increase in deflection or a point of bifurcation of strains measured on
both surfaces at a certain point on the plate. In this paper a new method is proposed for determining the critical
load from experimental data. A theoretical justification is furnished by using the energy approach and the
deformation theory of plasticity. The method was verified by carrying out plate and angle compression tests….

ABSTRACT: Explosive-loading and structural-response measurement techniques are described for obtaining definitive large dynamic and permanent-deformation data on simple structures which undergo (a) two-dimensional deformations, or (b) general three-dimensional deformations. In the former category, explosively loaded structures discussed include freely suspended single-layer circular rings, freely suspended unbonded concentric rings, and flat circular plates with clamped edges. Representing category (b) is an explosively loaded cylindrical panel with clamped edges. To define the impulse which was imparted explosively to these structures, appropriate impulse-calibration tests were performed on high-explosive-loaded single-layer and unbonded double-layer specimens; these testing techniques and the results obtained are discussed. General numerical methods for predicting large elastic-plastic dynamic and permanent deformations of structures which undergo either two-dimensional or general three-dimensional deformations are described briefly. Dynamic responses and permanent deformations predicted with these methods are compared with data from the present experiments. Certain problems, both experimental and theoretical, requiring further investigation are indicated.

ABSTRACT: The behavior of a shallow arch and a thin ring under a dynamic pulse loading is studied for a wide range of geometric and load parameters. The nonlinear dynamic response and static load deflection characteristics of the systems are related and employed to define dynamic elastic snapping and dynamic elastic buckling. When such a relationship cannot be established, the mechanism of dynamic elastic-plastic buckling is introduced. Critical dynamic load criteria are specified, and critical dynamic load data are developed as a function of structural geometry and load duration. Finally, a classification scheme for dynamic load problems is suggested.

INITIAL PART OF THE INTRODUCTION: The theory of large deformations is now applied in an extensive variety of problems, e.g. the calculations for the construction of modern flexible structures, matters pertinent to the study of blood flow in blood vessels, pressure fabrication of metal objects, geophysics, etc. Experimental observation of the loading of some systems suggests the existence of a critical buckling load, while the occurrence of creep gives indication of a critical time of application of a particular load. The task of determining a critical load for the case of momentless shells, i.e. membranes, is of some practical importance. The present paper deals only with the specific problem of tensile instability at large deformations. It is possible to observe such a phenomenon and to treat it theoretically in some special cases. The formation of a ‘neck’ in a tensile test piece during static loading or in subsequent creep is a classic example of a system that exhibits such a loss of stability. As another example, experimental study of the deformation of a right cylinder under the action of an internal pressure readily reveals the existence of a maximum confinable pressure and the localization of deformation. It is possible theoretically to demonstrate the existence of such a maximum confinable pressure for elasto-plastic cylinders at some finite deformation. It seems to us that a study of local bulging due possibly to a loss of stability in massive bodies such as plates, is of great interest to tectonophysics, but as a preliminary to this it is interesting to study the case of stability loss in membranes.

ABSTRACT: The collapse and recovery loads have been experimentally determined for glass-reinforced-plastic shells compressed along the axis. Compressive force-displacement diagrams have been recorded, and it is shown that the experimental and theoretical diagrams qualitatively coincide. The collapse and recovery times have been ascertained. It is shown that glass-reinforced plastics can be used as an elastic material for investigating shell stability at large deformations.

ABSTRACT: In this paper, the authors apply an extension of the direct stiffness method of structural analysis to the linear and nonlinear analysis of shells of revolution under arbitrary static loading with variable thickness properties in the circumferential direction and the meridional direction. The primary difference between this research and previously published research is that all the Fourier harmonics in the circumferential direction are now coupled. The thickness variation in the circumferential direction yields an 8N x 8N element stiffness matrix in which N is the number of harmonics. The resulting computer program is used to conduct a linear, nonlinear, and stability analysis of the Apollo aft heat shield.

PARTIAL ABSTRACT: For shallow caps under an axisymmetric external pressure distribution which is inward in a neighborhood of the pole and outward away from the pole, it has been shown previously that a finite axisymmetric dimple state of deformation is possible if the inward pressure is at least of the order of the classical buckling pressure for a complete spherical shell and that, asymptotically, the corresponding dimple base is located by the condition of no resultant vertical force over the dimpled region. In the present paper we treat the more difficult load magnitude range...

ABSTRACT: The application of the direct stiffness method in the solution of doubly curved shell stability problems is demonstrated. Discussed first are the modifications necessary to the basic linear matrix displacement approach of structural analysis to solve large deflection and stability problems. The resulting nonlinear system of equations is solved using the piecewise linearization technique. Buckling loads are predicted for several shallow spherical shells of varying geometry and compared to known solutions. Finally, the method is applied to a radome shell with nonuniform surface loads and the critical buckling load is established.

PARTIAL ABSTRACT: Publications by Korbet and Saksonov [5], Varvak [2], Kan [4], and by investigators abroad [5-9] are devoted to the solutions of the problem of stability of a cylindrical shell under axial compression, when the shell is strengthened by an elastic core. A considerable complication of the solution takes place in the case of one-sided constraints of the shell and the core. A theoretical investigation of such a problem is presented only in [3], where two variants of the solution are given for different specification of an
axisymmetric mode of the buckled surface of the shell… In the present article this problem is solved for a shell of an arbitrary length for arbitrary boundary conditions. Here the form of the bent surface is not specified beforehand: it is calculated simultaneously with the critical load. The elastic Winkler foundation, with the known bearing coefficients alpha1 and alpha2 respectively inside and outside the shell, is not joined to the latter…

ABSTRACT: A theory is postulated to explain the dynamic plastic buckling of short cylindrical shells subjected to uniform radially inward impulses. Formulas are derived which predict wavelengths (or mode numbers) and threshold impulses in general agreement with the experimental results that are presented. According to the theory, the restoring moment primarily consists of a directional moment brought about by yielding in a biaxial plastic state of stress; for the practical strain hardening values used the hardening contribution to the restoring moment is secondary. This conclusion is based on the relative influences on the preferred modes and threshold impulses.

ABSTRACT: This paper explores the nonlinear problem of determining the local shape of all possible equilibrium paths through a point where a unique path is not assured. For the sake of rapid insight the treatment is confined to systems having a potential energy depending on any finite number of variables, one direct application being in the theory of structures. The relation with stability is described. The problem is reduced to a readily defined sequence of linear and nonlinear governing equations. These are all expressed explicitly in terms of the orthonormal eigenvectors of an algebraic eigenvalue problem, and the case of a multiple zero eigenvalue (related to the existence of multiple buckling modes) is thereby concisely treated. Branching points which do not permit changes of load are distinguished from those which do. A comparison with Koiter’s work is given.

ABSTRACT: The bifurcation stress is calculated for a simply-supported elastic-plastic plate in uniaxial compression, in the case when the stress is at a vertex of the yield surface which is locally similar to that of Tresca. The effect of coupled hardening between yield-surface facets which meet at the vertex is included. It is found that the bifurcation stress may be substantially lower than that associated with the von Mises yield surface. The latter is known to give results too high to be reconciled with experiment. Reductions of order 10–30 per cent are shown to be unexceptional, even with the retention of an elastic value for the shear modulus.

ABSTRACT: The effect of initial geometric imperfections on the buckling and postbuckling behavior of composite cylindrical shells subjected to uniform axial compression is studied in this report. The solution is obtained by employing von Kármán-Donnell nonlinear strain-displacement relations and the principle of stationary potential energy. Numerical results are given for various fiber orientations in the three-layer shell consisting of either glass-epoxy or boron-epoxy composites, with different initial imperfections. Results indicate that the boron-epoxy composite shells are less imperfection sensitive than the glass-epoxy composite shells. Isotropic shells are found to be more imperfection sensitive than composite shells. It is noticed that the increase or decrease in the classical buckling load with change in fiber orientation is generally accompanied by a decrease or increase in imperfection sensitivity of the shell.

ABSTRACT: A linear finite element capability for predicting displacements, stresses, and natural frequencies of sandwich plates and cylindrical shells with unbalanced laminated faces is reported. The geometric admissibility conditions of the principle of minimum total potential energy are conveniently satisfied by representing the displacement variables in terms of assumed displacement patterns formed by the sum of products of one-dimensional Hermite interpolation polynomials. Stiffness and consistent mass matrices for small displacements are presented in terms of the element geometry, the stiffnesses of the faces (membrane, bending, and coupling) and the transverse shear stiffnesses of the orthotropic core. Specialization for the analysis of thin laminated plates and cylindrical shells is achieved by simply considering one face of the sandwich. Several numerical examples are presented and comparison is made with existing theoretical and experimental results.

ABSTRACT: A numerical graphic method, based on common assumptions of classical membrane theory, for determining the internal pressure that gives rise to plastic instability in membrane shells with a continuous meridional and simply connected surface is described.

ABSTRACT: A FORTRAN IV computer code for the micromechanics, macromechanics, and laminate analysis of multilayered fiber composite structural components is described. The code can be used either individually or as a subroutine within a complex structural analysis/synthesis program. The inputs to the code are constituent materials properties, composite geometry, and loading conditions. The outputs are various properties for ply and composite; composite structural response, including bending-stretching coupling; and composite stress analysis, including comparisons with failure criteria for combined stress. The code was used successfully in the analysis and structural synthesis of flat panels, in the buckling analysis of flat panels, in multilayered composite material failure studies, and lamination residual stresses analysis.

ABSTRACT: Theoretical results are presented for the buckling of anisotropic plates. The plates are subjected to simple and combined in-plane loading. The plates are made from fiber composite material of boron/aluminum or high-modulus graphite/resin. The results are presented in nondimensional form as buckling load against fiber orientation angle for various plate aspect ratios. The results indicate that buckling loads of boron/aluminum plates are independent of fiber direction if the plate aspect ratios are greater than about 1, and moderately dependent when this ratio is less than about 1. In addition, the results indicate that the buckling loads are independent of aspect ratio for plates with aspect ratios greater than about 2. Boron/aluminum composite plates can resist buckling loads more efficiently than graphite/resin composites on a specific buckling stress basis. The numerical algorithm and a listing of the computer code used to obtain the results are included.

ABSTRACT: NASA Lewis Research Center research in the field of composite laminate residual stresses is reviewed and summarized. The origin of lamination residual stresses, evidence of their presence, experimental methods for measuring them, and theoretical methods for predicting them are described. Typical results are presented which show the magnitudes of residual stresses in various laminates including hybrids and superhybrids, and in other complex composite components. Results are also presented which show the effects of
lamination residual stresses on laminate warpage and on laminate mechanical properties including fracture stresses. Finally, the major findings and conclusions derived therefrom are summarized.

ABSTRACT: A computationally effective method is described to evaluate the non-deterministic dynamic instability (probabilistic dynamic buckling) of thin composite shells. The method is a judicious combination of available computer codes for finite element, composite mechanics and probabilistic structural analysis. The solution method is incrementally updated Lagrangian. It is illustrated by applying it to thin composite cylindrical shell subjected to dynamic loads. Both deterministic and probabilistic buckling loads are evaluated to demonstrate the effectiveness of the method. A universal plot is obtained for the specific shell that can be used to approximate buckling loads for different load rates and different probability levels. Results from this plot show that the faster the rate, the higher the buckling load and the shorter the time. The lower the probability, the lower is the buckling load for a specific time. Probabilistic sensitivity results show that the ply thickness, the fiber volume ratio and the fiber longitudinal modulus, dynamic load and loading rate are the dominant uncertainties in that order.

ABSTRACT: A computationally effective method for evaluating the dynamic buckling and postbuckling of thin composite shells is described. It is a judicious combination of available computer codes for finite element, composite mechanics and incremental structural analysis. The solution method is an incrementally updated Lagrangian. It is illustrated by applying it to a thin composite cylindrical shell subjected to dynamic loads. Buckling loads are evaluated to demonstrate the effectiveness of the method. A universal plot is obtained for the specific shell that can be used to approximate buckling loads for different dynamic loading rates. Results from this plot show that the faster the rate, the higher the buckling load and the shorter the time. They also show that the updated solution can be carried out in the postbuckling regime until the shell collapses completely. Comparisons with published literature indicate reasonable agreement.

ABSTRACT: Reentry vehicle shell analysis capabilities and problem areas are surveyed as of the spring and summer of 1970. Some of the major reentry vehicle contractors were consulted in this survey. (GE, AVCO, LMSC, MDAC, Kaman Nuclear, and TRW). Each was asked to state his capabilities and was given an opportunity to give his opinion as to important problem areas that require attention. The contractors' opinions are summarized in addition to comments on development, documentation, and dissemination of computer programs, which is a topic that has become increasingly important in the technical community.

ABSTRACT: A technique is presented for simulating simply supported boundary conditions in axial cylinder buckling experiments. An internal mandrel is employed. The geometric and material constants of the mandrel can be carefully selected allowing it to expand, through a Poisson effect, at the same rate as the shell. The mandrel provides an expansion mechanism for the edges of the shell which allows the shell's generators to remain straight until buckling occurs. In addition, the mandrel can also be used to limit buckle deformations to the elastic region

ABSTRACT: An approximate numerical analysis procedure is presented which is capable of solving thin shells of arbitrary shape, boundary conditions and loading. The shell is idealized as an assemblage of triangular finite elements representing both membrane and flexural stiffness properties, and the solution is carried out by digital computer. Five examples are presented which demonstrate the versatility of the procedure in treating different shell configurations, as well as the accuracy of the results which may be obtained.

DTIC Accession No: ADA447741, Handle / proxy Url : http://handle.dtic.mil/100.2/ADA447741
ABSTRACT: The formulation of a fully compatible general quadrilateral plate bending element is described. The element is assembled from four partially constrained linear curvature compatible triangles, arranged so that no mid-side nodes occur on the external edges of the quadrilateral; thus, the resulting element has only 12 degrees of freedom. Also described is a simple shear distortion mechanism which may be incorporated into the element without changing its basic structure. Results are presented for static analyses with and without shear distortion, and for plate vibration and plate buckling studies, all performed with this quadrilateral element. It is concluded that this is the most efficient general bending element yet devised.

ABSTRACT: A brief review of the development of finite element procedures for the analysis of thin shells is presented, together with a discussion of the four types of approximations involved in the application of the method. Then two factors which influence the efficiency of the finite element solution are considered: the properties of the individual elements (including curvature, deformation refinement, etc.) and the nodal degree of freedom representing rotation about the shell surface normal. Comparative analyses are presented to illustrate the influence of these factors in practical cases. Finally, the formulation of the finite element system equations of motion is discussed and techniques of solution are outlined, taking account of both linear and non-linear classes of problems. A series of examples (both linear and non-linear) are presented which demonstrate the effectiveness and generality of this dynamic analysis technique.

ABSTRACT: An experimental investigation on the seismic response of ground-supported, cylindrical metal tanks is described. Experimental and analytical research by other investigators over the past forty years has provided a firm basis for the computation of free- and forced-vibration behavior in ideal liquid-filled circular cylindrical shells with a variety of elementary support conditions. However, the actual seismic behavior of ground-supported tanks has not been known, and practical design methods necessarily have been based on simplifying assumptions. The present results provide the first opportunity for rational evaluation of seismic design assumptions, and suggest theoretical developments which would enhance the realism of refined seismic analyses. The aluminum scale model discussed here, 12 ft in diameter and 6 ft high, represents a 36-ft diameter steel prototype. It was tested, in anchored and unanchored base configurations, under action of a time-scaled El Centro, 1940, earthquake with peak acceleration of 0.5 g, using the Earthquake Simulator Facility of the University of California, Berkeley. Stresses and displacements of the model, in both anchored and unanchored conditions, were dominated by effects of “out-of-round” response in higher-order circumferential modes, a result which is not predicted by current seismic analysis theory, and which contradicts basic assumptions of current design practice. The experimental observations are discussed in relation to dynamic analysis theory, practical design methods, and the history of tank performance in past earthquakes.

ABSTRACT: Equations are presented to describe the large deflection behavior of doubly curved shallow thin shells under nonuniform thermal loading. Approximate solutions are obtained by means of the Galerkin method for temperature distributions which a) vary over the surface of the shell and b) vary over the surface and linearly through the thickness of the shell. Load-deflection curves are plotted for simply supported shell panels. The results are used to study buckling and post-buckling behavior of the panels. It is shown, that the buckling temperature is a function of the sum of the curvature parameters, dimensions of the shell and its material properties.

ABSTRACT: The buckling stability analysis of long cylindrical shells with random imperfections subjected to axial load is treated using two different approaches. The first study is based on a Lyapunov method which enables one to establish sufficient conditions for buckling stability of a long cylindrical shell with axisymmetric random imperfections. A perturbed system of equations in the neighborhood of the prebuckling solution is investigated. By reducing the problem to a system of integral equations, it is observed that the stability boundary value problem of a long shell is similar to that of a dynamical system with random parametric excitations. Initial imperfections were assumed to have Gaussian distribution and an exponential cosine correlation function. The critical load was obtained as a function of the root mean square of the imperfections. Results obtained are qualitatively similar to those of Koiter for a periodic imperfection (Ref. 1). The second part is based on the approximate method of truncated hierarchy. The prebuckling state of equilibrium for asymmetric imperfections is found by a successive substitution technique. A homogeneous variational system of equations is set up in order to examine the existence of bifurcation in the neighborhood of the equilibrium state. These last equations involve random parametric terms. The truncated hierarchy method is applied and characteristic equations are obtained. Various exponential cosine correlation functions associated with asymmetric imperfections are examined numerically. Qualitatively the results obtained are as anticipated.

ABSTRACT: An experimental investigation of the effect of the cone semivertex angle alpha on the buckling load of a conical shell under axial compression was carried out. The effect of a specific type of initial imperfection was also investigated. The imperfection studied was axially symmetric in shape. The experiments were carried out with shells fabricated by a copper electroforming process. The shells had no longitudinal seams. Final results showed that the dependence of the buckling load on the semivertex angle alpha is adequately represented by the linearized theory. Also the upper bound to the experimental results of the cones with known axisymmetric initial imperfections agreed well with previously published analytical values.

ABSTRACT: An experimental and theoretical investigation of the effect of general imperfections on the buckling load of a circular cylindrical shell under axial compression was carried out. A non-contact probe has been used to make complete imperfection surveys on electroformed copper shells before and during the loading process up to the buckling load. The data recording process has been fully automated and the data reduction was done on an IBM 7094. Three-dimensional plots were obtained of the measured initial imperfection surfaces and of the growth of these imperfections under increasing axial load. The modal components of the measured imperfection surfaces were also obtained. The theoretical solution located the limit points of the post-buckled states. A simplified imperfection model was used consisting of one axisymmetric and one asymmetric component. For global buckling the correlation between the theoretical buckling loads and the experimental values was found to be good.

ABSTRACT: The results of an extensive imperfection survey on a 10-ft-diameter integrally stiffened cylindrical shell are presented. The shape of the measured initial imperfections is clearly influenced by details of the shell construction. The modal components of the measured imperfection surface as a function of the circumferential and of the axial wave numbers are calculated. The discrete axial power spectral density functions and the corresponding root-mean-square values of the imperfections are also determined for given circumferential wave numbers. Using the Fourier coefficients of the measured initial imperfections, buckling loads are calculated by solving the nonlinear Donnell-type imperfect shell equations iteratively. The calculated lowest buckling load compares favorably with the values usually recommended for similar shell structures.

J. Arbocz and C.D. Babcock, Jr., “The Buckling Analysis of Imperfection Sensitive Shell Structures” (Pamphlet), National Aeronautics and Space Administration, 30 pp, 1980
ABSTRACT: Several types of analyses used to predict the buckling behavior of imperfect Al shell structures are described. These analyses are used to study one well characterized stringer-stiffened cylindrical shell. The ability of each analysis to predict the actual experimental buckling load is examined. In addition, the information obtained from each analysis is used when proceeding to a higher level of analysis complexity. Based upon this study, a procedure for calculating a "knockdown" factor is proposed to replace the traditional empirical knockdown factor.

ABSTRACT: (none given)

SUMMARY: Despite decades of intensive research work most shells continue to be designed by the so-called Lower Bound Design Philosophy which has been in use since the turn of the century. It is shown that by collecting the data of extensive initial imperfection surveys on full scale structures in Initial Imperfection Data Banks improved design criteria can be developed. Especially the use of the Monte Carlo Method to derive reliability functions (based on measured initial imperfection distributions that are characteristic of the different fabrication processes), may finally provide the practicing structural engineers with a design procedure that incorporates the concept of imperfection sensitivity in a rational manner.

ABSTRACT: The effect of elastic end rings on the eigenfrequencies of thin cylindrical shells is studied by using an exact solution of the linear eigenvalue problem. The out-of-plane and torsional rigidities of the rings are responsible for the overall shell stiffness. Considerable mode interaction exists for modes with low circumferential wave numbers when the mass of the ring is comparable with that of the shell. The hypothetical simply supported and clamped boundary conditions are practically impossible to realize with a finite-mass ring for relatively short and thin shells.

ABSTRACT: A general form of perturbation analysis for discrete non-linear structural systems is presented. This generates a system of linear equations which can be solved sequentially for the path derivatives in the unloaded state. Each set of linear equations has the same basic non-singular matrix, and the method is thus ideally suitable for use with a digital computer. The general theory is illustrated firstly by an harmonic and secondly by a finite element analysis of a beam suffering large bending deflections, an exact beam formulation being employed and a continuum perturbation analysis being presented for comparison. The first seven path derivatives are evaluated and are observed to converge rapidly in each case to the continuum values which are then used to construct the load-deflection characteristic of the beam: the choice of independent variable in this final construction is seen to be highly significant. Good agreement is achieved with the known non-linear solution, and it is concluded that the perturbation analysis will be a useful tool in problems of moderate non-linearity.

ABSTRACT: A general perturbation theory for the branching analysis of perfect and imperfect discrete conservative structural systems is presented. Such systems are best analysed without resort to a scheme of diagonalization, and the absence of such a scheme distinguishes the present development from an earlier study by the author. The tensor notation and the system of sliding axes employed in that study are however of considerable analytical value and are therefore retained. The theory is presented for both a general and a specialized class of system and some general features of the perturbation scheme are established. For imperfect systems the concept of a spiralling eigenvector is introduced to yield the equations of imperfection-sensitivity explicitly in terms of the post-buckling derivatives of the perfect system and in a form that can be directly employed in numerical analysis.

ABSTRACT: The large deflection behaviour of a shallow circular arch subjected to a vertical point load is studied analytically using the Rayleigh-Ritz finite element method. The energy functional employed is a little more exact than that normally used for shallow arches and the functions used in the finite element method maintain continuity up to the second derivative of the normal displacement and up to the first derivative of the tangential displacement. The non-linear algebraic equations of equilibrium are solved to a high degree of accuracy using a Taylor's expansion technique together with the Newton-Raphson method. The stability of the symmetric deformation path is studied and a detailed analysis is carried out at the point of bifurcation to an asymmetric deformation path. The slope of this post-buckled path is computed and is shown to be accurate for deformations well beyond the point of bifurcation.

ABSTRACT: A general perturbation theory for the branching analysis of discrete conservative structural systems is presented. Such systems are best analysed without resort to a scheme of diagonalization, and the absence of such a scheme distinguishes the present development from earlier studies. The tensor notation and the system of sliding axes employed in earlier studies are however of considerable analytical value and are therefore retained. The theory is presented for both a general and a specialized class of system and some general features of the perturbation scheme are established. The application of the general theory to two branching problems is finally outlined and its merits discussed.

ABSTRACT: Bifurcation theories for the instability of slowly evolving systems have been developed in various disciplines, and a first step is here taken towards some desirable unification. A modern account of the authors' general branching theory for discrete systems is first presented, some new features being the introduction of principal imperfections and the delineation of the important semi-symmetric points of bifurcation. This theory, embedded in a perturbation approach ideal for quantitative analysis, is complementary to the far-reaching qualitative catastrophe theory of René Thom which offers a profound topological classification of instability phenomena. For this reason, we present here a detailed correlation of the two theories. Also presented in the paper is a survey of some fields of application ranging from classical fields such as hydrodynamics, through thermodynamics, crystallography and cosmology, to the newer domains of biology and psychology.

ABSTRACT: The classification of initial postbuckling behavior is known to be governed by the energy function of the critical equilibrium state, and this can be emphasized by viewing the load as a Lagrange multiplier in a constrained minimization. The energy of the critical branching point itself also uniquely determines the catastrophe theory classification of instability phenomena, and it is shown how a finer bifurcational classification arises when a load parameter, and hence an approach route in control space, is specified a priori. These ideas are illustrated for the compound, twofold, semisymmetric branching points with an examination of two pathological cases that have not been previously analyzed. The first of these is the degenerate situation typified by the rotationally-symmetric buckling of a complete spherical shell in which the load and engineering imperfections fail to fully unfold the topological singularity, and generate a trace of hill-top branching points. The second is the paracinal point of bifurcation (parabolic umbilic catastrophe) that forms the typical transition from a homeclinal to an anticlinal point of bifurcation, and represents an important practical problem in the interactive buckling of stiffened plates and shells.

ABSTRACT: The vibrations and stability of a thin cylindrical circular shell and a three-layered plate are studied. The structure is considered as a system with many degrees of freedom. This model permits investigations of the dynamic properties of the structure due to loads and temperature. An approximate solution of the wave problem is obtained.

ABSTRACT: A theoretical analysis of the buckling of a multilayered thin orthotropic composite circular cylindrical shell of finite length, subjected to (a) uniform axial compression, and (b) axial compression combined with radial pressure, is presented. At each end of the shell, four boundary conditions are satisfied. Four combinations of boundary conditions for simply supported shells, and four combinations of boundary conditions for clamped shells, are treated. These boundary conditions are reduced to the vanishing of a fourth-order determinant. Buckling loads for boron-epoxy composite shells are determined and the results are shown in a series of diagrams. The effect of boundary conditions on the buckling load for various geometrical dimensions of composite cylinders is investigated. Details of the boundary conditions are shown to have strong influence on the buckling load of the shell. The minimum critical axial compression for a simply supported shell with
boundary conditions SS1 is as low as 79 percent of the minimum critical axial compression for a shell with classical boundary conditions SS3. As a special case of a composite shell, the minimum critical axial compressive stress for a homogeneous, isotropic, simply supported shell with end conditions SS1 is found to be 43.7 percent of the classical critical stress.

ABSTRACT: The buckling of imperfection-sensitive elastic structures is examined from a statistical point of view. Given the relation between the imperfection and the buckling load, an account is given of the dependence of the statistical parameters of the critical load distribution upon the parameters of the imperfection distribution. It is shown that the statistics of the critical load distribution are highly dependent on both the mean and the dispersion about the mean of the imperfections. The question of the probability of failure at a specified nominal load, and its dependence on the degree of uncertainty of both load and imperfection, is also analysed. Numerical results are obtained on the basis of a normal imperfection distribution for two classes of structures, namely symmetric and asymmetric structures.

ABSTRACT: The erratic buckling behavior of cylindrical shells in axial compression is analyzed using the concept of equivalent imperfections. It is postulated that the sum of all departures from perfection in a real shell can be replaced by a hypothetical axisymmetric imperfection in a corresponding shell of infinite length. The equivalent imperfect is treated as a random variable with a normal distribution whose mean and variance are assumed to be directly proportional to the shell radius to thickness ratio. This leads to a design formula which is compared with the results of some 360 cylinder buckling experiments published elsewhere. An appropriate choice of proportionality constants yields a curve which gives a good lower bound on the experimental buckling loads over the whole range of radius to thickness ratios. An analogy is drawn between the Perry-Robertson strut formula and the one proposed here for cylinders.

ABSTRACT: Accurate equations for the neutral equilibrium of arbitrary elastic shells are derived. These equations involve no displacement components and thus complement alternate sets of neutral equilibrium equations proposed by Koiter and Budiansky. The equations are specialized to a uniformly loaded circular cylindrical shell and reduced to a single partial differential equation. For a simply supported cylindrical shell, expressions for the buckling loads are obtained which are as simple as those predicted by the Donnell equations, yet as accurate as those predicted by the more elaborate Flügge equations.

ABSTRACT: A non-linear shell theory valid for large displacements and finite strains is presented for thin homogeneous and elastic shells whose material exhibits curvilinear orthotropy, though it is subject to the restriction of the Kirchhoff hypothesis. By introducing certain simplifying assumptions of “orders of smallness”, approximate field equations are obtained for thin circular cylindrical shells. The equilibrium configuration of postbuckled states of isotropic circular cylinders under external lateral pressure is investigated with the aid of the basic equations derived above, and the results are compared with the solution due to the conventional large deflection theory.

ABSTRACT: The post buckling behavior of an axially compressed corefilled circular cylindrical shell is presented. The soft elastic core is represented by the Pasternak foundation model which is a Winkler foundation model with shear interactions. The Ritz energy method is employed to obtain the load-deformation relationship. The stabilizing effect of soft core on the buckling strength of shell is illustrated.

Koryo Miura (Institute of Space and Aeronautical Science, University of Tokyo), “Proposition of pseudo-cylindrical concave polyhedral shells”, University of Tokyo Report No. 442, November 1969

ABSTRACT: A proposition of a new shell form, which is cylindrical in a macroscopic sense and is concave polyhedral in a microscopic sense, is the purpose of this paper. It is shown that the inextensional post-buckling configurations of general cylindrical shells subjected to axial loading have peculiar geometrical characteristics, and that these configurations compose a general group of surfaces which may be designated as the pseudo-
cylindrical concave polyhedral surface. Then the fixed idea that these surfaces are essentially failed forms is abandoned and is replaced by the idea that these are the basic forms of a new shell which could function superbly as the structure under some loading conditions. It is shown that the new shell, which may be called for convenience, the pseudo-cylindrical concave polyhedral shell and the PCCP shell for its abbreviation, has many useful characteristics as follows: inclusion of an arbitrary curvature distribution, developability of its midsurface, intrinsically high circumferential bending rigidity, and simplicity of elementary faces. The application of PCCP shells to large span shell structures, reservoirs, expansion joints, and others is suggested.

ABSTRACT: Unidirectional boron/aluminum stiffeners have been used to save weight in stiffened panels, where the cross-sections were of such shapes as hats, rs, Z’s, channels, etc. The buckling analysis of these structures is usually found to be unconservative when tests are performed. Even so, a weight saving of approximately 50% can be achieved in the stiffeners themselves by replacing their metal counterparts. A no-edge-free crippling test was performed on a unidirectional boron/aluminum laminated plate, where collapse occurred at a compressive load considerably below the theoretical bifurcation buckling point. This premature failure is explained by a numerical analysis of the test by the use of a nonlinear computer code, which revealed the presence of high transverse bending stresses beyond the capacity of the composite.

ABSTRACT: The primary objective of the present work is to assess the effect of curvature upon the vibration frequencies of shallow shells. For this purpose, the shell is chosen to have a rectangular boundary supported by shear diaphragms and yields exact, closed form solutions for convenient comparison in the linear, small deflection regime and, at the same time, represents a situation which can readily occur in practical application. The shell is taken to have two independent radii of curvature, Rx and Ry whose planes are parallel to the edges. The linear eigenvalue problem is solved, both when tangential inertia is included and when it is neglected.
Extensive tabular and graphical results are presented which show the effect of curvature ratio $R_x/R_y$ in the interval $-1.5 < R_x/R_y < +1.5$ and the “average curvature” upon the frequencies. The analysis is extended into the non-linear, large deflection régime by assuming mode shapes and satisfying the non-linear field equations of motion and compatibility approximately by means of the Galerkin procedure. The effect of large deflections upon frequencies and phase plane plots as the curvature ratio changes is shown.

ABSTRACT: The differential equations which govern the vibrations with initial stresses of thin non-circular cylinders of arbitrary curvature are obtained by a variational approach. The initial stresses which are considered are stresses produced by axial loads, torsion, and normal pressure. The solution procedure is presented and numerical results are presented for the free vibrations of freely supported oval cylinders without initial stress. Frequency factors of oval cylinders are compared with those of circular cylinders as the length, thickness, and non-circularity are varied. The equivalence of the solutions for the free vibrations with and without initial axial stress is also established.

ABSTRACT: The paper describes external radial and hydrostatic pressure tests on 12 mild steel, thin-walled cylindrical shells. Radial deflections and surface strains on the inside and outside of the cylinders’ walls are related to the conventional small deflection theory. The elastic deformation patterns are found to be similar in shape to the lobar modes which can be predicted by elastic instability theory. The collapse pressures of the shells and their modes of failure are considered in relation to the rigid-plastic theory, the importance of initial imperfections is discussed and an attempt is made to relate the geometric and material properties of the cylinders to modes of failure and to appropriate collapse analyses.

ABSTRACT: Circular, thin-walled, steel tubes, with elongated, non-axisymmetric openings subjected to compressive, longitudinal load are examined. Thirteen laboratory tests are described in which careful measurements were made of displacements and strains. The tested specimens were in two geometrically dissimilar groups and their modes of failure were found to be different. In one group the free edges of the openings buckled before failure of the tube and in the other group large displacements at the free edges coincided with the reducing axial stiffness of the tubes. Two theories are proposed to explain these different kinds of behaviour and their predictions are compared with the experimental results.

ABSTRACT: A study was made to determine the mechanical behavior of boron-epoxy and S-glass-epoxy filament-wound cylinders under tensile, compressive, torsional, and pressure loads. These cylinders were fabricated in either an orthotropic winding pattern or an isotropic pattern. Conventional theory used to predict the elastic behavior of glass-epoxy filament-wound cylinders was discovered to be equally adequate for the boron-epoxy cylinders. Attempts to correlate cylinder failure strengths calculated from existing state-of-the-art theories with experimental failure strengths met with varying success.

ABSTRACT: This paper discusses a variety of experimental techniques used in the United States to characterize the static mechanical properties of filament-wound composites, such as used in vessels subjected to internal pressure. Also discussed are practical pitfalls to be avoided and the data reduction procedures necessary to reduce the test data. Properties covered include tension (flat, ring and tube specimens), in-plane shear (panel, off-axis tension, rail and torsion tube specimens) and multiaxial tension (plate and shell specimens).

ABSTRACT: A method of post-buckling analysis is described which is related to some work of W.T. KImage . Differences in starting data and objectives between this method and the author's recent general theory of equilibrium behaviour near critical points are pointed out. Some remarks are made about convergence difficulties which can arise when critical points are close together.

ABSTRACT: Previous work on mode interaction refers to a column model consisting of two equal flanges. This model is extremely sensitive to imperfection. Actual panel structures are unsymmetrical: the plate side has more cross section than the topside of the stiffeners; and the plate side is more affected by local buckling than the topside. This effect is exaggeratedly represented in a model where the stiffeners do not participate in local buckling. It appears that the sensitivity to imperfections of this model is very little and restricted to geometric parameters $R$ in the near vicinity of $R = 1$. These two models represent extreme cases. The position of actual tophat stiffened panels between these extremes is being explored. It appears that mode interaction is less severe than with the two flange model though still significant.

ABSTRACT: The implications of core shear deformations in the calculation of stresses, deflections and buckling loads are discussed in elementary terms. Simple criteria are given for the classification of panels according to the stiffness of the cores. Desirable attributes of good core materials are described.

ABSTRACT: The geometrically nonlinear analysis of elastic inplane oriented bodies, e.g. beams, frames and arches, is presented in a total Lagrangian co-ordinate system. By adopting a continuum approach, employing a paralinear isoparametric element, the formulation is applicable to structures consisting of straight or curved members. Displacements and rotations are unrestricted in magnitude. The nonlinear equilibrium equations are solved using the Newton-Raphson method for which a number of examples are given. The derivations are extended to include axisymmetric structures.

ABSTRACT: Using dimensions which are typical of current laboratory tubular specimens, critical buckling loads are determined for unidirectional and laminated cylinders subjected to torsion and to axial compression.
Buckling loads are obtained by using classical Fourier analysis in conjunction with Flugge's shell equations modified for anisotropic laminated materials. Comparison of buckling loads to composite strength, as estimated from maximum strain criterion, suggests that buckling is a potential problem in the use of tubular specimens. A relatively easy method for estimating buckling loads is also presented.

ABSTRACT: This report covers three topics in mechanics of advanced composites: effect of fiber cross-section on stiffness and strength of laminated composites; failure criteria for composites under combined loading; and stress analysis models for thick composites. In the area of fiber cross-sectional effect, micromechanics analysis addresses the effect of elliptical fibers on the stiffness and in-plane stress concentrations. Numerical results show that fiber cross-sectional geometry has only a modest influence on laminate elastic constants. The second topic addresses the interaction between longitudinal compression and transverse loading (tension and compression). Data obtained with a mini-sandwich beam are used to generate failure stresses. Classical lamination theory, including thermal residual stresses due to cure, is utilized for determining play stresses. Experimental results reveal little interaction between longitudinal compression and transverse stresses as long as the transverse load is below uniaxial transverse failure. Under the topic of thick composites, the effect of shear deformation and transverse normal stress on the cylindrical bending of laminated, anisotropic plates subjected to a uniform lateral load is investigated. closed form solutions indicate that the effect of transverse normal stress on maximum deflection is small, even for relatively thick plates.

ABSTRACT: On the basis of a statistical analysis of the test data it is shown that there is a difference between the mechanical characteristics (in tension and compression) of laminated glass-reinforced plastics obtained under laboratory and industrial conditions by impregnation under pressure in a closed mold. The stability of the strength properties of the glass-reinforced plastic in various conical shells, produced in large batches, is considered. Certain experimental relations between the material properties and the total number of shells produced are also established.

ABSTRACT: In the past, design of submarine pipelines has not taken full cognizance of the fact that such pipelines are structures and should be designed as structures. The submarine pipeline is, in fact, an extremely complex structure. It is much more complex than many larger and more impressive surface structures. Structural design considerations both during and after construction are discussed. The submarine pipeline is seen to function as a continuous beam, a beam on elastic foundation, a tension member, a compression member, a pressure pipe, an externally loaded conduit, and a suspension element. The system of loads on a submarine pipeline include gravitational, environmental, constructional and operational loads. These can be both static and dynamic. Additionally, when pipelines are buried, the loads from saturated and, in some cases, liquefied soils must be considered. This system of loading is very complex and involves environmental loadings that are extremely variable and location dependent. Recommendations are made for a systematic and rational approach to structural analyses which takes into account the individual nature of each submarine pipeline design problem. Areas where further research would be beneficial are also discussed.

PARTIAL INTRODUCTION: In a recent article [19], it was shown that the equations of the linear theory of elastic shells of revolution under arbitrary loads, after a harmonic analysis in the polar angle of the base plane of the shell, can be reduced to two simultaneous fourth order ordinary differential equations for a stress function and a displacement function. The exact reduction procedure of [19] was applied to a circular cylindrical shell. Also mentioned was the possibility of a simplified procedure based on the fact that there is an inherent error in shell theory of the order h/R, where h is the shell thickness and R is a representative magnitude of the two principal radii of curvature. In the present paper, the exact and the simplified procedure of [19] will be applied.
to a conical shell frustrum. The simplified procedure leads to two differential equations as well as to auxiliary equations for the calculation of stress resultants and couples which differ from those of the exact procedure only in terms which are O(h/R). . .

ABSTRACT: The character of the instability and the degradation of the moment-carrying capacity are found by Mylar model experiments for cylinders in bending when subjected to concentrated lateral loads. Lateral loads can seriously degrade the moment capability of cylinders. Critical combinations of moment and lateral load cause two distinct modes of failure—collapse and snapping. Collapse modes exhibit buckles which cover the compression half of the cylinder and are critical for large values of moment and small values of lateral load. Snapping modes of failure involve a single dimple and exist for smaller values of moment and larger values of lateral load.

ABSTRACT: An infinitesimal theory of instability of an elastic orthotropic shell of revolution subjected to uniform external normal pressure is developed. The theory leads to a linear eigenvalue problem for determination of the buckling pressure. Illustrative numerical calculations based on piecewise-polynomial approximations and the partition method are given for the Fort Martin tower erected in West Virginia by the Marley Co. The tower is a reinforced concrete hyperboloidal shell of revolution, 370 ft. high and 5.5 in. thick for most of its height.

ABSTRACT: A compressive test specimen has been developed for unidirectional carbon fibre reinforced plastics which enables the ultimate compressive strength to be determined. Failure occurs remote from the specimen ends and tests show good repeatability. Results are compared with theory and reasons for the differences are discussed.

ABSTRACT: Recent developments in the application of reticulated or shell-type construction are presented. Five general methods of analysis are given: (1) the stiffness approach; (2) continuum shell analogy; (3) concepts of discrete field mechanics; (4) split rigidity concepts; and (5) the use of models. Analysis, member loading, physical properties, edge effects, general buckling, and local buckling of domed structures are described. Equations and computer methods that have been used in the design of domed reticulated space structures are given. Suggestions are made for future research and development for these types of structures.

ABSTRACT: The problem of buckling of curved shear panels of corrugated sheets, which is encountered in the design of long shells is examined theoretically. Overall panel buckling, and not local buckling, is analyzed. Thus, the corrugated sheets are treated as orthotropic curved plates. Equilibrium conditions, as well as geometric and elastic relations of a deformed infinitesimal element, are governed by two linear simultaneous coupled differential equations in deflection w and stress function F. Series presentation for w and F yielded a set of homogeneous linear algebraic equations in the unknown deflection coefficients. A nontrivial solution of these equations is possible provided that the determinant of their matrix is equal to zero. The eigenvalues of the shear load are calculated and only the lower value is considered. The few experiments available show reasonable agreement with the theoretically obtained ones. For practical use, curves are given for the calculation of critical shear load.

ABSTRACT: The overall buckling of half-barrel shells made of corrugated steel sheets is studied in this paper. This type of buckling is recognized as a prime factor in defining ultimate load carrying capacity of such shells. The mathematical formulations are based on the linear theory or orthotropic cylindrical shells. The stability conditions are governed by two linear simultaneous differential equations in the deflection and a stress function. The series presentation of the deflection and the stress function yield a set of homogeneous linear simultaneous algebraic equations in the unknown deflection coefficients. The eigenvalues of this system are calculated with different load distributions representing the cases of snow and wind loads, as well as combined loading. Note that the magnitude of critical load as well as the mode of buckling are dependent on the ratio of length to radius of shell and the ratios between the rigidities in the longitudinal and circumferential directions.

ABSTRACT: Cylindrical shells made of cold formed deep profiles or corrugated steel sheets are analyzed, using the theory of orthotropic shells. The governing equations and solution are modified to correct a deficiency of a previously reported solution, especially for shells supported along their four edges. Improved solutions are obtained by: (1)Accounting for the effect of the transverse shear forces on the condition of equilibrium in the
radial direction; and (2) applying a particular solution that satisfies the governing equations. The modified solution is valid for long shells and converges to that of simple arches with the increase of length of the shell. Also, an experimental program is undertaken and the comparison shows good agreement between the theoretical and experimental results.

ABSTRACT: An incremental variational method is presented for the determination of the inelastic load-deformation relationship, as well as buckling or collapse load for a shell of revolution which is made of a work-hardening material and subjected to axisymmetric loadings. A variational principle involving Kirchhoff stress tensor, Green strain tensor, and their rates is employed. The isothermal stress-strain relationship based on a modified J2 incremental theory of plasticity is used. The finite difference method of variational calculus is utilized in a numerical procedure to determine discrete velocities and subsequent deformation process. A comparison of the buckling loads of a number of elastic conical shells and inelastic cylindrical shells obtained by the present approach with available experimental results is made. A reasonable agreement is found.

ABSTRACT: Buckling of open cylindrical shells with free longitudinal edges and simply supported ends, subjected to an axial compression, with imperfections due to end eccentricity or initial deflections, is examined. Field equations based on large deflection theory are reduced to a set of nonlinear finite difference equations and a computer technique for solving this set by the Newton-Raphson method is presented. Equilibrium paths and deflection patterns for examples with three types of imperfections (constant end moment, constant end eccentricity and specified initial deflection) are presented. The equilibrium paths exhibit an asymmetric type of postbuckling behavior; that is, negative imperfections which initially cause the shell to deflect outward would cause a buckling load lower than the linear buckling load without imperfections; whereas, positive imperfections would cause the opposite if there is no external disturbance. The behavior of a shell with Poisson’s ratio $\nu$ not equal to 0 and circumferential displacement equal to zero at the ends, is similar to a shell with negative imperfections since the axial compression would induce an outward (negative) displacement.

ABSTRACT: A technique for obtaining the buckling load of open cylindrical shells with simply supported ends and free longitudinal edges, subjected to lateral gravity loading, is presented. General equations based on
the large deflection theory are developed and a set of nonlinear finite difference equations is obtained and solved by the Newton-Raphson method. Using the linear terms only, deflections and stresses based on relatively coarse nets compared favorably with existing analytical solutions. The lowest nonlinear buckling load was found to be associated with a deflection pattern symmetric about the transverse centerline, but asymmetric about the longitudinal centerline. In an example, equilibrium paths and deflection patterns were obtained for a shell subjected to uniform load, and to uniform load with a small additional antisymmetric load. The lowest buckling under uniform load was obtained by reducing this additional load to zero. For the example examined, the buckling load was about 1/2 of the classical linear buckling pressure of a full cylinder.

ABSTRACT: Koiter's approach is used to formulate the influence of fiber orientation on the behavior of the cylindrical shell in the initial postbuckling region. Results are presented for three-layer composite cylindrical shells of either glass-epoxy or boron-epoxy subjected to uniform axial compressive load. The results show that the initial postbuckling coefficient that characterizes the extent of imperfection sensitivity of a structure is greater for the glass-epoxy shells than for the boron-epoxy shells. For the glass-epoxy cylinders the slope of the load vs. end-shortening curve in the initial postbuckling region is found to have high negative value, which is not significantly affected by the change in fiber orientation. This suggests that the buckling of a nearly perfect glass-epoxy cylinder under prescribed end-shortening will be catastrophic, regardless of fiber orientation. However, for the boron-epoxy cylinders the negative slope varies with the change in fiber orientation, and whether the failure will be catastrophic or not will depend on the fiber orientation.

INTRODUCTION: The safe design of a circular cylindrical shell structure subject to hydrostatic pressure and axial compression necessitates the determination of the loads which will produce elastic instability of the structure. There are two important modes of elastic instability to consider--local and general instability. Local instability is characterized by inward-outward dents which form on the shell surface in contrast to an overall collapse of the entire shell when general instability occurs. Failure by general instability is usually catastrophic and hence it is of primary concern. Analyses of perfect shells for general instability loads based on the solution of the governing differential equations are well known [21,23]. However, experimental tests on circular cylinders subject to hydrostatic pressure or axial compression loads show that in many instances the failure strength is 15 to 60 percent less than that predicted by theoretical analysis. The difference in analytical and theoretical results is attributed to geometrical and material imperfections of the test cylinders. Several empirical and semi-empirical modifications of the theoretical analysis have been proposed in order to gain better
correlation between analytical and experimental results [7,11]. No general method, however, exists to account for the various types of imperfections when applied to a perfectly general problem. Accounting for geometric imperfections, especially out-of-roundness, complicates the analytical solution, because the cylinder no longer can be treated as circular, but takes some other form such as an ellipse. The finite element method of analysis has been used recently to predict the elastic instability load of perfect cylinders and can be used to account for geometrical imperfections as well. However, care must be taken in choosing the type of finite element used or complications will arise in defining the character of the out-of-roundness and a large set of simultaneous equations will be required for the solution.

ABSTRACT: Koiter's approach to the analysis of load-displacement behavior in the neighborhood of a bifurcation buckling point is adapted to permit the analysis of behavior in the neighborhood of the buckling point for a structure that exhibits snap-through buckling. The essential concept is the consideration of pre-buckling nonlinearities as generalized initial imperfections of a derived perfect structure called the modified structure. The asymptotic character of Koiter's approach is preserved in this modified structure method of analysis. The development is stated in a functional notation and is then discretized into a matrix procedure based upon finite element idealization. Numerical results are presented for the load-displacement behavior of a circular arch.

ABSTRACT: The movement of the elements of a shell during the instability, i.e. during the “snap”, is subject to the general principles of mechanics, in particular, to the principle of the least constraint (the Gauss principle).

ABSTRACT: (Cannot cut and paste)

ABSTRACT: Since Kármán and Tsien [1] treated the buckling of cylindrical shells under axial compression, introducing the nonlinear theory based on the finite deformation, this problem has been improved and enlarged by the cumulative efforts of subsequent investigators [2 to 6] and the large discrepancy between the experimental buckling values and the classical value has been gradually clarified. In almost all the previous analyses, cylindrical shells are assumed to buckle in a periodic pattern over the whole surface, but localized diamond-shaped buckling patterns have usually been found. Apart from some analyses on local buckling very close to the ends resulting from the end constraint, Yoshimura [4] and Hoff [7] treated the two-tier buckling,
taking into account only the two tiers of periodic undamped waves. The difficulty encountered in such a local buckling is that the deflected shape is not exactly polyhedral. In this paper, the author will attempt to clarify the mechanism of the above-mentioned local buckling. The method of solution employed is based on the stationary principle of energy.

ABSTRACT: This paper deals with the buckling of a shallow spherical cap subjected to uniform edge moment and a clamped deep spherical shell under uniform pressure. The first problem is formulated in integral equations which are solved by an iterative procedure. The buckling moments are determined for a wide range of the shell geometrical parameter. The second problem is based on the concept that the highly deformed region around the apex is treated as a shallow spherical cap elastically supported by the rest of the shell. The stability of a thin sphere is treated as a special case. The results obtained in both problems are compared with existing solutions.

ABSTRACT: The transfer matrix method is extended to the analysis of non-circular cylindrical panels. The exact solution for the transfer matrix of a panel with exponential curvature is obtained by solving exactly the variable coefficient differential equations of motion of the shell using a Laplace transform—difference equation technique. The results are compared with respect to accuracy and computer time with various approximate methods of computing the transfer matrix for the same panel. Natural frequencies and mode shapes for typical non-circular panels are computed and compared with a constant curvature panel to show the effects of variable curvature.

ABSTRACT: A method of calculating the creep deflections and predicting the creep collapse of a thin-walled circular cylindrical shell, subject to uniform external radial pressure and arbitrary temperature gradients, is shown. This method may also be applied to investigate the behavior of a shell subject to time-dependent temperature gradients and deformations due to other inelastic causes. The set of simultaneous differential equations of equilibrium in terms of creep, thermal, and other inelastic strains is presented. Applications of this method to long cylindrical shells are illustrated by two numerical examples.

ABSTRACT: The snap-buckling instability of shallow shell-type structures that are subjected to a random transverse load is presented. The deformation of the structure is primarily under a symmetric and an antisymmetric mode and the investigation employs a method initially proposed by Kramers in the theory of kinetics of chemical reactions and later adapted by the present authors for the case of symmetric snap-through of shallow, two pinned arches. Analytical expressions are derived for the probability of snap-buckling in a time interval T in terms of the potential energy functions in the neighbourhood of the stable and unstable equilibrium states of the structure.

ABSTRACT: The relation of initial imperfections to the postbuckling behavior of thin-walled shells is explained, commencing with treatment of the cylindrical shell under external hydrostatic pressure. It is shown that from theoretical studies of the postbuckling behavior of perfect cylinders a lower bound for the scatter region of the buckling loads can be determined. Approximate buckling loads of imperfect cylinders are calculated, utilizing measured initial imperfections. In studying cylinders under axial load, theoretical and experimental postbuckling curves show good agreement, and a lower limit for the scatter region of the buckling loads can be determined from postbuckling investigations of perfect cylinders.

Glockner, “Experiments on the stability of spherical and paraboloidal shells” (The experimental part of an investigation of the elastic stability of clamped and hinged spherical and paraboloidal thin shell caps subjected to external uniform pressure is discussed by the authors), Experimental Mechanics, Vol. 11, No. 6, 1971, pp. 254-262, doi: 10.1007/BF02329036

ABSTRACT: This paper presents the experimental part of a study of the elastic stability of clamped and hinged spherical and paraboloidal shell caps subjected to external uniform pressure loading. Ninety-six poly-vinyl-chloride (PVC) shells of 15-in. base diameter and formed by thermovacuum process, were tested and their critical loads recorded. The effects of geometry, clamped and hinged boundary conditions, height/span and radius of curvature/thickness ratios on the critical pressure were investigated. The results are compared, where possible, with experimental data obtained by previous investigators.

ABSTRACT: This paper describes experiments carried out in a 17 in air-driven shock tube on polyvinyl-chloride (PVC) plastic shells. This series represents the preliminary phase of an experimental programme designed to study the non-linear dynamic response of such shells to blast waves. In addition to testing eight clamped models of identical geometry, a resin/plywood dummy model of the same configuration was subjected to shock waves in order to determine the pressure time-map over the surface. However, this dummy was found
to be too flexible for pressure calibrations and was subsequently redesigned. Pressures, deflections, and strains were recorded by means of pressure transducers, capacitance displacement transducers and strain gauges. In addition, photographic and video recording were used to monitor the deformation of the shells. The data obtained are presented in graphical form. Emphasis in the paper is given to a detailed description of the experimental techniques and procedures used.

ABSTRACT: This paper describes a series of experiments carried out in the six-foot diameter explosive-driven shock tube of the Defence Research Establishment Suffield (D.R.E.S.) on polyvinylchloride (PVC) plastic shells. The object of the program was to acquire data on the dynamic large-deformation behaviour of shells subjected to simulated blast waves. Spherical and paraboloidal shells with hinged or clamped boundaries, representing a total of 32 different geometries, were tested. In addition, pressure calibration shots were carried out on dummy models designed to simulate the various geometries of the shells. Shock wave pressure and velocity, as well as the deformation of the models were monitored and recorded by means of high-speed and television cameras. Results are presented in tabular, graphical and photographic form.

ABSTRACT: Non-linear snap-through behavior of a thin concrete shell roof characterized by free edges, or free edge members supported by several columns, is considerably influenced by the boundary conditions and the edge disturbances developed in the prebuckling state. This paper presents a method of realizing all four natural boundary conditions along a free edge of a roof shell model subjected to external pressure. The experimental method is shown to be useful for investigating non-linear behaviour of circular cylindrical roof shell models with free generator edge beams. The method has a wide applicability to a variety of roof shell models with free edge members lying on a horizontal plane.

ABSTRACT: The free vibration characteristics of a singly curved rectangular plate have been obtained by four theoretical methods and compared with experimental results. The variations of a non-dimensional frequency parameter with aspect ratio, a thickness parameter, curvature and fuselage pressurization are indicated.

ABSTRACT: The creep-buckling phenomenon of circular cylindrical shells subjected to axial compression is studied in the presence of initial imperfections when the creep strain rate is proportional to a power of the stress with the exponent greater than unity. A closed-form solution is obtained for the critical time; that is, for the finite time at which the analysis predicts the development of indefinitely large displacements.

C. L. Dym, N. J. Hoff (Department of Aeronautics and Astronautics, Stanford University, Stanford, Calif.), “Perturbation Solutions for the Buckling Problems of Axially Compressed Thin Cylindrical Shells of Infinite or Finite Length”, Journal of Applied Mechanics, Vol. 35, No. 4, pp. 754-762, December 1968, DOI: 10.1115/1.3601301

ABSTRACT: A study is presented of the effect of initial deviations on the load carrying capacity of thin circular cylindrical shells under uniform axial compression. A perturbation expansion is used to reduce the nonlinear equations of von Karman and Donnell to an infinite set of linear equations, of which only the first few need be solved to obtain a reasonably accurate solution. The results for both infinite shells and shells of finite length indicate that a small imperfection can sharply reduce the maximum load that a thin-walled cylinder will sustain. In addition, for a particular set of boundary conditions, it is shown that the effect of the length of a finite shell is small as far as the load carrying capacity is concerned, but significant when the number of waves around the circumference has to be determined. A further result of the study is that axisymmetric initial deviations reduce the load carrying capacity only slightly more than deviations characterized by a product of trigonometric functions of the axial and circumferential coordinates if the wave lengths are properly chosen.

ABSTRACT: The dynamic response of an initially imperfect circular cylinder to a load applied with constant velocity is considered. It is shown that the governing equation is essentially the same as the non-linear equation given by Hoff for the dynamic buckling of columns.

ABSTRACT: The report treats the buckling and postbuckling behavior of circular arches and rings under constant directional pressure. New exact and approximate solutions are given for the linearized eigenvalue problem. It is clearly demonstrated that the assumption of inextensibility is quite reasonable for the asymmetric buckling of steeper arches and of rings. Asymptotic analyses of early postbuckling behavior are given, based on the theory of Koiter and the formalism of Budiansky and Hutchinson. The postbuckling behavior is shown to be stable, and unaffected by the assumption of inextensibility.

ABSTRACT: The bifurcation buckling and postbuckling behavior of steep, compressible, circular arches is examined. The arches are loaded with a uniform constant directional pressure and may be either pinned or clamped. The development is based on Koiter's theory. Two different arch theories are used so as to facilitate a study of bending in the prebuckling state. It is shown that clamped arches are always unstable after bifurcation, while pinned arches exhibit a transition from unstable to stable behavior as a semi-circular arch is approached. The results are also compared to results obtained using shallow arch theory and the comparison is reasonably good for moderately steep arches. The effect of middle surface extensibility (compressibility) and of the prebuckling bending is virtually undetectable.

ABSTRACT: The purpose of this study is the evaluation of the effects of curvature, material orthotropy and internal pressure upon the non-linear vibrations of shallow shells. The shells considered here are complete in the circumferential coordinate. A mode shape that leads to a continuous circumferential displacement is used as the basic solution in a Galerkin type procedure. Among the results of interest are the effects of the aforementioned physical parameters on the relative hardness of the shell response, as well as some interesting new perspectives on jump phenomena in non-linear shell vibrations.

ABSTRACT: The buckling of integrally external ring-stiffened conical shells under axial compression was investigated experimentally. Experimental results were compared with theory to find the effect of the stiffener parameters (e 2 /h), (A 2 /a 0 h) and (I 22 /a 0 h^3 ) as well as of shell geometry. Agreement between classical linear theory and experiments was found to be governed primarily by the area parameter (A 2 /a 0 h), and correlation with theory was significantly affected in the range 0.1<(A 2 /a 0 h)<0.5 of that parameter. Beyond this region there is practically no improvement with increase in ring area, whereas the weight of the shell continues to increase linearly. An approximate formula is proposed for calculation of critical loads and found to yield results very close to the more exact critical values calculated by linear theory. A modified “Southwell plot” method was applied and both the intercept method and slope method were used. Critical loads computed from the strain records were found to be below the classical linear-theory predictions and closer to experimental ones.

**ABSTRACT:** The effect of in-plane boundary conditions on the buckling of ring-stiffened cylindrical shells is studied. As in the case of unstiffened shells, the 'weak' in-plane boundary conditions SS1 and SS2 yield here critical loads about one half of the 'classical' loads. It was observed that the SS1 critical loads are identical with the SS2 loads and the SS4 loads are almost the same as the 'classical' SS3...
loads. The combined effect of stiffener parameters and in-plane boundary conditions is studied. For internally stiffened shells the influence of in-plane boundary conditions is found to diminish with increasing values of stiffener eccentricity and area. No such effect is observed for externally stiffened shells. The buckling modes are also studied and found that they are dependent upon shell length (or Z) and upon stiffener location and parameters.

ABSTRACT: Theoretical and experimental research on the buckling of stiffened and unstiffened cylindrical and conical shells, and arches and rings carried out over a period of 2 years in the Department of Aeronautical Engineering is summarized. The topics of earlier work are outlined and the more recent topics are summarized. These include: the influence of in-plane boundary conditions for stringer and ring-stiffened cylindrical shells; extensive tests on integrally stringer-stiffened and ring-stiffened cylindrical shells under axial compression; thermal buckling of cylindrical shells; a collocation method for buckling analysis of elastically restrained conical shells; buckling of cylindrical panels under non-uniform axial compression; and instability of closely ring-stiffened conical shells.

References listed at the end of the report:
ABSTRACT: An experimental study of the buckling of closely spaced integrally stringer-stiffened cylindrical shells under axial compression was carried out to determine the influence of shell and stiffener geometry on the applicability of linear shell theory. 38 specimens fabricated from 7075-T6 aluminum alloy with different geometries were tested. Most test specimens were designed to fail in general instability and under low critical stresses to assure elastic buckling. Agreement of experiments with linear theory was found to be governed primarily by the stringer area parameter, \((A_1/bh)\) and the shell geometry parameter, \(Z\). Values of linearity, \(\rho\), (ratio of experimental buckling load to the predicted one) higher than 80% were obtained in the ranges \(Z > 100\).
and \((A_{1}/bh) > 0.5\) and a clear trend towards \(\rho = 1\) was observed with increasing values of these parameters. Correlation with linear theory was also found to be influenced by panel unstable postbuckling behavior.

T. Weller and J. Singer, “Further experimental studies on buckling of integrally ring-stiffened cylindrical shells under axial compression”, (Tests were carried out to verify the results of previous investigations and to establish a lower bound for applicability of linear theory), Experimental Mechanics, Vol. 14, No. 7, 1974, pp. 267-273, doi: 10.1007/BF02322830

ABSTRACT: An experimental study of the buckling of closely spaced integrally stiffened cylindrical shells under axial compression was carried out to determine the influence of shell and ring geometry on the applicability of linear theory. Twenty-nine specimens fabricated from 7075-T6 aluminum alloy with different geometries were tested. Test specimens were designed to fail in general instability and under low critical stresses to assure elastic buckling. Agreement of experimental results of the present study, and of those obtained in other studies with linear theory was found to be governed primarily by the ring area parameter, (A 2 /ah). Values of “linearity” rho (ratio of experimental buckling load to the predicted one), higher than 80 percent were obtained for (A 2 /ah)>0.3 and a clear trend towards rhov=1 was observed with increasing values of this parameter. Correlation with linear theory was also found to be influenced by ring spacing, (a/h), or rather the combination (a/h) [1+(A 2 /ah)] to the −1/2 power. No significant effect of shell and other ring parameters on the correlation with linear theory could be discerned for the shells tested. By a conservative structural-efficiency criterion it was observed that only for low values of the area parameter, (A 2 /ah)< approximately 0.5 ring-stiffened shells are more efficient than equivalent-weight isotropic ones. Highest efficiencies are obtained for (A 2 /ah) approximately equal to 0.2.

ABSTRACT: Theoretical and experimental studies on the influence of boundary conditions on the buckling of stiffened cylindrical shells and their vibrations are discussed. The effect of prebuckling deformation on the buckling loads and vibrations of stiffened shells is studied and compared with that in the case of unstiffened shells. The in-plane boundary conditions are found to be of particular importance for stiffened cylindrical shells and their effect differs significantly from that in unstiffened shells. Axial restraints are found to be of prime importance in stringer-stiffened shells, and therefore the effect of elastic axial restraints is also studied. By correlation with the vibration tests on the same shells a method is developed for definition of the actual boundary conditions of a stiffened shell non-destructively. The effect of eccentricity of loading on stringer-stiffened shells is studied experimentally and correlated with vibration tests on the same shells. Preliminary results of a non-destructive experimental method for prediction of buckling loads based on vibration testing of stiffened shells are also presented.

ABSTRACT: A theoretical and experimental investigation of the vibrations of axially loaded stiffened cylindrical shells is presented. In the theoretical study three sets of equilibrium equations and boundary conditions are derived from the Donnell and Flügge theories. These sets are solved in a manner usually referred, to as the “exact method”. In the experimental study seven different clamped cylindrical shells, stiffened by outside stringers or rings, were tested. The experimental investigation included frequencies and mode shapes. Good agreement was achieved between experiments and theory, and the predicted differences between the different types of shells were verified.

ABSTRACT: The influence of eccentricity of loading on the vibrations and buckling of stringer-stiffened shells is studied. An established nonlinear theory, which takes into account nonlinear prebuckling, is applied and the predictions are compared with experimental results. Two families of shells, one isquioheavilyrsquo stiffened and the other isquomoderatelyrsquo stiffened, were tested but detailed results are presented only for the isquioheavilyrsquo stiffened shells. In each family there are three identical shells, each with different eccentricity of loading. In all cases, different in-plane-boundary conditions are considered and correlated with experimental results.

ABSTRACT: A theory is derived for calculation of the influence of elastic edge restraints on the vibrations and buckling of stiffened cylindrical shells. The stiffeners are considered “smeared” and the edge restraints can be axial, radial, circumferential or rotational. Extensive computations are performed for special kinds of stringer-stiffened shells, and the theoretical predictions are compared with experimental results. A method of definition of equivalent elastically restrained boundary conditions by use of vibration tests is discussed. Application of this technique to tests on 10 shells significantly reduces the scatter in the ratio of experimental to predicted buckling loads.

ABSTRACT: An experimental study of the buckling of closely spaced integrally stringer-stiffened circular cylindrical shells under axial compression was carried out to determine the influence of stiffener and shell geometry, as well as mechanical properties of shell material, on the applicability of linear theory. Tests included 84 shells made of two different kinds of steel with completely different mechanical properties and 74 shells made of 7075-T6 Aluminum alloy. Agreement between linear theory and experiments was found to be governed primarily by shell geometry, Z, where for Z > 1000 values of “linearity” (ratio of experimental buckling load to the predicted one) of 70 percent and considerably above were obtained. Correlation with linear theory was also found to be affected by stringer area parameter (A1 /bh) where for (A1 /bh) > 0.45 the values of linearity obtained exceeded 65 percent and usually were much higher. No significant effect of other stiffener and shell parameters on the applicability of linear theory could be discerned for the specimens tested. The boundary conditions were found to be of importance and for some steel shells the inelastic behavior of the shell material was found to have a considerable effect on the linearity. Predictions of imperfection sensitivity studies could not be correlated with test results. By a conservative structural efficiency criterion all the tested stringer-stiffened shells were found to be more efficient than equivalent weight isotropic shells.

ABSTRACT: The influence of in-plane boundary conditions on the critical loads of axially compressed simply supported stiffened cylindrical shells, stiffened by stringers and by combinations of rings and stringers is studied. It is observed that the axial restraint, u = 0, at the edges and the dimensions of either the stringers or the rings characterize the type of influence experienced. In shells stiffened by medium and heavy stringers the axial restraint is a predominant factor and the weak in shear, Nxphi = 0, B.Cs. have only a slight secondary effect. For such shells a stiffening effect is observed for SS2 and SS4 B.Cs. As the stringers become weaker the influence of the axial restraint diminishes and the isotropic or ring-stiffened like type of behavior, sensitivity to the vanishing of the circumferential restraint, overtakes the stiffening effect due to u = 0. In shells stiffened by combinations of rings and stringers the influence of the in-plane boundary conditions is governed by the relative
magnitudes of the rings and stringers under consideration. Combinations of heavy stringers and weak rings behave like stringer-stiffened shells, exhibiting the stiffening effect due to $u = 0$ whereas shells stiffened by heavy rings and light stringers tend to behave like ring-stiffened shells, revealing their sensitivity to the weak in shear boundary conditions, $N_{\phi} = 0$.

Eduard Riks (Department of Aeronautics and Astronautics, Stanford University, California, USA), “The Influence of Periodic Axisymmetric Imperfections of Various Wavelengths on the Buckling Load of a Cylindrical Shell in Axial Compression”, March 1971, (un-numbered report in the DTIC citation), DTIC Accession Number: AD0747061

ABSTRACT: Koiter's well-known buckling analysis of cylindrical shells with periodic axisymmetric imperfections yields a solution which is valid for imperfection of different wavelengths and amplitudes. Numerical calculations were carried out to evaluate several of these cases. Of particular interest are imperfections of the wavelength which are larger than the one considered in Koiter's original analysis. In such cases, the validity of the solution may be extended to imperfection amplitudes of a much larger order of magnitude hitherto considered. The numerical results are plotted and tabulated. A rederivation of Koiter's analysis is added in an appendix together with a brief description of the computational method that was used.

ABSTRACT: A completely forgotten paper by C.T. Wang on the extension of the Southwell plot to inelastic buckling of columns is revived, rederived and amplified. A theoretical justification is presented for the application of the Southwell method to plastic buckling of columns made of a strain-hardening material, showing that it predicts the double (or reduced) modulus buckling load. Typical experimental verifications are recapitulated. This puts practical applications of the Southwell method in the plastic region on firmer ground.

References listed at the end of the paper:

ABSTRACT: An asymptotic integration technique is developed to describe the post-buckling behavior of thin elastic shells. The introduction of slow space and time scales directly into the shell differential equations permits a modeling of dynamic effects and a means of accounting for finite boundaries. In most cases, quadratic nonlinear interactions dominate the dynamics and lead to hexagonal shaped patterns in the buckled shell. The form of the initial imperfection is crucial in determining the critical buckling load, as, for a given plan form, there are two separated branches in the load-displacement curve. The critical points on each branch occur at different values of the load parameter. Finally, a minimal principle is derived which exhibits the consistency of the present approach with the variational procedures of Koiter and others.

ABSTRACT: The work of Ashwell and Sabir [1] assessing the power of curved finite elements by applying them to circular arches, is extended. An element I based on the cylindrical shell element of Bogner et al. [3] converges satisfactorily for deflexions, for all arch types, but is inferior to a new element II based on simple strain functions. A natural (“exact”) shape function is also presented. When stress resultants are calculated, both I and II converge rapidly if the stress resultants are calculated from an element stiffness matrix, but are sometimes unsatisfactory (except for mid-element stress resultants) if a normal type of stress matrix is used. Element I becomes unsatisfactory if nodal continuity of the gradient of circumferential displacement is imposed.

ABSTRACT: Gradient minimization methods have been successfully applied to the discrete element analysis of shells with geometric nonlinearities and to plates with material nonlinearities. More recently, the feasibility of using such methods for the lower buckling and vibration modes of large eigenproblems has been established. The present investigation extends this work by developing scaling criteria and rescaling strategies based on the second variation of the discretized Rayleigh quotient. The importance of scaling to the efficiency of the conjugate gradient algorithm is found to be similar to that reported for potential energy minimization. Several shell vibration and shell buckling problems are then analyzed using the 48 degree of freedom Bogner cylindrical panel element reformulated to include an incremental stiffness matrix. This element is based on bicubic Hermite polynomials for which discretization error bounds indicate rapid eigenvalue and eigenvector convergence in certain elliptic boundary value problems. These convergence rates are numerically tested in both shell buckling and vibration eigenproblems.

ABSTRACT: NASTRAN is a large digital computer program for static and dynamic structural analysis by the finite element approach. It is nearing completion after three years of development under NASA sponsorship. It will be made available to all interested users and it will be maintained by NASA. It is currently programmed for the IBM 360, the UNIVAC 1108, and the CDC 6600 computers. The major functional capabilities of NASTRAN are static analysis of structures with either linear or nonlinear material properties; buckling analysis; vibration modes analysis of either conservative or damped systems; frequency response analysis; and transient response analysis. Many convenience features are provided to the user including an extensive list of structural elements; the automatic generation of several types of loads including gravity loads and loads induced by thermal strains; plots of deformed and undeformed structures; and the choice of alternate methods of analysis, including, for example, either direct or modal formulations of dynamic problems. NASTRAN is intended primarily for large problems with hundreds or thousands of degrees of freedom. All mathematical subroutines have been designed to provide for the efficient solution of large problems by taking maximum advantage of matrix sparsity and bandedness. A flexible Executive System is provided that facilitates the addition of new functional capabilities to NASTRAN.

ABSTRACT: The paper describes a new four-noded quadrilateral shell element, called QUAD4, which is based on isoparametric principles with modifications which relax excessive constraints. The modifications include reduced order integration for shear terms, enforcement of curvature compatibility, and the augmentation of transverse shear flexibility to account for a deficiency in the bending strain energy. Practical features are discussed, including conversion to a nonplanar shape, coupling between bending and stretching, mass properties, and geometric stiffness. Experimental results are described which illustrate the accuracy and economy claimed for the element.

ABSTRACT: The subject is treated chronologically and in a manner which emphasizes the background for design decisions, including examination of the roles of element testing and failure analysis. The elements treated are the original nastran elements, the quad4, and the tria3, together with their modifications. The quad4 element, in particular, has become a much better element than its 1976 prototype through the process of evolutionary reform in response to weaknesses revealed by practical application.

ABSTRACT: The powerful technique of parametric differentiation is illustrated, coupled with numerical integration schemes for solving highly nonlinear problems in shell stability. As an example, the axisymmetric buckling pressures of clamped spherical shells of constant thickness, under external pressure are obtained. The application of this technique to the study of postbuckling behavior is demonstrated. This technique is equally applicable to the solution of a wide class of nonlinear differential equations arising out of various physical problems.

ABSTRACT: A review is presented of the shear buckling of isotropic and orthotropic plates with a detailed consideration of the latter. An extensive bibliography is given and the details of the analyses in these papers are also discussed briefly in order to illustrate the development of theoretical and analytical technique. The relevant theoretical information for shear buckling and for the determination of buckling under combined stress systems including shear is presented graphically in the form of data sheets. (Cannot cut and paste references)

ABSTRACT: The buckling of a ring subjected to external pressure but supported by a rigid cavity wall is investigated using small deflection linear theory. It is assumed that the cavity wall moves in with the deflection of the ring prior to the onset of buckling. The ring buckles locally with an arc length no greater than pi
depending on the ratio of the radius of the ring to the radius of gyration of the cross section, \( R/\rho \). A curve is given for numerical evaluation of the critical pressure for all values of \( R/\rho \) in a ring or an infinitely long cylindrical shell.

ABSTRACT: Buckling and post buckling behavior of axially loaded cylindrical shells is studied. Linear and nonlinear equations are solved by finite difference techniques. Eight boundary conditions that differ from those assumed in the classical solution are considered. It is shown that changes in the boundary conditions have a significant effect on both the linear buckling load and on the shape of the post buckling curve. Critical loads and buckling mode shapes are obtained for a wide range of shell curvature.

ABSTRACT: The effects of inelastic strains on the deflection and stability of thin spherical domes with roller-supported edges under point loads at the apex are studied analytically and experimentally. The governing nonlinear differential equations are derived by applying Reissner’s nonlinear shell theory and the total deformation theory of plasticity. These equations are solved by a finite difference scheme using Newton’s method. Four domes, hydroformed from 6061-O aluminum, are tested. It is concluded that the inelastic strains do account for most of the discrepancies existing between the analytically predicted (based on elastic analysis alone) and the experimentally observed shell responses. It is found that for certain geometric configurations (i.e., \( \lambda > 6 \)) the local existence of finite strains and significant strain reversal indicates that closer correlation between theory and experiment is possible using an incremental plasticity theory.

ABSTRACT: Elastic buckling under axial compression of finite, oval cylindrical shells with clamped boundaries was investigated experimentally. The determination of the buckling strength was made on a series of oval shells made of Mylar A. The test results indicated that the discrepancy between theoretical and experimental initial buckling loads for the ovals is similar to that of the circular cylindrical shells. However, in contrast to the circular case, a collapse load significantly exceeding the initial buckling load is observed in the case of ovals with moderate-to-large eccentricity.

NASA Technical Reports Server (NTRS)
ABSTRACT:
A general solution for the forced, linear axisymmetric response of a fluid filled spherical shell is derived with the effects of shell transverse shear and rotational inertia included. The fluid is assumed to be inviscid and compressible. Expressions for the shell radial displacement are computed for the problem of a uniform radial Heaviside load on a cap of the shell surface. In addition, the time history of the shell inner fiber stresses at the impact pole is obtained. Some comparisons with the in vacuo shell theory are also given.

ABSTRACT: When the designers of reinforced concrete shell structures consider buckling, they have to apply data derived from elastic analyses or elastic model tests to a nonelastic material. The research described was designed to reduce the uncertainties involved by investigating the effect of tension cracking and nonlinearity on the buckling of concrete shells. The information desired was obtained experimentally by comparing the buckling of reinforced mortar models to geometrically similar models fabricated from plastics. The program included tests on 4 long-span single-barrel cylindrical roof shells, on 5 shallow spherical caps, and on 11
cylindrical panels. The results from the cylindrical shells and spherical caps are summarized, while the cylindrical panel tests are described in some detail. The complete curve for interaction of axial and circumferential buckling was established for the cylindrical panels. Conclusions are made about the use of appropriate models in buckling studies, and on the effects of tension cracking and nonlinearity in concrete shells.

ABSTRACT: The special phenomena of reinforced concrete shell buckling is described on the basis of the latest results of research. The method presented takes into consideration the special properties of the reinforced concrete including, plasticity, creep, and quantity of reinforcement. Snap-through critical loads calculated by the described method are compared to the results of model tests and to the loads and critical loads of erected domes. The shell buckling stiffness was seen to be composed of two parts; the bending and the axial stiffness of the reinforced concrete cross section. The critical load is reduced by the plasticity and the imperfections. The critical load of the reinforced concrete shells decreases by the craks of concrete and increases by the reinforcement.

ABSTRACT: The paper presents a simple procedure to establish the buckling load of shell structures. It is essentially based on the assumption that the various factors influencing buckling can be assessed as multipliers of the ‘classical’ critical load. These factors are: imperfections, creep, plasticity, cracks and the steel reinforcement. The paper gives the values of these factors, thus establishing a method which can be used in practical design.

Koryo Miura and Masamori Sakamaki, “Discontinuity in buckle pattern tessellation of cylindrical shells of variable curvature”, Institute of Space and Aeronautical Science, University of Tokyo, Report No. 461, March 1971, pp. 77 – 82
ABSTRACT: This paper presents experimental evidence that the discontinuity of buckle pattern tessellation exists in the elastic postbuckling configuration of cylindrical shells of variable curvature. This raises the question on the validity of some assumptions generally prevailing in analytical studies about the problem. References listed at the end of the paper:

ABSTRACT: When the flow velocity in a finite, thin, circular cylindrical shell, either clamped at both ends or cantilevered, exceeds a certain critical value, the system is observed to lose stability by flutter in its second circumferential mode. This paper describes the phenomenon, and presents a theory for its analysis which is based on Flügge's equations for the description of shell motion and a classical potential-flow theory for the coupled hydrodynamic forces. Complex frequency calculations reveal the existence of flutter in the case of cantilevered shells; for clamped-clamped shells the theory predicts buckling instability followed by coupled-mode flutter. Theory and experiment are in adequately close agreement.

ABSTRACT: An analysis is presented of the interaction between longitudinal and transverse motions of a circular cylindrical shell under impact on the end surface. At infinite and finite velocities of perturbation propagation along the generatrix this analysis reveals the instability modes in the shell which build up fastest and are similar to those revealed if the buckling process at a finite velocity of perturbation propagation were described in the real time of compressive loading action. It is established that a cylindrical shell under intensive loading can be simulated by a rod under longitudinal impact (the similarity parameters are indicated). This conclusion is confirmed by a comparison with experimental results.

ABSTRACT: Pogorelov used a geometric method to investigate the post-critical elastic states of cylindrical shells under axial compression in [4] under the assumption that the nature of the periodicity of the shell deflections is conserved throughout the whole time of strain. An investigation is made herein without the mentioned constraint. The domain of existence of the solution obtained is determined, and it is shown how this domain can be extended. An isometric surface is constructed by using the deflection function obtained from the strain compatibility equation.

ABSTRACT: An approximate method is presented for predicting elastic collapse of complete spherical shells subject to uniform external pressure. The shell contains an imperfection in the form of an isolated flat spot and the snap through behavior of the flat spot region is analyzed. The existence of higher modes is demonstrated and the effect of various choices for the stiffness coefficients at the edge of the flat spot is investigated.

ABSTRACT: The effect of random geometric imperfections on the maximum load-carrying capacity of an axially compressed thin cylindrical shell is studied. Following a perturbation approach, equations are derived which relate the first and second-order statistics of the maximum load to the statistics of the initial imperfections. Assuming that the imperfections are represented by Gaussian stationary and ergodic random processes, it is shown that the mean maximum load is expressible in quadrature forms involving the power spectral density of the initial imperfection. Furthermore, the maximum load is seen to be equal to its mean value with probability one. A simple asymptotic formula for the maximum load is derived assuming the variance of the initial imperfection is small. In this case the critical load depends only upon the imperfection variance and the power spectral density at a given wave number. For the types of imperfections considered, it is found that random axisymmetric imperfections reduce the load-carrying capacity of the cylindrical shell more than nonaxisymmetric imperfections.

ABSTRACT: A study is presented concerning the buckling characteristics of spherical shells with small initial symmetric and asymmetric imperfections in the geometry. The governing nonlinear partial differential equations are formulated using general relations with no restriction on shallowness. The effect of initial geometric imperfections is included in the equations. The shell material is assumed to be linearly elastic. The solution of the differential equations is carried out numerically using the method of L.V. Kantorovich in combination with finite differences. Numerical results are obtained by means of a digital computer, for spherical shells clamped at the boundary and subjected to uniform external pressure. Buckling pressures are determined from the load deflection relationship. The cases of asymmetric imperfections, and symmetric imperfections are studied. A wide range of shell geometries and imperfections is covered. Comparison with earlier experimental results shows good agreement.

ABSTRACT: A numerical method for determining the buckling loads and stresses for elastic-plastic spherical shells subjected to uniform external pressure is presented. No restriction is placed on shallowness in the
analysis. The incremental theory of plasticity and the von Mises yield criterion are used in formulating the problem. The governing differential equations are formulated in terms of displacements and are solved with the aid of finite differences, an incremental-iterative technique, and a high speed digital computer. Buckling loads are taken as the first maximum of a load-average deflection curve. Numerical results are presented for a clamped spherical shell. Buckling loads are compared to the elastic complete sphere value and the limit analysis load. The relationship of the radius-thickness ratio to buckling stress is presented.

ABSTRACT: Theoretical and experimental studies of the free vibrations and the loss of stability of thick-walled cylindrical and spherical shells subjected to external pressure are presented. General equations for the oscillations of the shell under pressure are formulated on the basis of a rigorous theory of finite elasticity. Loss of stability is determined when the fundamental natural frequency of the prestressed shell ceases to be real-valued. Numerical solutions are obtained by solving the specialized equations that are applicable to neo-Hookean materials. Experiments using specimens made of silicone rubber closely verify the theoretical results.

ABSTRACT: Layered spherical shells of arbitrary wall thickness subjected to uniform external and/or internal pressure and undergoing large elastic deformations are investigated. Layers are assumed to be made of neo-Hookean materials and perfectly bonded to one another along the interfaces. The stability of the finitely deformed state is studied using the theory of small deformations superposed on large elastic deformations where the secondary displacement field is assumed to be vibratory. The governing equations are solved numerically by a finite difference scheme to yield the frequencies of the small, free, asymmetric vibrations about the prestressed state. The loss of stability occurs when the superposed motions cease to be periodic.

Chandrakant S. Desai and John F. Abel, Introduction to the finite element method, Van Nostrand Reinhold Co., 1972

ABSTRACT: The finite element method is employed to study the nonlinear dynamic effect of a strong wind gust on a cooling tower. Geometric nonlinearities associated with finite deformations of the structure are considered but the material is assumed to remain elastic. Load is applied in small increments and the equation of motion is solved by a step-by-step integration technique. It has been found that the cooling tower will collapse under a wind gust of maximum pressure 1.2 psi (8.27 kN/m²). The collapse is caused by a local buckling phenomenon along the waist of the cooling tower. The response of the structure before collapse is presented and compared with a linear solution. These results have demonstrated the importance of considering nonlinear behavior in the analysis.

ABSTRACT: Extensive tests on inverted umbrella and saddle-shaped models indicate that the design of thin-steel hypar roofs is usually governed by stiffness, rather than by stress limitations. The rise-span ratio and the shear rigidity of cold-formed decks are the most important factors determining the stiffness of the structure. Deck buckling is caused by the uniform shear stresses in the shear-diaphragm type of action of the shell which dominates the response of hypar shells. This experimental investigation yielded empirical design information in thin-steel hypars and also provided checks on other analytical studies.

“Analysis of Thin-Steel Hyperbolic Paraboloid Shells”, ASCE Journal of the Structural Division, Vol. 98, No. 11, November 1972, pp. 2605-2621
ABSTRACT: Finite element analyses of orthotropic hypar structures, using flat and curved elements, are compared with experimental results. The flat element approach tends to predict the deflections of flat corners better than the curved element formulation. The buckling of the deck is also studied for a range of edge member and deck properties.

ABSTRACT: A generalized eigenvalue algorithm is presented herein along with the complete listing of the associated computer program, which may be conveniently utilized for the efficient solution of certain broad classes of eigenvalue problems. Extensive applications of the procedure are envisaged in the analysis of many important engineering problems, such as stability and natural frequency analysis of practical discrete structural systems, idealized by the finite element technique. The procedure based on the Sturm sequence method is accurate and fast, possessing several significant advantages over other known methods of such analysis. Numerical results are also presented for two representative structural engineering problems.

ABSTRACT: This article presents an efficient and numerically stable algorithm, along with a complete listing of the associated computer program, developed for the accurate computation of specified roots and associated vectors of the eigenvalue problem \( Aq = \lambda Bq \) with band symmetric \( A \) and \( B \), \( B \) being also positive definite. The desired roots are first isolated by the Sturm sequence procedure; then a special variant of the inverse iteration technique is applied for the individual determination of each root along with its vector. The algorithm fully exploits the banded form of relevant matrices, and the associated program written in FORTRAN V for the JPL UNIVAC 1108 computer proves to be most significantly economical in comparison to similar existing procedures. The program may be conveniently utilized for the efficient solution of practical engineering problems including free vibration and buckling analysis of structures. Results of such analyses are presented for representative structures.

Stuart E. Swartz and Vernon H. Rosenbraugh (Department of Civil Engineering, Kansas State University, Manhattan, Kansas, USA),” Experiments with Elastic Folded Plate Models”, ASCE Journal of the Engineering Mechanics Division, Vol. 98, No. 3, May/June 1972, pp. 711-729

ABSTRACT: Three series of tests were conducted on small scale aluminum models of single cess, folded plate structures with symmetrical cross sections. In the first series of tests, the models were supported on plexiglass plates at the ends and were subjected to uniform, symmetrical loads. In the second series, the models were subjected to asymmetrical loads. A third series of tests was made on the models with the ends and center supported on plexiglass plates and subjected to symmetrically applied, uniform loads. In the first two series of tests, the models were loaded into the post-buckling range. The load which caused a plate element to exhibit local buckling was determined from deflection profiles taken along the longitudinal direction of the models.

ABSTRACT: This paper investigates the effect of external lateral pressure on the free vibrations of hyperboloidal shells of revolution. A finite element computer program was developed based on Sander’s linear shell theory. This analysis was in good agreement with available experimental results and can be used in the future cooling tower structures. The most interesting result obtained from the investigation was the discovery that for certain hyperboloidal shell geometrics, the lowest frequency mode shapes contain more than one meridional half wave. This result was verified experimentally in the reference.

ABSTRACT: A computer method is presented to obtain solutions for buckling of the open cylindrical shell, or panel, with the curved edges simply supported. The radius of curvature may vary. The boundary conditions along the straight edges of the panel are arbitrary. The solution is accomplished by the substitution of mixed trigonometric-power series into equations similar to Donnell’s stability equations, with the curvature expression written as a power series. The resulting infinite-terms recurrence relations are truncated to form an eigenvalue problem. Examples involving various combinations of loading, boundary conditions, and noncircularity are presented.

ABSTRACT: Solutions are developed for non-axially symmetric shallow shells subjected to normal surface loading or thermal loading. The singular solutions which correspond to the concentrated normal load, the concentrated application of heat and the concentrated thermal gradient are identified by a consistent limiting process applied to the complete set of singular solutions. Numerical results are presented for the case of the normal concentrated load acting on shallow shells having negative, zero or positive Gaussian curvature. The behavior of the shallow shells in the neighborhood of the applied concentrated load is seen to be similar to that of a disc subjected to the same load. The influence of the concentrated load is felt over a wider region in shells of negative Gaussian curvature compared to shells of positive Gaussian curvature. However, for the case of the concentrated load, the stress and deflection parameters of the shell do not change dramatically as the Gaussian curvature of the shell is varied from positive to negative values.

ABSTRACT: An experimental and theoretical investigation of the effect of a circular hole on the buckling of thin cylindrical shells under axial compression was carried out. The experimental program consisted of tests performed on seamless electroformed copper shells and Mylar shells with a lap joint seam. The copper shells were tested in a controlled displacement testing machine equipped with a noncontacting surface displacement measuring device. Three-dimensional surface plots obtained in this manner showed the changes in the displacement field over the entire shell, including the hole region, as the applied load was increased. The Mylar shells were tested in a controlled load testing machine and demonstrated the effect of increasing the hole radius on the buckling loads of the cylinder. The theoretical solution was based on a Rayleigh-Ritz approximation. The solution provided an upper bound for the buckling stresses of the cylinders tested for hole radii less than ten per cent of the shell radii. The theoretical solution also identified the governing parameter of the problem as being related to the hole radius, the shell radius, and the shell thickness. The theoretical part of the investigation showed that even a small hole should significantly reduce the buckling stresses of circular cylinders. Experimentally, it was found that the effect of a small hole is masked by the effects of initial deformations but, at larger hole radii, the reduction in buckling stress took the form predicted by the theory. The experimental results also showed that the character of the shell buckling was dependent on the hole size. For very small holes the shell buckled into the general collapse configuration and there was no apparent effect of the hole on the buckling mode of the shell. For slightly larger holes the shell still buckled into the general collapse configuration, but the buckling stresses of the shell were sharply reduced as the hole size increased. For still larger holes the buckling stresses did not decrease as sharply as the hole size increased and the shell buckled into a stable local buckling configuration.

ABSTRACT: An experimental and analytical investigation of the effect of a circular hole on the buckling of thin cylindrical shells under axial compression was carried out. The experimental results were obtained from tests performed on seamless electroformed copper shells and Mylar shells with a lap joint seam. These results indicated that the character of the shell buckling was dependent on a parameter which is proportional to the hole radius divided by the square root of the product of the shell radius and thickness. For small values of this parameter, there was no apparent effect of the hole on the buckling load. For slightly larger values of the parameter, the shells still buckled into a general collapse configuration, but the buckling loads were sharply reduced as the parameter increased. For still larger values of the parameter, the buckling loads were further reduced, and the shells buckled into a stable local buckling configuration.

ABSTRACT: This paper provides the basis for a very general approach to the determination of initial buckling stresses of long stiffened panels in uniform longitudinal compression. The panels are assumed to consist of a series of long flat strips, rigidly connected together at their edges, as in panels with top-hat or Z-section stringers, or in sandwich panels with corrugated cores. Whatever the buckling mode, the individual flats are subjected, just after buckling, to sinusoidally varying systems of both out-of-plane and in-plane edge forces and moments, superimposed on the basic state of uniform compression. The stiffness matrices corresponding to these sinusoidal edge loads are derived, taking account of the destabilising effect of the basic longitudinal compressive stress, not only in the out-of-plane but also in the in-plane deformations. For the latter purpose a non-linear theory of elasticity is used. The application of these stiffness matrices to specific panels is briefly
described. All possible modes are incorporated within one determinantal equation. For panels with identical stiffeners spaced at equal intervals, the order of the determinant is independent of the number of stiffeners.

ABSTRACT: Prismatic plate assemblies include closed and open section struts, stiffened panels with open or closed section longitudinal stiffeners and longitudinally stiffened tubes. Recent theoretical advances have made possible the computation of critical buckling loads (or natural frequencies) for such assemblies. The answers obtained are “exact”, in the sense that only the usual thin plate assumptions are made, so long as the ends of each component plate are simply supported or the longitudinal half-wavelength of the buckling mode is short compared with the length of the assembly. Initially, the theory only applied to assemblies of uniformly compressed, flat, isotropic plates. However, results can now be computed for assemblies which include curved anisotropic plates which carry in-plane bending and uniform in-plane shear and transverse stresses. Existing computer programs enable one to investigate the critical buckling behaviour of a vast range of interesting plate assemblies. So far, results obtained cover only a relatively small part of this range. In this paper, a summary is given of the more interesting conclusions drawn from these results. The results include (a) comparisons with results from simpler, approximate analyses, (b) investigations of novel, advantageous structural forms, (c) examples of the effects of idealisations such as ignoring eccentricities between connected plates and finite radii of curvature at bends, (d) interaction between shear, bending and longitudinal compression for stiffened panels and (e) critical loads other than the lowest.

References listed at the end of the paper:

ABSTRACT: The non-linear post-buckling behaviour of a complete spherical shell is studied analytically in the vicinity of the buckling load. It is assumed that the shell buckles in a rotationally symmetric wave pattern and specific attention is given to deformation modes symmetric about the equator, in the longitudinal direction. The energy functional is reduced to approximate functions using the Rayleigh-Ritz method with which two types of assumed functions are considered, viz. Legendre polynomials and localized Rayleigh functions (finite elements). The algebraic equations of equilibrium are solved approximately using a series expansion technique, and it is shown that the use of Legendre polynomials gives exact values for the coefficients of the series, whilst use of the finite element method results in coefficients which converge monotonically to the exact values as the number of elements is increased.

L.J. Hart-Smith (Department of Mechanical Engineering, Monash University, Wellington Road, Clayton, Victoria, 3168, Australia), “Buckling analyses of ideal thin shells and new thin elastic shell theory formulations”, International Journal of Mechanical Sciences, Vol. 10, No. 8, August 1968, pp. 665-667, doi:10.1016/0020-7403(68)90071-4 (no abstract; this is a letter to the editor.)

ABSTRACT: The problem of the elastic buckling under uniform axial compression of an ideal thin cylindrical shell is examined using a new self-consistent theory of thin shells derived according to the Kirchhoff-Love hypotheses. The collapse stress deduced lies between half of the classical value and that value depending on the exact nature of the end-conditions. The onset of buckling, at which the diamond wrinkles first appear, is shown to be at a stress as low as one-sixth of the classical value. This is a close lower bound of the published experimental data. The solution agrees with the observed diamond wrinkling pattern and predicts nominally square diamonds. The analysis is linear and the actual buckling stress is obtained, not the post-buckling minimum. The present analysis is, in fact, directly comparable with the classical analysis. A classical-type bifurcation analysis of the equilibrium equations is carried out to determine the wavelengths under which buckling can occur for a prescribed axial load. This is complemented with a strain-energy analysis to identify the particular wavelength coinciding with the lowest collapse load.

ABSTRACT: The results are presented of an experimental investigation of creep buckling of circular cylindrical shells. The test specimens, manufactured from an aluminum alloy similar to 24S, had radius to thickness ratios between 30 and 150 and length to radius ratios greater than 2. They were subjected to axial compression or bending at a temperature of 225 deg C (430 deg F) and at various stress levels. The critical time under a constant load was determined as a function of the stress level, the shell geometry, and the type of loading. It was found that the shells subjected to pure compression had a substantially shorter lifetime than those subjected to pure bending with the same maximum applied stress. The thickest test specimens failed through collapse into a “wrinkling” mode which for the pure compression case is axisymmetric, whereas the
thinner cylinders buckled into a typical diamond pattern. In all cases, buckling occurred at one of the edges. The postbuckling configuration was found to depend not only on the geometry of the shell but also on the load level. For very low stress levels, even the thinner cylinders buckled in the short wave pattern (symmetric for compression). A comparison between the present experimental results and theoretical values of the critical time presented in earlier works showed that a fairly good estimate may be obtained for the case of axial compression, whereas the approximate theory for creep buckling under pure bending gives an unduly conservative result.

ABSTRACT: A method of analysis is presented for circular cylindrical shells under non-uniform external loads. The equations are valid for moderately large displacements and take secondary creep into account. Thermal effects and initial imperfections are included. As the general equations are non-linear, an iterative method is used in the numerical analysis. The nonlinear terms are at a certain iteration considered as known, generally determined by the previous iteration. They may thus be regarded as pseudo loads which are added to the actual external load terms. The variables of the thus linearized differential equations are expanded in Fourier series with respect to the circumferential coordinate. As a result, a series of sets of ordinary differential equations is obtained, one set for each Fourier index. These sets of equations are solved by use of a finite difference method. For each load or time step the equations are repeatedly solved until convergence is obtained. A computer program was developed and was verified by comparison with known solutions for elastic buckling of shells. The theoretical behavior of a cylinder under creep is demonstrated for a number of different loading conditions, in particular the response is studied of an imperfect shell under uniform loads. In the case of external pressure, the critical time was found to be extremely sensitive to the imperfection shape. For a short cylinder under axial compression the presence of initial imperfections was shown to shorten the creep life substantially in comparison with the critical time corresponding to axisymmetrical collapse of the perfect shell.

ABSTRACT: The possibilities to analyze complicated shell stability problems have improved enormously during recent years through the development of powerful computer programs. Still there is a need for simple design rules for shell geometries commonly used in practice. The present investigation forms part of the work by task group TWG 8/4 “Shell Stability” of the European Convention for constructional steelworks, ECCS. The purpose is to provide simplified methods of analysis for the design of circular cylindrical shells with longitudinal stiffeners and subjected to axial compression. Various methods of analysis are discussed and comparisons with tests are carried out. The design procedures proposed for the ECCS recommendations are presented. In view of the complexity of the problem it is necessary for the simplified rules to be fairly conservative in order to guarantee a safe design over the range of geometries considered. However, the designer should always have the option to use improved design methods whenever required.

(1) Bloms Ingeniörsbyrå, PO Box 1080, S-17222, Sundbyberg, Sweden
ABSTRACT: Shell structures are often designed to carry compressive loads which may cause buckling. Openings and cutouts in the shell are known to reduce the carrying capacity, sometimes to a substantial degree. Although extensive research has been devoted to the problem, very few attempts have been made to incorporate the results into existing design codes. One reason for this may be the fact that even the design of simple shell elements under uniform loading conditions is complex, and the emphasis has been to develop design methods for these standard cases. The present paper discusses a number of problems associated with cutouts in shells subjected to buckling. Simple design rules are proposed based on theoretical (finite element analysis or equivalent) and experimental results.

PARTIAL ABSTRACT: Rules for design of structures with respect to buckling have existed for a long time. The stability behavior of columns and plates is fairly well known among engineers and design methods are available for many of the problems arising in practical applications. Shell buckling has been studied intensively during the last decades and the behavior is now fairly well known. The tendency of shells to be imperfection sensitive has caused problems in defining a safe design procedure and the code cases developed up till the present time are fairly limited in scope. This fact has also resulted in a reluctance to address other practical problems such as the effect of local disturbances because “we do not even have sufficient knowledge on how to design shells subjected to uniform loads”. Such special problems have so far been left to the designer to solve through, for instance, testing, rigorous nonlinear analysis or alternative design avoiding the problems….

N. Yamaki, “Influence of prebuckling deformations on the buckling of circular cylindrical shells under external pressure (Prebuckling deformations influence on circular cylindrical shell buckling under external pressure, applying Galerkin method to Donnell equations)”, Tohoku University, Institute Of High Speed Mechanics, Reports. Vol. 21, pp. 81-104. 1970

ABSTRACT: Applying the Galerkin procedure to the Donnell basic equations, solutions of exact nature are obtained for the postbuckling behavior of circular cylindrical shells under hydrostatic pressure. Through detailed calculations, connections of the edge shortening, deflection and volume change with applied pressure are clarified for a wide range of shell geometries. The results here obtained are ascertained to be in good agreement with experimental results.

ABSTRACT: On the basis of the Donnell-type shell equations with the effect of nonlinear prebuckling deformations taken into consideration, a theoretical analysis is performed on the buckling of clamped truncated conical shells under two loads combined out of uniform pressure, axial load, and uniform heating. The problem is solved by a finite difference method. It is found that the interaction curves of buckling loads are changed remarkably by the difference in the shape of conical shells. This is due to the large nonlinear prebuckling deformation and the difference in the buckling mode between two cases of single load.

ABSTRACT: From Von Karman’s large deflection equation of the plate and by assuming that a plate has an initial deflection in the form of a spherical cap, the equilibrium equation of a spherical cap subjected to hydrostatic pressure is obtained, simplified and solved in the same way as an equilibrium equation of a beam on an elastic foundation subjected to axial and lateral loads. The influence of pre-buckling deformations and stresses on the buckling of the spherical shell may be evaluated, and the relation between the buckling strength of the spherical shell and the column is obtained by analyzing the buckling problem of the beam on an elastic foundation. The formula presented for calculating the stability of the spherical shell gives a lower limit of buckling pressure and is in good agreement with test data recorded in the literature.

ABSTRACT: The buckling mode of a structure is defined to be symmetric if its sign is indefinite; this happens when the potential energy expansion near the buckling point does not contain terms which are cubic in the buckling mode. If, in addition, the cubic terms vanish identically for all possible modes then the structure is defined to be “completely symmetric”. Many structures of technical significance are included in this definition, such as columns, plates, frameworks, etc. If certain technically realistic order-of-magnitude assumptions are made, the analysis of the buckling and post-buckling behavior of completely symmetric structures can be carried out in great generality. For example, it is shown in the present paper that structures of this type buckle under increasing loads and are therefore insensitive to initial imperfections. The post-buckling state is characterized by the satisfaction of a minimum complementary energy principle, which represents an extension of the corresponding classical principle into the nonlinear domain. Moreover, the energy can be bracketed between upper and lower bounds and an error estimate is thus established at least in an averaging sense. Under certain circumstances the load approaches a finite value as the structure approaches collapse. This collapse load can also be bracketed between classes of “statically admissible” load parameters (representing lower bounds) and “kinematically admissible” load parameters (representing upper bounds). The gap between these bounds can be reduced arbitrarily. The example of a slender statically indeterminate beam subjected to lateral and torsional buckling is introduced to demonstrate the general principles developed in the paper.

ABSTRACT: A general discussion of the behavior of the shallow circular arch is presented. It is shown that, irrespective of specific loading or boundary conditions, it is possible to arrive at general conclusions regarding buckling, postbuckling, and imperfection sensitivity. General methods of analysis are established which lead to the determination of points of bifurcation and of postbuckling paths under symmetric loads. Modifications accounting for antisymmetric load components are introduced, with special emphasis on their asymptotic and limit load effect.

ABSTRACT: A systematic derivation of the expression for the complementary energy in elastic buckling problems is presented. Compatibility is identified with variation with respect to the stress components, and the resulting eigenvalue problem is shown to be equivalent to, and sometimes more convenient than, the corresponding formulation in terms of the potential energy. Similarly, approximate techniques may lead to better as well as simpler estimates, whose upper bound property can, however, be assured only through appropriate safeguards. The method is applied in some detail to buckling of columns of arbitrary boundary conditions and axial force distribution. Another example is the problem of lateral beam buckling, with the effect of warping restraint included. In both cases (and presumably in many others) the complementary energy formulation is of lower order than the conventional potential energy formulation, and it is clear that the same simplification should also apply to finite elements or other discrete formats. The method is restricted to the (technically significant) case of a linear prebuckling state.

David Bushnell, “Axisymmetric deformation of a shallow spherical cap clamped at the edge and submitted to uniform external pressure”, Chapter 1 in Some Problems in the Theory of Thin Shells, Ph.D dissertation, Aeronautics and Astronautics, Stanford University, Stanford, California, February 1965

ABSTRACT: In Chapter 1 a shallow spherical cap clamped at the edge and subjected to uniform external pressure is studied. This non-linear problem is approached from the equilibrium and the potential energy points of view. In both approaches the dependent variables, which are the displacement components of points on the middle surface, are expanded in trigonometric series each of whose terms satisfies the boundary and symmetry conditions. Undetermined coefficients of the terms in the series are evaluated by solving the set of non-linear algebraic equations which is generated in the equilibrium approach by direct substitution and in the potential energy approach by minimization of the total potential. Load-deflection curves are established for various cap geometries, and the stability curve is obtained by plotting the values of the pressure for which the load-deflection curves have maxima versus a parameter LAMBDA-squared which describes the geometry of the cap. The early post-buckled behavior is explored and the effect of deviations from sphericity on the critical pressure determined. A limited investigation is made of the effect of small non-linear terms in the meridional strain-displacement expression on the stability and early post-buckling characteristics of shallow clamped caps.
ABSTRACT: The finite-difference method is used for the nonlinear analysis of shells of revolution consisting of elastic shell segments of various geometries and wall constructions joined by elastic rings. The analysis and associated digital computer program were developed in response to the need for a better design tool for practical shell structures. Numerical results are presented for displacement and stress distributions in various pressure vessels. Particular emphasis is given to systems in which nonlinear effects are important and may influence the design. Values calculated with linear theory are compared with those from nonlinear theory.

ABSTRACT: Two computer programs, BOSOR3 and STAGS, have been developed for the general analysis of shells. These programs are based on a finite-difference energy method. BOSOR3 performs stress, stability and vibration analyses of ring-stiffened, segmented shells of revolution with various wall constructions. STAGS performs similar analyses for shells of general shape. The analysis on which both programs are based is similar to the finite-element method in that extensive use is made of matrix algebra in the development of the governing equations. These equations are derived by the digital computer in terms of mesh point displacement variables. Several example cases from BOSOR3 and STAGS are given. Effects are shown of various finite-difference schemes, comparison with finite-element results, and complex nonlinear behavior involving large deflections and redistribution of stress during loading.

ABSTRACT: An energy formulation is used in conjunction with the method of finite differences to develop equations leading to buckling loads and vibration frequencies of segmented elastic shells of revolution supported by rings which are treated as discrete elastic structures. A quadratic form for the total potential and kinetic energy is derived through extensive use of matrix methods. The development is similar to that used in the finite element method, and is ideally suited for programming on the digital computer. Numerical results are presented in which two types of finite difference approximations are compared, and convergence properties of eigenvalues and eigenvectors are explored.

ABSTRACT: A comprehensive computer program BOSOR4 for the stress, stability, and vibration analysis of segmented, ring-stiffened, branched shells of revolution is presented. The program includes nonlinear prestress effects and is very general with respect to geometry of meridian, shell wall design, edge conditions, and loading. Despite its generality the program is easy to use. Branches are provided such that for commonly cases the input data involve only basic information such as geometrical and material properties. The computer program has been verified by comparisons with other known solutions and test results. This manual consists of several sections in which the program scope is described, the analysis on which it is based is given, the flow of calculations is outlined, the input data are defined with sample cases, various possible pitfalls are emphasized, and sample list and plot output are given and described.

David Bushnell (Lockheed Missiles and Space Company, Palo Alto, California USA), “Local and general buckling of axially compressed semi-sandwich, corrugated, ring-stiffened cylinders (Axially compressed semi-sandwich corrugated ring-stiffened cylindrical shell crippling local buckling and general instability prediction by finite difference energy method)”, AIAA Aerospace Sciences Mereting, San Diego, California, 17-19 January, 1972
ABSTRACT: A finite-difference energy method is used for prediction of crippling, local buckling, and general instability. Reasonably good agreement is obtained between test and theory for shells that cripple due to pure axial compression, shells that cripple due to axial compression combined with hoop compression induced by local radial restraint at rings and boundaries, shells that buckle locally due to axial load path eccentricity, and shells that buckle between ring stiffeners. Crippling loads are calculated by treatment of a portion of the corrugation-sheet combination as a shell of revolution with radius very large compared with a typical dimension of the corrugation. Critical loads for buckling between rings are rather strongly dependent on boundary conditions, load eccentricity, and length of cylinder, even for cylinders with many bays.

ABSTRACT: An iterative procedure for solving axisymmetric shell problems involving large deflections and
nonlinear material behavior is described. Deformation theory and incremental flow theory with isotropic strain hardening and secondary creep are both included as analysis branches in a computer program called BOSOR5 for the treatment of axisymmetric shells. Numerical examples show that the deformation theory is surprisingly accurate, even if the material is loaded nonproportionally. The iteration method seems to be reliable and generally permits accurate determination of deformations even if very large load increments are used in the analysis. Axisymmetric stresses and displacements are calculated for centrally loaded circular plates and creep buckling analyses performed for axially compressed elastic-plastic cylinders and columns.

ABSTRACT: A comprehensive computer program, designated BOSOR4, for analysis of the stress, stability and vibration of segmented, ring-stiffened, branched shells of revolution and prismatic shells and panels is described. The program performs large-deflection axisymmetric stress analysis, small-deflection nonsymmetric stress analysis, modal vibration analysis with axisymmetric nonlinear prestress included, and buckling analysis with axisymmetric or nonsymmetric prestress. One of the main advantages of the code is the provision for realistic engineering details such as eccentric load paths, internal supports, arbitrary branching conditions, and a ‘library’ of wall constructions. The program is based on the finite-difference energy method which is very rapidly convergent with increasing numbers of mesh points. The organization of the program is briefly described with flow of calculations charted for each of the types of analysis. Overlay charts and core storage requirements are given for the CDC 6600, IBM 370/165, and UNTVAC 1108 versions of BOSOR4. A large number of cases is included to demonstrate the scope and practicality of the program period.

ABSTRACT: Experimental buckling pressures are given in the paper for six cylinder-cone combinations which were carefully machined and stress-relieved and then tested under uniform external pressure. Failure in all cases occurred by asymmetric buckling (i.e. with circumferential waves); although some failures were elastic, others were elastic-plastic. Theoretical buckling pressures for the models (assumed perfect) were obtained from a variational finite-difference formulation of the problem which has been incorporated into a comprehensive digital computer program. The agreement between theory and experiment was very satisfactory and may be summarized as: (i) for elastic buckling, it was within 5% and (ii) for elastic-plastic buckling, it was within 2%. This latter figure is surprisingly good. With regard to the repeatability of experimental results, the tests conducted so far have agreed to within 3%.

ABSTRACT: A summary is first presented of the conceptual difficulties and paradoxes surrounding plastic bifurcation buckling analysis. Briefly discussed are nonconservativeness, loading rate during buckling, and the discrepancy of buckling predictions with use of J2 flow theory vs J2 deformation theory. The axisymmetric prebuckling analysis, including large deflections, elastic-plastic material behavior and creep is summarized. Details are given on the analysis of nonsymmetric bifurcation from the deformed axisymmetric state. Both J2 flow theory and J2 deformation theory are described. The treatment, based on the finite-difference energy method, applies to layered segmented and branched shells of arbitrary meridional shape composed of a number of different elastic-plastic materials. Numerical results generated with a computer program based on the analysis are presented for an externally pressurized cylinder with conical heads.

ABSTRACT: Experimental and analytical buckling pressures are presented for very carefully fabricated thin cylindrical shells with 45, 60 and 75° conical heads and for cylindrical shells with torispherical heads pierced by axisymmetric cylindrical nozzles of various thicknesses and diameters. Nonsymmetric buckling occurs at pressures for which some of the material is loading plastically in the neighborhoods of stress concentrations caused by meridional slope discontinuities. The buckling pressures for the cone-cylinder vessels are predicted within 2.6 per cent and for the pierced torispherical vessels within 4.4 per cent with use of BOSOR5, a computer program based on the finite difference energy method in which axisymmetric large deflections, nonlinear material properties and nonsymmetric bifurcation buckling are accounted for. The predicted buckling pressures of the pierced torispherical specimens are rather sensitive to details of the analytical model in the neighborhood of the juncture between the nozzle and the head. The buckling pressures of the cone-cylinder vessels can be accurately predicted by treatment of the wall material as elastic, enforcement of the full compatibility conditions at the juncture in the prebuckling analysis, and release of the rotation compatibility condition in the bifurcation (eigenvalue) analysis.

ABSTRACT: The theory is summarized for axisymmetric prebuckling and nonsymmetric bifurcation buckling of ring-stiffened shells of revolution. The analysis is based on finite difference energy minimization in which moderately large meridional rotations, elastic-plastic effects, and primary or secondary creep are included. This theory is implemented in a computer program called BOSOR5, for the analysis of segmented and branched ring-stiffened shells of revolution of multi-material construction. Comparisons between test and theory are given for axisymmetric collapse and nonsymmetric bifurcation buckling of 69 machined ring-stiffened aluminum cylinders submitted to external hydrostatic pressure. Because most of the cylinders fail at an average stress which corresponds to the knee of the stress-strain curve, the analytical predictions are not very sensitive to modeling particulars such as nodal point density or boundary conditions. Agreement between test and theory is improved if the analytical model reflects the fact that the shell and rings intersect over finite axial lengths.

ABSTRACT: B0S0R5 can handle segmented and branched shells with discrete ring stiffeners, meridional discontinuities, and multi-material construction. The shell wall can be made up of as many as six layers, each of which is a different nonlinear material. In the prebuckling analysis large-deflection axisymmetric behavior is presumed. Bifurcation buckling loads are computed corresponding to axisymmetric or nonaxisymmetric buckling modes. The strategy for solving the nonlinear prebuckling problem is such that the user obtains reasonably accurate answers even if he uses very large load or time steps. B0S0R5 has been checked by means of numerous runs in which the results have been compared to other analyses and to tests. The prebuckling and plastic bifurcation (eigenvalue) analyses are described, with the most important equations given. These equations are derived from a finite difference energy method. The strategy for solving problems simultaneously
involving large deflections, elastic-plastic material behavior, and primary and secondary creep permits the use of rather large time and load steps without undue sacrifice in accuracy. This strategy is based on a subincremental iteration method in which the size of the subincrement is automatically determined such that the change in stress is less than a certain prescribed percentage of the effective stress. The theoretical treatment of discrete ring stiffeners, the material of which is elastic-plastic and can creep according to a primary or secondary creep law, is also given. Discrete rings of arbitrary cross-section are considered to be assemblages of thin rectangular elements. The structure of the BOSOR5 computer program, which runs on the CDC 6600 and on the UNIVAC 1108 and 1110, is described. The paper gives comparisons between test and theory for many configurations, including axially compressed cylinders and internally and externally pressurized shells of various shapes with and without ring stiffeners. The results of sensitivity studies are given in which the effect on predicted critical load of various analytical models of the ring-shell wall intersection area are explored. A method of predicting the effect of welding on buckling load is described, and an example involving a ring-stiffened doubly-curved shell is given. Welding the ring stiffeners to a shell introduces residual stresses and geometrical imperfections, both of which reduce the load-carrying capability.

ABSTRACT: The analysis is applicable to bodies of revolution composed of thin shell segments, thick segments and discrete rings. The thin shell segments are discretized by the finite difference energy method and the thick or solid segments are treated as assemblages of 8-node isoparametric quadrilateral finite elements of revolution. Suitable compatibility conditions are formulated through which these dissimilar segments are joined without introduction of large spurious discontinuity stresses. Plasticity and primary or secondary creep are included. Axisymmetric prebuckling displacements may be moderately large. The nonlinear axisymmetric problem is solved in two nested iteration loops at each load level or time step. In the inner loop the simultaneous nonlinear equations corresponding to a given tangent stiffness are solved by the Newton-Raphson method. In the outer loop the plastic and creep strains and tangent stiffness are calculated by a subincremental procedure. The linear response to nonaxisymmetric loading is obtained by superposition of Fourier harmonics. Many examples are given to demonstrate the scope of the computer program, BOSOR6, derived from the analysis and to illustrate certain stress concentration effects in shell-type structures which cannot adequately be treated with use of thin shell theory.

ABSTRACT: A strategy for solving problems involving simultaneously occurring large deflections, elastic-plastic material behaviour, and primary creep is described. The incremental procedure involves a double iteration loop at each load level or time. In the inner loop the material properties are held constant and the non-
linear equilibrium equations are solved by the Newton-Raphson method. These equations are formulated in terms of the tangent stiffness. In the outer loop the plastic and creep strains are determined and the tangent stiffness properties are updated with use of a subincremental algorithm. The magnitude of each time subincrement is determined such that the change in effective stress is less than a preset percentage of the effective stress. The strategy is implemented in a computer program, BOSOR5, for the analysis of shells of revolution. Examples are given of elastic-plastic deformations of a centrally loaded flat plate and elastic-plastic-creep deformations of a beam in bending. The major benefits of the subincremental technique are the increased reliability with which problems involving non-linear plastic and time-dependent material behaviour can be solved and the greatly relaxed requirement on the number of load or time increments needed for satisfactory results.

ABSTRACT: Comparisons of test and theory are presented for the nonaxisymmetric bifurcation buckling of ten aluminium vessel heads fabricated and tested by Patel and Gill at the University of Manchester in 1976. In the test specimens, the sphere radius was equal to the cylinder diameter and only the torus radius was varied. All specimens were of constant internal cylinder diameter to nominal thickness ratio of 531.5. Meridional variation of thickness was accounted for in the analysis, which was carried out with the BOSOR5 computer program. The analysis includes both material and geometrical nonlinear prebuckling behavior. The results indicate that incipient nonsymmetric buckling can be predicted with reasonable accuracy by means of an eigenvalue formulation.

ABSTRACT: Task I Hygrothermal, viscoelastic plane stress and generalized plane strain analysis codes were developed and employed to determine the influence of hygrothermal history on laminate in-plane and free edge stresses and dimensional stability. Task II Monographs were written on plastic buckling, stability and optimization of panels, and buckling of shells. The surveys include many examples of nonlinear collapse and bifurcation buckling in which moderately large deflections, nonlinear material effects, and imperfections are accounted for. Their purpose is to give the reader a physical 'feel for thin shell behavior that will help him to design appropriate tests and perform efficient numerical analyses with existing computer programs for the treatment of structures composed of thin sections.

ABSTRACT: Techniques for the branching analysis of structural systems possessing a potential function are classified according to the order in which the conditions of stationarity, perturbation and discretization are imposed. It is shown that the recently developed algorithm for branching analysis of discrete systems, in which contraction of the algebraic perturbation equations plays a significant role, has an even closer analogy with the
related continuum analysis than hitherto supposed. The proposed algorithm for the continuum branching analysis is outlined in general terms, and its use is illustrated by reference to the “elastica”. More important than the analytical treatment of the resulting differential perturbation equations, however, is that the method proposed offers a viable alternative means of deriving practical numerical solution analogues. Broadly, numerical analogues derived on the present basis possess all the advantages and disadvantages of the generalized finite difference technique over the generalized finite element technique.

ABSTRACT: Previously postulated, lower bound estimates of the buckling loads for axially loaded unstiffened cylinders are simplified by means of a Donnell-type approximation to provide compact, explicit, analytical expressions which could prove particularly suited to design. For a wide range of practical geometric parameters these simplified expressions are shown to provide close approximations of the exact lower bound loads and associated modes. In addition they allow the independent and significant influence of length to radius, radius to thickness, and Poisson's ratio to be isolated, and suggest a convenient means of summarising buckling loads in terms of a single composite geometric parameter.

doi:10.1115/1.3408738 (or the title is: “Snapping of Imperfect Thin-Walled Circular Cylindrical Shells of Finite Length”)
ABSTRACT: The nonlinear partial differential equations of von Karman and Donnell governing the deformations of initially imperfect cylindrical shells are reduced to a consistent set of ordinary differential equations. A numerical procedure is then used to solve the equations together with the associated boundary conditions and to determine the number of waves at buckling as well as the load-carrying capacity of imperfect cylindrical shells of finite length subjected to uniform axial compression in the presence of a reduced restraint along the simply supported boundaries. It is found that details of the boundary conditions have little effect on the number of waves into which the shell buckles around the circumference. This number is determined essentially by the length-to-radius and radius-to-thickness ratios. The absence of an edge restraint to circumferential displacement reduces the classical value of the buckling load by a factor of about two. On the other hand, shells with these boundary conditions appear to be less sensitive to initial imperfections in the shape, and thus the maximal load supported in the presence of unavoidable initial deviations can be the same for shells with and without a restraint to circumferential displacements along the edges.

ABSTRACT: This paper describes an analysis and its application in design for compressive buckling of flat stiffened plates considered as an assemblage of linked orthotropic flat plate and beam elements. Plates can be multilayered, with possible coupling between bending and stretching. Structural lips and beads are idealized as beams. The plate and the beam elements are matched along their common junctions for displacement continuity and force equilibrium in an exact manner. Buckling loads are found as the lowest of all possible general and local failure modes. The mode shape is used to determine whether buckling is a local or general instability and is particularly useful to the designer in identifying the weak elements for redesign purposes. Typical design curves are presented for the initial buckling of a hat stiffened plate locally reinforced with boron fiber composite.

ABSTRACT: This paper summarizes the major computer programs in existence for the analysis of shells of revolution by numerical integration and finite difference procedures. The report describes programs for (1) linear and nonlinear analysis of shells subjected to axisymmetric and asymmetric static loads, (2) buckling and vibration behavior including effects of axisymmetric nonlinear prestress, and (3) transient response. Extensions of these programs which are currently underway and some of the primary assets of both the numerical integration and finite difference procedures are discussed. In addition, a summary of the shell theory formulation, the numerical approximation, and the solution techniques of a set of programs denoted SALORS (Structural Analysis of Layered Orthotropic Ring-Stiffened Shells), developed at the NASA Langley Research Center, are described. Stress, vibration, and buckling results from the SALORS program are given for several shell configurations having a variety of structural complexities that illustrate the current capability of shell of revolution programs.

ABSTRACT: Solutions are developed herein for the evaluation of frequency and stability eigenvalues of macro-scopically fully anisotropic circular cylindrical shells subjected to nonuniform lateral prestress. Included in the analysis is the presence of torsional prestress. The results obtained are applicable to any type of prestress which satisfy Dirichlet's conditions for Fourier series. Furthermore, in the manner of Kalnins [3], using the procedure outlined herein, similar results could be obtained for general anisotropic shells of revolution.

ABSTRACT: Applying Vlasov-Ambartsumyan shell theory to anisotropic and laminated cylinders, equations are developed for calculating the stresses in a composite tube under combined axial load, torsion, and internal pressure. Comparison to results obtained from exact elasticity theory shows that the shell equations are capable of predicting, with a reasonable degree of accuracy, the large stress gradients found in highly anisotropic tubes. Thus the shell theory provides the experimentalist with a set of closed form expressions for readily defining the proper specimen dimensions for precise characterization of unidirectional and laminated composite tubes. A modification to the shell theory, in which the effects of transverse normal strain are included is also discussed. Numerical results show that such a modification is necessary for determining stresses induced by free thermal expansion. It is also shown that certain classical thin shell kinematic relations are incapable of predicting stresses in composite tubes.

ABSTRACT: The results of testing the stability of glass-reinforced plastic cylindrical shells under hydrostatic pressure are examined. The initial imperfections and deflections of the shells were directly measured. It is found that during loading or in the course of time (under load) the shape of the initial imperfections is transformed. An algorithm (see [11]) based on the approximation of the experimental deflection function by a Fourier series is used to establish the characteristic coefficients of the series important in connection with the elastic loss of stability and progressive buckling of the shell.

References listed at the end of the paper:

ABSTRACT: The creep buckling of polyethylene cylindrical shells in axial compression has been investigated. The changes in the shape of the shell surface up to loss of stability were measured with a special radial
deflection gauge. The experimentally determined shape of the buckled surface at discrete moments of time is approximated by a double Fourier series. The characteristic coefficients of the series of importance in creep buckling are established. From an analysis of the coefficients of the series it follows that the amplitudes of the axisymmetric coefficients diminish with time, while those of the coefficients giving a nonaxisymmetric buckled shape grow.

Arturs Kalnins, “Static, Free Vibration, And Stability Analysis Of Thin, Elastic Shells Of Revolution”, Lehigh University, Bethlehem PA, Technical rept. Apr 66-Jul 68, October 1968, DTIC Accession Number : AD0686446,

ABSTRACT: This project was undertaken to present workable methods of analyses for thin, elastic shells of revolution, and to provide computer programs for performing such analyses. By means of these methods, the following problems for a thin, elastic shell of revolution can be solved: (1) stresses and deflections can be determined when the shell is subjected to arbitrary mechanical and/or thermal loads; (2) natural frequencies and mode shapes can be found for free vibration when the shell is subjected to or is free of prestress; (3) buckling loads, according to the classical stability theory, can be found when the shell is subjected to axisymmetric or sinusoidal nonsymmetric prestress.

ABSTRACT: This paper presents the first phase in the analysis of the deformation of a shell of revolution when it is being crushed by a rigid wall. In this paper, the analysis accounts for finite deflections and rotations but assumes that the material remains linearly elastic. The load-deflection behavior is obtained for a hemispherical shell, and it shows that the shell cannot collapse with a flat contact region. The conditions for the buckling of the contact region are determined.

ABSTRACT: Starting from the equations of a 3-dimensional medium, governing equations for infinitesimal, elastic deformations, superimposed upon a prestressed state, are derived for a thin shell. No further approximations are made except those of the Kirchhoff hypothesis of shell theory. The equations are referred to the prestressed state for which geometry, initial stress, and material properties are assumed known. The final equations are listed in terms of physical components of all variables and are referred to the lines of curvature of the reference surface of the shell in the prestressed state. They can be used directly for such problems as the stability or free vibration of initially stressed shells.

ABSTRACT: The authors have previously shown that a thin, complete spherical shell compressed between two parallel rigid plates deforms initially with the polar portion of the shell flattened against the plates and that at a critical deformation the flat region may buckle into an axisymmetric inward dimple. The present paper presents an analysis of the stresses and deflections produced during axisymmetric postbuckling and determines the deformation states at which the shell may buckle into a nonsymmetric shape. The analysis accounts for finite deflections and rotations, but assumes that the material remains linearly elastic throughout the deformation. An experiment shows that both the primary axisymmetric bifurcation point and the secondary nonsymmetric bifurcation point are stable for a shell with R/h \(\approx 40\).

ABSTRACT: Thin shells are widely used structural elements and are sometimes subjected to time-dependent loads after they have already acquired some prestress. The response of such a shell can be very different from that when the prestress is absent. The general methods of calculation of the response of the shell are discussed. The stability limit of the shell is viewed as a special result obtained in the free vibration analysis. An example of a typical containment shell of a nuclear power plant, housing the reactor, is worked out in detail.

ABSTRACT: A procedure for the analysis of dynamic buckling of axisymmetric shells subjected to axisymmetric, periodic loads of long duration is proposed that is based on the calculation of the nonsymmetric modes of free vibration and associated mode integrals over the reference surface of the shell. Numerical results are presented for the evaluation of dynamic stability of an actual shell that is designed for the cooling system of a nuclear power plant.

(2) Department of Mechanical Engineering and Mechanics, Lehigh University, Bethlehem, PA, 18015, USA
ABSTRACT: The problem of dynamic stability is substantially more complex than the buckling analysis of a shell subjected to static loads. Even at this date suitable criteria for dynamic buckling of shells, which are both logically sound and practically applicable, are not easily available. Thus, a variety of analyses are available to the user, encompassing various degrees of complexity, and involving a range of simplifying assumptions. The purpose of this paper is to compare and evaluate some of these solutions by applying them to a specific problem. A shallow spherical cap, subjected to an axisymmetric, uniform-pressure, step loading, is used as the structural example. The predictions, by various methods, of the dynamic buckling of this shell into unsymmetric modes, are then investigated and compared. The approximate methods used by Akkas are compared to the more rigorous and general solutions of the KSHEL, STARS, DYNASOR, and SATANS computer programs, and the various simplifying assumptions utilized are evaluated. Also included in the comparisons, are the predictions of the relatively simple “dynamic buckling model” approach of Budiansky and Hutchinson. The approaches utilized by the more complex programs [KSHEL (spatial integration, modal superposition, perturbation approach), DYNASOR (finite elements, time integration of non-linear dynamic equilibrium equations), SATANS (finite differences, pseudo load method, time integration), STARS (spatial and time integration, non-linear equilibrium or perturbation approaches)] will in turn be compared in terms of accuracy, idealization complexity, ease of use, and user expertise and experience required for analysis. The comparisons show that the more approximate methods underpredict the dynamic buckling loads for this problem. In addition, some basic assumptions of the simpler solutions are found to be invalid.

ABSTRACT: The use of numerical integration for the analysis of practical shell-of-revolution structures was documented almost simultaneously in the United States by three independent groups of researchers (Cohen, Kalnins, Mason et al.). These early efforts have been refined, reformulated, and increased in scope and applicability to become major program systems (SRA, Kalnins, STARS). While all three programs utilize basically the same mathematical formulation for integrating the shell differential equations, the matrix solution procedures from this point are basically different. The purpose of this paper is twofold, as follows: (1) to present the differences in solution procedures of the largest system (the Grumman — NASA STARS) from the other two, and point out the inherent advantages of this approach; and (2) compare the numerical integration procedure, as utilized in the STARS, with finite difference and finite element procedures, noting the relative advantages of each in the analysis of shells of revolution for static, buckling, and dynamic loadings. To fulfill the above purpose, a brief review of the numerical integration procedure for the analysis of shells of revolution is presented, and the matrix solution procedures of the SRA, Kalnins, and STARS programs are contrasted. The limitations imposed by the relative procedures are discussed. The unique formulation utilized by STARS for the solution of stability and vibration problems, and its advantages, are discussed in detail. The STARS program's analytical capabilities, capacity, and user options are compared with those of other major systems utilizing either finite differences or finite elements for the analysis of shells of revolution. Comparisons are made in terms of program size, program accuracy, number of degrees of freedom required for analysis, ease of idealization and user inputs, limitations imposed on analysis capability or output, running time, and so forth. All advantages and differences are demonstrated by use of solutions for realistic shell problems in the areas of statics, stability (including dead and live load distributions), vibrations, and dynamic response of shells subjected to time-dependent loadings.
D.B. Simmons, “NASA automatic system for computer program documentation, volume 2 (Computer program for dynamic analysis of shells of revolution)” [Final Report], no publisher or date given, ProQuest-CSA

ABSTRACT: The DYNASOR 2 program is used for the dynamic nonlinear analysis of shells of revolution. The equations of motion of the shell are solved using Houbolt's numerical procedure. The displacements and stress resultants are determined for both symmetrical and asymmetrical loading conditions. Asymmetrical dynamic buckling can be investigated. Solutions can be obtained for highly nonlinear problems utilizing as many as five of the harmonics generated by SAMMSOR program. A restart capability allows the user to restart the program at a specified time. For Vol. 1, see N73-22129.

ABSTRACT: The approximate load-deflection behavior of a simply supported cylindrical shell subjected to external pressure is determined for the case where the shell has a dimple shaped initial deflection. This is accomplished by the use of a “two-timing” perturbation expansion applied to the Kármán-Donnell shell equations. We show that if the shell is imperfection-sensitive to an initial deflection in the shape of the linear buckling mode, then it is also imperfection-sensitive to a dimple imperfection. The degradation in buckling load for the dimple imperfection depends linearly upon the initial deflection amplitude epsilon whereas for the modal imperfection it is proportional to the two-thirds power of epsilon.

R. S. Sendelbeck and N. J. Hoff (Stanford University), “Loading rig in which axially compressed thin cylindrical shells buckle near theoretical values”, (A holding and alignment test rig for use when buckling thin circular cylindrical shells is described. The consistency of high buckling values is demonstrated along with results concerning different holding restrictions), Experimental Mechanics, Vol. 12, No. 8, 1972, pp. 372-376, doi: 10.1007/BF02321695

ABSTRACT: Fifteen near-perfect electroformed nickel cylindrical shells of highR/t ratios have been buckled by axial compression using a special loading-rig system. Buckling-stress values averaged 85 percent, and ranged from 80 to 96 percent, of the classical theoretical bucklingstress value. The loading rig described in this report makes use of a simple procedure for accurately aligning the thin shell with the load axis and, also, for maintaining the circularity of the shell at its end by accommodating for slightly different diameters, with the use of tapered circular end caps which provide exact fits in each case. The rig also provides a setup in which shells may be free to twist, tip and translate, or be restrained from these motions. Comparison between restrained and unrestrained tests revealed no noticeable change in the buckling load. However, with the restraining mechanism, slightly higher postbuckling loads, repeated buckling loads and an increased number of circumferential waves resulted.

ABSTRACT: Thin shells of revolution, closed in the circumferential direction, and with an arbitrary meridian shape, are considered. The density of the vibration frequencies is determined by using an asymptotic method of integration [1 – 3]. The density of the frequencies in the neighborhoods of condensation points is investigated. The question of the density of vibration frequencies of thin shells has been examined in [4 – 7]. Shallow shells of rectangular planform were examined in [4, 5].

ABSTRACT: The nonlinear membrane problem is presented in terms of the curvatures and stresses (or strains) as field variables. As a part of the formulation, appropriate boundary conditions are studied. The significant features of the equations are discussed. Among the topics are included: dependence on initial shape, types of equations, ability to clarify anomalies of the linear membrane problem, stability and the membrane edge effect problem. A perturbation series scheme for the solution of the equations is also presented. The usefulness of the theory in solving practical problems is demonstrated by presenting a solution to the problem of the noncircular cylindrical membrane shell under lateral pressure.

ABSTRACT: A procedure is presented which relates the solution of the stability problem for an elastic structure subjected to a complex prebuckling stress distribution, to that of a solved stability problem for the same structure but with a “simple” stress distribution. The procedure reduces to obtaining the characteristic roots of a symmetric matrix. It is then applied to the buckling problem of a circular cylindrical shell subjected to a circumferentially varying compressive stress field and boundary conditions of the SS1-2 types. The main result is that for the boundary conditions and number of harmonic terms in the edge load taken, the buckling parameter approaches, as h/R \rightarrow 0, that of a cylinder uniformly subjected to the maximum circumferential stress.
ABSTRACT: The buckling analysis of a circular cylindrical shell under non-uniform axial compression is considered, using Donnell's equations with a Galerkin procedure and with boundary conditions of the SS3-SS4 types. Three problems are studied: (1) It is proven analytically that in the limiting case (h/R tending to zero) the eigenvalue for any load distribution approaches that of uniform loading. (2) A numerical parametric study of the effects of finite thickness, length and load distributions on the buckling load is presented. (3) The interactions among several load distributions are investigated numerically. The numerical results confirm the limiting behavior and indicate that a linear interaction formula is justified.

ABSTRACT: The linear buckling problem of a cylindrical shell subjected to circumferentially varying axial edge loads or thermal loads is considered. The case of an oscillatory loading having a cosinusoidal form with a single arbitrary harmonic index is treated first. Closed-form expressions for the critical eigenvalues are obtained, spanning the entire range of the harmonic index. Buckling modes are also presented. An interaction law among harmonic loadings based on existing numerical evidence is then postulated. This leads to the capability of calculating the buckling load for any given distribution. The method is compared, and good agreement is obtained, with published results on the heating of an axial strip. It is then used to calculate the buckling of a cylindrical shell subjected to a concentrated axial force.

ABSTRACT: The results of a numerical study of the buckling and initial post-buckling behavior of clamped shallow spherical shells under axisymmetric band type loads are presented. This behavior is studied, first, for a cap with fixed geometry when the radial location of a band load of constant width is allowed to vary; second, for a cap with fixed geometry under a uniform pressure distributed over the outer region of the cap; and third, for a band load of constant width and radial location when the shell geometry is allowed to vary. It is found in each of these studies that, for a significant range of the geometric shell parameter, lambda, the spherical cap under axisymmetric band load is imperfection-sensitive.

ABSTRACT: This paper presents the results of a numerical study of the buckling and initial post-buckling behavior of clamped shallow spherical shells under axisymmetric ring loads. This behavior is studied for a cap with fixed geometry when the location of the ring load is allowed to vary from the equivalent of a concentrated load at the apex to a location near the midpoint of the shell base radius, and for a fixed ring load location when the shell geometry is allowed to vary. It is found in both studies that a significant range of the geometric shell...
parameter, lambda, exists such that buckling is accompanied by a loss in load-carrying capacity.

ABSTRACT: The boundary-value problems associated with the axisymmetrical, asymmetrical, and initial postbuckling behavior of the clamped shallow conical sandwich shell under a uniform pressure are developed for face sheets of the same material and equal thicknesses. The numerical results presented show that the buckling and initial postbuckling behavior of the sandwich cap is similar to that of the conical homogeneous cap. The effects of the thickness and material parameters on the axisymmetric snap-through buckling behavior of the clamped shallow spherical and conical sandwich shells are also studied. For one material parameter considered the axisymmetric buckling behavior of the sandwich shells is similar to that of the corresponding homogeneous shells; so it is suggested that, without any further analysis, the asymmetric buckling and the initial postbuckling behavior of the sandwich cap can be obtained by conjecture. For the other material parameters considered, the axisymmetric buckling behavior of the sandwich caps is different from the axisymmetric buckling behavior of the corresponding homogeneous caps.

ABSTRACT: The buckling and initial postbuckling behavior of clamped shallow spherical sandwich shells with dissimilar face sheets under a uniform pressure is studied. The numerical results show that the buckling and initial post-buckling behavior of clamped shallow spherical sandwich shells with dissimilar face sheets is similar to that of the corresponding homogeneous shell. The classical buckling analysis for spherical sandwich shells under a uniform pressure is also presented. The results indicate that it is possible to obtain the buckling curves of spherical sandwich caps from those of the homogeneous cap using a magnification factor which is obtained via the classical buckling analysis, for large values of the sandwich shell parameter.

ABSTRACT: The asymmetric dynamic behavior of clamped shallow spherical shells under a uniform step pressure of infinite duration is investigated. The solution of a linear eigenvalue problem yields the bifurcation paths and also the lower bound for the asymmetric dynamic snap-through buckling pressure. The asymmetric dynamic response of shells with a shape imperfection is studied. The asymmetric dynamic snap-through buckling load is defined to be the threshold value of the step pressure at which the asymmetric response shows significant growth rate. The snap-through buckling loads are obtained for a few shell parameters. The numerical results are compared with the available experimental results and they are in good agreement. Finally, a preliminary study of the phase planes is presented.

ABSTRACT: This paper investigates the dynamic behaviour of a shallow, viscoelastic, spherical shell under a harmonic excitation. The time evolutions of the response of the corresponding nonlinear dynamical system are described by the phase portraits and the bifurcation of the parameter dependent system is studied numerically so as to identify qualitative changes in the phase portrait. The viscoelastic shell, having more than one equilibrium configuration for some problem parameters, shows periodic and/or randomlike chaotic oscillations under the given excitation according to the dimensions of the attracting set. The occurrence and nature of the chaotic attractors are verified by evaluating Lyapunov exponents.

DOI: 10.1080/1075941993054858

ABSTRACT: The purpose of this work is to present some numerical results on nonlinear, snap-through buckling of shallow spherical shells made of laminated composite materials under general static loading. Isotropic shells are covered as a special case of the general problem. A special-purpose finite-difference computer program has been developed. Moreover, the general-purpose computer program ANSYS has also been used. Effects of various material properties on the nonlinear behavior of the shells are investigated. One of the conclusions of the study is that ANSYS may yield erroneous results in some cases. Another conclusion is that the buckling curves of composite shallow spherical shells have a shape similar to that of the corresponding isotropic shell. This finding implies that the geometry of a shell may be an important factor in giving a characteristic shape to the buckling curve, at least for the shell parameters considered here.

ABSTRACT: In this study, the snap-through buckling behaviour of axisymmetric shells, subjected to axisymmetric horizontal peripheral load or displacement for various shell parameters and various boundary conditions, is investigated. Results obtained seem not to have been reported previously. An application of peripheral displacement type of loading is seen in metal-ceramic composite transducers developed by sandwiching a piezoelectric (PZT) ceramic between two metal end caps which serve as mechanical transformers for converting and amplifying the lateral displacement of the ceramic into an axial motion normal to the metal cap. In our numerical search, we have observed that snap-through and snap-back buckling is possible for shallow spherical caps for a very narrow range of the shell parameter used. When a hole is opened around the apex of the cap, buckling is possible for a larger range of the shell parameter. Obtaining the displacement amplification and the blocking or generative force for various material and geometric properties is necessary for the possible application of the findings in transducer design. The numerical results are presented in graphical forms.

ABSTRACT: The nonlinear dynamic buckling behavior of axisymmetric spherical shells subjected to radial dynamic edge loading has been investigated. The peripheral dynamic loading is in the form of step loading of infinite duration in the time domain. This kind of loading is seen in actuators known as displacement transducers, where the radial motion of the edges is converted into a flex-tensional motion in the spherical caps. As a result a large displacement is obtained in the perpendicular direction, which may result in snap-through buckling. It is theoretically possible to develop magnification mechanisms that produce sizeable displacements necessary for actuating functions. For the numerical solution of the problem a computer program, using a linearized finite element incremental-iterative approach based on updated Lagrangian formulation is developed, and the whole process is accomplished using the Newmark β method as the time integration scheme.

ABSTRACT: In using the finite element method to compute a transient response, two choices must be made. First, some form of mass matrix must be decided upon. Either the consistent mass matrix prescribed by the finite element method can be employed or some form of diagonal mass matrix may be introduced. Secondly, some particular time integration procedure must be adopted. The procedures available divide themselves into two classes: the conditionally stable explicit schemes and the unconditionally or conditionally stable implicit schemes. The choices should be guided by both economy and accuracy. Using exact discrete solutions compared to the exact solutions of the differential equations, the results of these choices are displayed. Concrete examples of well-matched methods, as well as ill-matched methods, are identified and demonstrated. In particular, the diagonal mass matrix and the explicit central difference time integration method are shown to be a good combination in terms of accuracy and economy.

ABSTRACT: The instability of thin elastic shells still remains the most challenging of all the classical problems of the theory of elasticity. It is the aim of this investigation to verify a rational experimental technique for predicting the buckling loads of cylindrical tubes under axial load as well as under external radial pressure, by measuring their natural frequencies under different loadings. Cylindrical tubes made of Hostaphan (thickness 0.254 mm and radius 100 mm) were tested under axial load and under external radial pressure in the German Air and Space Research Laboratory (Deutsche Forschungsanstalt für Luft und Raumfahrt) at Braunschweig, West Germany, and the results compared with an actual buckling test. The tests revealed that the buckling load can be predicted satisfactorily by the proposed non-destructive vibration method of testing.

ABSTRACT: The nonlinear, damped dynamic response of a simply supported, nearly circular cylindrical shell due to an exponentially decaying, uniform radial pressure is computed for peak pressures and total impulses between the static and dynamic buckling limits. The analysis employs Fourier series expansions of the dependent variables in the circumferential coordinate, finite difference approximations of the axial derivatives, and Newmark’s beta-method for the time integration. All nonlinear coupling between the retained modes is included. The inclusion of damping reduces the maximum amplitudes of the dominant modes by approximately 30%, but stresses larger than the yield stress can occur at peak pressures and total impulses well below the dynamic buckling limit. The amplitudes of the static buckling modes are found to be linearly proportional to the magnitude of the initial imperfections, but the parametrically excited modes are unaffected by the initial imperfections.

Ball, “A digital computer study of the buckling of shallow spherical caps and truncated hemispheres” (Digital computer program used for thin shell buckling analysis of spherical caps under pressure loading and truncated hemispheres under axial tension), (no publisher given; csa.com), 1972
ABSTRACT: A study of the buckling of thin shells was conducted using a digital computer program for the geometrically nonlinear analysis of arbitrarily loaded shells of revolution. The objective was an evaluation of the program's applicability to bifurcation buckling and imperfection sensitivity analysis. Clamped spherical caps under pressure loading and clamped truncated hemispheres under axial tension were investigated. Buckling loads were determined for axisymmetric and nearly axisymmetric loads and are compared with previously published analytical results based on geometric imperfections.

ABSTRACT: As a part of the Air Force Flight Dynamics Laboratory's program to assess the current U. S. capability for computer analysis of shell structures, the Lockheed Palo Alto Research Laboratory prepared and distributed to the structures community a series of three sample problems. These problems are intended to be representative of current engineering situations. The analyses requested consisted of linear stress, free vibration, bifurcation buckling, elastic and inelastic collapse, and linear and nonlinear transient response. Solutions to these problems were solicited with the objective of obtaining information that could be used to compare and assess contemporary computer-oriented analysis methods. The solutions that were submitted are presented in this report. Comparison of the several solutions for each analysis reveals that in general there is good agreement for the linear and eigenvalue analyses. For the nonlinear analyses, multiple solutions were received only for the transient response problem. Comparison of these solutions shows limited agreement between any of the results.

ABSTRACT: A digital computer program for the geometrically nonlinear static and dynamic response of arbitrarily loaded shells of revolution is described. The governing partial differential equations are based upon
Sanders' nonlinear thin shell theory for the conditions of small strains and moderately small rotations. The governing equations are reduced to uncoupled sets of four linear, second order, partial differential equations in the meridional and time coordinates by expanding the dependent variables in a Fourier sine or cosine series in the circumferential coordinate and treating the nonlinear modal coupling terms as pseudo loads. The derivatives with respect to the meridional coordinate are approximated by central finite differences, and the displacement accelerations are approximated by the implicit Houbolt backward difference scheme with a constant time interval. At every load step or time step each set of difference equations is repeatedly solved, using an elimination method, until all solutions have converged. Results from the program are compared to previously published data for several problems, and the versatility, efficiency, and limitations of the program are candidly evaluated.

ABSTRACT: A comparison between the linear and nonlinear seismic analysis of a thin unreinforced steel reactor containment vessel is presented. The effects of the nonlinear coupling between the low Fourier harmonic excitations and the higher Fourier harmonics producing an ovalling response are examined. Imperfection shapes of the containment vessel are employed to provide the mechanism for this response.

ABSTRACT: The dynamic behavior of clamped shallow spherical shells subjected to axisymmetric and nearly axisymmetric step-pressure loads is examined using a digital computer program for the geometrically nonlinear static and dynamic analysis of arbitrarily loaded shells of revolution. A criterion for dynamic buckling under the nearly axisymmetric load is proposed and critical buckling pressures are determined for a large range of shell sizes.

ABSTRACT: Solutions from five computer codes for both the linear and the geometrically nonlinear response of an impulsively loaded, truncated elastic cone are presented. The codes used are DYNAPLAS (Von Riesemann), REPSIL (Huffington), SATANS (Ball), SHORE (Underwood), and SMERSH (Hubka). Displacements and strains at two locations on the shell are plotted for the period 0 - 1500 micro sec. The
solutions are presented to illustrate the state of the art of linear and nonlinear dynamic response computations of shell structures and to provide users of other codes an opportunity to compare results. The five codes provide essentially identical linear results for all quantities except the meridional strain at the outer surface. There is fair agreement between the nonlinear results for the first 750 micro sec; for later times the solutions, except for DYNAPLAS and SATANS, progressively diverge. Thus, the linear analysis appears to be well in hand, but the nonlinear problem cannot be considered solved. Additional studies are required to determine the cause(s) of the differences between the nonlinear results.

ABSTRACT: Computer programs are considered for the dynamic buckling of beam, plate, and shell type structures due to deterministic forces. The material presented is intended to assist the analyst in selection of the proper software and in the development of a meaningful numerical model for dynamic buckling. Several examples of dynamic buckling are described to illustrate the various aspects that must be considered such as snap buckling, asymmetric buckling, and parametric resonance. The most common methods of solution are briefly discussed and some modeling guidelines are given. Most of the public and commercially available programs for the geometrically nonlinear, dynamic analysis of thin beam, plate, and shell structures are described in detail. User evaluations are also listed.

ABSTRACT: This paper presents the equations for thin shell-of-revolution tanks containing an arbitrary level of fluid. The mass matrix can be used with any finite element or finite difference digital computer program that computes either the dynamic response or the natural frequencies and modes of a thin shell of revolution and that has provision for a nondiagonal mass matrix. The method does not require a numerical finite difference or finite element discretization of the fluid, but instead provides, in series form, a mass matrix that exactly satisfies the governing field equations for the fluid and satisfies the fluid-shell interface condition with a least-squares fit.

ABSTRACT: The frequency versus wave number characteristics of four O(deltaS2) finite difference formulations for one-dimensional linear shell (ring and axisymmetric) equations are investigated and compared with the exact continuum characteristics. It is found that three of the formulations give virtually identical results. These are half-spacing techniques with equilibrium in terms of displacements or resultants and whole-spacing with equilibrium in terms of displacements. The formulation based on whole-spacing with equilibrium in terms of resultants produces some dramatically different results. These discrepancies partially explain some
late time instability problems and critical time step behaviour that have been reported by other investigators.

ABSTRACT: A large deflection elastic-plastic analysis is presented applicable to orthotropic axisymmetric plates and shells of revolution subjected to monotonic and cyclic loading conditions. The analysis is based on the finite-element method. It employs a new higher order, fully compatible, doubly curved orthotropic shell-of-revolution element using cubic Hermitian expansions for both meridional and normal displacements. Both perfectly plastic and strain hardening behavior are considered. Strain hardening is incorporated through use of the Prager-Ziegler kinematic hardening theory, which predicts an ideal Bauschinger effect. Numerous sample problems involving monotonic and cyclic loading conditions are analyzed. The monotonic results are compared with other theoretical solutions. Experimental verification of the accuracy of the analysis is also provided by comparison with results obtained from a series of tests for centrally monotonically-loaded circular plates that are simply supported at their edges.

ABSTRACT: Tests were performed on three simply supported circular plates of aluminum alloy 2024-0, under a central concentrated load, with large deflection. The load was provided by a small diameter hard steel rod. Measurements were made of load, deflections, and strains, and membrane and bending strains were calculated from the test data. Twenty electrically bonded strain gauges were used to measure the distribution of radial and circumferential strain components along a radial line on both faces of each plate. The test data are presented in comparison with theoretical predictions generated by the Grumman-developed finite element computer code PLANS.

C. A. Fisher, C. W. Bert (School of Aerospace, Mechanical and Nuclear Engineering, The University of
ABSTRACT: As an exploratory effort toward improving the crashworthiness of light aircraft cabins, a theoretical analysis was made to predict the dynamic buckling load and buckling time of a stiffened, thin-walled circular cylindrical shell. To provide for the large stiffener spacing in light aircraft, the stiffeners were considered as discrete elements by means of a Dirac delta procedure. The nonlinear governing equations were derived using Hamilton’s principle and the final equations were obtained by means of Galerkin’s method. Solution was carried out by using a Gauss-Jordan technique on the algebraic equations and a Runge-Kutta technique on the nonlinear differential equations. Numerical results are presented for an idealized model of a typical light aircraft cabin.

ABSTRACT: An alternative to the currently used Perzyna's theory of viscoplasticity for small strains is presented. The plastic strain rate vector is normal to the quasistatic yield surface which in turn may not include the origin. Consequently, new loading/unloading criteria are introduced.

ABSTRACT: The concepts of yield surface and loading surface at room temperature and elevated temperature are discussed and experimental results on pure aluminum in support of these concepts are presented. Recommendations for future experimental research are presented.

ABSTRACT: The current version of the computer program SAP for the static and dynamic analysis of linear structural systems is described. The analysis capabilities of the program, the finite element library, the numerical techniques used, the logical construction of the program and storage allocations are discussed. The main advantages of the program as a general purpose code become apparent. Results of analyses as comparisons with other existing solutions are given, and running times which demonstrate the efficiency of the program are included.

ABSTRACT: The computer is frequently used in the solution of structural problems involving composite materials. The algebraic manipulations required to cast the problem into a form suitable for direct computer
solutions have become the most tedious and error-prone parts of the solution process. This step may now be markedly simplified by using a symbolic algebra manipulation language. The use of PL/I FORMAC for this purpose is described.

ABSTRACT: The behavior of natural draft cooling tower wind pressure is investigated. Buckling loads of the towers of different meridional curvatures and shell thicknesses are computed and compared. The results show that: (1) an increase in stiffness of the structure with an increase in meridional curvature; and (2) changes of buckling load caused by changes in shell thickness is approximately proportional. A dynamic analysis of the tower is also presented. The response of the structure is increased by the dynamic effect. The amount of increase depends upon the wind time history.

ABSTRACT: A new design approach is presented to provide a conservative estimate of the buckling strength of laminated anisotropic circular cylinders under axial compression. The analysis is based on Koiter’s “special theory” for uniform axisymmetric shape imperfections which is valid for imperfections of the order of the shell wall thickness. Fourteen three-ply, glass-epoxy cylinders containing random imperfections of small mean square amplitude were characterized in terms of an equivalent axial imperfection component. Good agreement was found between theory and experiment for the range of imperfection amplitudes encountered.

ABSTRACT: Both ring and stringer stiffened circular cylinders with and without shape imperfections have been studied under axial compression, external hydrostatic pressure and combined loading of compression-hydrostatic pressure. To provide reference data for the stiffened shell results, compressive buckling tests were performed on unreinforced cylinders containing asymmetric imperfection distributions. In addition, hydrostatic buckling of unstiffened cylinders was also investigated to assess the effects of different boundary conditions on the critical pressure for varying values of cylinder lengths.

P. G. Bergan and T. Søreide (Institutt for statik, The Norwegian Institute of Technology, The University of Trondheim, Norway), “A comparative study of different numerical solution techniques as applied to a nonlinear

ABSTRACT: This paper describes and compares a number of different numerical methods frequently used in solution of nonlinear problems in structural mechanics. A simple mechanical system is chosen. By varying the geometry and the stiffness of the members, different types of nonlinear structural behavior may be simulated. A comparative study of various solution techniques applied to the sample problem is given. The solution paths followed by these methods are illustrated by use of map plots of the strain energy and the total energy of the system. Also, a new method for automatic computation of steps for incremental techniques is suggested.

ABSTRACT: The paper describes a general formulation for geometrically nonlinear analysis of shells using very simple flat finite elements. The approach is based on the “updated Langrangian” description of motion (co-rotational coordinates), in which the geometry of the shell structure is continuously updated during deformation to establish new reference configurations. The numerical solution technique adopted in the paper allows tracing of the entire nonlinear load-deflection path including unstable branches in the solution space. Numerical studies are presented in order to demonstrate the accuracy and efficiency of the proposed method.

ABSTRACT: The paper describes briefly a class of shell elements based on the free formulation by Bergan and Nygård. The elements include the “drilling” freedom that gives a significantly improved membrane action as compared to traditional elements. The elements may undertake arbitrarily large displacements and rotations and account for material nonlinearities. The “hyperplane displacement control” method is applied for solution of the static instability problems including singularities. The presented examples cover snap-through analysis of shells and buckling of plates. The examples verify that the shell elements and the solution algorithms are accurate, reliable and efficient.

References listed at the end of the paper:

ABSTRACT: The present paper describes a hybrid stress finite element formulation for geometrically nonlinear analysis of thin shell structures. The element properties are derived from an incremental form of Hellinger-Reissner's variational principle in which all quantities are referred to the current configuration of the shell. From this multi-field variational principle, a hybrid stress finite element model is derived using standard matrix notation. Very simple flat triangular and quadrilateral elements are employed in the present study. The resulting non-linear equations are solved by applying the load in finite increments and restoring equilibrium by Newton-Raphson iteration. Numerical examples presented in the paper include complete snap-through buckling of cylindrical and spherical shells. It turns out that the present procedure is computationally efficient and accurate for non-linear shell problems of high complexity.

ABSTRACT: A buckling theory valid for finite prebuckling deformations is presented for thin homogeneous, isotropic and elastic shells. It is subject to the restriction of the Kirchhoff hypothesis. A set of stability equations is derived by decomposing strain and stress components into four classes according to their characteristics. The influence of the prebuckling deformations on the buckling of thin circular cylindrical shells under lateral pressure is investigated with the aid of the basic equations derived above and the results are compared with the solutions of the Flügge equations and those obtained by Yamaki.

James C. Frauenthal (Anderson Hall, Tufts University, Medford, Massachusetts 02155 U.S.A), “Initial postbuckling behavior of optimally designed columns and plates”, International Journal of Solids and

ABSTRACT: The initial postbuckling behavior of optimally designed structures of two generic types is investigated. The structures are straight, simply-supported, inextensional columns, loaded by axial thrust and flat, simply-supported, axisymmetric circular plates, loaded by radial thrust. The structures are optimal in the sense that they withstand the largest possible loads prior to buckling, while satisfying fixed volume and minimum allowable gage constraints. The stability analysis is based upon Koiter's general theory of the postbuckling behavior of structures.

ABSTRACT: The static, vibration, and buckling analysis of axisymmetric circular plates using the finite element method is discussed. For the static analysis, the stiffness matrix of a typical annular plate element is derived from the given displacement function and the appropriate constitutive relations. By assuming that the static displacement function, which is an exact solution of the circular plate equation down triangle, open2down triangle, open2W = 0, closely represents the vibration and buckling modes, the mass and stability coefficient matrices for an annular element are also constructed. In addition to the annular element, the stiffness, mass, and stability coefficient matrices for a closure element are also included for the analysis of complete circular plates (no center hole). As an extension of the analysis, the exact displacement function for the symmetrical bending of circular plates having polar orthotropy is also given.

ABSTRACT: A computer program for the linear and nonlinear analysis of shell structures (STAGS) is applied to the instability analysis of a complex stiffened structure subjected to complicated sets of distributed and concentrated loads. Results obtained from two-dimensional bifurcation and nonlinear collapse analyses are presented. The nonlinear analysis includes the effects of an imperfection in a shell stiffened by heavy longerons. Several problems associated with the analysis of very large eigenvalue problems are discussed (one case involved a model with 20,910 degrees-of-freedom). These include the use of the appropriate finite-difference formulation to ensure convergence in a desired direction (approaching the asymptotic value either from above or from below) and the use of variable grid spacing to induce buckling in one part of the structure or the other. A technique of finding higher eigenvalues by removing the prestress at the point of bifurcation is described.

ABSTRACT: The dynamic buckling of thin viscoplastic cylindrical shells is considered in the formulation developed by Abrahamson and Goodier [1]. The constitutive equations employed describe the rate sensitive plastic material and a biaxial state of stress is considered. The influence of the viscosity parameter on the buckling process is discussed in detail and in the limiting case the solution for a perfectly plastic material is obtained. From the analysis of the final deflections as a function of the applied impulse the “stability effect” of the viscous properties of the material on the buckling process is determined.

ABSTRACT: This thesis has the objective of establishing the stability behaviour of a thin clamped-ended pipe with internal flow. The unsteady fluid forces on the pipe wall is determined by using classical potential flow theory for an incompressible, inviscid fluid and the motion of the pipe is represented by Flügge-Kempner shell equation. The solution is obtained using Fourier integral theory and the method of Galerkin. It is found that the pipe becomes unstable statically in a mode being comprised of one axial half-wave and a number of circumferential waves depending on the length and thickness ratios. For the limiting case of a relatively long thin pipe the mode of instability is the first beam mode and a particularly simple expression is found for the critical flow velocity. Furthermore, the mode shape at instability always corresponds to that of the lowest natural frequency of the pipe. The theoretical results are compared with experiments and previous work developed by different methods and the agreement found is good.

ABSTRACT: In this paper the stability behaviour of a thin, clamped ended pipe with a high velocity internal flow is considered. The dynamic fluid loading is developed by using potential theory for an incompressible, inviscid fluid and the motion of the pipe is represented by the Flügge-Kempner shell equation. The solution is obtained by using Fourier integral theory and the method of Galerkin. For the limiting case of a relatively long thin pipe a particularly simple expression is found for the critical velocity. When both ends of a pipe are fixed, static divergence always precedes the onset of flutter and, hence, a relatively simple approach is sufficient for predicting the critical velocity. Furthermore, the mode shape at divergence instability always corresponds to that of the lowest natural frequency of the pipe, being comprised of one axial half-wave and a number of circumferential waves depending on the length and thickness ratios.

ABSTRACT: The stability behaviour of thin-walled tubes conveying fluid is examined with an emphasis on the effects of tube flattening. Two simplified theoretical models are developed which represent a flattened tube as two parallel flat plates. The first model is in terms of standing waves on finite length plates whereas the second model is in terms of travelling waves on infinitely long, finite width plates. The fluid forces are determined by using potential flow theory. Experiments were conducted with three different tubes, one of which was initially flat. The experimental observations agree with the predictions of the first theoretical model, at least qualitatively.

ABSTRACT: Bifurcation stresses and initial postbuckling behavior of both unstiffened and outside ring stiffened circular cylindrical shells under axial compression are analyzed. The shells are assumed to have axisymmetric sinusoidal imperfections with arbitrary wavelengths and amplitudes. It is found that for large imperfection amplitudes and wavelengths both the unstiffened and the stiffened shells have extremely small bifurcation loads. The postbuckling analysis shows that for small imperfection amplitudes the bifurcations from the axisymmetric state are initially unstable and collapse is associated with the bifurcation points. However, for larger values of the imperfection amplitudes the bifurcations are stable. For unstiffened shells the transition from unstable to stable bifurcations can take place at very small values of the load. On the other hand, for stiffened shells it is found that bifurcations at load levels less than about 40 per cent of the classical buckling load have stable initial postbuckling behavior.

ABSTRACT: A generalized beam theory, earlier developed by the author, is applied to a rotationally symmetrical shell structure consisting of cylindrical and conical sections. It is shown that this theory, in which the flexibility of the beam is specified by four functions, is adequate for treating the shell structure as a beam in bending in cases where the Bernoulli-Euler and Timoshenko beam theories prove to be deficient. Flexibility functions are derived from the membrane equations of the shell structure, and modifications at the boundaries are obtained from the complete shell equations.

ABSTRACT: The initial post-buckling behaviour is determined for an integrally stiffened wide panel under compression. Overall buckling of the panel as a wide Euler column and local buckling of the plates between the
stiffeners are considered. Designing the panel so that the critical bifurcation load is the highest possible for a given amount of material per unit width tends to lead to a structure in which Euler-type buckling and local buckling occur simultaneously. It is shown that such a panel is very sensitive to geometrical imperfections. Thus, the critical bifurcation load cannot be reached in a practical structure and the two-mode design may not be optimal.

ABSTRACT: For an eccentrically stiffened wide panel under compression the optimality of a design with simultaneous occurrence of buckling as a wide Euler column and local buckling of the plate between the stiffeners is investigated. The total amount of material per unit width of the panel is prescribed. As a function of the distribution of this material in the plate and the stiffeners the maximum carrying capacities are calculated approximately by application of Galerkin's method. The design with the highest carrying capacity and the design with the best ability to retain axial stiffness, corresponding to given imperfections, are determined. It is shown that imperfections move the optimum away from the coincident buckling mode design.

ABSTRACT: For an axially compressed elastic-plastic cylindrical shell with elliptical cross-section the buckling behaviour is investigated. The initial post-bifurcation behaviour of a perfect shell compressed into the plastic range is determined in terms of an asymptotic expansion. The behaviour of shells with initial stress free imperfections is computed numerically using an incremental procedure. For shells with sufficiently eccentric cross-sections elastic analyses predict final collapse loads considerably above the bifurcation load, but the present numerical results show that elastic-plastic material behaviour reduces these collapse loads to such an extent that the elastic-plastic shells are moderately imperfection-sensitive.

ABSTRACT: The behaviour of elastic-plastic spherical shells under internal pressure is investigated numerically for thickness-to-radius ratios ranging from cases of thin shells to very thick shells. The shells under consideration are made of strain-hardening elastic-plastic material with a smooth yield-surface. Attention is restricted to axisymmetric deformations, and results are presented for initial thickness inhomogeneities in various axisymmetric shapes. For smooth thickness-variations in the shape of the critical bifurcation mode, the reduction in maximum pressure is studied together with the distribution of deformations in the final collapse mode. Also, the possibility of flow localization due to more localized, initially thin regions on a spherical shell is investigated.

ABSTRACT: For an elastic-plastic, wide panel with eccentric stiffeners plastic buckling due to axial compression is investigated. Special attention is directed to panels designed so that overall buckling as a wide column and local buckling of the plate between the stiffeners occur simultaneously or nearly simultaneously. The bifurcation behaviour for a perfect panel compressed into the plastic range is determined analytically, and the asymptotic initial post-bifurcation analysis is mentioned briefly. Mode interaction and imperfection-sensitivity is investigated numerically by application of an incremental method. Computations for panels that bifurcate in the plastic range show a considerable imperfection-sensitivity, in some cases due to mode interaction and in some cases due to a single mode.

ABSTRACT: For a simply supported elastic-plastic square plate under axial compression the post-bifurcation behaviour and the sensitivity to initial imperfections are investigated. An exact asymptotic expansion is given for the initial post-bifurcation behaviour of a perfect plate compressed into the plastic range. The imperfection sensitivity is studied through an asymptotic analysis of the behaviour of the hypoelastic plate that results from neglecting the effect of elastic unloading. The results of the asymptotic analyses are compared with results of a numerical incremental solution by means of a combined finite element—Rayleigh Ritz method. The paper considers the effect of different in-plane boundary conditions and the effect of various degrees of strain hardening.

ABSTRACT: Through the use of an integral transform, the present paper extends the applicability of the multisegment numerical integration technique to include the solution of general macroscopically anisotropic multilayered shells of revolution. It is found that compared with orthotropic shells, material anisotropy induces a doubling in the number of transformed fundamental equations characterizing the static response. Employing the transform together with the multisegment integration technique and several concepts from the direct stiffness method of structural analysis, procedures are developed which can handle branched anisotropic multilayered shells of revolution in a more effective manner than was previously possible. Based on the procedures outlined in the paper, numerical studies are presented which show the effect of segment size on the solution accuracy and the effects of material anisotropy on selected shell configurations.

ABSTRACT: Through the use of a complex series representation, a complex multi-segment numerical integration procedure is developed which can handle the static analysis of mechanically and thermally loaded branched laminated anisotropic shells of revolution with arbitrary meridional variations in thickness and material properties. In contrast to the real numerical integration treatment of anisotropic shells, the present procedure develops local and global stiffness matrices which require only half the computer storage and which requires significantly less overall computer time. Furthermore, since the overall procedure requires fewer computational steps, an improvement in numerical resolution is also obtained for a given word size machine. To illustrate the procedure several numerical examples are included.

ABSTRACT: The vibration of stiffened cylindrical panels with simply supported boundary conditions in the presence of initial axial and pressure loads is investigated by using a direct method. The effects of in-plane, transverse and rotary inertias are included in the formulation. The results are obtained for the stability and free
vibration of cylinders and panels as special cases and compared with other solutions. The behavior of a cylinder and the behavior of a panel (a segment of the cylinder) in stability and vibration are similar if the panel is wide enough to contain at least half a wave of the circumferential wave pattern of the cylinder.

ABSTRACT: A computer program, STAGS, for analysis of the behavior of shells of general shape has been extended by the addition of a capability for transient response analysis. A brief discussion of the numerical integration procedures included as options in STAGS is presented here, together with some numerical results obtained by use of the program. The results are included to demonstrate how rapid development of computers and numerical analysis methods has enhanced our capability to solve complex shell stability problems. In addition, they illustrate some facets of shell behavior under transient and static loading. The applications are concerned with an axially loaded cylindrical shell with unstiffened rectangular cutouts. The effect of the loading rate on the shell response is studied. The definition of a dynamic buckling criterion is discussed in view of the results obtained. Also considered is the possibility of determining a static collapse load (limit point) by use of a transient response analysis with the load applied slowly.

ABSTRACT: The equations of a symmetrically loaded elastic thin shell of revolution are set up in such a way that the effects of small deviations of the meridian from a “perfect” form may be analyzed with ease. Solutions are found for several kinds of imperfection and the results plotted in a specially compact form. The structural effects depend strongly on the meridional length of the imperfection. Some shell junction problems can be
analyzed in terms of imperfections. The method can be extended to find classical buckling loads for axially symmetric modes.

ABSTRACT: Rayleigh successfully analysed inextensional deformation of thin elastic shells by using a simple energy method. Subsequent workers seem to have been put off from using similar methods for shells which suffer extensional as well as bending deformations by the fact that the calculations get messy. In this paper we develop the kinematic relation between surface strains and changes in Gaussian curvature, and show that this is a very convenient tool for use in energy calculations. We give two examples of energy calculations for shells loaded by point forces. We find that once the energy expressions have been set up, certain analogies with simpler and already-solved problems become obvious. This leads to simple solutions. A feature of the method is that physically important quantities are not obscured, and distinct regimes of structural action are clearly delineated.

ABSTRACT: It is proved that cylindrical shells and two dimensional flat panels constrained to zero displacement at their leading and trailing edges, and exposed to subsonic flow, can lose their stability by divergence (buckling) while in supersonic flow two-dimensional panels can only flutter. Moreover, it is proved that in incompressible flow flutter can only occur—if at all—above the critical divergence velocity. The proofs are based on a qualitative analysis of the expressions for generalized aerodynamic forces derived in references [1]–[3], and on the assumptions that linearization of the stability problem is admissible and that Galerkin's method is convergent.

ABSTRACT: An exact solution and numerical results are presented for simply supported circular cylindrical shells that are laminated unsymmetrically about their middle surface. The coupling between bending and extension induced by the lamination asymmetry substantially decreases buckling loads and vibration frequencies for common composite materials such as boron/epoxy and graphite/epoxy. For antisymmetric laminates, the effect of the coupling dies out rapidly as the number of layers is increased. However, for generally unsymmetric laminates, the effect of coupling dies out very slowly as the number of layers is increased. That is, having a large number of layers is no guarantee that coupling will not seriously degrade the shell buckling resistance and vibration frequencies. Thus, designers must include coupling between bending and extension in all analyses of unsymmetrically laminated shells.

ABSTRACT: A description is given in this paper of part of a larger study directed toward the investigation of the buckling characteristics of thin, open cylindrical shells. The load-deflection response of transversely loaded shells is treated in this study. A subsequent paper will deal with the behavior of end-loaded open shells. Measured values of buckling loads are compared with analytical predictions based on the presumption that prior to the onset of buckling the shell material behaves elastically but large deflections of the shell surface may occur.

ABSTRACT: Applying the strain energy principle, the stiffness matrix Cij is derived for a triple-layered fibre-reinforced laminate having fibre orientations (beta, alpha, -beta). Next, the stiffness coefficients, CBARij, are determined for laminated composites consisting of such triple layers. The present formulation is more general in nature, since it permits analysis for arbitrary stacking sequences. A few numerical results are presented for commonly used fibre-reinforced composites, employing the effective micromechanics properties as summarised by Tsai [1] for unidirectional composites.

ABSTRACT: This paper presents some numerical results of the effects of several nondimensional parameters
on the buckling and initial post buckling behaviors of shallow sandwich panels under axial compression. Results are presented that show these effects due to transverse shearing resistance of the core material, different face-sheet thicknesses, and different core thicknesses. Further effects on the buckling and initial postbuckling behaviors of sandwich panels are presented due to the torsional resistance of longitudinal edge stiffeners. The results show that the range of flatness parameter, _¥/d, for which sandwich panels remain imperfection-insensitive increases with increases in transverse shearing resistance of the core material and with larger core thicknesses. These results also indicate that this range of _¥/d is smallest when the face-sheet thicknesses are equal. Finally, as in the case of homogeneous panels, torsional resistance of the longitudinal edge stiffeners has the effect of making the sandwich panel less imperfection-sensitive.

ABSTRACT: Design study methods and results are presented of a composite reinforced base ring for the conical aeroshell structure of the planetary lander vehicle for Project Viking, an unmanned mission to Mars. The aeroshell is a ring and stringer-stiffened conical shell structure having a half angle of 70° with a large base ring mounted at the outer edge of the cone and a large pay-load ring in the interior with many smaller rings spaced along the inside shell surface. The purpose of the structure is to develop the aerodynamic drag required to decelerate the lander in the Mars atmosphere to facilitate a soft landing. The shell, therefore, must be designed to resist external pressure loads during Martian entry. Unlike conventional shell structures, the Viking aeroshell has no connecting supports at its large diameter edge and, therefore, it must resist the external pressure as an unsupported inertia-loaded shell. Very little design information is available on large shell structures under these loading conditions. The structural weight of the aeroshell must be reduced to the minimum possible level while still retaining structural integrity. A currently proposed design for this structure is all metal, and the base ring accounts for 41 per cent of the total aeroshell structural weight. One possible method of reducing the weight of the proposed design is to selectively apply filamentary composites to reinforce a redesigned base ring. The filamentary reinforced base ring must be designed to take into account all possible modes of failure under the maximum design load conditions. The possible modes of failure are local or general buckling of the shell, ring buckling, and exceedence of the maximum permissible stress levels. The design of a shell structure of this complexity requires the use of the latest technology available in a large general purpose shell buckling program. A large general purpose non-linear shell buckling program developed by Lockheed (BOSOR 2) was used. Since the amount of computational effort is considerable for such a study, the turnaround time for using such a program as an aid in the design process was reduced by adapting the program to an interactive real time graphical system using the facilities of the Langley Research Center CDC computer complex. This paper describes the shell structure model and the stability results of a large Langley Research Center Viking aeroshell model, the BOSOR 2 computer program and its adaptation to an interactive system, and the design strategy used to re-design the base ring and the weight savings achievable by composite reinforcements.

Paul A. Cooper and Cornelia B. Dexter (Langley Research Center, Hampton, CA 23665), “Buckling of a conical shell with local imperfections”, NASA Technical Memorandum NASA TM X-2991, July 1, 1974

ABSTRACT: Small geometric imperfections in thin-walled shell structures can cause large reductions in buckling strength. Most imperfections found in structures are neither axisymmetric nor have the shape of buckling modes but rather occur locally. This report presents the results of a study of the effect of local imperfections on the critical buckling load of a specific axially compressed thin-walled conical shell. The
buckling calculations were performed by using a two-dimensional shell analysis program referred to as the STAGS (Structural Analysis of General Shells) computer code, which has no axisymmetry restrictions. Results show that the buckling load found from a bifurcation buckling analysis is highly dependent on the circumferential arc length of the imperfection type studied. As the circumferential arc length of the imperfection is increased, a reduction of up to 50 percent of the critical load of the perfect shell can occur. The buckling load of the cone with an axisymmetric imperfection is nearly equal to the buckling load of imperfections which extended 60 deg or more around the circumference, but would give a highly conservative estimate of the buckling load of a shell with an imperfection of a more local nature.

ABSTRACT: An incremental finite element procedure is presented for nonlinear buckling (collapse) analysis of composite shells undergoing large elastic deformations. The type of element employed is a modified version of Clough-Felippa's quadrilateral shell element. The element is made of any number of rigidly bonded orthotropic layers of different thicknesses and material properties. Transverse shear deformations are neglected but the coupling between the inplane and bending, as well as between shear and normal deformations, is retained. A number of buckling problems of composite panels and shells are worked out and the results are presented.

ABSTRACT: This paper analyze the nonlinear buckling and post buckling of thin composite cylindrical shells under axial load. In order to analyze and validate the results of analytical and numerical methods are used. In this paper the effects of orthotropic materials, boundary conditions, geometry, geometric imperfections and buckling modes of thin-walled composite cylindrical shells are studied. Static buckling of shells under axial load obtained for two type of lay up. This calculation was applied to finding the critical buckling load with some methods that included the linear static analysis of to modes shape of buckling, nonlinear static analysis (Analysis Riks) and dynamic analysis (explicit). The results, showed less difference in response to dynamic analysis to analytical solution method compared with other methods. It also became clear that the nonlinear static analysis, the smallest difference with the experimental test response is compared to other methods. In the first cylindrical shell without of geometric imperfections and then the effects of imperfections modeled and studied. Type text or a website address or translate a document. [Did you mean:The results showed that the static buckling load decreases with increasing structural geometric imperfections?]. Sensitivity to geometric imperfections depends on the type of lay up.

ABSTRACT: In structures subjected to high temperatures and large thermal gradients, the total strain consisting of the sum of thermal, elastic, plastic, and viscous (creep) parts must be considered. Elastic and thermal strains are reversible and depend on the instantaneous stress and temperature levels; plastic and viscoelastic (creep) strains are irreversible, and their complete determination requires that loading and temperature histories be
known. For many practical applications high mechanical or thermal loadings are of short duration; hence, viscoelastic (creep) strains are not significant. In such cases, the elastic and plastic strains represent the significant response of a structure to the applied loadings. An adequate description of the behavior of such structures can be obtained by the use of the theory of non-isothermal plastic deformation of elastic strain-hardening solids. For structures exposed to high temperature, long duration loadings, such as liquid metal fast breeder reactor components, the above theories do not provide adequate design evaluation and the knowledge of creep strain as a design allowable is necessary. Further, since the loading is transient with multiple complex cycles, creep and plasticity strain portions must be considered simultaneously. This paper presents a method for solving the problem of non-isothermal elastic-plastic creep structures. Finite element discretization is utilized, based on a number of flat and curved, thick and thin shell elements of triangular and quadrilateral form. Material nonlinearities are treated by the tangent stiffness method; geometric nonlinearities are considered by updating the geometry after each loading increment. Non-isothermal loading is considered by making a transition to the new temperature at the beginning of the load step and allowing the solution to settle at the position of overall equilibrium by iterative steps.

ABSTRACT: Most early discharges of nuclear reactor fuel elements have been associated with exposure of the fuel to the coolant. Such failures have dominated the design and developments of gas and water-cooled thermal reactor fuel. It is less well known that a number of fuel discharges and reactor output limitations have taken place in thermal reactors because of fuel element deformations which have occurred without loss of clad integrity. The paper reviews recent developments in the physical understanding of fuel element deformations during life. The important features of these deformations are established in this paper using approximations leading to simple theoretical analyses of fuel elements deforming in the presence of creep. This theoretical treatment is applied illustratively to the following problem areas: (1) the change of thermal bow as the bending moments induced by lateral restraints relax due to creep; (2) the restraint of fast reactor sub-assembly bowing; (3) the estimation of lateral deflections in lengthening fuel pins which are restrained axially; and (4) the causes of waving of the heat transfer surfaces of certain uranium-magnox fuel elements. It is concluded from these examples that many of the characteristics of fuel element deformations during life can be obtained from quite simple ideas and mathematical analyses. The methods thus provide a useful tool for design and research.

ABSTRACT: A numerical procedure is presented for determining the unsymmetrical buckling pressure for clamped, elastic-plastic spherical shells. The general deep-shell equilibrium equations are used along with an incremental plasticity theory based on the Prandtl-Reuss equations. The material is assumed to obey a Ramberg-Osgood type uniaxial stress-strain law. A linear eigenvalue problem is formulated where the buckling pressure is obtained by plotting the pressure versus the determinant of the stability matrix. Coefficients in the governing system of homogeneous equations are evaluated by solving the nonlinear problem for the axisymmetric deformation prior to unsymmetrical buckling. Buckling pressures are computed for a wide range of geometries and compared with existing theoretical results.

DTIC Accession Number: AD0778756, Handle / proxy Url: http://handle.dtic.mil/100.2/AD778756
ABSTRACT: The objectives of this research were to determine the theoretical and experimental load-deformation response and buckling loads of reticulated shells and to study the growth of imperfections in reticulated shell models. Two types of theoretical analyses (elastic material behavior was assumed) of reticulated shells were conducted to predict load-deformation relationships. A 'split rigidity' concept was used in which equivalent membrane and bending thicknesses were calculated. The second technique was a space frame analyses using the NASTRAN computer code. Three spherical reticulated shell models (two brass and one plastic) were fabricated and tested experimentally. Results of the study indicated that the NASTRAN code predicted the deflection patterns well and identified the final buckle locations.

ABSTRACT: It is the purpose of this dissertation to investigate the dynamic stability of elastic shells of revolution. Two specific areas of this broad field are treated in detail. First, this analytical study generates previously unavailable interaction relations for combined dynamic loadings as they interact to cause passage from a dynamically stable state to other states. Secondly, the concept of linearized dynamic stability is extended to include geometrically nonlinear effects. One role of these effects is to allow the possibility of autoparametric excitation of preferred flexural modes by the driven modes. The question of whether such excitation can occur during the primary dynamic instability motion sufficiently to affect the magnitude of critical dynamic loads is studied. A modified version of the subdomain method in combination with circumferential modal analysis is developed for the solution method. A computer program is constructed to obtain numerical results and the dynamic stability characteristics of a conical frustum are studied under a variety of combined dynamic loadings. Interaction curves for static stability, linearized dynamic stability, and nonlinear dynamic stability are generated. For the particular loading conditions studied, the results indicate that dynamic instability will occur at loads below critical static loads. This reduction in critical dynamic loads was shown to be the result of both the dynamic load factor effect and of autoparametric excitation. The interaction curves which are generated illustrate these effects quantitatively under conditions of combined dynamic loading. A criterion for dynamic buckling is established based on meridional mode shape changes. This ability to detect sudden jumps in the meridional profile helps to verify instability detected by divergence on displacement time history curves and provides additional information about the poststable state.

ABSTRACT: Plexiglass cylindrical shell models with nearly perfect geometry and constant thickness were tested under various combinations of membrane stresses. In cylinders under axial compression alone and axial compression with internal pressure, the buckling procedure was initiated by means of a small dynamic disturbance which reduced the dispersion of the test results. The normal forces and bending moments in the middle of the model were measured. The number of buckling waves observed in the tests agreed quite well with the result of the classical theory for the laterally loaded cylindrical shell. Only the shape, the length, and the depth of the buckling waves changed with the stress state. A buckling criterion and an interaction curve realistic for civil engineering purposes are proposed for checking the stability of cylindrical shells with fixed ends under combined membrane stress states.

ABSTRACT: Araldite hyperboloidal shell models with nearly perfect geometry and constant thickness were tested under various axisymmetric combinations of membrane stresses. During the tests the normal forces and bending moments in the middle of the model were measured and the initiation of the buckling process was studied. The experimental results are compared with calculated values using the classical linear buckling theory. The experimental values fitted an empirical law. A new approach, based on the theoretical results and the tests carried out, is proposed to determine the buckling safety of hyperboloidal shells.

Ihsan Mungan (Wissenschaftlicher Angestellter, Ruhr-Universität Bochum Institut fur Konstruktiven Ingenieurbau, Bochum, West Germany), “Buckling Stresses of Stiffened Hyperboloidal Shells”, ASCE Journal of the Structural Division, Vol. 105, No. 8, August 1979, pp. 1589-1604
ABSTRACT: Three hyperboloidal shell models made of epoxy resin (araldite) having nearly perfect geometry and constant wall thickness were tested first without stiffeners, afterwards with five, nine and 19 rings and 19 rings plus 36 meridional ribs. The axisymmetric loading resulting in various combinations of membrane stresses in ring and meridional directions was increased in steps until the first buckling wave could be observed. The initiation of the buckling process and the shifting of the region where the first buckling wave was observed were studied. The experimental results are compared with calculated values using a classical linear buckling theory. The experimental values fitted a nondimensional empirical law in terms of the uniaxial buckling stresses for each type of stiffening. An approach, based on the theoretical results and the tests carried out, is proposed to describe the buckling behavior of hyperbolic shells of revolution with and without stiffeners.

Ihsan Mungan (1) and Otto Lehmkamper (2)
ABSTRACT: With increasing dimensions of the cooling towers built of reinforced concrete, the buckling behavior becomes crucial in the proportioning of the shell. Ring stiffeners prove to be most effective in this respect with up to four stiffening rings the so called optimal position provides the highest efficiency. After five rings the equidistant positioning becomes effective as well. However, after a value of approx 6 this ratio doesn’t influence the buckling load because the local buckling between the stiffening rings becomes decisive. The quality of the numerical analysis is checked by calculating the buckling loads obtained in tests on stiffened hyperboloidal models. The deviation between the theoretical results and experimental values is approximately the same and about 0.83 both for unstiffened models and stiffened models with five or nine rings. Also the high efficiency of the rings with ring depth to shell thickness ratio of about 6 could be verified.

ABSTRACT: In addition to geometric parameters buckling of shells of negative Gaussian curvature depends mainly on the membrane stress state present. According to buckling tests the effect of boundary conditions is relatively low whereas the numerical results are highly dependent on the boundary conditions. Again according to tests the hyperboloidal shell has a higher buckling resistance than a cylindrical shell having the same throat radius. The buckling resistance of hyperboloidal shells against circumferential compression can be increased by arranging stiffening rings of adequate size and number. Due to nonlinear behavior of reinforced concrete the buckling load factor drops to the half or less of the value obtained assuming a linear elastic behavior. This high reduction is mainly due to orthotropy and descending tangent modulus at the near of ultimate load of reinforced concrete cooling tower shells.

ABSTRACT: A two-degree of freedom structural system with both buckling loads equal or nearly so is examined, allowing for the presence of small imperfections specified by the values of two general imperfection parameters. A discrete generalized coordinates energy method is used, and the system considered is non-symmetric in the two modes of deflection. Conclusions regarding the types of behaviour possible are obtained by examination of all possible equilibrium path shapes. Comparison is made to behaviour of idealized systems. Change in buckling load value with imperfection size, or imperfection sensitivity, is established and imperfection sensitivity surface forms are sketched.

ABSTRACT: An energy principle is employed to derive the equations governing the stability of a simply-supported, eccentrically ring-stiffened, oval, orthotropic cylindrical shell. The kinematic relations used are those of Love-type shell theory and the effect of reinforcing rings is accounted for by a distributed stiffness approach. The cylinder is subjected to a combination of uniform axial and lateral pressures. It is determined that the domain of stability of such a stiffened cylinder is bounded by two distinct solutions, herein denoted as corresponding to ‘long’ and ‘short’ axial wavelengths, with the extent of the short wavelength solution being dependent upon the degree of stiffening afforded by the rings. The analysis of the effects of ring eccentricity
shows that ovals are affected in a similar manner to circular cylinders in that outside rings provide the greatest capacity for sustaining axial compression, while inside rings are capable of supporting the greatest lateral pressure. Finally, it is found that the buckling load of an oval cylinder under uniform lateral pressure slightly exceeds the corresponding value for an equivalent circular cylinder. As a further verification of this phenomenon, a Rayleigh-Ritz procedure is employed to determine the buckling load of an oval ring under uniform radial load. The results of this analysis corroborate those obtained for the cylinder.

ABSTRACT: An analytical method is developed to solve approximately the bifurcation buckling load of a circular cylindrical shell under nonaxisymmetrical lateral pressure. The assumption of semi-inextensible deformation is made, which sets the circumferential strain to zero and simplifies the system of equations as well as the boundary conditions. In order to investigate the accuracy of the new method, solutions are first obtained for a cylindrical shell under uniform lateral pressure with either simple-simple or clamped-free boundary conditions. Comparisons are made in the former case to Flugge’s theory and, in the latter case, to a finite element analysis. Agreement in both cases is very good. The theory is then applied to find the buckling load of a clamped-free cylindrical shell under nonaxisymmetrical lateral pressure created by wind. Disagreement with a
previous theory by Langhaar and Miller is examined. Comparisons with results of some experiments are also made and possible reasons of the discrepancies are considered.

Herbert Anton Mang (Texas Tech University, USA), “Analysis of doubly corrugated shell structures by the finite element method”, Ph.D. Dissertation, August, 1974

PARTIAL INTRODUCTION: The specific purpose of this investigation is to develop a new and more accurate technique for the static and dynamic analyses of cylindrical, doubly corrugated shell structures used, for example, as protective shelters for aircraft …, and to verify the suitability of this technique by comparing some of the results of the analyses with analytically and experimentally obtained data due to Smith (1) and with experimentally obtained data due to Stokley (89). As a by-product of the investigation a general concept developed by Bogner et al. (2), which utilizes products of Hermitian interpolation polynomials of the same order as shape functions, is extended to encompass products of Hermitian polynomials of different order.…

“Buckling of Cooling-Tower Shells: Bifurcation Results”, ASCE Journal of the Structural Division, Vol. 101, No. 6, June 1975, pp. 1205-1222

ABSTRACT: This paper describes studies of bifurcation buckling of hyperboloids used for large-scale cooling towers. Those studies include the effects of flexible supports, combined loadings from wind, dead weight, and temperature, shell cracking, different variations in the wind pressure distribution, and changes in the shell thickening. Comparisons are made between numerical and wind-tunnel results. The finite element formulation used is examined and results are presented for the tower at the Trojan Nuclear Power Plant on the Columbia River, Oregon.

ABSTRACT: In the light of recent contributions by Batoz’ and Hibbitt, two aspects of finite element formulations for shell stability analysis are examined. The first is the consistency of the shell strain-displacement equations employed; the second is the proper representation of ‘follower forces’—pressures that are always normal to the deforming surface. Numerical studies of an arch indicate that improper representation of either of these factors can have a significant effect on predicted buckling loads. Numerical studies of an arch indicate that improper representation of either of these factors can have a significant effect on predicted buckling loads.

ABSTRACT: The paper presents an initial post buckling analysis for the rotationally symmetric branching of a cylindrical shell with a free edge following the linear eigenvalue analysis of Ashwell. The shell is supposed to be infinitely long and a closed form solution is obtained for the initial curvature of the post buckling path. This curvature is seen to be negative and more severe than that of the corresponding classical solution. The solution is shown to be relevant to the buckling of a cracked concrete shell such as a cooling tower.

ABSTRACT: Large amplitude flexural vibration of some moderately thick, straight and curved elements have been analysed in a unified way. Transverse shear and rotatory inertia effects have been included. The final approximate governing equation comes out as a second order total differential equation, which on integration gives a relationship between amplitude and period. Phenomena like dynamic buckling, transition from a slightly curved element to a shallow element, etc., have been studied.

ABSTRACT: A finite element is developed to analyse the vibration characteristics of initially stressed shells of revolution. The meridional, circumferential and normal displacements over the element are assumed to be cubic polynomials of the meridional co-ordinate. Numerical integration is used to generate the elastic stiffness, geometric stiffness and mass matrices. The element is used to analyse three typical problems pertaining to the vibrations of initially stressed thin shells of revolution.

ABSTRACT: A theoretical investigation of an efficient numerical solution scheme to solve approximately the nonlinear Donnell equations for imperfect isotropic cylindrical shells with edge restraints and under axial compression was carried out. The nonlinear partial differential equations have been reduced to an equivalent set of nonlinear ordinary differential equations. The resulting two-point boundary value problem was solved, first, by using "Newton's Method of Quasilinearization" to obtain a set of linearized differential equations for the correction terms and, secondly, these differentials were approximated as finite differences to cast the linearized system of equations into the form of a block tridiagonal matrix equation. The Potters' Method solution scheme was used to solve efficiently the block tridiagonal matrix equation. By successive iterations a solution to the set
of nonlinear ordinary differential equations was obtained. The use of this method makes it possible to investigate how the axial load level at the limit point is affected by the following factors: the choice of inplane boundary conditions, the prebuckling growth caused by the radial edge constraint, the orientation and shape of the axisymmetric and asymmetric imperfection components, and the finite length of the shell.

ABSTRACT: Starting from continuum mechanics principles, finite element incremental formulations for nonlinear static and dynamic analysis are reviewed and derived. The aim in this paper is a consistent summary, comparison, and evaluation of the formulations which have been implemented in the search for the most effective procedure. The general formulations include large displacements, large strains and material nonlinearities. For specific static and dynamic analyses in this paper, elastic, hyperelastic (rubber-like) and hypoelastic elastic-plastic materials are considered. The numerical solution of the continuum mechanics equations is achieved using isoparametric finite element discretization. The specific matrices which need be calculated in the formulations are presented and discussed. To demonstrate the applicability and the important differences in the formulations, the solution of static and dynamic problems involving large displacements and large strains are presented.

ABSTRACT: A computer code, based on finite difference techniques, has been developed to analyze finite length soft-bonded multilayered shells of revolution for dynamic loadings. The paper reviews the capabilities of the basic shell dynamics code used to analyze the individual shell layers and then discusses the development of the code for soft bonded shells. The implementation of the computer code with emphasis on the bond modeling is also presented. Several numerical examples are included that provide a comparison with an analytical solution, illustrate various design parameter studies performed with the code, and show experimental-numerical data correlation studies. These examples serve to illustrate the validity and usefulness of the code plus the necessity of including bond deformation effects to properly analyze bonded shell structures.

PARTIAL INTRODUCTION: The theoretical aspects of the stability of smooth longitudinally compressed cylindrical shells of a cross section different from circular have been most extensively investigated in the case of oval and elliptical shells and shells whose cross sections deviate from the circular shape in accordance with certain definite periodic laws [1-6]…. This article describes the results of an experimental investigation of the stability of smooth thin-walled longitudinally compressed cylinders having either slightly elliptical cross sections or cross sections whose deviation from the circular shape is describe by \( w = A \cos(4\theta) \), where \( w \) and \( A \) denote the deviation and the amplitude of the deviation of the cross section from the circle, and \( \theta \) is the circular coordinate….

ABSTRACT: In some technically important structures, finite prebuckling displacements have a profound effect on the bifurcation load. To ignore these displacements, as is done in most instability analyses, is to invite major errors, usually on the unsafe side. A method is presented which approximates this effect without the necessity of
solving nonlinear equations. The general theory is developed for any elastic body under conservative loads. The governing equations are subsequently discretized by a finite element approach and it is shown that for planar framed structures, the second order approximation to the buckling load can be found in terms of the standard linear and geometric stiffness matrices of structural analysis; the solution procedure does not require iterations. For illustrative purposes, a computer program was developed for planar structures and the results are compared to the exact solution for the buckling of shallow circular arches.

ABSTRACT: Computational algorithms for the analysis of fluid and structural dynamics are reviewed, with particular emphasis on methods that are employed or of potential benefit in reactor safety analysis, where coupled fluid-structure analyses are of interest. The fluid dynamics algorithms are classified according to time integration methods, mesh descriptions, and compressible/incompressible flow, while the structural dynamics algorithms are summarized from the view-points of time integration and the types of nonlinearities which can be treated. Alternative means of coupling these various fluid and structures algorithms are examined. Finally the principal features of some existing programs are summarized.

ABSTRACT: The nonlinear collapse behavior of long cylindrical shell structures subject to a bending load only or combined bending and uniform normal pressure loads is studied using the STAGS computer code. Two modes of nonlinear collapse are investigated to determine maximum strength. One mode of collapse is described by circumferential flattening of the cylinder cross section and the other mode is represented by axial wrinkling of the region of maximum compression. Results compare favorably with available published data for cylinders loaded by pure bending and results are presented for combined loads which have not been previously reported. The collapse loads obtained in this study show that current design criteria are conservative except for a narrow range of length-to-radius ratios and pressures.

Daniel R. Veronda (1) and Victor I. Weingarten (2) (1) Hughes Aircraft Co., Fullerton, California, USA (2) Department of Civil Engineering, University of Southern California, Los Angeles, California, USA “Stability of Pressurized Hyperboloidal Shells”, ASCE Journal of the Engineering Mechanics Division, Vol. 101, No. 5, September/October 1975, pp. 663-678
ABSTRACT: The data obtained are compared with predicted results using a linear finite element stability analysis and a corresponding nonlinear analysis wherein the effects of geometric nonlinearities are included. Experimental buckling loads were in good agreement with linear theory predictions, and the geometric nonlinearities were found to have little effect on the calculated critical loads of the hyperboloids tested. The experimental results were also compared to analytical data for cylindrical shells. The ratio of experimental
results to analytical predictions were far lower for cylindrical shells than hyperboloidal shells. These results indicate that hyperboloidal shells have a lower sensitivity to geometric imperfections than cylindrical shells. The experimental data for internally pressurized hyperboloidal shells under axial load indicate that the axial buckling value asymptotically approaches a constant value when the additional load carried by the internal pressure is subtracted. Sanders thin shell (strain-displacement) equations were used to develop finite element models for both the linear and nonlinear analyses.

ABSTRACT: Static stability analysis of clamped-free cylindrical shells subjected to wind pressure is presented, using the energy theory of buckling. The criterion used is the vanishing of the second variation of potential energy, i.e., expressed in terms of prebuckling membrane strains and the assumed virtual displacement components. The prebuckling analysis has been carried out using Donnell’s linear shell theory. Numerical results are presented for various shell geometries. Supporting experimental evidence is also provided. The effect of relaxing the axial displacement and rotation at the “clamped” base has also been theoretically studied. Current engineering practice of determining buckling load for maximum uniform pressure condition is shown to be conservative.

ABSTRACT: An analytical and experimental investigation was carried out to determine the buckling loads of hyperboloidal shells with different geometries subjected to the axisymmetric loadings of external pressure and axial compression. Sander’s thin shell equations were used in conjunction with the finite element method to determine the bifurcation buckling load of the shell. The experimental program yielded data on the instability behavior of hyperboloidal shells subjected to combined loadings. Molded PVC specimens were used in the experiments. Shell specimens were: (1) Clamped on both ends; and (20 clamped on one end and free on the other end. The experimental data were found to be in good agreement with the analysis for all types of loading conditions.

ABSTRACT: The effect upon the buckling strength of a soft elastic core attached to a shell of revolution subjected to axisymmetric loads is investigated. The axisymmetric stress problem is solved by using the finite element method to solve the body of revolution problem with an axis of material symmetry subjected to Fourier expandable thermal, body force, and surface traction loading. The governing equations are derived for a
triangular toroidal continuum element attached to shell elements. The elastic core influence coefficient matrix of the core is derived by applying the unit line load at the interface nodal point of the core. The inversion of the influence coefficient matrix yields an equivalent stiffness matrix of the core which is then combined with the shell stiffness matrix. Results from this investigation are in good agreement with available analytical and experimental results for cylindrical shells. New results are obtained for conical and spherical shells.

ABSTRACT: The buckling characteristics of hyperbolic paraboloid shells loaded by uniform pressure were first analyzed by Reissner. Governing equations of elastic stability have been derived by Wilson and are based on the existence of an adjacent equilibrium position.

ABSTRACT: Several aspects of the axisymmetric buckling of elastic-plastic circular plates are investigated. For plates that bifurcate in the plastic range, a comparison is made between the results of a numerical calculation of the postbuckling behavior and the predictions of an asymptotic analysis. Also, the imperfection sensitivity of elastic-plastic circular plates is investigated numerically when bifurcation of the perfect plate occurs in the elastic range and when bifurcation of the perfect plate occurs in the plastic range.

ABSTRACT: Results have been collected on studies relating the stability load of a structure to stiffness and natural frequency. Additional experimentation has been done to include effects of residual stresses and the major portion of this paper is devoted to a discussion of these studies. Finally, further examinations have been made of recent theories to relate stability load, stiffness, frequency and residual stress. The results have been reported here in order to reveal the range of relationships that can be found among these four structural features, and to demonstrate a reasonably sound basis for non-destructive testing procedures to determine residual stresses and structural stability. Hopefully, it also will stimulate further research in this hitherto neglected area.

ABSTRACT: Several finite-element models are applied to the linear static, stability, and vibration analysis of laminated composite plates and shells. The study is based on linear shallow-shell theory, with the effects of shear deformation, anisotropic material behavior, and bending-extensional coupling included. Both stiffness (displacement) and mixed finite-element models are considered. Discussion is focused on the effects of shear deformation and anisotropic material behavior on the accuracy and convergence of different finite-element models. Numerical studies are presented which show the effects of (a) increasing the order of the approximating polynomials, (b) adding internal degrees of freedom, and (c) using derivatives of generalized displacements as nodal parameters.

ABSTRACT: Mixed isoparametric elements are presented for the geometrically nonlinear analysis of laminated composite shells. The analytical formulation is based on a form of the nonlinear shallow shell theory with the effects of shear deformation, material anisotropy and bending-extensional coupling included. The fundamental unknowns consist of the 13 stress resultants and generalized displacements of the shell. The generalized stiffness matrix is obtained by using a modified form of the Hellinger-Reissner mixed variational principle. Both triangular and quadrilateral elements are considered. The accuracy of the mixed isoparametric elements developed is demonstrated by means of numerical examples and their advantages over commonly-used displacement elements are discussed. Also, computational procedures are presented for the efficient evaluation of the elemental matrices and for overcoming the difficulties associated with the large, sparse system of equations of the mixed models thus making them competitive with displacement models.

ABSTRACT: A computational procedure is presented for predicting the dynamic response of curved beams with geometric nonlinearities. A mixed formulation is used with the fundamental unknowns consisting of stress resultants, generalized displacements and velocity components. The governing semidiscrete finite element equations consist of a mixed system of algebraic and differential equations. The temporal integration of the differential equations is performed by using an explicit half-station central difference method. A procedure is outlined for lumping both the flexibilities and masses of the mixed model, thereby uncoupling all the equations of the system. The advantages of the proposed computational procedure over explicit methods used with the displacement formulation are discussed. The effectiveness and versatility of the proposed approach are demonstrated by means of numerical examples.

J.G.A. Croll, “Towards simple estimates of shell buckling loads”, Der Stahlbau, 1975

ABSTRACT: A series of experiments has been carried out on electroformed cylindrical shells under axial compression to determine the effect of the stiffness of the testing machine on the buckling load. The effect of the testing machine has also been calculated using Tsien's criteria. It is shown that the calculated energy loads have a strong dependence on the testing machine while the experimental data are virtually independent of the testing machine stiffness.

ABSTRACT: The effect of prismatic imperfections on the buckling load of circular cylindrical shells under axial compression is examined by considering the problem as one of interaction between panels forming the shell. The imperfections are in the form of flat spots. Numerical results are presented to show the effect of shell geometric parameters and the number, size, and the type of flat spots on the buckling load.

ABSTRACT: This review is specifically directed toward experimental shell buckling. The time period is primarily over the past 20 years. The subjects covered are specimen fabrication, initial imperfections, mounting and loading, and special techniques. The main purpose is a discussion and evaluation (with appropriate author bias) of experimental methods and techniques used in shell buckling research. The message that is clear from past work is that carefully conducted and reported work is infinitely more useful than tests carried out without much pretest thought. The emphasis is on model structures.

ABSTRACT: Correlation studies between experimental buckling loads and analytical predictions based on experimentally measured initial imperfections were carried out for axially compressed isotropic and stiffened cylindrical shells. By expanding the response of a cylindrical shell in truncated Fourier series, the nonlinear Donnell type shell equations for imperfect stiffened shells were reduced to a set of linear equations in the
correction terms by Newton's method of quasi-linearization. Solutions were obtained for isotropic and for ring and stringer stiffened shells. The amplitudes of the initial imperfections used in the analysis were calculated from the corresponding Imbert-Donnell imperfection models. The free parameters in this imperfection model were obtained by least square fitting the harmonics of the experimentally measured initial imperfections. It was possible in all cases to achieve satisfactory correlation using only a few suitably chosen deflection and imperfection modes.

ABSTRACT: A study has been made to determine the dynamic stability of an imperfect circular cylindrical shell subject to a step loading in the axial direction. In the analysis, the radial displacement of the shell is approximated by a finite degree-of-freedom system. The dynamic analysis includes not only the effect of the radial inertia, but also, in an approximate manner, that due to the axial inertia. The critical loads are determined by numerical integration of the equation of motion. Compared with the static case, there is a significant reduction of the dynamic buckling load for the high wave number range of the radial modes. It is concluded that due to frequency coupling between axial and radial motions, the axial inertia plays an essential role in characterizing the dynamic instability of a finite length shell.

ABSTRACT: The field method, presented previously for the solution of linear boundary-value problems defined on one-dimensional open branch domains, is extended to one-dimensional domains which contain
circuits. This method converts the boundary-value problem into two successive numerically stable initial-value problems, which may be solved by standard forward integration techniques. Also presented is a new treatment of singular boundary conditions (kinematic constraints) — this is problem independent with respect to both accuracy and efficiency. The method has been implemented in a computer program which calculates the asymmetric response of ring-stiffened orthotropic multicircuit shells of revolution.

ABSTRACT: The additional constitutive equations required by transverse shear deformation theory of anisotropic heterogeneous shells are derived without the usual assumption of thickness distribution for either transverse shear stresses or strains. The derivation is based on Taylor series expansions about a generic point for stress resultants and couples which identically satisfy plate equilibrium equations. These equations give the in-surface stress resultants and couples in terms of the transverse shear stress resultants at the point and arbitrary constants, which may be interpreted as redundant “forces”. Starting from these expressions, we derive statically correct expressions (in terms of the transverse shear stress resultants and redundants) of the following variables: (1) in-surface stresses, using the stretching-bending constitutive equations and the Kirchhoff distributions of in-surface strains, (2) transverse shear stresses, by integration in the normal direction of the three-dimensional equilibrium equations, and (3) the area density of transverse shear strain energy, by integration in the normal direction of the corresponding volumetric density. Finally, by applying Castigliano's theorem of least work, the shear strain energy is minimized with respect to the redundants, thereby leading to the desired constitutive equations. Corresponding transverse shear stiffnesses are presented for several laminated walls, and reasonable agreement is obtained between transverse shear deformation plate theory using these stiffnesses and exact three-dimensional elasticity solutions for the problem of cylindrical bending of a plate.

ABSTRACT: FASOR (Field Analysis of Shells of Revolution) is a user-oriented code for the analysis of stiffened, laminated axisymmetric shells. Very general shell geometries are allowed in that the reference surface meridian may form a branched, multi-circuit figure. Modes of response treated are linear asymmetric and geometrically nonlinear axisymmetric prebuckling, and asymmetric buckling and vibration under static axisymmetric loads. Bifurcation buckling under asymmetric loads is also treated by using a symmetrized prebuckling state based on the linear response of a user-specified meridian. For each mode of response, the user may specify any combination of orthotropic or anisotropic material properties with classical or transverse shear deformation shell theories. FASOR employs a numerical integration method (called the field method) whereby a numerically unstable linear boundary-value problem (all modes of response reduce to a sequence of such problems) is converted into two successive numerically stable initial-value problems. In this context, numerical stability means that round-off errors introduced at each step of the integration process tend to decay out. As a consequence, solution accuracy is controlled essentially by a single number, the truncation error tolerance, which is satisfied by automatically adjusting the size of each integration step. The field method thus eliminates the need for mesh generation required by finite element and finite difference methods, and the associated problem of numerical convergence. It also provides for automatic determination of response storage points so as to obtain a uniformly valid discrete approximation of the continuous response. In this paper the field method is
briefly described, basic aspects of the mathematical model are discussed, the organization of input data is presented, and input and plot output are given for specific examples.

ABSTRACT: An integrated computer program entitled Field Analysis of Shells of Revolution (FASOR) currently under development for NASA is described. When completed, this code will treat prebuckling, buckling, initial postbuckling and vibrations under axisymmetric static loads as well as linear response and bifurcation under asymmetric static loads. Although these modes of response are treated by existing programs, FASOR extends the class of problems treated to include general anisotropy and transverse shear deformations of stiffened laminated shells. At the same time, a primary goal is to develop a program which is free of the usual problems of modeling, numerical convergence and ill-conditioning, laborious problem setup, limitations on problem size and interpretation of output. The field method is briefly described, the shell differential equations are cast in a suitable form for solution by this method and essential aspects of the input format are presented. Numerical results are given for both unstiffened and stiffened anisotropic cylindrical shells and compared with previously published analytical solutions.

ABSTRACT: The subspace iteration method used in the buckling options of the shell code FASOR is discussed. Buckling modes of a laminated anisotropic cylindrical shell and a sandwich spherical cap are presented and compared with previously published results.

ABSTRACT: The present theoretical investigation studies the effect of small multilobed initial deviations from the exact shape upon the deformations and the critical time of a thin-walled circular cylindrical shell which was manufactured with initial axisymmetric deformations. To facilitate the analytical work, the actual solid wall of the shell is imagined to be replaced by an equivalent sandwich wall. The general equilibrium equations derived for shallow shells are expressed in terms of stresses and deviations corresponding to the equivalent sandwich model. The radial displacement as well as the meridional, circumferential and membrane shear stresses are expressed by finite Fourier series for each face of the sandwich model. The compatibility conditions used in conjunction with the equilibrium equations lead to a system of linear and nonlinear equations. It is assumed that all deformations are due to nonlinear steady creep governed by Odqvist's power law. The solution of this system of equations is carried out by introducing the solution obtained from the axisymmetric creep buckling theory.
developed by N.J. Hoff. Furthermore, in order to simplify the equations, it is assumed that the deformations remain small compared to the shell thickness. A closed form solution is found for the multilobed deformation rates and for the critical time as well. However, the latter is too complicated to be evaluated by hand. A numerical integration of the deformation rates shows, for a given cylinder, that the multilobed creep buckling deformations grow much faster than the axisymmetric. Indeed, we find that Koiter's theory of bifurcation buckling for perfectly elastic axially compared circular cylindrical shells has its counterpart in creep buckling.

ABSTRACT: This paper examines the thesis that a process of structural optimization leads inevitably to designs which exhibit the notorious failure characteristics often associated with the buckling of thin elastic shells. This means that an idealized perfect structure exhibits an unstable and often compound branching point and would fail by an explosive instability while nominally perfect real structures containing inevitable small imperfections fail at scattered loads which can be quite considerably lower than that of the idealization. It is shown via a fairly wide spectrum of examples that an increasing degree of optimization is likely to lead in turn to an unstable bifurcation, a very unstable bifurcation, and finally a very unstable compound bifurcation with the possible added danger of an unsuspected nonlinear coupling action.

ABSTRACT: A theoretical investigation is undertaken into the dynamic instability of complete spherical shells which are loaded impulsively and made from a rigid-plastic material. The threshold velocities for the rigid-plastic spherical shells are larger than those for cylindrical shells having the same R/h ratios and material parameters, while the critical mode numbers are similar.

ABSTRACT: A theoretical investigation is undertaken into the dynamic instability of complete spherical shells which are loaded impulsively and made from either linear elastic or elastic-plastic materials. It is shown that certain harmonics grow quickly and cause a shell to exhibit a wrinkled shape which is characterized by a critical mode number. The critical mode numbers are similar for spherical and cylindrical elastic shells having the same R/h ratios and material parameters, but may be larger or smaller in an elastic-plastic spherical shell depending on the values of the various parameters. Threshold velocities are also determined in order to obtain the smallest velocity that a shell can tolerate without excessive deformation. The threshold velocities for the elastic and elastic-plastic spherical shells are larger than those which have been published previously for cylindrical shells having the same R/h ratios and material parameters.

ABSTRACT: An experimental investigation was undertaken into the dynamic plastic buckling of circular rings subjected to uniformly distributed external impulsive velocities. The experimental values of the average final radial deflections, critical mode numbers and dimensions of the permanent wrinkles in the mild steel and aluminum specimens are compared with various theoretical predictions and other experimental results.

ABSTRACT: The advantages and limitations of a perturbation method of analysis for the creep buckling of shells is explored in this note by examining the particular case of a long cylindrical shell subjected to a uniform external pressure. It turns out that the oval deformation mode is the most critical as assumed in previous theoretical investigations. However, other modes can make important contributions to the deformation of a cylindrical shell and can, in fact, dominate the response if important imperfections are present in these harmonics.

ABSTRACT: The creep buckling behavior of a complete spherical shell which is subjected to a uniform external pressure is investigated using a perturbation method of analysis. The spherical shell has an arbitrary initial imperfect shape and is made from a material which creeps according to the generalized Norton's law. It turns out that the critical mode number of the deformed profile is identical to that obtained previously by various authors for the linear elastic instability of complete spherical shells. It also appears that the resistance to creep buckling of complete spherical shells is greater than the resistance of a long cylindrical shell having the same R/h ratio and material properties.

ABSTRACT: This article contains a brief survey of the literature on the creep buckling of shells published since the second IUTAM Symposium on Creep in Structures held at Gothenburg in 1970. The authors provide further details of their recent numerical study into the creep buckling of spherical shells subjected to external pressures together with some additional results. These numerical results and those of OBRECHT on axially loaded cylindrical shells are used to assess the accuracy of the simple methods of analysis proposed recently by HAYMAN, CHERN, GERDEEN and co-workers.

ABSTRACT: A theoretical analysis of the local buckling of corrugated-core sandwich panels with truss-type (i.e. triangular) corrugations in compression is developed. It has the unusual feature that the nodal lines of the buckling mode are not assumed to be straight and perpendicular to the direction of compression. Such modes are found to correspond to slightly lower buckling stresses than the usual type, for panels with a wide range of geometries. The existence of modes of this type has been observed experimentally.

ABSTRACT: The postbuckling behavior of simply supported columns with thin-walled open cross section is investigated by means of the general nonlinear theory of elastic stability. Fourth-order terms in the series expansion of the total potential energy are disregarded. It is shown that interaction between linearly independent simultaneous buckling modes is responsible for neutral equilibrium at bifurcation if the column cross section has two axes of symmetry, and unstable if it has only one. If the buckling modes are not simultaneous, the equilibrium is neutral in both cases. Finally, the equilibrium at bifurcation is usually unstable if the cross section has no axis of symmetry.

ABSTRACT: The buckling of an axially loaded cylindrical shell is considered when imperfection components corresponding to all of the classical buckling modes are taken into consideration. The analysis represents an extension of Koiter's axisymmetric solution and in the asymptotic sense due to Koiter the imperfections
considered are as general as possible. The results obtained reveal many interesting aspects of shell buckling which arise for various imperfection forms. The buckling behaviour which results is associated with both bifurcation and limit point critical states.

ABSTRACT: A recent test has provided significant results important for laminate composite shell design. The buckling load of composite shells may be increased substantially through the careful choice of laminate configurations. An increased buckling load capability may be combined without paying a severe penalty with regard to imperfection sensitivity, and the presence of imperfections can cause a change in failure mode from global to local. This characteristic has been observed experimentally and is consistent with analytical predictions.

“The Dynamic Behaviour of Stiffened Composite Fuselage Shell Structures”, December 1988
ABSTRACT: This report presents an overview of the development of a computer model for analysing the crash response of stiffened composite fuselage structures together with the experimental validation program. Using a finite element formulation based on Reissner/Mindlin plate theories, the numerical model can treat stiffened laminated shell buckling, large deflections, nonlinear material behaviour and element failure. Numerical results are presented for several 'test cases', although experimental comparisons are not yet available. Details on the design and construction of our first prototype composite fuselage model are also provided together with a description of the crash test facility.

ABSTRACT: This paper proposes a technique to optimize structural components for buckling when the applied loads are partially unknown or unpredictable. As opposed to the traditional buckling optimization situation where the loading configuration is specified, the load ratios are assumed uncertain and are incorporated as variables in the optimization problem formulation. As a result, the optimal designs obtained are insensitive to load variations within an admissible convex set. Additionally, in order to generalize the results and therefore provide a systematic solution procedure, a theorem concerning the shape of the stability boundary of structures whose buckling loads are the solution of linear eigenproblems is stated and proven.

ABSTRACT: Optimal elastic buckling loads of composite axisymmetric circular cylinders under uncertain loading conditions are investigated. The mechanical loads applied to the cylinder are a combination of axial compression, lateral pressure, and torsion. Additionally, these loads are allowed to vary within a certain class of admissible loads during the optimization search, as opposed to the restriction of fixed loads in the traditional optimization. The consideration of a degree of uncertainty in the mechanical loads leads to optimal designs which are inherently insensitive to perturbations and/or randomness in the applied loads.

Alfredo R. de Faria (Instituto Tecnologico de Aeronautica – ITA, Sao Jose dos Campos, SP, Brazil),

ABSTRACT: Crooked beams and plates with arbitrary initial geometric imperfections are optimized in order to improve their prebuckling response in the presence of uncertain loadings. A novel optimization approach is presented to simultaneously handle the two types of uncertainties: arbitrary initial imperfection patterns and arbitrary loadings. A remarkable improvement in the prebuckling response of optimal designs is achieved by reducing the level of prebuckling displacements measured in some appropriate norm, irrespective of the uncertain imperfection pattern or loading. Two different norms are proposed, each one applicable to the beam or to the plate problem. The definitions of appropriate norms allow for the use of a minimax optimization approach that can consider the arbitrariness of both geometric imperfections and loadings. It is shown that the minimax procedure leads to optimum structural designs, in terms of optimal stiffness distribution, that are at the same time insensitive to perturbations in the loading space and to the pattern of initial imperfections in structure.
ABSTRACT: Under operational conditions, some loads acting on a beam are known (deterministic loads), but there usually exist other loads the magnitude and distribution of which are unpredictable (uncertain loads). If the uncertainty in the loading is not taken into account in the design, the likelihood of failure increases. In the present study beams are designed for minimum weight subject to maximum stress and buckling loads, which are unpredictable (uncertain loads). The uncertain load, which is subject to a constraint on its magnitude and uncertainty levels. Results are given for a number of problem parameters including the axial load, elastic foundation modulus and uncertainty levels.

ABSTRACT: The buckling of ring and stringer stiffened cylinders under axial compression, external hydrostatic pressure and combined loading of axial compression with internal or external hydrostatic pressure
was studied. The effect of initial sinusoidal axisymmetric and asymmetric shape imperfections on the reduction of the buckling strength of stiffened cylinders was investigated for varying reinforcement parameters. Calculations were performed by extending Koiter's special theory taking into account nonlinear prebuckling deformations in the form of the shape imperfection, the eccentricity and the bending stiffness of the ring stiffeners. The Donnell-von Kármán shell equations were solved using the Galerkin method. The quantitative effect of asymmetric shape imperfections (in the form of the buckling mode) on reducing the buckling strength of stringer stiffened shells was determined with Hutchinson's Model and experimentally investigated on four stringer stiffened cylinders.

ABSTRACT: In the following paper new variational methods for the solution of problems of postbuckling of elastic plates are formulated, and approximate solutions for various cases are obtained using finite element methods. Initially, the postbuckling problem is phrased as a nonlinear eigenvalue problem. Variational principles for the nonlinear eigenvalue problem of the postbuckling of structures are developed. These variational principles have a form which can be characterized as a nonlinear Rayleigh principle, finite-element models are introduced and are used to implement the postbuckling variational principle. Incremental amplitude solution schemes are developed to solve the corresponding finite-element equations. Sample results are presented for the postbuckling behavior of circular plates.

ABSTRACT: This paper investigates the effects of boundary conditions and panel width on the axially compressive buckling behavior of unstiffened, isotropic, circular cylindrical panels. Numerical results are presented for eight different sets of boundary conditions along the straight edges of the panels. For all sets of boundary conditions except one (SSI), the results show that the panel buckling loads monotonically approach the complete cylinder buckling load from above as the panel width is increased. Low buckling loads, sometimes less than half the complete cylinder buckling load, are found for simply supported panels with free in-plane edge displacements (SSI). The SSI buckling loads are below the complete cylinder load even for '360° panels'. It is also observed that the prevention of circumferential edge displacement is the most important in-plane boundary condition from the point of view of increasing the buckling load, and that the prevention of edge rotation (i.e. clamping) in the circumferential direction also significantly increases the buckling load. Parametric studies are also performed to determine the effects of variations in panel length and thickness on the buckling loads.

Buckling of eccentrically stringer-stiffened cylindrical panels under axial compression

ABSTRACT: This paper investigates the effects of boundary conditions and panel width on the axially compressive buckling behavior of eccentrically stringer-stiffened circular cylindrical panels. Numerical results are presented for eight different sets of boundary conditions along the straight edges of the panels. As the panel width is increased, the results show that the complete cylinder buckling load is reached only for one set of boundary conditions (SS3, classical simple support conditions). However, for 180∞ and wider panels, the panel buckling loads are within ± 10% of the complete cylinder load for all cases except SS1 panels (free in-plane edge displacements) with outside stringers. Low buckling loads, as low as half the complete cylinder load, are found for some SS 1 panels. It is also observed that the prevention of circumferential edge displacement is the most important in-plane boundary condition from the point of view of increasing the buckling load, and that the prevention of edge rotation (i.e. clamping) in the circumferential direction is more effective in increasing the buckling loads of panels with free circumferential edge displacement _≈ that it is for panels with _≈ = 0. From stringer-eccentricity studies, it is shown that buckling loads are generally at least 40 _50% higher for the case of outside stringers, and that eccentricity effects are generally similar for clamped and simply supported panels with the same in-plane boundary conditions.

ABSTRACT: This work presents optimum designs for unstiffened, hat stringer-stiffened and honeycomb sandwich cylinders under axial compression. Optimization results for graphite-epoxy cylinders show about a 50 percent weight savings over corresponding optimized aluminum cylinders for a wide loading range. The inclusion of minimum gage considerations results in a significant weight penalty, especially for a lightly loaded cylinder. Effects of employing a smeared stiffener buckling theory in the optimization program are investigated through comparison of results obtained from a more accurate branched shell buckling computer code. It was found that the stiffener cross-sectional deformations, which are usually ignored in smeared stiffener theory, result in about a 30 percent lower buckling load for the graphite-epoxy hat stiffened cylinder.

ABSTRACT: This paper presents a finite element analysis of the in-plane bending behavior of elastic elbows. Rules and guidelines are presented for the systematic selection of the dimensions of the finite element meshes and for the interpretation of the numerical results. A simple asymptotic formula is presented that gives the dimensions of a so-called “optimum” (or “upper bound”) mesh as a function of the geometry of the elbow. This mesh, along with a companion one, the “lower bound” mesh, serve to establish the basis for the selection of the range of mesh dimensions that are used in the convergence studies of the MARC finite element computations for stresses, displacements and stress intensification and flexibility factors appropriate to a typical FFTF elbow. Reasonable good agreement is found in a comparison of the MARC results with those obtained from the ELBOW computer program, as well as with results predicted by Clark and Reissner's asymptotic formulas.

ABSTRACT: Analytical and experimental results are presented for the axisymmetric plastic buckling of axially compressed cylinders made from strain hardening materials. Buckling loads predicted by two simple bifurcation buckling formulas (simplified analysis) and by the STAGS finite difference computer program (detailed analysis) are compared with buckling loads measured in room temperature tests on Type 304 stainless steel cylinders. The comparison shows that the loads predicted by Gerard’s bifurcation buckling formula agree well with the test results and the STAGS solution. Thus, the present results provide further confirmation that Gerard’s simple formula furnishes a reasonably good approximation to the load carrying capacity of strain hardening cylinders that buckle axisymmetrically at nominal axial stresses equal to or greater than the yield stress.

ABSTRACT: Large amplitude asymmetric vibrations of shells of revolution are analysed in this paper by using a finite element method. Sanders’ non-linear strain displacement relations are used to derive the element stiffness matrix. In the derivation of the mass matrix, the effect of in-plane inertia is included. Three numerical examples are presented to show the reliability and effectiveness of the present finite element formulation.

ABSTRACT: This study was intended to contribute to the development of more rational practical methods for predicting the transient responses of structures which are subjected to transient and impact loads. Attention is restricted to the global structural response; local (or stress-wave-induced) response is not included. The use of higher-order assumed-displacement finite elements (FE) is investigated to seek more efficient and accurate strain predictions; these studies were carried out for 2-d structural deformations typical of beams and curved rings to minimize cost and labor. These studies were done in conjunction with the use of various approximations to the nonlinear strain-displacement relations since large deflections and rotations need to be taken into account. Transient large-deflection elastic-plastic structural response predictions are made for these various FE models for impulsively-loaded beams and a free initially-circular ring, for which high quality experimental measurements of strains and deflections are available. From comparisons of (a) predictions with each other for the various FE models investigated and (b) predictions vs. experimental data, it appears to be more efficient for the same number of degree-of-freedom (DOF) unknowns to use the simple 4 DOF/node elements rather than fewer of the more sophisticated 8 DOF/node elements although the latter provide a physically superior and more realistic distribution of strain along the structural span at any given time instant compared with the use of the 4 DOF/N elements. Comparisons of measured with predicted transient strain and final deformation of a thin aluminum beam with both ends clamped and impacted at midspan by a 1-inch
diameter steel sphere show very good agreement. Extensions to the present analysis to accommodate more general types of fragments and fragment-impacted structures are discussed briefly.

ABSTRACT: This paper discusses computer-aided design procedures for antenna reflector structures and related components. The primary design aid is a computer program that establishes cross sectional sizes of the structural members by an optimality criterion. Alternative types of deflection-dependent objectives can be selected for designs subject to constraints on structure weight. The computer program has a special-purpose formulation to design structures of the type frequently used for antenna construction. These structures, in common with many in other areas of application, are represented by analytical models that employ only the three translational degrees of freedom at each node; The special-purpose construction of the program, however, permits coding and data management simplifications that provide advantages in problem size and execution speed. Size and speed are essentially governed by the requirements of structural analysis and are relatively unaffected by the added requirements of design. Computation times to execute several design/analysis cycles are comparable to the times required by general-purpose programs for a single analysis cycle. Examples in the paper illustrate effective design improvement for structures with several thousand degrees of freedom and within reasonable computing times.

ABSTRACT: This paper describes the combined use of symbolic formula manipulations and numerical computations in the study of the interaction, within the elastic range, of local (plate) and overall (column) buckling of rectangular thin-walled tubular columns. The study is made using the Rayleigh-Ritz procedure. The selection of the analytical expression for the assumed deflected shape has been based on existing solutions for column and plate action considered individually. The minimization of the total energy of the column is performed by the computer using a symbol manipulation package (Macsyma). This minimization yields a set of nonlinear simultaneous algebraic equations which are then solved numerically. The problems encountered in implementing the formal and numerical parts of the computations (as well as their interaction) are discussed in the paper. The results of the computer analysis are presented in the form of diagrams showing the variation of the important generalized coordinates with the applied load.

ABSTRACT: This paper presents a procedure and computer program for the minimum weight design of circular, cylindrical, ‘T’ frame (ring) reinforced, submersible shells where all metal thicknesses may be confined to specified gage thickness values. Using the designer specified parameters defining shell radius shell length, eccentricity, operating depth, design factors of safety, construction materials properties and when used, the specified gage thickness values, the program will generate those values of skin thickness stiffener web and
flange thicknesses, stiffener web depth and flange width, and if desired, stiffener spacing that will produce the smallest shell weight to liquid weight displaced ratio. Experience with the program has demonstrated that there is usually little weight penalty associated with the use of discrete metal thickness values when the stiffener spacing can be optimized. This weight penalty can, however, be significant where the number of stiffeners is held fixed.

ABSTRACT: The new “Direct Search-Feasible Direction” (DSFD) nonlinear mathematical programming optimization algorithm is applied to the design of stiffened submersible shells. An automated design capability for this problem (SBSHL6) is described wherein the program will generate the least weight design by locating the optimal, or near optimal, values of skin thickness, web thickness and height, flange thickness and width, and stiffener spacing given the design parameters such as shell size, immersion pressure, shell eccentricity, materials properties, and minimum natural frequency. Constraint equations control, general, panel (between stiffener), web, and flange instability, skin and stiffener yielding, and minimum natural frequency. The DSFD procedure appears capable of reliably locating optimal designs whereas earlier attempts in investigations using other optimization methods, including the popular SUMT procedure, failed to provide optimal solutions to the same problem. This and an earlier detailed comparison study strongly suggest that SUMT is not a reliable procedure for structural optimization while DSFD seems to provide reasonably reliable performance. Designs generated by SBSHL6 are presented and compared with those of the earlier studies. The results of a series of synthesis runs from widely separated starting points are also presented. The designs developed by SBSHL6 are substantially lighter than those reported earlier. The multipath runs for each set of parameters studied all converged to similar designs of essentially identical weights demonstrating program reliability.

ABSTRACT: This paper describes an experimental investigation of the buckling behavior of axially-loaded thin open cylindrical shells. The results of experiments with 36 aluminum shell specimens are compared with predictions of buckling made by means of two separate theoretical approaches. Discrepancies between measured and predicted values of buckling load are treated in detail. Generally speaking, the experiments revealed a satisfactory agreement between measured buckling loads and predicted values especially in instances where the slenderness ratio exceeds 1.5.

ABSTRACT: This paper describes a new finite element scheme for the analysis of instability phenomena of arbitrary thin shells. A computationally efficient procedure is proposed for calculating the non-linear stiffness
and tangential stiffness matrices for a doubly-curved quadrilateral element defined by co-ordinate lines. The essential feature is the explicit addition of the non-linear terms into the rigid-body motion of the element. Thus the non-linear and tangential element stiffness matrices can easily be generated by transforming the generalized element stiffness matrix for linear analysis, and the non-linear terms of these matrices are separated into a number of component terms multiplied by the rigid-body rotations. These component terms can be stored permanently and used to calculate efficiently the non-linear and tangential stiffness matrices at each iteration. Illustrative examples are presented which confirm the validity of the present approach in the analysis of instability phenomena of thin plates and shells.

ABSTRACT: A finite element formulation is presented to study the non-linear buckling of arbitrary shallow elastic thin shells with general boundary conditions and subjected to conservative pressure loading. Pre and post buckling behaviour of a large number of shallow and semi deep doubly curved shells is studied in detail. Unsymmetrical bifurcation paths of a shallow spherical shell subjected to uniform inward pressure are also investigated.

ABSTRACT: The choice of strain-displacement relations to formulate curved finite elements for the geometrically nonlinear analysis of deep thin shells of general shape is discussed. It is clearly demonstrated on a simple arch problem how the strain-displacement relations can affect the buckling pressure and it is concluded that inconsistent expressions should be avoided.

ABSTRACT: Detailed experimental studies are performed on the postbuckling behavior of circular cylindrical shells under hydrostatic pressure, by using lap-jointed polyester test cylinders with radius 100 mm, thickness 0.25 mm and lengths ranging from 23 to 165 mm. Connections of the edge shortening and radial displacement with applied pressures as well as wave forms for typical postbuckling configurations are determined for various values of the shell curvature parameter $Z$ ranging from 20 to 1000. It is found that the buckling pressure and the corresponding wave number for each cylinder compare favorably with those theoretically predicted, and that the minimum pressure after buckling decreases with the increase in $Z$, until it becomes about 70 percent of the theoretical buckling pressure for long shells with $Z$ greater than 200.

“Experiments on the postbuckling behavior of circular cylindrical shells under compression” (Precise experimental results are presented clarifying the whole aspect of the postbuckling behavior of circular cylindrical shells under compression for a wide range of shell geometries), Experimental Mechanics, Vol. 15, No. 1, 1975, pp. 23-28, doi: 10.1007/BF02318521

ABSTRACT: Detailed experimental studies are performed on the postbuckling behavior of circular cylindrical shells under compression, by using polyester test cylinders with the geometric parameter Z ranging from 20 to 1000. In each case, variations of the equilibrium load, circumferential wave number and maximum inward and outward deflections, with applied edge shortenings, are clarified. Contour lines for typical postbuckling configurations are also shown. It is found that, as the cylinder is compressed beyond the primary buckling, secondary bucklings take place successively with diminishing wave numbers, and that postbuckling equilibrium loads become significantly lower than those at buckling as Z increases. Further, for short shells with Z less than or equal to 100, the buckled waveforms are always symmetric with one-tier diamond buckles, while for longer shells, asymmetric postbuckling patterns with two tiers of buckles dominate.

ABSTRACT: Applying the Galerkin procedure to the Donnell basic equations, reasonably accurate solutions are obtained for the postbuckling behavior of clamped circular cylindrical shells under axial compression. To make a distinct comparison with the previous experimental results, calculations are carried out for shells with the same elastic and geometric parameters and the relations between the waveform, axial shortening and maximum deflections with applied loads are clarified. The results here obtained are found to be in reasonable agreement with experimental ones throughout the regions with fairly large deformations.

ABSTRACT: The dynamic von Karman field equations are used to analyse the influence of large amplitude on the free vibrations of shallow cylindrical shells made of orthotropic material and resting on an elastic Winkler foundation. The “snap-through” phenomenon for such shells subjected to a dynamically applied uniform pressure that increases linearly with time is also investigated.

CONCLUSIONS: 1. The number of natural vibration frequencies in any frequency interval for an empty cylindrical shell increases in direct proportion to the second power of the interval size, and for a shell with filler — in direct proportion to the third power of it. 2. The widest (and also located at the smallest frequencies) dynamical instability region of a cylindrical shell with elastic filler corresponds to nonaxisymmetrical modes of wave formation. 3. The limiting transition in the equations of this paper in the case of the frequency of the driving force tending to zero results in an expression for the critical static force for a shell with an incompressible filler. Numerical calculations in this case show, in particular, an increase of the critical force upon an increase in the modulus of elasticity of the filler, which has been noted in a number of the papers of other authors.

ABSTRACT: This paper has two main objectives. First to describe a very simple facet triangular plate and shell finite element called TRUMP which includes, if required, transverse shear deformation and is based on physical lumping ideas with a simple mechanical interpretation [ 1,2,4,5 ]. Second to give an account of some non-trivial numerical examples of large deflection and post-buckling of shells. There are two types of non-linear structural problems which give rise to particularly delicate numerical experimentation. They are those involving deflections of the order of the structural dimensions, such as three-dimensional elastica, and the instability phenomena of the type leading to dynamic snapthrough, e.g. in cylindrical panels. To tackle such problems using a highly sophisticated shell element such as SHEBA is neither easy nor inexpensive. It is shown that the TRUMP element with only 18 displacement and rotation degrees of freedom is relatively economical to use and yet capable of engineering accuracy. The paper makes use of the theory of simplified geometrical stiffness based on the natural mode method which has been described fully in previous publications [1,2].

ABSTRACT: A review of the most important publications and computer programmes dealing with shell structures is presented. Most of the information is available through open technical publications; however, some of the listings of these programmes may be of a proprietary nature. A brief development of composite shell theory is presented, and an outline of the major methods of solution to the governing equations of motion is included.

ABSTRACT: A perturbation method is presented for the analysis of postbuckling behavior and imperfection sensitivity of elastic structures which have more than one buckling mode. The method is exemplified by analyzing a complete spherical shell under external hydrostatic pressure. For this analysis, use is made of two- and three-mode models of the shell derived earlier from the shallow shell equations.

ABSTRACT: The problem examined in this paper concerns the use of the procedure encountered in the literature that, in investigating instability phenomena of systems with nontrivial prebuckled equilibrium branches, a linearized prebuckling analysis may be employed provided that “buckling” takes place in the small deflection range. In clarifying this problem it will be shown that, although this procedure has been used with reasonable success on symmetrical systems, such an approach may in fact yield totally misleading results when applied to nonsymmetrical systems. The principal tool that will be employed in the investigation of this problem will be the systematic application and analysis of the techniques associated with regular perturbation expansions. Using this approach it will also be shown that there are two possible characteristic equations that one can use to determine critical points of neutral equilibrium; and that by using these two equations, one can immediately determine whether a point of neutral equilibrium is a bifurcation point (generally characterized by sidesway or adjacent path buckling) or a limit point (generally characterized by snap-thru or discontinuous buckling).

ABSTRACT: An exact analytic expression for the unsteady fluid pressure acting on the internal walls of a simply-supported circular cylindrical tube of finite length, carrying flow, is presented. The generalized force coefficients corresponding to specific modes of deformation are given explicitly. The results are applied to two problems: (1) the interaction of flow and buckling of thin-walled cylindrical shells subjected to lateral pressure and/or end thrust; (2) the aeroelastic stability of the shells. The second problem is aimed at resolving some
controversy about post-divergence flutter oscillation of cylindrical shells or plates exposed to a subsonic flow. The shell equation, of the Morley type, is solved by Galerkin's method and an analytic approach is used to examine the stability of the system. It is important that damping be taken into account in the analysis. The undeformed configuration is always unstable when the flow speed exceeds the minimum divergence boundary.

ABSTRACT: Because of intractable ventricular arrhythmias after a near-fatal episode of ventricular fibrillation, a patient with idiopathic mitral valve prolapse was subjected to mitral valve replacement. Vector analysis and intraoperative epicardial mapping localized the ectopic focus to the region of the posterior papillary muscle. The patient is alive and well two years after surgery; chronically inverted T waves have become upright. But propranolol and diphenylhydantoin are needed to prevent arrhythmias and T wave abnormalities during standing and exercise. Preoperatively, with the onset of mitral regurgitation and a second rapid phase of prolapse, the ventriculogram was deformed by abnormal midsystolic hyperkinesis at both sites of papillary muscle insertion. Postoperatively, focal hypokinesis appeared in the same areas, implying that they had been retracted by the prolapsing valve. Preoperatively, a papillary tip could be seen entering the mitral ring while coronary arteriography showed late systolic elongation of a small vessel feeding the anterior papillary muscle, suggesting that the papillary apparatus was indeed subject to damaging stress during the abnormal basal movement. Three other persons with severe mitral prolapse (but intact chordae) have had valve replacement and developed qualitatively similar changes in the ventriculogram. Papillary specimens in two showed significant fibrosis. Indication for operation in one of these was episodic ventricular fibrillation, which has not recurred. A spectrum of ventriculographic abnormality associated with mitral prolapse could be partly explained by hypokinesis of the papillary loops, variably disguised by retraction stress transmitted from the billowing leaflets, translocation of blood into the expanding valve sail, and various degrees of unloading into the left atrium. Abnormal intraventricular flow may probably result from associated prolapse of the anterior leaflet and from buckling of the papillary sites toward the mitral annulus. Unusual physical findings in the operated cases and in eight other patients define a clinically recognizable syndrome in which severe prolapse abbreviates left ventricular ejection. Liability to symptoms and to progression of disease seems high in this group.

ABSTRACT: A study of the non-linear pre-buckling state and the bifurcation and initial post-buckling behaviour of infinitely long, cylindrical, elastic tubes subjected to bending, pressure and axial loads is presented. The collapse behaviour is analysed by determining both the limit load and the possibility and significance of axial wrinkling of the compressed region of the shell prior to the limit load.

ABSTRACT: The analysis is applicable to bodies of revolution composed of thin shell segments, thick segments and discrete rings. The thin shell segments are discretized by the finite difference energy method and
the thick or solid segments are treated as assemblages of 8-node isoparametric quadrilateral finite elements of revolution. Suitable compatibility conditions are formulated through which these dissimilar segments are joined without introduction of large spurious discontinuity stresses. Plasticity and primary or secondary creep are included. Axisymmetric prebuckling displacements may be moderately large. The nonlinear axisymmetric problem is solved in two nested iteration loops at each load level or time step. In the inner loop the simultaneous nonlinear equations corresponding to a given tangent stiffness are solved by the Newton-Raphson method. In the outer loop the plastic and creep strains and tangent stiffness are calculated by a subincremental procedure. The linear response to nonaxisymmetric loading is obtained by superposition of Fourier harmonics. Many examples are given to demonstrate the scope of the computer program, BOSOR6, derived from the analysis and to illustrate certain stress concentration effects in shell-type structures which cannot adequately be treated with use of thin shell theory.

Y. Frum and M. Baruch (Aeronautical Department, Technion, Haifa, Israel), “Buckling of cylindrical shells heated along two opposite generators combined with axial compression” (Experimental technique developed during a study of buckling under a combination of axial load and heated generators is described, and test results are compared with theory), Experimental Mechanics, Vol. 16, No. 4, 1977, pp. 133-139, doi: 10.1007/BF02321107

ABSTRACT: A series of tests was carried out on clamped cylindrical shells under a combination of thermal and mechanical loads. The shells were linearly heated along two opposite generators in addition to a uniform axial pressure applied before the heating. The paper describes the test setup, equipment and techniques used. Systems for rapid measurement, data analysis and storage designed for the experimental work are presented. As an outcome of this study, a linear-interaction line is proposed in order to express the interaction between thermal and mechanical-buckling loads.

ABSTRACT: Postbuckling behavior and imperfection sensitivity associated with mode interaction in axially stiffened cylindrical shells are studied. The two modes considered are an overall mode compared to stiffener spacing and a short-wavelength panel mode involving buckling between the stiffeners. A restricted optimization study is made where the number of stringers is treated as a design parameter, and the range of designs considered includes the optimum design for the perfect shell, where the two modes are simultaneous. The influence of a given level of imperfections on the optimum is explored. A general method for analyzing initial postbuckling behavior is proposed for structures with simultaneous or nearly simultaneous modes. Asymptotic expansions of all fields in the amplitudes of the competing modes provide a set of uniformly valid results.

ABSTRACT: Tests were performed on two simply supported plates of aluminum alloy 2024-0, under a central concentrated load, with peak deflections up to 2.6 times the thickness. The load was provided by a small-diameter hard-steel rod. The plates had diameter-to-thickness ratios (D/h) of 20 and 41. Measurements were made of load, deflections and strains; membrane and bending strains were calculated from the test data. The test data are presented in comparison with theoretical predictions generated by the Grumman-developed finite-element-computer code PLANS, which includes material and geometric nonlinearities. The theoretical prediction was excellent for deflections, and generally good for strains, when the central force was represented by a line load around the loading rod's contact circle. Using a uniform pressure as the central force caused the theory to slightly overpredict the peak deflections and greatly overpredict the peak strains at the plate center. The plates exhibited initial loss of stiffness under the plastic-bending behavior, followed by a restiffening when the large deflections caused a rapidly increasing membrane action that provided much additional resistance to the applied load.

SUMMARY: The geometry of the middle surface lines of curvature of a thin conical shell, whose cross-section is bounded by a certain closed convex plane curve, is studied. Then, for such a shell, several sets of linear and nonlinear equations of motion are derived in terms of its middle surface orthogonal line-of-curvature coordinate system. As an application of the presented analysis, the free vibration problem of thin circular and elliptical frustums is investigated by means of linear Donnell-type equations of motion. These equations are expressed in terms of the shell middle surface displacement components and they are solved approximately by means of Galerkin's method. Numerical results are presented for frustums with clamped both edges.

ABSTRACT: By employing the finite element displacement method using the tangent stiffness approach, the paper presents results of post-buckling analysis of plates and three-dimensional thin-walled members subjected to uniaxial compressive loads. A simple rectangular element with six degrees of freedom at each node, suitable for the analysis of nonplanar prismatic members with slope discontinuities (folded plates), is employed. Both geometric and material nonlinearities have been considered based on a Lagrangian coordinate system and the flow theory of plasticity. The nonlinear equations are solved using the Newton–Raphson method in the elastic range and the step-by-step method with equilibrium corrections in the plastic range. A modified Cholesky decomposition technique is employed to solve the basic stiffness equations.

ABSTRACT: A nonlinear finite element computer program has been developed to analyse thin-walled metal structural members. The program has the ability to handle both geometrical and material nonlinearities so that the post-buckling behaviour and ultimate strength of members can be predicted. A bending-membrane rectangular element with six degrees of freedom at each node forms the basic type of element used in the program. Marguerre's shallow shell theory is adopted for the strain-displacement relationships and hence the bifurcation point at buckling can be bypassed by providing an initial imperfection. The finite element formulation is based on the total Lagrange coordinate system and the flow theory of plasticity. Explicitly shown in the paper is the formation of the tangent stiffness matrix and the tridiagonal block form of solution procedure. Two problems of a square tube and a channel section beam subjected to pure bending were tested and found to be in close agreement with previous theoretical work.

ABSTRACT: This technical note indicates alternative applications of the nonlinear programming techniques and the finite element discretization to the limit analysis of shells of revolution. The numerical results are good even though the numbers of degrees-of-freedom used are limited. Both statically and kinematically finite element formulations are general, so extension to more complicated structures is possible. The flexibility and the efficiency of the finite element technique are preserved and combined with the algorithms of nonlinear programming.

ABSTRACT: Over the past few years, fibre-reinforced laminates have been found to be highly desirable for aerospace structural applications. This paper is concerned with one of the problem areas connected with these
applications; namely, the stability of midplane symmetric, laminated composite plates. The results of plate buckling analyses performed by means of the BENST module of the PLANS system of finite element structural analysis programs are presented. These analyses involve a wide variation in laminate orthotropic and material axis orientation and a number of plate aspect ratios and support conditions. The efficacy of the BENST finite element program is demonstrated by comparison with published results. Peak buckling loads for simply supported plates at material axes orientation other than the plate principal axes are predicted for laminate material properties ranging from mildly orthotropic to severely orthotropic. This indicates that the common design practice of calculating simply supported plate buckling levels by applying a ‘knock down’ factor to existing clamped plate data may often be unnecessarily conservative. Also included in this paper are details on the finite element method implemented in BENST and the development of the expressions that permit the calculation of laminate effective material properties from the properties of the individual layers.

ABSTRACT: The visco-plastic model is used in the context of large displacement (geometrically non-linear) analysis. As the process now involves in numerical computation an updating of relevant stiffness matrices, formulation which is stable and computationally more efficient. The applications shown demonstrate the applicability of the process to large displacement elasto-plastic shell analysis as well as to problems of creep buckling.

ABSTRACT: A method is presented for determining the linear critical force of thick-faced sandwich cylinders compressed along the generatrix. Contrary to deductions neglecting transversal shear deformations, critical buckling form of sandwich cylinders under uniform compression along the generatrix is always so-called annular buckling, hence by no means an indeterminate buckling form. Critical forces deduced according to flexural theory assumptions for thin- and thick-faced sandwiches significantly differ: upper bound of the critical force of thin-faced sandwich plates is the effective shear rigidity value of the sandwich, while for thick-faced sandwich structures (with non-negligible flexural rigidity of facings) the critical force may exceed the shear stiffness. An illustrative analogy, useful for practical computations, may be found between the buckling of sandwich cylinders and elastically bedded sandwich beams. In either case, the exact solution of the used mathematical model yields a formula, the same as given by the Bijlaard’s principle which is a known method of stability analysis for estimating the critical force.

ABSTRACT: This paper extends the use of the Semiloof shell element to geometrically and materially nonlinear situations. For the geometrically nonlinear analysis a moving coordinate process is used. Local coordinate systems are considered, one at each integrating point, which move with the structure and allow deformation and rotation within the element to be taken into account. For elasto-plastic analysis the initial stress method is used and the yield conditions are expressed in terms of nondimensional stress resultants. The element formulation is briefly considered and in particular the definition of the global and local displacements and their first and second derivatives in the non-constrained and constrained form of the element are discussed. Numerical results are presented and comparisons made with other sources where available.

DOI: 10.1108/eb023586
ABSTRACT: A generalized displacement method has been previously presented for the analysis of thin plate-shell structures with the use of bilinear 4-node isoparametric shell elements. Following this approach, a procedure for the geometrically non-linear analysis of thin plates and shells based on both updated and total Lagrangian formulations is developed. The results of some numerical examples are presented to show the versatility and effectiveness of the method.

ABSTRACT: The Structural Analysis Program, SAP, has been widely accepted and modified to perform a wide variety of structural analyses at many universities, government and industrial organizations. This paper will document the development of SAP into a user-oriented program for linear dynamic and static analysis of large complex structures which is referred to as FESAP (Finite Element Structural Analysis Program). The paper will also describe companion computer programs which constitute a total design system for thermo-structural analysis. The total system includes mesh generation programs, a heat transfer program, the structural analysis program, batch and interactive graphic computer programs, and post-processors for the results of the heat transfer and structural analysis programs.

ABSTRACT: The purpose of this paper is to look at the analysis of a nuclear reactor system as a total analysis task and to examine the assumptions which are made in the separation of the analysis task into its component disciplines. The structural analysis discipline is then examined in more detail to try to define a workable approach to an integrated structural analysis of the reactor system. We will start with a general discussion of the
total analysis task, starting from the initial concept of the reactor plant. The total task will then be subdivided into the respective disciplines and an attempt will be made to rationalize or criticize the division into separate disciplines. The discipline of structural mechanics will then be examined in view of its interactions with other disciplines such as fluid flow and nuclear analysis to determine the degree of coupling which exists among these disciplines. This will be done by examining the interactions of the state variables which apply at each point of the system. The state variables considered will include fluence, temperature, displacement and pressure. The state variables defined will then be used as the basis for the definition of an overall structural model of the reactor system. Such an overall model can be conceived in terms of the present status of analytical techniques, by the use of such concepts as substructuring, constraint equations, coupled solutions for heat transfer, stress and dynamic analysis, along with fourth generation computer capabilities. A block design for an overall structural model will be discussed and also the areas which require new analysis techniques. The last section will present an outline of a mode of operation of a structural design/analysis activity which is established to implement a comprehensive integrated structural analysis of an entire reactor system. The concept of an evolving model of the system will be presented and the coordination required to successfully manage such a design/analysis approach will be discussed. A brief discussion of the effects of non-linear effects such as creep, plasticity, gaps on the overall approach will be included.

ABSTRACT: This paper is intended to review the present state-of-the-art in computerized structural analysis, to look at the present trends in analysis, and to project these trends over the next 3–5 yr and try to predict the forms which computerized structural analysis will take over the next few years. The various components making up the structural analysis system are examined in some detail followed by an assembly of the present components into the present state-of-the-art system and an attempted assembly of the projected components into a future state-of-the-art system. This projection is the basis for the present hardware and software developments being done at Swanson Analysis Systems, Inc., in conjunction with the ANSYS Computer Program.

PARTIAL INTRODUCTION: The known solutions [3,5,7,10] of the problem of the stability of a toroidal shell have been based on the conversion to a Sturm-Liouville problem. Since the linearization was performed in the neighborhood of the initial zero-moment stressed state, which can be calculated relatively simply, the authors of the papers were able to obtain an analytic solution…

PARTIAL INTRODUCTION: By methods of the theory of perturbations [1-4], upper critical loads have been obtained for nonideal cylindrical shells under transverse and hydrostatic loading. Problems of approximation are studied in particular. When determining the total and ordinal numbers of degrees of freedom, the information about the density of the spectrum of the corresponding linear stability problems is used [5-7]. The band of scatter of the upper critical load is obtained. A numerical experiment allowed the probability
characteristics of the process of stability loss to be calculated. We consider a nonlinear system of equations of the theory of shells which relative to the stress function $F$ and the normal deflection $w$ describes the buckling of ideal thin-walled cylindrical shells under transverse or hydrostatic loading.

PARTIAL INTRODUCTION: The inevitable initial irregularities arising in the construction of structures or the perturbations in loading cause a premature loss of stability (compared with Euler loading) of elastic constructions and are the main reason for the scatter in experimental data. In the present paper a combined (numerical-analytical) approach to the solution of nonlinear boundary problems is expounded, as applied, by way of example, to the study of the buckling of closed ideal cylindrical shells under transverse or hydrostatic loading with perturbations taken into account. Numerical analysis of the buckling process under transverse and hydrostatic loading shows that the process of successive loading of a shell is accompanied by the distortion of the initial section of the critical load spectrum and by the reconstruction of buckling modes.

ABSTRACT: The objectives of the program reported here are to advance lightweight composite shell design technology and evaluate appropriate design and analysis procedures for lightweight composite shells that must satisfy buckling requirements. To accomplish those objectives the primary effort was to design and fabricate a graphite-epoxy cylindrical shell 3.05m (10 ft) in diameter by 3.05m (10 ft) long for evaluation in shell bending tests to be conducted by the Structures and Dynamics Division of the NASA Langley Research Center. Through such tests, the use of advanced composite materials will be evaluated for structural applications in future space missions such as those that involve spacecraft and structural assemblies to be used in geosynchronous missions. Spacecraft for such missions will require ultralightweight structures to achieve maximum payloads. Of equal importance is the requirement to provide designs that are cost-competitive with current structural approaches. For space structures that must resist buckling under compression or shell bending loads, composite materials offer an attractive approach for providing lightweight, low-cost structural components for future spacecraft. In recognition of the potential weight savings available through structural applications of graphite-epoxy materials, an earlier test program (Reference 1) was undertaken by the ASA to provide a technology base for flat, stiffened graphite-epoxy compression panels and to evaluate their effectiveness in reducing structural weight. The panels used in the earlier test program were designed using an advanced version of the analytical methods developed in (Reference 2) Other tests were conducted with stiffened graphite-epoxy shear panels.

CONCLUSIONS: 1. In loading with a force whose value lies between the long-term and instantaneous critical values, a loss of shell stability by rupture takes place at a certain time after loading. This time is naturally taken as the critical one. 2. Numerical estimates show that the level of the initial irregularities has a very great effect
on the magnitude of the critical time. Therefore, in a theoretical estimate of the critical time it is necessary to take account of them as accurately as possible.

ABSTRACT: A computer program for the analysis of semi-monocoque structures loaded through a rigid bulkhead is presented. A matrix algebra approach is utilized to generate the governing equations. The program is an efficient and valuable tool for the analysis of aircraft structure components in the preliminary design phase.

ABSTRACT: In recent years, there have been many developments in constitutive relations, finite element idealization, and failure criteria. This paper will try to bring out the impact of the various developments from the point of view of the analyst. The paper is somewhat more extensive in creep-fatigue evaluation than in other areas as a result of the fast breeder reactor program. Inelastic fracture, inelastic buckling, and residual stresses due to fabrication processes, are briefly reviewed. An application in each case is discussed, with emphasis on the difficulties requiring additional work.

ABSTRACT: A spherical submarine hull element is analyzed by means of a nonlinear finite-difference program. The imperfection sensitivity of this stiffened shell is greatly dampened by the structural discontinuities introduced through the stiffened portholes. The influence of shape imperfection or geometric manufacturing tolerance is studied by varying the imperfection amplitude and by changing its distribution (different shapes).
Several grades of steel are considered for the present hull structure as well. The analytical results are presented on various graphs visualizing the buckling characteristics of the present structure. Other simplified analytical tools are reviewed with the purpose of serving as a cross-check. Finally, model test results are compared with the finite-difference results.

ABSTRACT: The current status of inelastic structural analysis is reviewed relative to the needs and requirements for design of elevated temperature nuclear reactor components. The classes of inelastic problems that can be solved in a practical way are identified and the overall scope of ongoing validation programs is reviewed. Three classes of problems are identified where the further development of simplified analysis techniques is necessary to make them tractable for design application.

ABSTRACT: This work describes the development of a curved quadrilateral shell finite element which demonstrates very good convergence properties. A general description is used in deriving the element so that it may be applied to any thin shell problem. The element is shown to be very efficient. It has a total of 36 degrees-of-freedom with 9 at each of the corners of the element. There are several distinct advantages that the element offers for practical applications. Most of the shell elements that have been presented in the past are limited to problems in which the coordinates on the shell surface are orthogonal. The element that is described in the paper is derived using a general description so that it may be applied to any thin shell problem including those in which the shell coordinates are not orthogonal. The degrees-of-freedom at each of the four nodes are the three Cartesian displacements and their first derivatives with respect to the two surface coordinates. The imposition of boundary conditions is simplified since each of the degrees-of-freedom can be associated with a quantity which has a simple physical meaning. During the course of the derivation of the element, the strain displacement relationships are derived in a very simple manner consistent with Love's first approximation for thin shells. The derivation in the paper starts from basic principles and should help to shed some light on the proper form for the bending strain. Two primary contributions are presented in this work. The first is the presentation of a procedure for the development of a general quadrilateral shell element. The second is the simple derivation of the bending strain for the thin shells which apparently has not been presented previously.

ABSTRACT: This paper describes the results of collapse tests on two models of longitudinally and circumferentially stiffened leg sections of an offshore platform. Methods of predicting buckling loads are discussed and predicted platform. Methods of predicting buckling loads are discussed and predicted buckling loads are compared with the model test results.

ABSTRACT: The dynamic response of a pressurized plane strain cylinder is investigated in the case of impulsive distributed loading. The investigation is based on a finite element method which accounts for the influence of internal pressure on the effective stiffness and the response history of a pressurized unconstrained cylindrical shell. The numerical results suggest that significant changes in stiffness occur as functions of internal pressure and the ratio of shell radius to thickness. It is noted that a linear superimposition of the results of a membrane state plus those of an unstressed state subjected to identical dynamic loading does not yield the precise state of stress and deformation in a pressurized cylindrical shell under dynamic loading.

ABSTRACT: A general solution procedure, based on the linear theory, is presented for arbitrary shells of revolution subjected to arbitrary axisymmetric dynamic loads. The equations of motion admit shear deformation and rotational inertia. The numerical solution is obtained by Houbolt's method and by finite differences.

ABSTRACT: The discrete energy method—a special form of finite difference energy approach—is presented as a suitable alternative to the finite element method for the large deflection elastic analysis of plates and shallow shells of constant thickness. Strain displacement relations are derived for the calculation of various linear and nonlinear element stiffness matrices for two types of elements into which the structure is discretized for considering separately energy due to extension and bending and energy due to shear and twisting. Large deflection analyses of plates with various edge and loading conditions and of a shallow cylindrical shell are carried out using the proposed method and the results compared with finite element solutions. The computational efforts required are also indicated.

ABSTRACT: Variational equations are derived for thin elastic shells of arbitrary geometry from their related non-linear modal equations. The advantages of this procedure compared to methods commonly used in engineering applications are discussed. Numerical calculations are carried out for a simply supported circular cylinder to obtain the variation of natural frequencies of the cylinder under internal pressure, and its static buckling stress under uniform axial load. A discrepancy between the results of shell theory and those of three-
dimensional elasticity theory is found and discussed.

ABSTRACT: The stability of the steady state response of simply supported circular cylinders subjected to harmonic excitation is investigated by using variational equations reduced from “exact” non-linear modal equations. The inertia of the unperturbed vibration motion is included as well as the non-linearities in the steady state resonant response. The existence of a new mechanism of parametric excitation is predicted and the conditions by which it develops are discussed. Unstable regions are established on frequency response plots for different shell geometries. Numerical integration results for unstable conditions indicate considerable overloading of the structure and underline the practical significance of this instability mechanism.

ABSTRACT: A finite element method is presented for the analysis of the vibratory characteristics of laminated orthotropic cylinders. The cylinder may have an arbitrary number of bonded elastic orthotropic cylindrical laminates, each with distinct thickness, density and mechanical properties. The formulation is capable of treating a three-dimensional initial stress state which is radially symmetric. Biot's incremental deformation theory is the basis for this study. A homogeneous, isotropic cylinder was analyzed and these numerical results were in excellent agreement with those from an exact analysis. Additional examples of two geometries of a three-layer composite and a sandwich cylinder are given to further illustrate the influence of the initial stress on the physical behavior of such structures.

ABSTRACT: Cylindrical shells, with wall thickness-to-diameter ratios varying in steps from 1:2000 to 1:500 are used in large floating-roof storage tanks, where buckling under partial vacuum is a potential risk. To examine the validity of several methods of analysis, aluminum models with a nominal diameter of 150 mm were tested. Some models exhibited a sudden buckling, at the pressure predicted by one of the methods of analysis, others deformed at increased rate as the critical pressure was approached. A gradual change in, modal-buckling pattern, under decreasing pressure, was also observed.

ABSTRACT: Experimental results are interpreted in the light of numerical analysies, imperfection sensitivity and Design Codes. Two cases are discussed: spherical shells under uniform external pressure and partly filled spherical shells, supported on a continuous equatorial ring. The imperfection sensitivity associated with the first loading case leads to the selection of safety factors that depend on the actual shell stiffness. The second case, in which the load results in a biaxial tension-compression state of stress, is treated approximately in terms of a plate under biaxial load.

“Comparison between analytical, numerical and experimental determination of dynamic buckling in thin cylindrical shells”, Chapter in Computational Mechanics ’88, pp 793-796, 1988

ABSTRACT: The effect of blast loads on cylindrical shells has been studied by means of approximate analytical methods and by numerical analysis, using commercial programs (ABAQUS). Both axisymmetric and lateral loads have been considered. The results are compared to experiments in which shells, made by electro-depositing copper onto disposable wax molds exposed to an external pressure pulse.

ABSTRACT: The buckling characteristics of shells with double curvature is an important design consideration of such structures. Aircraft structural components are commonly of the double curvature type. Classical elastic buckling of toroidal shell segments with positive and negative Gaussian curvatures under pressure loading is given by Stein and McElmann. A further investigation of elastic toroidal shells, including bowed-out segments subjected to axial tension and a study of the initial post-buckling behavior, is performed by Hutchinson.

ABSTRACT: The post-buckling behaviour of J.W. Hutchinson’s (1973) plastic buckling model is investigated. The aim is to predict, approximately, the load-deflection curve up to the maximum load. Hutchinson's theory for post-bifurcation behaviour of structures usually fails to predict the behaviour up to the maximum load. An alternative approach is formulated in which the construction of an (approximate) equation for the “locus of maxima” plays a central role. The results of this approach are compared with “exact” numerical solutions.

ABSTRACT: A general solution of Bolotin's differential equations for the dynamic stability of a homogenous isotropic medium is given. This takes the form of displacement functions which express the solution as a sum of dilatational and distortional effects. Using these functions, solutions are found for the vibration of cylinders of finite thickness when initial axial stresses are present. The behaviour of solid rods, simple vibration and simple buckling are all seen to be special cases of the general solution. The results are compared with approximate formulae for the buckling of thin cylinders and it is shown that the known solution for the natural frequency of unloaded cylinders is a particular case.

ABSTRACT: This communication presents a relatively simple formula for the prediction of the initial postbuckling behavior (in the sense of Koiter) of hingeless elastic circular arches of uniform crosssection subjected to a uniform external gas pressure. Calculations are performed on the basis of an asymptotic method which contains elements of the techniques of analysis used by Budiansky and Hutchinson, and Chien.

ABSTRACT: The results obtained in this communication characterize the initial postbifurcation behavior of thin elastic rings subjected to a constant-directional and normal uniform external pressure. They complement the calculated postcritical values presented by Budiansky and Sills in previous publications.

ABSTRACT: An asymptotic method based on Koiter's elastic stability theory is presented for geometrically nonlinear structure analysis; these structures are subjected to a proportional applied load system. An approach that makes possible the choice of the modes which are necessary to obtain a good representation of the reduced energy is developed as an iterative process. The approach is transferred into the framework of the finite element method. Applied to the study of thin walled structures through some sample tests, the method gives, at low cost, numerical results which are in good agreement with the preceding studies.

ABSTRACT: The complementary energy approach for stability analysis of elastic structures under conservative loading is based on Fraeijs de Veubeke's variational principle. The associate equations of neutral equilibrium and stability criterium are presented for arbitrarily large deformations and rotations. When specialized to the structural behavior of thin plates in moderate rotations this functional yields the von Karman equations. Efficient mixed flat shell finite elements are derived from this functional. If the fundamental path is moderately nonlinear, the buckling load and the initial postbuckling behavior can be obtained by an iterative process of Rayleigh-Ritz type, which is based on Koiter's asymptotic approach. Development of the iterative method within the complementary energy principle allows improvement of computational effectiveness and of the rate of convergence, as shown by means of numerical examples.

ABSTRACT: Uemura and Byon (Int. J. Non-Linear Mech. 13, 1–14, 1978) presented experimental results and a numerical analysis about the secondary buckling of clamped flat plates under uniaxial compression. However, their numerical analysis is based upon an inconsistent flat plate finite element and it does not take into account the important influence of antisymmetric imperfections. This paper presents and discusses F.E.M. results obtained by two computer codes using very different approaches, and compares these results with the experimental ones.

ABSTRACT: Plastic buckling analysis of thin shell structures is generally performed by employing a Newton's type method within an incremental approach. This process becomes more efficient if a good estimate of the critical buckling load is available. This one can be obtained as the solution of an eigenvalue problem that generalizes the elastic bifurcation analysis. The stability matrix of the eigenvalue problem involves an additional term with respect to the elastic bifurcation problem; that is the material stiffness matrix that accounts for the change of the tangent modulus along the fundamental path. The proposed approach is applied to the elastoplastic buckling of spherical caps under pressure.

ABSTRACT: Implicit-explicit finite-element “mesh partitions” are developed for transient problems of nonlinear mechanics. The methods are shown to have improved implementational properties and may be easily coded into many existing implicit computer programs. The stability and accuracy properties of the methods are discussed, and techniques for improving the accuracy in the explicit group, without adversely affecting stability, are described. Implicit-explicit “operator splitting” methods, which enable the efficient treatment of kinematic constraints (e.g. incompressibility) in transient analysis, are also presented.

ABSTRACT: A nonlinear finite element formulation is presented for the three-dimensional quasistatic analysis of shells which accounts for large strain and rotation effects, and accommodates a fairly general class of nonlinear, finite-deformation constitutive equations. Several features of the developments are noteworthy, namely: the extension of the selective integration procedure to the general nonlinear case which, in particular, facilitates the development of a ‘heterosis-type’ nonlinear shell element; the presentation of a nonlinear constitutive algorithm which is ‘incrementally objective’ for large rotation increments, and maintains the zero
normal-stress condition in the rotating stress coordinate system; and a simple treatment of finite-rotational nodal degrees-of-freedom which precludes the appearance of zero-energy in-plane rotational modes. Numerical results indicate the good behavior of the elements studied.

ABSTRACT: A general nonlinear finite element formulation is given for two-dimensional problems. The formulation applies to the practically important cases of shells of revolution, tubes, rings, beams and frames. The approach is deduced from a corresponding three-dimensional formulation [4] and this enables a simplified implementation, especially with respect to constitutive software. Uniform reduced-integration Lagrange elements are employed and shown to be very effective for the class of problems considered.

ABSTRACT: A previously developed nonlinear finite element shell formulation is generalized to accommodate large membrane strains. The formulation is demonstrated on the bending and inflation of a circular plate and the axisymmetric stretching of an annular plate. Both problems are modeled with a Mooney-Rivlin material and involve large membrane strains.

ABSTRACT: The concept of isogeometric analysis is proposed. Basis functions generated from NURBS (Non-Uniform Rational B-Splines) are employed to construct an exact geometric model. For purposes of analysis, the basis is refined and/or its order elevated without changing the geometry or its parameterization. Analogues of finite element h- and p-refinement schemes are presented and a new, more efficient, higher-order concept, k-refinement, is introduced. Refinements are easily implemented and exact geometry is maintained at all levels without the necessity of subsequent communication with a CAD (Computer Aided Design) description. In the context of structural mechanics, it is established that the basis functions are complete with respect to affine transformations, meaning that all rigid body motions and constant strain states are exactly represented. Standard patch tests are likewise satisfied. Numerical examples exhibit optimal rates of convergence for linear elasticity problems and convergence to thin elastic shell solutions. A k-refinement strategy is shown to converge toward monotone solutions for advection–diffusion processes with sharp internal and boundary layers, a very surprising result. It is argued that isogeometric analysis is a viable alternative to standard, polynomial-based, finite element analysis and possesses several advantages.

ABSTRACT: We have extended the subdivision shell elements of Cirak, Ortiz and Schroder [20] to the finite-deformation range. The assumed finite-deformation kinematics allows for finite membrane and thickness stretching, as well as for large deflections and bending strains. The interpolation of the undeformed and deformed surfaces of the shell is accomplished through the use of subdivision surfaces. The resulting ‘subdivision elements’ are strictly C1-conforming, contain three nodes and one single quadrature point per element, and carry displacements at the nodes only. The versatility and good performance of the subdivision

elements is demonstrated with the aid of a number of test cases, including the stretching of a tension strip; the inflation of a spherical shell under internal pressure; the bending and inflation of a circular plate under the action of uniform pressure; and the inflation of square and circular airbags. In particular, the airbag solutions, while exhibiting intricate folding patterns, appear to converge in certain salient features of the solution, which attests to the robustness of the method.

ABSTRACT: This thesis presents the linear and nonlinear analysis of thin shell structures. The linear formulation is based on three finite elements namely the: four nodes degenerated shell element (DE4), the four nodes flat shell element (FE4) and the nine nodes degenerated shell element (DE9). Each one of these elements has six degrees of freedom per node. Additional elements have been developed; these are: the four nodes element, employing the Mixed Interpolation of Tensorial Components approach (MITC) proposed by Bathe to avoid shear locking applied on DE4 and FE4 , the Non-Conforming Element (NCE) to improve the behavior in bending situations, and the nine nodes element with Selective Reduced Integration (SRI) and Weighted Modified Integration (WMI). These elements are used to overcome the shear and membrane lock in lieu of using reduced integration. The verification of linear formulation was based on using patch test. The DE4 element passes all patch tests except the pure bending test, while the other elements pass the tests partially. Further verification was done by using numerical examples; and the elements perform very well when the results are compared with exact ones as they are in good agreement. The problems of shear and membrane locks result in the divergence of the solution for these shells with increase in the number of elements. A solution is proposed to correct the convergence curve to be asymptotic to the exact solution curve by using extrapolation. This was done by selecting a Weibull model to correlate the displacement and mesh size through the number of joints. The model depends on parameters; the values of which depend on the values of displacements before the divergence occurs. Good results are obtained when applying the method in different numerical examples for the DE4 element.

ABSTRACT: Many of the formulations of current research interest, including isogeometric methods, the extended finite element method, and meshless methods, use nontraditional basis functions. Some, such as subdivision surfaces, may not have convenient analytical representations. The concept of an element, if appropriate at all, no longer coincides with the traditional definition. Developing new software for each new class of basis functions is a large research burden, especially if the problems involve large deformations, nonlinear materials, and contact. The objective of the current research is to separate as much as possible the generation and evaluation of the basis functions from the analysis, resulting in a formulation that can be...
implemented within the traditional structure of a finite element program but that permits the use of reasonably arbitrary sets of basis functions that are defined only through the input file. Examples of this framework to applications with Lagrange elements, isogeometric elements and XFEM basis functions for fracture are presented.

ABSTRACT: A Reissner–Mindlin shell formulation based on a degenerated solid is implemented for NURBS-based isogeometric analysis. The performance of the approach is examined on a set of linear elastic and nonlinear elasto-plastic benchmark examples. The analyses were performed with LS-DYNA, an industrial, general-purpose finite element code, for which a user-defined shell element capability was implemented. This new feature, to be reported on in subsequent work, allows for the use of NURBS and other non-standard discretizations in a sophisticated nonlinear analysis framework.

ABSTRACT: While studies of post-buckling behavior and load-carrying capacities of thin plates subjected to uniaxial compression have been limited to stable conditions, further post-buckling loading generates an unstable condition. The secondary buckling which occurs with snap-through to higher-order deflections under such unstable conditions has not been analyzed in detail as yet. In the first part of this paper, a thin square plate under uniaxial compression, which is simply supported along four edges, is considered. A method based on the second variation of the total potential energy is then proposed for evaluating the stability of the post-buckling equilibrium state and inevitable secondary buckling is derived analytically. The effects of various factors, such as initial imperfections, assumed virtual displacement pattern, post-buckling deflection pattern and in-plane boundary conditions, on the secondary buckling values are discussed. In part 2, secondary buckling of clamped plates is analyzed by use of the finite element method and the resultant numerical results are compared with experimental results.

ABSTRACT: In Part 1, a theoretical analysis was used to study the secondary buckling of a simply supported plate. In Part 2, a clamped plate is analyzed by the finite element method. The stability criterion for a non-linear post-buckling equilibrium state is evaluated by the sign of the determinant of the stiffness matrix. It should be noted that the secondary buckling loads of clamped plates are unexpectedly smaller than those of simply supported plates and are only one and a half times the primary buckling loads. In previous analyses, only a quarter segment of the plate was considered by assuming a stable equilibrium state with symmetrical mode. However, instability can also be predicted by considering the unsymmetrical mode over the whole plate. Results

of experimental analysis of secondary instability of clamped square plates under uniaxial compression agreed with the numerical results.

ABSTRACT: An investigation of delamination crack growth in a unidirectional composite laminate under static and fatigue loading conditions is presented. An experimental program was conducted to study failure mechanisms and characterize the crack growth rate; analytical modeling based on microscopic observations was carried out using an advanced singular finite element method of the hybrid-stress model. Using a mixed-mode failure criterion, the delamination growth under a monotonically increasing load can be predicted; the rate of delamination crack propagation under fatigue loading is directly related to the amplitudes of cyclic opening and shearing mode stress intensity factors by a power law relationship.

ABSTRACT: The problem of the buckling of a simply supported thin, elastic, cylindrical panel subjected to a uniform axial compression is studied by constructive methods. In the case of “narrow” panels we obtain near the classical buckling load a description of all stable and unstable buckled states which branch from the unbuckled state. The method also yields useful information on the asymptotic form of the buckled states near the bifurcation load, the exchange of stabilities at the bifurcation point, and whether the buckling at the ends of a narrow panel is “inward or outward”.

ABSTRACT: Secondary buckling and post-secondary-buckling behaviours are theoretically studied for simply-supported rectangular plates, whose primary buckling modes of deflection contain more than half-waves in the load acting direction. Modal coupling effects more complex than one two-term-coupling effects are incorporated into the secondary buckling and post-secondary-buckling analyses. Then, unstable or stable symmetric secondary branching points are found on the post-primary-buckling paths and “snap through” motions involving an abrupt change in wave-form are shown to be possible. Wave-form variations along post-secondary-buckling paths are also disclosed by means of a numerical analysis of equilibrium paths.

ABSTRACT: This paper is concerned with the numerical solution of systems of equations of discrete variables, which represent the nonlinear behaviour of elastic systems under conservative loading conditions. In particular, an incremental approach to the solution of buckling and snapping problems is explored. The topics that are covered can be summarized as follows:—The computation of nonlinear equilibrium paths with continuation through limit points and bifurcation points.—The determination of critical equilibrium states. Characteristic to the procedures employed is the use of the length of the equilibrium path as control parameter. This feature, together with the second order iteration method of Newton, offers a reliable basis for the procedures described. Actual computations, carried out on a finite element model of a shallow circular arch, illustrate the effectiveness of the methods proposed.

ABSTRACT: Riks [1] has recently proposed a new solution procedure for overcoming limit points. To this end, he adds, to the standard equilibrium equations, a constraint equation fixing the length of the incremental load step in load/deflection space. The applied load level becomes an additional variable. The present paper describes a means of modifying Rik's approach so that it is suitable for use with the finite element method. The procedure is applied in conjunction with the modified Newton-Raphson method in both its original and accelerated forms. The resulting techniques not only allow limit points to be passed, but also, improve the convergence characteristics of the unconstrained iterative procedures. Illustrative examples include the large deflection analysis of shallow elastic shells and the collapse analysis of a stiffened steel diaphragm from a box-girder bridge.

ABSTRACT: The redistribution of stresses in ductile structures, although beneficial from the safety viewpoint, introduces another source of uncertainty, which requires specific methods when the probabilistic approach to reliability evaluation is followed. Practicable procedures have been developed for structures that satisfy the classical assumptions of plastic limit analysis. In particular, two theorems that allow to find rigorous upper and
lower bounds on the probability of full plastic collapse under given loads, are presented. Other methods for probabilistic limit analysis are also indicated, including in particular a specifically developed parametric simulation procedure. The last part of the paper is devoted to the reliability analysis of plastic structures subject to loads varying (slowly) in time. It is recalled first that probabilistic limit analysis can be easily extended to the shakedown—incremental collapse problem, provided the loads vary within a finite domain: however, the significance of such an approach for stochastically varying loads is questioned. In fact, as time increases, the probability also increases that the loads cross any given threshold. Therefore, it is more appropriate to speak of “plastic adaption” rather than “shakedown”, and to focus the attention on the probability of reaching, in any given time interval, a certain permanent deformation. Again, only approximate solutions (in the form of upper and lower bounds) can be found to this question, but this appears to be a more rational and promising approach to the problem.

ABSTRACT: The article discusses characteristic types of nonlinearities in structural systems. Various ways of illustrating such nonlinearities are suggested. Mathematical equations that form the basis for alternative numerical solution algorithms are stated. The use of the current stiffness parameter for characterizing nonlinear systems is discussed. Some new formulations and applications of this parameter are suggested. A new class of solution techniques utilizing simultaneous iteration on the loading parameter as well as the displacements is also proposed. By these techniques it is not necessary to formulate a nonlinear stiffness matrix and incrementation of displacement pattern can be used instead of load incrementation. No special load reversal criterion is normally required for passing limit points.

ABSTRACT: The paper compiles the current status of the finite element method in linear and nonlinear buckling analysis of shells. The classical concept via shell theory, the degeneration method, continuum mechanics based and corotationalformulations used in the displacement approach and the corresponding incremental stiffness expression are briefly described. Some comments on the problem of non-uniqueness and stability of the solution and their practical evaluation are given. A classification of displacement dependent pressure loads is presented discussing the symmetry of the problem. The main characteristics of the different classes of shell elements are outlined. Besides flat and curved elements derived from shell theory the survey concentrates on degenerated elements. A detailed review on the main solution strategies in nonlinear shell analyses is presented. Among these are quasi-Newton methods combined with line search and iteration
techniques in the displacement and load space. Finally selected numerical examples are described applying isoparametric degenerated elements to bifurcation buckling and nonlinear collapse analyses of shells.

ABSTRACT: A computer program called STAR (Shell Transient Asymmetric Response) has been developed for the two-dimensional dynamic response of arbitrary shells. The program is based, in part, on Kempner's shell equations which include nonlinear geometric terms. The partial differential equations of motion have been reduced to a set of time-dependent ordinary differential equations by use of two-dimensional finite difference approximations for derivatives with respect to the shell's middle surface coordinates. An explicit numerical integration method is employed for the solution of the ordinary equations.

A.S. Volmir, “The nonlinear dynamics of plates and shells”, Accession Number: AD0781338, Foreign Technology Div Wright-Patterson AFB, OHIO, Report Date: 16 April 1974

ABSTRACT: The book consists of ten chapters. Chapter I contains the fundamental equations of dynamic theory of large-deflection plates and shells. Chapters II-V examine the various types of vibratory motions of plates and shells. Specific problems pertaining to natural and forced vibrations are apparently presented here for the first time. In the section pertaining to self-induced vibrations, principal attention is given to new data on panel flutter. Chapters VI-IX describe the behavior of thin-walled systems under dynamic loading. It includes an analysis of deformation of plates and shells under rapid and very rapid impact loads of different types. Finally, Chapter X presents some problems of shell and plate dynamics requiring a statistical approach.

ABSTRACT: Application of the DSISR program to recessed shells of revolution is illustrated on the examples of a cylinder with two diametrically-opposite rectangular cutouts and a sphere with a single trapezoidal cutout. The program which is suitable for a wide range of static and dynamic problems was developed for general linear analysis of shells of revolution with arbitrary stiffness and mass density distributions. In the analysis, the equations of motion are derived with the aid of Sanders' theory, and the numerical solution procedure is based on Fourier expansion in the circumferential direction, on finite differences in the meridional direction, and on Houbolt's method in the time domain.

Orhan Gürbüz, “Behavior and analysis of steel liners for prestressed concrete reactor vessels”, Ph.D. dissertation, Dept. of Civil Engineering, Iowa State University, 1974

INTRODUCTION: Prestressed Concrete Reactor Vessels (PCRV's) are structures which contain reactor systems directly without any other intervening pressure barrier. As such, they are continually subject to the
pressure of the primary coolant which is usually a gas. The use of gas-cooled PCRV's has found wide acceptance recently. Today, there are about thirty vessels in operation, under construction or, being planned, all over the world. A PCRV is usually cylindrical in shape and consists of five major components: (1) the concrete structure; (2) the post-tensioning system; (3) the nonprestressed reinforcement; (4) the liner assembly; (5) the thermal control system. The subject matter of this thesis is confined to the fourth component; the others will be discussed only to the extent that they affect the behavior of the liner. One of the important problems in PCRV design is the provision for leak-tightness of the vessel. Since the radioactive coolant must be contained within the vessel cavity, the cavity is always lined with a suitable material. In the United States and abroad, steel liners are used as the primary leakage barrier. There are numerous penetrations in a typical PCRV. These penetrations house mechanical equipment and provide access to reactor interior and, are also lined with steel (Fig. 1). The liner assembly consists of the liner plates, closely spaced anchors and, cooling tubes. The liner plate is essentially a thin shell, rigidly connected to the surrounding concrete by means of continuous (e.g., angles, tees) or discreet (e.g., studs) anchors. Cooling tubes are either square or circular in cross section and are usually welded to the concrete side of the liner. The PCRV liner is in biaxial compression throughout most of its design life. The compressive stress field is due mainly to prestressing loads, shrinkage and creep and, thermal loads. Under operating conditions internal pressure reduces the magnitude of the concrete-imposed compressive strains in the liner. But the resultant stresses are still compressive even under the maximum cavity pressure. In the design of liners, the usual approach is to determine the liner thickness and cooling tube spacing (hence anchor spacing, since anchors are provided between the tubes) considering the construction and heat transfer requirements. Design analyses are then conducted to verify that liner assembly stresses and displacements are within the allowable limits under normal operating and accident conditions. For this purpose, the liner structure is considered as a separate entity, independent of the backing concrete but, subject to concrete-imposed strains and displacements. In design analysis, the problem is considered indirectly, as it affects the behavior of individual liner panels between anchor supports. Stress analysis methods for liners were given in papers presented at Conference on Prestressed Concrete Vessels (1, 2, 3, 4) and First and Second International Conference on Structural Mechanics in Reactor Technology (5, 6). In these and other methods, it is customary to analyze a one-dimensional section of the liner assembly under appropriate loading and boundary conditions. A similar approach was taken in the design of the Fort St. Vrain PCRV liner, the only vessel constructed so far in the United States. In all one-dimensional stress analysis methods, the problem is formulated based on equilibrium at the nodes (the liner-anchor, joint) and compatibility between the nodes. Because of material nonlinearity the problem is usually reduced to solving a set of nonlinear simultaneous equations. Local effects which tend to increase unbalanced forces between liner panels and thus increase anchor forces, must also be considered in the analysis. For this purpose a panel which is weaker in compression than other panels (due to causes such as lower yield point, less thickness, existence of lateral pressure, etc.) is usually termed a "weak" panel, the remainder being "strong" panels. Since such local variations may occur anywhere, it is necessary to consider the most critical weak panel location in the stress analysis so that the magnitude of absolute maximum stresses and displacements can be determined and evaluated in the light of code allowances. The Prestressed Concrete Containment Vessels (PCCV's) are also lined, usually with a thin steel liner and thus present similar design problems. One-dimensional stress analysis methods used in the design of PCCV liners were described in Refs. (7, 8, 9). In Ref. (8) a two-dimensional analysis method, for the analysis of a PCCV or PCRV liner cross section perpendicular to the plane of the liner and including a portion of the backing concrete, was also briefly discussed. The stability of liners in a rigid cavity has been investigated by numerous researchers (10, 11, 12, 13, 14). The analytical models used are of two types: (1) ring or flat strips without anchors (10, 11); (2) rectangular panels or curved strips with anchors (12, 13, 14). Analysis of the former models result in minimum buckling strains at which an alternate equilibrium position exists and thus the liner may buckle into that position with an external disturbance.
Buckling may be prevented by providing anchors at a spacing less than the buckled length for a given strain. The latter models give minimum buckling strains and/or anchor stresses for a known anchor spacing. The above summary indicates that, in the design of PCRV and PCCV liners with closely spaced anchors, it is usual to treat the liner analysis as a stress problem. There are procedures proposed, based on a stability approach, for determining an adequate anchoring system for the liners. The PCRV liner stress analysis problem is considered in this dissertation. Specific objectives include:

1) To evaluate the adequacy of one-dimensional stress analysis methods,
2) To present a more refined, and two-dimensional, stress analysis method, and
3) To present an approximate method with which all local effects may be taken into account in design analysis.

As a basis for evaluating the appropriateness of the stress analysis approach, an overview of current liner design practice is presented in Chapter II. Available stability and stress analysis methods are reviewed and, loading conditions and component behavior are briefly discussed. Considering the fact that most PCRV and PCCV liners have been designed on the basis of a one-dimensional analysis, mainly because of the simplicity and conservativeness of these methods, there is a need to evaluate the adequacy of this approach. Since there is no test available, this evaluation is to be based on a comparison with the more refined analysis. For this purpose, a one-dimensional analysis method, similar to Parker's formulation (5) but using a different solution technique was developed first (Chapter III). A more accurate two-dimensional analysis method was developed next using the finite element approach (Chapter IV). Computer programs were written for both methods. Then a parametric study, based on Fort St. Vrain design data, was conducted using selected parameters (Chapter V). There is also a need for a technique with which the effect of all local variations can be taken into account in design analysis. Some local variations can be considered through modification of the weak panel characteristics while others need to be incorporated in the analytical procedure in some manner. Chapter VI summarizes a technique whereby the effects of various local variations may be studied. The characteristics of a weak panel needed in one-dimensional analysis may be developed using the approximate method presented in Appendix A. The findings and conclusions of this study are intended to apply to general PCRV liner stress analysis. The stress analysis methods discussed in Chapters III and IV are also applicable to PCCV liners. However, due to greater anchor spacing-liner thickness ratio of the PCCV liner panels, the approximate method of strut analysis presented in Appendix A may not be applicable to the case of PCCV liners. Furthermore, some of the local variations discussed in Chapter VI simply do not exist for PCCV liners, although the procedure for taking local effects into account should be applicable to both types of liners.

ABSTRACT: The response of the rolling tire is formulated in terms of the natural modes and frequencies of the non-contacting tire for contact loading due to rolling, braking, accelerating or cornering. The tire is viewed as an equivalent thin shell. Formulation is by way of the three-dimensional dynamic Green function of this shell. As the application example, the response of the tire during pure rolling is evaluated. The critical rolling speed at which the tire develops its first large amplitude standing waves is calculated in a novel fashion, showing the relationship between the standing wave phenomenon and natural tire modes and frequencies. Findings underline the need for measuring or calculating higher order tire modes than those considered in what seems to be the present standard practice.

ABSTRACT: The paper presents the theoretical and computational procedures which have been applied in the design of a general purpose computer code for static and dynamic response analysis of non-linear structures. A general formulation of the incremental equations of motion for structures undergoing large displacement finite strain deformation is first presented. These equations are based on the Lagrangian frame of reference, in which constitutive models of a variety of types may be introduced. The incremental equations are linearized for computational purposes, and the linearized equations are discretized using isoparametric finite element formulation. Computational techniques, including step-by-step and iterative procedures, for the solution of non-linear equations are discussed, and an acceleration scheme for improving convergence in constant stiffness iteration is reviewed. The equations of motion are integrated using Newmark's generalized operator, and an algorithm with optional iteration is described. A solution strategy defined in terms of a number of solution parameters is implemented in the computer program so that several solution schemes can be obtained by assigning appropriate values to the parameters. The results of analysis of a few non-linear structures are briefly discussed.

ABSTRACT: A formulation and computer program is developed for the geometrically nonlinear dynamic analysis of shells of revolution under symmetric and asymmetric loads. The nonlinear strain energy expression is evaluated using linear functions for all displacements. Five different procedures are examined for solving the equations of equilibrium, with Houbolt’s method proving to be the most suitable. Solutions are presented for the symmetrical and asymmetrical buckling of shallow caps under step pressure loadings and a wide variety of other problems including some highly nonlinear ones.

ABSTRACT: The natural frequencies and mode shapes for the vibrations of stiffened cylindrical shells with, or without, hemispherical end caps are evaluated. The approach utilizes a theory in which the shell elements and the circumferential stiffeners are considered as separate structures and compatibility is enforced at their junctures. The results are compared with those from orthotropic theory in which the stiffener effects are smeared over the shell. Numerical results are presented for frequencies and mode shapes for several cases of interest. The theoretical results have been compared with a set of experimental results from the Ordnance Research Laboratories and excellent agreement has been found. Comparisons of theory and experiment are presented in this paper.

Chang-Hua Yeh (Dept. of Civil Engineering, University of California, Berkeley, USA), “Large deflection dynamic analysis of thin shells using the finite element method”, UCB/SES-970/18, October 1970
ABSTRACT: An analytical procedure is presented for the evaluation of the nonlinear dynamic response of thin shells of arbitrary geometry. Geometric nonlinearity associated with the finite deflections of the structures is considered; the material is assumed to remain elastic throughout the analysis. The nonlinear dynamic response is obtained using a direct step-by-step integration of the equations of motion.

ABSTRACT: The response of an infinitely long elastic cylindrical shell imbedded in an infinite elastic medium and subjected to internal tractions is obtained. Inextensional and extensional motions are determined due to applied tractions given as step functions in time and varying with the angular coordinate. The interaction effect of the shell and medium is determined by means of compatibility conditions which are expressed as a set of coupled integro-differential equations in each mode and are solved numerically by a forward step integration in time. Numerical results are presented for the response in the axisymmetric mode and for higher modes. The response of the shell-medium system is observed to behave as a damped oscillating system whose long time response approaches that of the corresponding static problem.

ABSTRACT: A general step-by-step solution technique is presented for the evaluation of the dynamic response of structural systems with physical and geometrical nonlinearities. The algorithm is stable for all time increments and in the analysis of linear systems introduces a predictable amount of error for a specified time step. Guidelines are given for the selection of the time step size for different types of dynamic loadings. The method can be applied to the static and dynamic analysis of both discrete structural systems and continuous solids idealized as an assemblage of finite elements. Results of several nonlinear analyses are presented and compared with results obtained by other methods and from experiments.

ABSTRACT: Incremental equations of motion are derived from a Lagrangian variational formulation for the large displacement elastic-plastic and elastic-viscoplastic dynamic analysis of deformable bodies. The material constitutive behaviour is described in terms of the symmetric Piola–Kirchhoff stress and Lagrangian strain
tensors. Degenerate isoparametric elements, permitting relaxation of the Kirchhoff–Love hypothesis, are used in a finite element formulation specialized for the analysis of shells of revolution subjected to axisymmetric loading. The linearized incremental equations of motion are solved using direct integration procedures, with added accuracy obtained from application of equilibrium correction at each step. The effectiveness of the numerical techniques is illustrated by the dynamic response analyses carried out on a shallow spherical cap subjected to uniform external step pressure loadings.

ABSTRACT: The results of carefully-controlled small-scale experiments on the elastic buckling of stiffened plates are presented. Overall and local imperfections have been systematically varied to provide detailed curves of imperfection-sensitivity for geometries spanning the range of interaction between Euler and local plate buckling. The interaction of a third mode associated with the torsional buckling of relatively thin stiffeners is also examined. The analysis of a Shanley model is used to suggest a possible engineering approach to the design problem. This approach is based on a proposed application of the well-known Perry formula in which the material yield stress is simply replaced by the relevant local buckling stress, together with the predicted asymptotic approach to a reduced modulus load.

ABSTRACT: This paper gives an up-to-date account of chaos and fractals, in a popular pictorial style for the general scientific reader. A brief historical account covers the development of the subject from Newton’s laws of motion to the astronomy of Poincaré and the weather forecasting of Lorenz. Emphasis is given to the important underlying concepts, embracing the fractal properties of coast-lines and the logistics of population dynamics. A wide variety of applications include: NASA’s discovery and use of zero-fuel chaotic ‘superhighways’ between the planets; erratic chaotic solutions generated by Euler’s method in mathematics; atomic force microscopy; spontaneous pattern formation in chemical and biological systems; impact mechanics
in offshore engineering and the chatter of cutting tools; controlling chaotic heart-beats. Reference is made to a number of interactive simulations and movies accessible on the web.

“Probing shells against buckling: a non-destructive technique for laboratory testing”, International Journal of Bifurcation & Chaos, in press in October 2017

ABSTRACT: This paper addresses testing of compressed structures, such as shells, that exhibit catastrophic buckling and notorious imperfection sensitivity. The central concept is the probing of a loaded structural specimen by a controlled lateral displacement to gain quantitative insight into its buckling behaviour and to measure the energy barrier against buckling. This can provide design information about a structure’s stiffness and robustness against buckling in terms of energy and force landscapes. Developments in this area are relatively new but have proceeded rapidly with encouraging progress. Recent experimental tests on uniformly compressed spherical shells, and axially loaded cylinders, show excellent agreement with theoretical solutions. The probing technique could be a valuable experimental procedure for testing prototype structures, but before it can be used a range of potential problems must be examined and solved. The probing response is highly nonlinear and a variety of complications can occur. Here, we make a careful assessment of unexpected limit points and bifurcations, that could accompany probing, causing complications and possibly even collapse of a test specimen. First, a limit point in the probe displacement (associated with a cusp instability and fold) can result in dynamic buckling as probing progresses, as demonstrated in the buckling of a spherical shell under volume control. Second, various types of bifurcations which can occur on the probing path which result in the probing response becoming unstable are also discussed. To overcome these problems, we outline the extra controls over the entire structure that may be needed to stabilize the response.

ABSTRACT: Tee-section columns have been tested under conditions that provide a close relationship between the results so obtained and the behavior of certain classes of stiffened plate structures. It is shown that severe imperfection sensitivity arises when the overall column critical load is coincident, or nearly coincident, with the local torsional critical load of the stiffener. And, although the present results are clearly not directly applicable to stiffened plate design, it is suggested that, if these systems are to be designed with even greater material efficiencies than at present, the interactive mechanics observed could acquire increasing design importance.
Accordingly, suggestions are made as to the form of research needed to provide a rational basis for the design of such ‘optimized’ stiffened plate structures.

DOI: 10.1007/978-3-642-50992-6_29

ABSTRACT: Ship hull structures yearly consume in the order of 15 million tons of steel. An appreciable amount of this goes into parts of the structure which are either designed on the basis of buckling criteria or a combination of stress and buckling criteria, or it is included with no other function than that of preventing buckling of the structure. Most of the ship structures consist of a fairly complex system of stiffened plates which are subjected to hydrostatic and dynamic lateral loads as well as in plane stresses which may be both tensile and compressive in a more or less bi-axial fashion. The theoretical buckling strength of stiffened plates in various bi-axial stress fields is of course reasonably well defined. But there are still some problems related to the influence of initial deviations, the corrections for elasto-plastic behaviour, the influence of lateral loading, and the evaluation of “realistic” boundary conditions. Slender unstiffened or lightly stiffened shells have not been typical for ship structures. However, the present developments of LNG-carriers with very thin shell of revolution type tanks have necessitated development of buckling design criteria both for unstiffened spherical shells and for lightly stiffened cylinders. The importance of the relationship between shape imperfection and reduction (knock down) factor is for both types of shells rather obvious. For circular cylinders even light stiffening gives large increases in the theoretical buckling strength. The extent to which this constitutes a real increase is an important factor for the designer. Typical for the cylinders is also that they operate in the elasto-plastic region. For these and for several other important aspects of buckling, design decisions have had and have to be made. Regrettably the basic theoretical and experimental knowledge is uncomfortably sketchy pointing to a need for further basic and design-oriented research.

ABSTRACT: Using the theory for buckling of laminated, anisotropic, thin plates presented by Whitney and Leissa, optimal designs for simply supported rectangular plates, laminated of composite material and subjected to uniaxial compressive loading, are investigated. Numerical results are presented for optimal-design plates laminated of glass/epoxy, boron/epoxy, and carbon/epoxy composite materials.

INTRODUCTION: A major potential advantage claimed for fibrous composite materials in structural applications is that the material can be "tailored" by proper orientation of the fibers in the various layers so as to optimize the desired structural behavior. Yet the very nature of fibrous composites with their anisotropic elastic behavior has kept such optimal tailoring beyond the reach of most design engineers. In comparison to the numerous analyses available in the literature on buckling of anisotropic plates, very few optimal-design syntheses have been published for this problem. In 1960, Gerard (1) gave a synthesis for uniaxially compressed structurally orthotropic plates, but it was devoted only to longitudinally, transversely, or grid stiffened plates. For composite-material plates, Rothwell (2) presented a crude synthesis using netting analysis for the composite layers. Such an analysis completely neglects the contribution of the matrix material and is known to be in considerable disagreement with experimental results for laminated composite-material plates (3). Recently Hayashi (4) synthesized for maximum uniaxial buckling load in both symmetric cross-ply and symmetric angle-ply plates. However, his synthesis was based on the treatment of the number of axial half waves as a continuous rather than discrete variable. The present synthesis considers both symmetric and unsymmetric laminates subjected to uniaxial compressive loading parallel to two of the plate edges.

ABSTRACT: It is well-known that a straightforward process of structural optimization often demands the simultaneity of two or more failure modes. It has, however, been emphasized by Koiter and others that this can lead to a dangerous situation in which the nonlinear coupling of two quite stable post-buckling modes can generate highly unstable behaviour and associated imperfection-sensitivity. The question then arises as to how the imperfection-sensitivity might invalidate the apparent optimum, and it is a study of the mechanics of this that is presented here. A two-degree-of-freedom buckling model which exhibits this unexpected coupling action is introduced and its primary and secondary branching characteristics are derived analytically and numerically.

The simultaneity of the primary buckling loads is shown to arise as the solution of a simple but realistic optimization scheme, and the subsequent erosion of this optimum is observed. It is seen that the compound imperfection-sensitivity can quite seriously modify and perhaps destroy the apparent optimum solution, and the key role of secondary bifurcations is delineated.

DOI: 10.1002/nme.1620050207

ABSTRACT: A displacement method of matrix analysis for local instability of plates, stiffened panels and thin-walled columns is presented. The analysis is applicable to stiffened panel and columns for which the cross-section is made up of thin flat plates. For these cases it may be assumed that during buckling deformation no flat component of the cross-section is translated in its own plane and the edge lines at the junctions between flats remain fixed in space. The analysis leads to the standard eigenvalue equation from which the buckling stress can be determined. The elastic and geometrical stiffness matrices derived for this analysis depend on the wavelength of the buckled pattern and this dependence is of a simple form since all coefficients in the resulting stiffness matrices contain the buckling wavelength only as a common factor allowing for considerable simplification in any numerical computations. With this new formulation of local instability analysis very few elements are required to obtain high accuracy for the buckling stress. Several examples illustrating typical applications of this new method have been included.

ABSTRACT: When a thin steel plate with flat stiffeners is loaded either axially or in bending it will eventually undergo large deformations in either Mode I or Mode II, where for Mode I the free edges of the stiffeners have only tensile stresses and for Mode II these stresses are predominantly compressive. Thus Mode I is a plate buckle whereas Mode II is a stiffener buckle. Associated with each mode is a plastic mechanism the load-deflexion curve of which defines a panel’s post-buckling behaviour. These mechanisms are analysed
theoretically and then a study is made of the effects of each parameter. Laboratory tests on large stiffened panels are briefly described.

Ralph E. Ekstrom, “Buckling of Cylindrical Shells Under Combined Torsion and Hydrostatic Pressure,” Experimental Mechanics, 3 (8), 192–197 (1963), DOI: 10.1007/BF02325793

ABSTRACT: Tests conducted to determine the stability of thin cylindrical shells under combined loads show that the nondimensional critical hydrostatic and torsional loads, P and T, follow the parabola P+T^2=1.

ABSTRACT: The development of finite element calculational procedures for thin shell instability analysis has involved the definition of appropriate element representations (i.e. the geometric form of the element and the approximation of displacement and/or stress), constitutive expressions, and computational algorithms. Among these, the status of thin shell finite element representations remains unsettled. This paper therefore emphasizes recent developments in the basic aspects of thin shell finite element analysis and discusses one simplified approach in more detail. Formulative and computational procedures for elastic instability analysis are then summarized and numerical results are shown for the simplified shell element formulation.

ABSTRACT: A finite element method is presented for geometrically nonlinear large displacement problems in thin, elastic plates and shells of arbitrary shape and boundary conditions subject to externally applied concentrated or distributed loading. The initially flat plate or curved shell is idealized as an assemblage of flat, triangular plate, finite elements representing both membrane and flexural properties. The 'geometrical' stiffness of the resulting eighteen degree-of-freedom triangular element is derived from a purely geometrical standpoint. This stiffness in conjunction with the standard small displacement 'elastic' stiffness is used in the linear-incremental approach to obtain numerical solutions to the large displacement problem. Only stable equilibrium configurations are considered and engineering strains are assumed to remain small. Four examples are presented to demonstrate the validity and versatility of the method and to point out its deficiencies.

Maquoi (University of Liege, Belgium), “Recent progress in the field of structural stability of steel structures”, International Association for Bridge and Structural Engineering (IABSE) Surveys, 1978. ABSTRACT: (Cannot cut and paste the abstract nor the long list of references.)

ABSTRACT: This paper represents a progress report of some of the research that we are conducting in the finite element analysis of thin shell structures. We consider our isoparametric displacement-rotation thin shell element and our discrete-Kirchhoff-theory (DKT) plate/shell element, which we are continuously refining for accurate and effective geometric and materially nonlinear analysis. In the paper we briefly discuss the locking phenomenon of the isoparametric element, the use of this element as a transition element between shell surfaces and in shell-solid transitions, and we give some results using the DKT element.

ABSTRACT: Structural technology of laminated filamentary-composite stiffened-panel structures under combined in-plane and lateral loadings is discussed. Attention is focused on (1) methods for analyzing the behavior of these structures under load and for determining appropriate structural proportions for weight efficient configurations, and (2) effects of impact damage and geometric imperfections on structural performance. Recent improvements in buckling analysis involving combined in-plane compression and shear loadings and transverse shear deformations are presented. A computer code is described for proportioning or sizing laminate layers and cross-sectional dimensions, and the code is used to develop structural efficiency data for a variety of configurations, loading conditions, and constraint conditions. Experimental data on buckling of panels under in-plane compression is presented to validate the analysis and sizing methods and to illustrate structural performance and efficiency obtained from representative structures. Experimental results show that strength of panels under in-plane compression can be degraded by low-velocity impact damage. Mechanisms of impact-damage initiation and propagation are described. Finally, data are presented that indicates the matrix is a significant factor influencing tolerance to impact damage.

ABSTRACT: Three computer programs for nonlinear dynamic analysis, ADINA, STAGS and ILDYN, are compared with regard to accuracy of results and computer utilization. However, only two test cases are studied. The results presented in this report must consequently be handled with care. The main parameters of the test cases are: Thin shell structures, Linear elastic material, Non-linear geometric behaviour, Dynamic analysis, Stepwise linear load function, Unconservative pressure load. The analyses are compared to described test case and experimental measurements and show that nonlinear dynamic analyses may be very sensitive to the formulation of the problem.

(The Paper was presented at the 14th Int. Cong. Theoretical and Applied Mechanics, Delft, The Netherlands, 30 August-4 September 1976.)
ABSTRACT: This paper is concerned with the numerical solution of systems of equations of discrete variables, which represent the nonlinear behaviour of elastic systems under conservative loading conditions. In particular, an incremental approach to the solution of buckling and snapping problems is explored. The topics that are covered can be summarized as follows: — The computation of nonlinear equilibrium paths with continuation through limit points and bifurcation points. — The determination of critical equilibrium states. Characteristic to the procedures employed is the use of the length of the equilibrium path as control parameter. This feature, together with the second order iteration method of Newton, offers a reliable basis for the procedures described. Actual computations, carried out on a finite element model of a shallow circular arch, illustrate the effectiveness of the methods proposed.

ABSTRACT: This paper describes an analysis procedure for use in the design of stiffened laminated composite plates loaded simultaneously by biaxial compression, or tension, and shear acting in the plane of the laminate. The magnitude of the loading is such that the initial buckling limit of the laminated plate is exceeded. The method used is an extension of the shear field theory developed by Koiter for long isotropic plates. General expressions are derived which relate the average stress resultants acting along the edges of the plate to the strains in the stiffeners. The laminate is assumed to possess mid-plane symmetry to eliminate bending-
extensional coupling but the bending-twisting terms $D_{16}$ and $D_{26}$ are retained in the analysis. Stresses resulting from thermal mismatch between stiffener elements and between skin and stiffener are considered. In order to account for manufacturing tolerances and other imperfections, initial eccentricities are imposed in the analysis. Also considered a failure mode is torsional or torsional-flexural buckling of the stiffeners, with the effect of attached skin included.

ABSTRACT: For a number of years, the author has used the finite element method to investigate the collapse strength of thin plated steel structures [1–3]. The work has been directed primarily towards steel bridges which are usually fabricated from engineering steel for which the stress-strain curve exhibits a significant plateau. The collapse behaviour usually involves an interaction between material and geometric non-linearities and is influenced by initial geometric imperfections and residual welding stresses. The present communication describes a number of numerical techniques that the author has developed in order to analyse such structures. The topics covered include approximate yield criteria, accelerated iterative methods and incremental solutions using a ‘length constraint’.

References listed at the end of the paper:

ABSTRACT: This paper describes a method for introducing line searches into the arc-length solution procedure. Such line searches may be used at each iteration to calculate an optimum scalar step-length which scales the normal iterative vector. In practice, a loose tolerance is provided so that on many iterations the line searches are avoided. However on ‘difficult iterations’, the line searches are shown to lead to a substantial improvement in the convergence characteristics. A simple single-parameter acceleration is also developed using line search concepts. The new arc-length method is applied to both the geometrically nonlinear analysis of shallow shells and the materially nonlinear analysis of reinforced concrete beams and slabs. Significant improvements are demonstrated in relation to the standard arc-length method.

SUMMARY: Dynamical aspects of a general nonlinear finite element shell analysis procedure are described. The work extends previous endeavors of the authors on quasistatic plate and shell analysis. Several sample problems of a two- and three-dimensional nature are presented which demonstrate the applicability of the methodology.

DOI: 1016/S0045-7949(82)80008-4

ABSTRACT: This paper presents applications of a new code for shells of arbitrary shape. The geometrically non linear dynamic analysis is based on a total Lagrangian formulation and the direct time integration of the equations of motion. The cost effectiveness of a static condensation is shown and comparison of numerical
results for classical examples of the literature (plates, arches and spherical shells) are presented using a full 3-D code.

ABSTRACT: Pipelines are widely used for the transport of material. While pressure is the dominant sustained design load with gaseous materials, the weight of the contents becomes important with liquid transport and hydraulic solids transport.

INTRODUCTION: In order to produce efficient, reliable designs & to avoid unexpected catastrophic failure of structures of which thin shells are important components, the engineer must understand the physics of shell buckling. The objective of this survey is to convey to the reader a “feel” for shell buckling, whether it be due to nonlinear collapse, bifurcation buckling, or a combination of these modes. This intuitive understanding of instability is communicated by a large number of examples involving practical shell structures which may be
stiffened, segmented, or branched & which have complex wall constructions. With such intuitive knowledge the engineer will have an improved ability to foresee situations in which buckling might occur & to modify a design to avoid it. He or she will be able to set up more appropriate models for tests & analytical predictions. The emphasis here is not on the development of equations for the prediction of instability. For such material the reader is referred to the book by Brush & Almroth. Emphasis is given here to nonlinear behavior caused by a combination of large deflections & plasticity. Also illustrated are stress redistribution effects, stiffener & load-path eccentricity effects, local v. general instability, imperfection sensitivity, & modal interaction in optimized structures. Scattered throughout the text are tips on modeling for computerized analysis. The survey is divided into nine major sections describing: 1) several examples of catastrophic failure of expensive shell structures; 2) the basics of buckling behavior; 3) “classical” buckling & imperfection sensitivity & nonlinear collapse & the appropriateness of linear bifurcation buckling analyses for general shells; 5) bifurcation buckling with significant nonlinear pre-buckling behavior; 6) effects of boundary conditions, load eccentricity, transverse shear deformation, & stable post-buckling behavior; 7) optimization of buckling-critical structures with consequent modal interaction; 8) a suggested design method for axially compressed cylinders with stiffeners, internal pressure, or other special characteristics; & 9) two examples in which sophisticated buckling analyses are required in order to derive improved designs. The paper focuses on static buckling problems.

ABSTRACT: Coverage has been given to subjects dealing with the strength and stability of columns, including biaxially loaded members and tubular components. Much information is still lacking about laterally unsupported beams, and detailed research needs are outlined for these as well as for steel building frames. A separate section discusses unresolved problems in the stability analysis of shells and shell-like structures, some of which also are pertinent to large-size tubular structures. The research needs of thin-walled, light-gage construction are discussed in one section. Extensive attention is paid to the stability aspects of plate, box and curved girders. Problems related to dynamic stability phenomena are outlined, as are the needs of composite structures. Brief data are given on needed research regarding material properties of steels, local buckling phenomena, and the behavior of stiffened plates.

ABSTRACT: The paper presents a finite element Mindlin shallow shell formulation. Compared to a previous flat plate formulation it is shown that the addition of a shallow shell capability adds very little extra computational effort. Results are given for the postbuckling behaviour of square and circular plates subject to direct inplane loading and a square plate subject to inplane shear loading. Examples are also presented of the analyses of a shallow truss and cylindrical and spherical shells, all exhibiting snap through behaviour. Agreement with existing solutions is generally good and where possible the results are presented numerically.

ABSTRACT: A brief survey of weld-induced stresses and deflections in steel-plated structures is given. A finite element approach for analyzing stiffened panels is presented. The stiffener formulation accounts for torsional buckling. Yielding is taken into account and, based on the updated Lagrangian formulation, the effect of large deflections is allowed for. By using the so-called volume approach the development of plastic zones can be followed. The non-linear equations are solved using a combined step-iterative procedure. The examples presented comprise an unstiffened rectangular plate under biaxial compression, and two stiffened panels under uniaxial compression. The effect of initial deflections and stresses is considered.

ABSTRACT: In this paper nonlinear stability of thin elastic circular shallow spherical shell under the action of uniform edge moment is considered by the modified iteration method to obtain second and third approximations to decide the upper and lower critical loads. Results are plotted in curves for the engineering use and are
compared with results of Hu Hai-chang. We also investigate the neighbor situation of the critical point, i.e. the double points of the upper and lower critical loads and denote the range of validity of the second approximation. In the end, we obtain the special case, the design formulas of rigidity and stress as well as the corresponding curves as \( \nu = 0.3 \) of large deflection of circular plate under the same load. These results are also compared with Huang Tse-yen’s.

ABSTRACT: Definitions of plastic and elastic deformation are discussed which are directly related to the physical characteristics of the phenomena and which provide essential uncoupling of elastic and plastic variables. Using finite deformation kinematics and appropriate strain-rate variables in order to carry out total incremental theory, analysis is presented concerning the fact that the total strain rate is not equal to the sum of elastic and plastic rates as is universally assumed. The consequences of this circumstance are examined. It is shown that a conflicting approach to the finite-deformation kinematics of elastic-plastic theory by Nemat-Nasser[4], which generates summable elastic and plastic strain rates, exhibits undesirable features and in particular the associated kinetics does not permit completion of the objective of developing an elastic-plastic constitutive relation on this basis.

ABSTRACT: The article contains a summary description of ABAQUS, a finite element program designed for general use in nonlinear as well as linear structural problems, in the context of its application to nuclear structural integrity analysis. The article begins with a discussion of the design criteria and methods upon which the code development has been based. The engineering modelling capabilities currently implemented in the program - elements, constitutive models and analysis procedures - are then described. Finally, a few demonstration examples are presented, to illustrate some of the program's features that are of interest in structural integrity analysis associated with nuclear power plants.

ABSTRACT: This paper investigates the general instability of cylindrical shells in which the stiffeners formed spirals along the length and at an arbitrary angle with the axis. Two loading conditions are considered: uniform axial and lateral compressions and torsion. The stress-strain relations of the stiffeners are developed by rotation
of the strain tensor. The buckling determiate is obtained by introducing into the equilibrium equations the
admissible displacement functions consistent with the end constraints, thereby enforcing equilibrium by
satisfying the characteristic equations. The buckling equations are programmed for a computer which searches
through a finite set of stress resultants for assigned values of spiral angle and modes and printed out the
buckling load. The optimum structure weight of the stiffened shell is determined by iterating the design
parameters at the required spiral angle so that the buckling load approaches the applied load as a limit until the
difference between these loads are within the design allowance.

Konstruktiven Ingenieurbau, Bochum, West Germany), “Construction and Design of Large Cooling Towers”,
ABSTRACT: Large natural-draft cooling towers are required for dry-type cooling of power plants having high
capacity. Through the choice of an appropriate offset distance between the axis of the hyperbola and axis of
rotation the stress distribution as well as buckling and vibration behavior can be influenced considerably. In
order to keep the required buckling safety and lowest natural frequency as the dimensions of the cooling tower
shell are increased stiffening of the shell becomes indispensable. Numerical investigations and tests carried out
show clearly that the efficiency of the stiffeners is different, rings being more effective than meridional ribs.
Stiffening rings can be built easily after slight modification of the existing climbing formwork. Reinforced
concrete shells stiffened by rings can compete with cable network structures, even beyond a height of 200 m
(656 ft).

ABSTRACT: The creep buckling of thin nonshallow spherical shells is treated, the material of which is
assumed to be isotropic and linearly viscoelastic with special temperature dependence of its mechanical
properties so as to fit the thermorheologically simple body model. The shell is subjected to uniform external
pressure smaller than the classical buckling pressure for corresponding elastic shells. The prebuckling stress
state is assumed to be the membrane state, and total deflections are less than or equal to the shell thickness. The classical stability criteria, uniqueness of equilibrium, is used in formulating the problem, defined by a linear integrodifferential equation in terms of displacement field \( W \), and describing the adjacent equilibrium configuration, and it is assumed to be a function of coordinates and time. A first-step approximation to the governing equation is derived and used to determine the external critical pressure loading as a function of temperature, time, and shell geometry. For a shell made of a three-element model material a “safe load limit” is established.

ABSTRACT: A theoretical and experimental study was undertaken into the crushing behavior of axially compressed short thin-walled open-section columns. The effect of initial geometry of panels as well as distribution and magnitude of shape imperfections on the efficiency of energy absorption was examined. Results of model test on 0.1mm thick aluminum foil specimens have shown that the panels collapsing in the symmetric and asymmetric deformation mode provide respectively, upper and lower bound for the energy absorbed in any other buckling mode. In both of the extreme cases, the crush response of the panel was predicted theoretically with a reasonable accuracy. It is shown that an optimum design of columns against crush can be achieved by introducing a beneficial geometric imperfections of a specified magnitude shape so that the structure will be forced to collapse in the most energy efficient deformation mode.

ABSTRACT: In this paper, basing on ref. [1] we improved and extended that which is concerned with a view of investigating the finite deflection equations of anisotropic laminated shallow shells subjected to static loads, dynamic loads and thermal loads. We have considered the most general bending-stretching couplings and the shear deformations in the thickness direction, and derived the equilibrium equations, boundary conditions and initial conditions. The differential equations expressed in terms of generalized displacements \( u_0, v_0 \) and \( w \) are obtained. From them, we could solve the problems of stress analysis, deformation, stability and vibration. For some commonly encountered cases, we derived the simplified equations and methods.

ABSTRACT:

ABSTRACT: A nonlinear formulation of the 9-node shell element is given for large deformation and post-buckling analysis of shells. The formulation is based on updated Lagrangian description and finite deformation constitutive equations. The post-buckling analysis is conducted via either the modified or full Newton-Raphson procedure with a constant-displacement-length method when the limit load of the structure is reached. Several numerical examples are included to demonstrate the post-buckling analysis procedure.

ABSTRACT: A theoretical investigation into the effectiveness of a stiffener against the ultimate strength of a stiffened plate is carried out. Series of the buckling analyses, the elastic large deflection analyses and the elastic-plastic large deflection analyses are performed by the analytical method and the finite element method on the stiffened plate under thrust. Experiments are also carried out on the stiffened plate under thrust to confirm the theoretical results. On buckling of a stiffened plate, it is well known that there exists a minimum stiffness ratio of a stiffener to the plate, $\lambda_{B\text{min}}$, which gives the maximum limiting value of the buckling strength. Concerning the ultimate strength it was confirmed that there exists a significant stiffness ratio of a stiffener to the plate, $\lambda_{U\text{min}}$, similar to $\lambda_{B\text{min}}$ for the buckling strength. It was also found that there are three typical collapse modes for the stiffened plate under thrust, that is: (1) MODE OO, overall collapse after overall buckling; (2) MODE LO, overall collapse after local buckling; (3) MODE LL, local collapse after local buckling. Approximatelmethods are proposed to evaluate the ultimate strength and $\lambda_{U\text{min}}$ of a multi-stiffened plate under thrust. The effects of initial imperfections such as welding residual stresses and initial deflection on ultimate strength and $\lambda_{U\text{min}}$ of a stiffened plate under thrust are also discussed.

ABSTRACT: We derive a generalized version of the known system of two simultaneous second order differential equations for the problem of axi-symmetric torsionless deformations of elastic shells of revolution, for finite deformations and including transverse shear deformations and membrane drilling moments. Our generalization, which involves the introduction of a semicomplementary energy density, comes out in a particularly simple and compact form. We furthermore consider the effect of transverse normal stress deformations and discover the possibility of reducing this problem to a system of three simultaneous second order equations, with the supplementary third equation harmoniously adding itself to the two equations without consideration of transverse normal stress deformation effects.

ABSTRACT: The analysis of pipework systems which operate in an environment where local inelastic strains are evident is one of the most demanding problems facing the stress analyst in the nuclear field. The spatial complexity of even the most modest system makes a detailed analysis using finite element techniques beyond the scope of current computer technology. For this reason the emphasis has been on simplified methods. It is the aim of this paper to provide a reasonably complete, state-of-the-art review of inelastic pipework analysis methods and to attempt to highlight areas where reliable information is lacking and further work is needed.

ABSTRACT: Using a thin shell theory developed by Reissner, a nonlinear model for the in-plane bending of a curved pipe is described. It is shown how classical thin shell models of this component can be deduced on
making certain simplifying assumptions concerning the mode of deformation. By way of a numerical nonlinear analysis the problem of Brazier buckling of the curved pipe in pure bending is examined and compared to previous simplified solutions.

ABSTRACT: Advances in the understanding of vibration and buckling behavior of laminated plates made of filamentary composite material are summarized in this survey paper. Depending upon the number of laminae and their orientation, vibration and buckling analyses of composite plates may be treated with: (7) orthotropic theory, (2) anisotropic theory, or (3) more complicated, general theory involving coupling between bending and stretching of the plate. The emphasis of the present overview is upon the last. Special consideration is given to the complicating effects of: inplane initial stresses, large amplitude (nonlinear) transverse displacements, shear deformation, rotary inertia, effects of surrounding media, inplane nonhomogeneity and variable thickness. Nonclassical buckling considerations such as initial imperfections are included, as well as postbuckling behavior.

References listed at the end of the paper:

ABSTRACT: There is considerable confusion in the existing literature as to whether an unsymmetrically laminated, composite plate will remain flat due to the application of inplane compressive or shear loads. If it does not remain flat, then bifurcation buckling would not normally take place, and transverse displacements would occur no matter how small the inplane loads. This paper investigates the conditions under which arbitrarily laminated and arbitrarily loaded plates remain flat, and therefore when buckling can occur. It is demonstrated that for uniform or linearly varying inplane loads no transverse pressure is necessary to keep a plate flat, although edge moments or transverse forces may be required at the boundaries.

ABSTRACT: Some information on the buckling of composite laminated plates is summarized. Loading stresses for buckling orthotropic plate are plotted. Orthotropic plates have fibers parallel to each other and to the edge or a cross ply with fibers in adjacent plies oriented at 90 to each other. Anisotropic and unsymmetric laminate instability are also reviewed. Uniaxial and shear stress buckling parameters for graphite/epoxy angle ply plates are shown in graphs. Test data show that shear deformation effects decrease the buckling stress for plates with a length to thickness ratio of < 30. The buckling characteristic of circular shell panels differs considerably from that of plates. The buckling load increases with the shell curvature, until a maximum value is reached. Data show that, although a shell panel has a higher critical buckling stress than the plate, a decreasing compressive stress is required to maintain equilibrium.

ABSTRACT: A method is developed for the analysis of free vibration and buckling of generally laminated composite plates having arbitrary edge conditions, such as clamped, simply supported or free. The procedure is an extension of the Ritz method utilizing a strain energy functional containing both bending and stretching effects and accommodating arbitrary ply stacking sequences. Displacement functions are taken in the form of polynomials, and an algorithm for satisfying the geometric boundary conditions is presented. Numerical results are compared with those of other researchers in order to establish the correctness and effectiveness of the method. Some additional new results are also presented.

ABSTRACT: The ‘reduced bending stiffness’ (RBS) method has been used on occasions in the past as a means of simplifying the analysis of the flexural behavior of unsymmetrically laminated composite plates. However, the validity of the method has never been established. This paper makes direct comparisons between relatively simple, exact solutions for the static deflections, buckling loads and vibration frequencies of simply-supported
plates and those arising from the RBS method. Extensive calculations are made for wide ranges of the physical parameters involved (aspect ratio, moduli ratio, lamination orientation angle, numbers of plies). The RBS method is found to yield sufficient accuracy for cross-ply plates, but errors up to 29% are obtained for angle-ply plates constructed with materials currently under development.

ABSTRACT: This is a summary of the first known work which analyzes the structural behavior of composite plates having nonuniformly spaced fibers. The present investigation is limited to single layer composites having parallel fibers. This results in a plate which is macroscopically orthotropic, but nonhomogeneous. The free vibrations and buckling of such plates subjected to inplane boundary loadings are studied. A plane elasticity problem must first be solved to determine the inplane stresses caused by the applied boundary loading, and these stresses become input to the vibration and buckling problem. Both problems are dealt with by the Ritz method. Numerical results are obtained for six nonuniform distributions of E-glass, graphite and boron fibers in epoxy matrices in simply supported, square plates. The redistributions are seen to increase the buckling load by as much as 38%, and the fundamental frequency by as much as 21%.

ABSTRACT: The effects of changing edge constraints upon the frequencies of shallow shells with rectangular planforms are studied. Attention is focused upon a single edge, with the other three edges remaining completely free. For that edge clamped, simply supported, and free edge conditions are imposed; however, each of these has four possibilities depending upon the existence of either or both types of membrane constraint along the single edge. The Ritz method, assuming algebraic polynomials as displacement functions, is used to obtain accurate results. Frequencies for three types of shallow shells (circular cylindrical, spherical, hyperbolic paraboloidal) are obtained, for two shallowness ratios and two thickness ratios each. Careful attention is paid to the number of rigid body modes (zero frequencies) present, for these enter quite strongly into considerations of the effects of changing edge constraints.

ABSTRACT: This work presents a three-dimensional (3-D) method of analysis for determining the free vibration frequencies and corresponding mode shapes of truncated hollow cones of arbitrary thickness and having arbitrary boundary conditions. It also supplies the first known numerical results from 3-D analysis for
such problems. The analysis is based upon the Ritz method. The vibration modes are separated into their
Fourier components in terms of the circumferential coordinate. For each Fourier component, displacements are
expressed as algebraic polynomials in the thickness and slant length coordinates. These polynomials satisfy the
geometric boundary conditions exactly. Because the displacement functions are mathematically complete, upper
bound values of the vibration frequencies are obtained that are as close to the exact values as desired. This
convergence is demonstrated for a representative truncated hollow cone configuration where six-digit exactitude
in the frequencies is achieved. The method is then used to obtain accurate and extensive frequencies for two sets
of completely free, truncated hollow cones, one set consisting of thick conical shells and the other being tori
having square-generating cross sections. Frequencies are presented for combinations of two values of apex
angles and two values of inner hole radius ratios for each set of problems.

A. W. Leissa and J. -D. Chang (Department of Engineering Mechanics, The Ohio State University, Columbus,
OH 43210, USA), “Elastic deformation of thick, laminated composite shells”, Composite Structures, Vol. 35,

ABSTRACT: A rigorous theory is derived which governs the linearly elastic deformation of shells made of
laminated composite materials, including shear deformation and rotary inertia effects. The equations presented
are applicable to static and dynamic problems for shells of arbitrary curvature, but constant thickness. Non-
principal shell coordinates (alpha,beta) are used in order that shells with initial twist (Ralphabeta not equal to
infinity) may be straightforwardly accommodated. Equations of motion, boundary conditions and energy
functionals are given for laminates with arbitrary fiber stacking sequences. An accurate theory is developed
based upon the assumptions that terms containing zeta2/RiRj(i,j = alpha,beta) are small in comparison with
unity, where zeta is the thickness coordinate, and Ralpha and Rbeta are radii of curvature. A more simple but
less accurate theory is also given, corresponding to zeta/Ri much less-than 1 (i = alpha,beta). Shallow shell
theories are obtained by setting the LamÈ parameters equal to unity and using projected planform coordinates
(x,y) in place of the shell coordinates (alpha,beta). Further simplification to a Donnell-type shallow shell theory
is also made.

ABSTRACT: A three-dimensional method of analysis is presented for determining the free vibration
frequencies and mode shapes of hollow cones and cylinders with variable thickness. Displacement components
us, uz, and utheta in the meridional, normal, and circumferential directions, respectively, are taken to be
sinusoidal in time, periodic in theta, and algebraic polynomials in the s and z directions. Potential (strain) and
kinetic energies of the cones and cylinders are formulated, and upper bound values of the frequencies are
obtained by minimizing the frequencies. As the degree of the polynomials is increased, frequencies converge to
the exact values. Novel numerical results are presented for thick, linearly tapered, hollow cones and cylinders
with completely free boundaries. Convergence to four-digit exactitude is demonstrated for the first five
frequencies of the cones and cylinders. The method is applicable to thin cones and cylinders, as well as thick
and very thick ones.
ABSTRACT: This paper describes three types of situations in structural analysis where singularities at points can greatly influence the global behavior of the configuration: (1) concentrated forces acting upon flat or curved membranes, (2) concentrated moments acting upon plates or shells, and (3) sharp corner singularities in plates and shells. These singularities may have strong effects upon static or dynamic deflections, free vibration frequencies and buckling loads. It is shown that the concentrated forces acting upon flat or curved membranes, or concentrated moments acting upon plates and shells, are improper models, and that correct theoretical analysis indicates that they are meaningless. Examples of sharp corners discussed are (1) the re-entrant corner of a cantilever skew plate, (2) a free circular plate with a V-notch, and (3) the obtuse corners of a simply supported parallelogram plate.

ABSTRACT: A three-dimensional (3-D) method of analysis is presented for determining the free vibration frequencies and mode shapes of thick, hyperboloidal shells of revolution. Unlike conventional shell theories, which are mathematically two-dimensional (2-D), the present method is based upon the 3-D dynamic equations of elasticity. Displacement components ur, utheta, and uz in the radial, circumferential, and axial directions, respectively, are taken to be sinusoidal in time, periodic in theta, and algebraic polynomials in the r and z directions. Potential (strain) and kinetic energies of the hyperboloidal shells are formulated, and the Ritz method is used to solve the eigenvalue problem, thus yielding upper bound values of the frequencies by minimizing the frequencies. As the degree of the polynomials is increased, frequencies converge to the exact values. Convergence to four-digit exactitude is demonstrated for the first five frequencies of the hyperboloidal shells of revolution. Numerical results are tabulated for 18 configurations of completely free hyperboloidal shells of revolution having two different shell thickness ratios, three variant axis ratios, and three types of shell height ratios. Poisson's ratio (nu) is fixed at 0.3. Comparisons are made among the frequencies for these hyperboloidal shells and ones which are cylindrical or nearly cylindrical (small meridional curvature). The method is applicable to thin hyperboloidal shells, as well as thick and very thick ones.

ABSTRACT: Rayleigh's classical book Theory of Sound was first published in 1877. In it are many examples of calculating fundamental natural frequencies of free vibration of continuum systems (strings, bars, beams, membranes, plates) by assuming the mode shape, and setting the maximum values of potential and kinetic energy in a cycle of motion equal to each other. This procedure is well known as "Rayleigh's Method." In 1908, Ritz laid out his famous method for determining frequencies and mode shapes, choosing multiple admissible displacement functions, and minimizing a functional involving both potential and kinetic energies. He then
demonstrated it in detail in 1909 for the completely free square plate. In 1911, Rayleigh wrote a paper congratulating Ritz on his work, but stating that he himself had used Ritz's method in many places in his book and in another publication. Subsequently, hundreds of research articles and many books have appeared which use the method, some calling it the “Ritz method” and others the “Rayleigh–Ritz method.” The present article examines the method in detail, as Ritz presented it, and as Rayleigh claimed to have used it. It concludes that, although Rayleigh did solve a few problems which involved minimization of a frequency, these solutions were not by the straightforward, direct method presented by Ritz and used subsequently by others. Therefore, Rayleigh's name should not be attached to the method.

ABSTRACT: A parametric study of postbuckled through-width delaminations in laminated coupons was performed. A finite element analysis was developed to analyze the coupons as a combination of linear and geometrically nonlinear components. Because most of the coupon configuration studied behaves linearly, the mixed linear and nonlinear analysis greatly reduced computational costs. The analysis was verified by comparing numerical with exact solutions for simple hypothetical problems. In addition, measured lateral deflections of postbuckled through-width delaminations in laminated coupons were compared with predicted deflections. In the parametric study, stress distributions and strain-energy release rates were calculated for various delamination lengths, delamination depths, applied loads, and lateral deflections. Also, a small number of coupons with through-width delaminations were fatigue tested to obtain delamination growth data. Calculated strain-energy release rates were compared with the observed growth rates to determine the relative importance of the Mode I and Mode II components of energy release. GI was shown to dominate the growth process.

ABSTRACT: Buckling of a delaminated region can cause high interlaminar stresses which, in turn, lead to delamination growth. Hence, buckling strain is an important parameter in assessing the potential for strength loss due to the delamination. The objective of this study was to predict the buckling of an elliptic delamination embedded near the surface of a thick quasi-isotropic laminate. The thickness of the delaminated ply group (the sublaminate) was assumed to be small compared to the total laminate thickness. Finite-element and Rayleigh-Ritz methods were used for the analyses. The Rayleigh-Ritz method was found to be simple, inexpensive, and accurate, except for highly anisotropic delaminated regions. Effects of delamination shape and orientation, material anisotropy, and layup on buckling strains were examined. Results showed that (1) the stress state around the delaminated region is biaxial, which may lead to buckling when the laminate is loaded in tension, (2) buckling strains for multi-directional fiber sublaminates generally are bounded by those for the 0 deg and 90 deg unidirectional sublaminates, and (3) the direction of elongation of the sublaminate that has the lowest buckling strain correlates with the delamination growth direction.

ABSTRACT: In order to formulate the equations for the study here, the Fourier expansions upon the system of orthonormal polynomials are used. It may be considerably convenient to obtain the expressions of displacements as well as stresses directly from the solutions. Based on the principle of virtual work the equilibrium equations of various orders are formulated. In particular, the system of thirddorder is given in detail, thus providing the reference for accuracy analysis of lower-order equations. A theorem about the differentiation of Legendre series term by term is proved as the basis of mathematical analysis. Therefore the functions used are specified and the analysis rendered is no longer a formal one. The analysis will show that the Kirchhoff-Love's theory is merely of the first-order and the theory which includes the transverse deformation but keeps the normal straight is essentially of the first order, too.

ABSTRACT: Computer costs for structural dynamics, rise an order of magnitude over those associated with static analysis. To reduce these costs significantly, a computationally economical triangular plate bending element was developed. This element, designated as the TRP2 element, while simpler than existing high-order accuracy elements, yields results that are sufficiently accurate for engineering analysis. TRP2 is an eighteen degree of freedom triangle. In global coordinates it possesses three translations and three rotations at each vertex. The element linear elastic stiffness matrix was taken from the existing literature. Additional matrices were developed to account for mass properties, applied loads, large deflections and plasticity. Published results that ranged over a spectrum of linear and nonlinear static and dynamic analyses were used in a numerical evaluation of the element. The TRP2 element was found to be capable of yielding results that in most cases were certainly acceptable, and in some cases excellent.

ABSTRACT: The theory of finite rotations in thin shells is developed and many shell relations in terms of finite rotations are presented. Three forms of geometric boundary conditions and energetically compatible static boundary conditions are constructed. Various sets of Eulerian and Lagrangean shell equations are discussed and their consistent simplification within the first-approximation geometrically non-linear theory of isotropic elastic shells is given. A classification of shell problems with small, moderate, large and finite rotations is proposed and appropriate sets of simplified shell equations are presented.

ABSTRACT: A general approach to the derivation of variational principles is given for the geometrically non-linear theory of thin elastic shells undergoing moderate rotations. Starting from the principle of virtual displacements, a set of sixteen basic free functionals without subsidiary conditions is constructed. From these free functionals and without subsidiary conditions may be generated. As examples, the functionals of the total potential energy and the total complementary energy are derived.

Emmerling, Springer, 1984, pp 76-90, DOI: 10.1007/978-3-642-48013-3_6

ABSTRACT: The present paper deals with geometrically non-linear first approximation Kirchhoff-Love type theories for thin elastic shells undergoing small strains accompanied by moderate, large or unrestricted rotations. All theories will be given in an entirely Lagrangian description. We shall start our considerations with a general theory valid for small strains and arbitrary, unrestricted rotations. Then, this general theory will be simplified for shell problems in which the shell material elements undergo large rotations according to the classification scheme given below. Three variants will be derived which admit large rotations about tangents to the shell middle surface and either large, moderate or small rotations about the normal. Finally, the general shell equations will be simplified for shells undergoing moderate rotations about tangents to the shell middle surface and either moderate or small rotations about the normal. All theories presented here are derivable from variational principles.

ABSTRACT: Equations of equilibrium and four geometric and static boundary conditions are constructed for an entirely Lagrangian non-linear theory of shells. In the case of a linearly-elastic material and conservative surface and boundary loadings the shell relations are derivable as stationarity conditions of the Hu-Washizu free functional. For the geometrically non-linear first-approximation theory of elastic shells several consistently simplified versions of the shell equations are discussed. Several sets of equations for theories of shells undergoing moderate or large/small rotations are presented. The majority of the simplified versions allow an exact variational formulation using a Hu-Washizu free functional. A unified theory of superposition of non-linear deformations in thin shells is outlined and two equivalent incremental formulations of shell equations in the total Lagrangian and the updated Lagrangian descriptions are given.

ABSTRACT: A non-linear bending theory of rubber-like shells undergoing large elastic strains is proposed. The theory is based on a relaxed normality hypothesis and the incompressibility condition. Using series expansion in the normal direction and applying some estimation technique a consistent first approximation and a simplest approximation to the elastic strain energy of the shell are constructed. Lagrangian displacement shell equations are derived and the incremental shell deformation is considered. The numerical results presented for one- and two-dimensional large strain shell problems confirm the accuracy and efficiency of the proposed shell theory.

ABSTRACT: Non-linear problems of thin elastic shells may conveniently be formulated in the Lagrangian description in terms of three displacement components of the reference surface. Assuming that an approximation to an equilibrium state of the shell is known, the explicit form of incremental equations for the correcting increment of displacements, which allows one to calculate the next approximation, is derived for arbitrary configuration-dependent external static loads, and for arbitrary work-conjugate boundary conditions. The derivation is performed applying the Newton-Kantorovich method which is based essentially on successive approximations to the exact solution of some linearized shell problem. As a special case, the ultimate Lagrangian buckling equations for thin shells are constructed.

ABSTRACT: A thorough analysis is presented of the non-linear deformation of the shell lateral boundary surface. The deformation is compatible with the linear distribution of displacements across the shell thickness. It is found that the total rotation of the boundary element can be defined in two ways, by means of two alternative orthonormal triads associated with the deformed shell lateral boundary surface. For both definitions of the rotation, exact expressions for three components of the vector of change of curvature of the boundary contour are derived in terms of shell strain measures. These expressions are then consistently reduced for several particular shell theories.

ABSTRACT: The non-linear theory of thin shell structures with irregularities of geometry, material properties, loading and deformation is developed. The irregular shell is modelled by a reference network being a union of piecewise smooth surfaces and curves, with various fields satisfying relaxed regularity requirements. By transforming the virtual work principle postulated for the entire reference network, we derive the corresponding local field equations and side conditions. Particular attention is paid to formulate the general form of static and kinematic jump conditions at singular geometric and physical curves. Several special kinds of irregularities are considered and some particular forms of the jump conditions are discussed.

ABSTRACT: We develop the general nonlinear theory of elastic shells with an account of phase transitions in the shell material. Our formulation is based on the dynamically and kinematically exact through-the-thickness reduction of three-dimensional description of the phenomenon to the two-dimensional form written on the shell base surface. In this model shell displacements are expressed by work-averaged translations and rotations of the shell cross-sections. All shell relations are then found from the variational principle of the stationary total potential energy. In particular, we derive the new global dynamic continuity condition at the singular surface curve modelling the phase interface. We also discuss particular forms of the local dynamic continuity conditions at coherent and incoherent interface curves. The results are illustrated by an example of a phase transition in an infinite plate with a circular hole.

ABSTRACT: We establish the local symmetry group of the dynamically and kinematically exact theory of elastic shells. The group consists of an ordered triple of tensors which make the shell strain energy density invariant under change of the reference placement. Definitions of the fluid shell, the solid shell, and the membrane shell are introduced in terms of members of the symmetry group. Within solid shells we discuss in more detail the isotropic, hemitropic, and orthotropic shells and corresponding invariant properties of the strain energy density. For the physically linear shells, when the density becomes a quadratic function of the shell strain and bending tensors, reduced representations of the density are established for orthotropic, cubic-symmetric, and isotropic shells. The reduced representations contain much less independent material constants to be found from experiments.

ABSTRACT: We formulate the exact, resultant equilibrium conditions for the non-linear theory of branching and self-intersecting shells. The conditions are derived by performing direct through-the-thickness integration in the global equilibrium conditions of continuum mechanics. At each regular internal and boundary point of the base surface our exact, local equilibrium equations and dynamic boundary conditions are equivalent, as expected, to the ones known in the literature. As the new equilibrium relations we derive the exact, resultant dynamic continuity conditions along the singular surface curve modelling the branching and self-intersection as well as the dynamic conditions at singular points of the surface boundary. All the results do not depend on the size of shell thicknesses, internal through-the-thickness shell structure, material properties, and are valid for an arbitrary deformation of the shell material elements.

“On shear correction factors in the non-linear theory of elastic shells”, International Journal of Solids and
ABSTRACT: Theoretical values of two correction factors \( \pm s = 5/6 \) and \( \pm t = 7/10 \) are established for the respective transverse shear stress resultants and stress couples within the general, dynamically and kinematically exact, six-field theory of elastic shells. These values do not depend on the shell material symmetry, geometry of the base surface, the shell thickness, or any kind of kinematic and/or dynamic constraints. The analysis is based on the complementary energy density following from the transverse shear stresses acting only on the shell cross section. The appropriate quadratic and cubic distributions of the stresses across the thickness allow one to derive the consistent constitutive equations for the transverse shear stress resultants and stress couples with \( \pm s \) and \( \pm t \) as the respective correction factors. Four numerical examples of highly non-linear shell structures illustrate the influence of different values of \( \pm s \) and \( \pm t \) on the results. In particular, some influence of \( \pm t \) is noticed on the placement of bifurcation points. In dynamic problem of flight of three intersecting plates analysed with Newmark-type temporal algorithm, the value of \( \pm t \) influences the moment at which the relative error of total energy of the system begins to grow indefinitely leading to the solution failure.

ABSTRACT: We formulate the complete boundary value problem (BVP) for the geometrically non-linear theory of thin elastic shells expressed entirely in terms of intrinsic field variables—the stress resultants and bendings of the shell reference surface. Applying a perturbation technique the corresponding intrinsic buckling equations are also derived. These intrinsic shell and buckling equations are then consistently simplified in three special cases: (a) the almost inextensional bending state, (b) the almost membrane state, and (c) the bending state. For each special case we derive also consistent sets of dynamic and kinematic boundary conditions expressed entirely through the intrinsic field variables. Additionally, the complete BVP for shells with slowly varying curvatures is formulated in terms of stress and deformation functions. The relatively simple BVPs given here are applicable to highly non-linear problems of flexible shell structures without any restriction of shell geometry, displacements, deflections, and/or rotations.

ABSTRACT: The local buckling of weakly supported thin-walled square tubes under axial compression is studied. By means of asymptotic methods, an expression for the critical pressure is found. The asymptotic results agree well with the numerical results obtained with the finite element method (FEM) and with the sweep method. The dependence of the critical loading on the shell length and on the type of edge supporting is analyzed.

ABSTRACT: Work–conjugate boundary conditions for a class of nonlinear theories of thin shells formulated in terms of displacements of the reference surface are discussed. Applying theorems of the theory of differential forms it is shown that many of the sets of static boundary conditions which have been proposed in the literature do not possess work–conjugate geometric counterparts. The general form of four geometric boundary conditions and their work–conjugate static boundary conditions is constructed and three particular cases are analyzed. The boundary conditions given here are valid for unrestricted displacements, rotations, strains and/or changes of curvatures of the reference surface.

“Lagrangian nonlinear theory of thin elastic shells with finite rotations”, Proc. of JSCE, No. 344/I-1, April 1984

ABSTRACT: Accurate equilibrium equations and appropriate static and geometric boundary conditions are derived for the geometrically nonlinear theory of shells undergoing finite rotations without restriction to small strains. The principle of virtual work is used to obtain the shell equations in which a nonrational tensor of change of curvature is employed. The introduction of variations of displacement vectors instead of those of displacement components makes it possible to reduce computational efforts for deriving the shell equations. The effects of finite rotations at the shell boundary are strictly taken into account utilizing the total finite rotation vector for the boundary.

ABSTRACT: A nonlinear theory of plates and shells based on only one consistent kinematical approximation is employed to investigate finite strain and large deformation structural problems. The kinematics, expanded with respect to the thickness parameter, include consistently and adequately higher-order terms to allow fibers initially straight to deform nonlinearly in the large deformation range. A full Lagrangean formulation is
considered. Starting from a three-dimensional principle of virtual work, the equilibrium equations and the resultant stresses of the shell together with their incremental form are derived employing an incremental constitutive relation valid for a wide class of rate-independent material. And, to assess the accuracy of the theory adopted, some boundary value problems are solved using a proposed hyperelastic material to model the constitutive behavior of a semi-infinite plate. The analytical and numerical (finite element method) results show good agreements between the exact and the approximate theories.

ABSTRACT: Buckling of axially compressed circular cylindrical shells is examined within the framework of small strain elastoplasticity. A linear bifurcation model is used along with the J2 flow and deformation theories. All four possibilities of simple supports (SS1–SS4) and clamped edges (CL1–CL4) are considered. A general solution is given with special emphasis on the axially symmetric modes. Numerical results show that the weakening effect of the relaxed simple supports (SS1–SS2) is considerably reduced in the plastic range. A detailed comparison with available experimental data points in favour of the deformation theory.

ABSTRACT: We review the geometric rod theory for the case of a naturally straight, linearly elastic, inextensible, circular rod suffering bending and torsion but no shear. Our primary focus is on the post-buckling behaviour of such rods when subjected to end moment and tension. Although this is a classic problem with an extensive literature, dating back to Kirchhoff, the usual approach tends to neglect the physical interpretation of solutions (i.e., rod configurations) to the models proposed. Here, we explicitly compute geometrical properties of buckled rods. In a unified approach, making use of Kirchhoff's dynamic analogy, both the classical helical and the more recently investigated localised buckling are considered. Special attention is given to a consistent treatment of concepts of link, twist and writhe.

ABSTRACT: For an archetypal two-degree-of-freedom forced oscillator, relevant to a large class of mechanical problems, we examine the patterns of bifurcation that govern the internal 1:2 resonance of the system. A knowledge of these bifurcations allows the counter-intuitive suppression and control of escape by internal modal interactions. The bifurcations examined include symmetry-breaking pitchforks, Neimark bifurcations (secondary Hopf bifurcations) to a toroidal attractor, and chaotic crises which trigger dangerous large-amplitude excursions. We particularly focus on the effect that a symmetry-breaking imperfection has on the suppression of escape.

ABSTRACT: An experimental study was conducted to investigate the use of advanced composite materials in unstiffened thin-walled cylindrical structures subjected to hydrostatic pressure. Specifically, graphite/epoxy was looked at for potential application for small submersible pressure hulls. The investigation concentrated on the fabrication, instrumentation, testing, and evaluation of several 12-ply graphite/epoxy cylinders of four different laminate configurations. The test specimens were 18 inches long with radii of 2.76 inches, and each was instrumented with 8 circumferentially and 2 axially mounted strain gages. Data collected from the strain gages throughout the tests were used in a modified Southwell type analysis and an analysis to deduce the buckling mode shape. The Southwell analysis method was shown to have a valid applicability to the buckling of laminated fiber-reinforced composite pressure vessels. A method was developed to use the bending strain data at locations around the centerline of the specimen to deduce the number of, circumferential buckling waves. In addition, 1/2 inch ring specimen were cut from the excess ends of each specimen and tested under two-point compression, yielding information about the material properties of the laminates as fabricated. The hydrostatic tests were designed to verify the results of an analytical and numerical study that was conducted to determine the optimal laminate stacking sequences for buckling considerations. The test results indicate that the classical solution method presented by R.M. Jones produced accurate predictions of buckling strengths and correct relative rankings of the different laminate types.

ABSTRACT: Many useful thin-walled structures of interest to the U.S. Army, such as rifle barrels, automotive parts, rocket casings, helicopter blades, driveshafts, and containment vessels, are often constructed of layers of anisotropic, filament or fiber-reinforced materials. While many of these structures are subject to severe mechanical, inertial, or thermal loads, they often must be designed to remain elastic. This means that it is particularly important to be able to compute accurately global characteristics, such as buckling loads and natural frequencies, as well as local information such as stresses near holes or edges. Two important, complementary regions of such structures, have been studied, namely, the interior where there are no steep stress gradients, and the edge zone(s) where stress gradients are high. For both regions, simplified, cost-effective asymptotic methods have been developed. These considerations are particularly important in layered, anisotropic structures because many investigators have (1) claimed that higher-order (and hence computationally expensive) beam, plate, or shell theories are needed for such structures and (2) not paid sufficient attention to the particularly severe end effects (breakdown of Saint-Venant's principle) such structures engender. (DTIC)

ABSTRACT: Analyses to predict inelastic buckling of axially loaded thin cylindrical shells are carried out using the finite element technique. The analyses use a bilinear elastic–perfectly plastic material response based upon the associated flow rule of plasticity. Nonlinear geometric effects, combined with initial imperfections, produce load-deflection curves with descending branches for which the limit points are imperfection sensitive. Results from these analyses are compared with two tests of axially loaded cylinders fabricated from 10-gauge (3.4-mm) and 5-mm plate and approximately 1525 mm in diameter. These tests were carried out in the Structural Engineering Laboratory at the University of Alberta. A rational technique for using measured imperfections to obtain effective initial imperfections for use in the analyses is investigated, and is shown to result in accurate predictions of ultimate load.
ABSTRACT: A general sinusoidal stiffness matrix for the buckling analysis of thin, prismatic flat-walled elastic-plastic structures is derived. The constitutive laws of the flow-theory of plasticity associated with smooth yield surfaces are used. The use of this stiffness matrix to predict the buckling stresses and the associated modes is illustrated and some numerical results are used to show the range of applications which can be covered.

ABSTRACT: An experimental program to determine the phenomenological aspects of composite-panel failure under simultaneous compressive in-plane loading and low-velocity transverse impact [0-75 m/s (0-250 ft/s)] is described. High-speed photography coupled with the shadow-moiré technique is used to record the phenomenon of failure propagation. The information gained from these records, supplemented by plate sectioning and observation for interior damage, has provided information regarding the failure-propagation mechanism. The results show that the failure process can be divided roughly into two phases. In the first phase the plate is impacted, and the resulting response causes interlaminar separation. In the second phase the local damage spreads to the undamaged portion of the plate through a combination of laminae buckling and further delamination.

ABSTRACT: The effect of the use of the ‘area replacement method’ (ARM) of reinforcing around circular penetrations in a cylindrical shell on the buckling strength of that shell under a uniform axial compressive loading condition is studied both experimentally and analytically. In shells that are of such quality that the penetration reduces the buckling strength, the use of the ARM will increase the buckling strength of the shell, but will not increase it to the unpenetrated value. In any case, the conservative ‘knockdown’ factors suggested for buckling design by the ASME Boiler and Pressure Vessel Code should ensure an adequate margin to failure under this loading condition.

ABSTRACT: Six steel shells having nuclear containment like features were fabricated and loaded to failure with an offset axial load. The shells (R/t = 500) buckled plastically. Four of the shells had reinforced circular cutouts. These penetrations were sized to cut no ring-stiffener, a single, two- or three-ring stiffeners. Reinforcing and framing around the penetrations were based upon the area-replacement rule of the applicable portion of the ASME Boiler and Pressure Vessel Code and were of a design to simulate actual practice for nuclear steel containments. Prior to testing, imperfections were measured and strain gages were applied to determine information on load distribution at the ends of the cylinder and strain fields at areas likely to buckle. Buckling loads were determined for an axial load applied with an eccentricity of R/2 where R is the cylinder radius. The results showed that the buckling load and mode for the shell having a penetration that did not cut a ring stiffener were essentially the same as those for the unpenetrated shell. The buckling loads for the penetrated shells in which stiffeners were interrupted were less than that for the unpenetrated shells. Results of all tests are compared to numerical solutions carried out using a nonlinear collapse analysis and to the predictions of ASME Code Case N-284.

ABSTRACT: This paper describes the method for and results of, determining the static buckling interaction curves for both ring-stiffened and unstiffened cylindrical geometries that have radius-to-thickness (R/t) ratios and other parameters characteristic of nuclear steel containments. The purpose of developing these test methods and interaction curves is to have this information available for a dynamic buckling study on the same or similar shells that will be directed at answering questions regarding the freezing-in-time analysis method.

ABSTRACT: The problem of dynamic effects for steel containment shells subjected to time-dependent loadings that produce large compressive membrane stresses in the shell wall is considered. Loadings on typical containment structures are reviewed, along with a description of the complete dynamic-buckling problem. Simplifications and the assumptions that are currently used are critically examined and reviewed with respect to buckling analysis. Based on these reviews, three program objectives are defined and the tasks that can accomplish these objectives within a 2-year effort at level funding are outlined in detail.

ABSTRACT: Buckling of freestanding nuclear steel containment buildings from dynamic base excitation was investigated in a combined experimental/numerical program. A polycarbonate scale model of a containment building was excited with scaled earthquake transients and single-frequency harmonic transients to determine the peak base acceleration levels required to induce buckling. Buckling was identified using recorded signals from strain gages and accelerometers, with high-speed video records, and by audibility. Experimental results are compared with numerical results obtained by using a freezing-in-time technique. The results are preliminary, since several more tests are to be performed. However, the limited data obtained indicate that the freezing-in-time technique approximates the required acceleration levels reasonably well, although not conservatively. Additional experiments are described that will take containment asymmetries into account, as well as use instrumentation that will provide more accurate measures of the occurrence of buckling.

ABSTRACT: A displacement-based versatile and effective finite element is presented for linear and geometric and material nonlinear analysis of plates and shells. The element is formulated by interpolating the element geometry using the mid-surface nodal point coordinates and mid-surface nodal point normals. A total and an updated Lagrangian formulation are presented, that allow very large displacements and rotations. In linear

ABSTRACT: (cannot cut and paste)

ABSTRACT: The objective of this paper is to gain insight into finite element discretizations of shells using the basic shell mathematical model and, in particular, regarding the sources of “locking”. We briefly review the “basic shell mathematical model” and present a formulation of shell finite elements based on this model. These shell finite elements are equivalent to the widely-used continuum mechanics based shell finite elements. We consider a free hyperboloid shell problem, which is known to be difficult to solve accurately. Using a fine mesh of MITC9 elements based on the basic shell mathematical model, a detailed analysis is performed giving the distributions of all strain terms. A similar analysis using the MITC6 shell element shows why this element locks when the shell thickness is very small.

ABSTRACT: An efficient procedure for the nonlinear analysis of elasto-plastic shells is obtained based on an incremental variational functional of the Hellinger-Reissner type. For computational efficiency an updated Lagrangian description is used, referring the kinematical and mechanical field variables to local corotated coordinate frames. The constitutive equations are given in terms of increments of midsurface strains and curvatures and corresponding stress resultants, thus avoiding the integration over the shell thickness. Two models are considered for the description of subsequent yield surfaces, and modifications are introduced to represent the behaviour of hardening materials. The shell surface is descretized by flat elements of triangular and quadrilateral shape. Relaxing the interelemental continuity requirements, the resulting modified hybrid stress elements are expressed in the standard displacement format of the finite element method. The material models are verified against results obtained by numerical integration through the thickness for the special case of bending and stretching of a beam. Comparative studies for arches, rectangular plates subjected to transverse and inplane loads and cylindrical shells subjected to gravity loading indicate that the accuracy compares favourably with the results obtained by the traditional displacement formulation and numerical integration through the thickness. However, studies on two plastic buckling of axially loaded tubes reveal the need for further studies on the models for hardening materials.

ABSTRACT: This paper presents two numerical modeling approaches to analyze the wrinkles in the space membrane structures. The nonlinear buckling method based on our wrinkle analytical technique incorporating ANSYS thin shell element is used to simulate the wrinkle characteristics in the plane membrane. The explicit time integration method incorporating the AIRBAGS model in LSDYNA code is used to predict the dynamic wrinkle characteristics and the stress state of inflatable membrane structures. Numerical approaches presented
in this paper are applied in two numerical studies. One is the wrinkle analysis of the square plane membrane subjected to symmetric corner tension, and the other is the analysis of the square inflatable membrane airbag under the action of the internal variable inflatable pressure. The detailed wrinkling information, such as wrinkle wavelength, wrinkle amplitude, wrinkle region and the stress state of the wrinkled membrane structures, can be accurately obtained by using the approaches presented in this paper. Comparisons were made with experimental results for the wrinkle shape and distribution. The numerical predictions agreed well with the experimental results. The wrinkling results from the numerical computation can be used to support the studies on the nonlinear behaviors of the space membrane structures.

Changguo Wang, Huifeng Tan and Xingwen Du, “Pseudo-beam method for compressive buckling characteristics analysis of space inflatable load-carrying structures”, Acta Mechanica Sinica, October 2009, ABSTRACT: This paper extends Le van’s work to the case of nonlinear problem and the complicated configuration. The wrinkling stress distribution and the pressure effects are also included in our analysis. Pseudo-beam method is presented based on the inflatable beam theory to model the inflatable structures as a set of inflatable beam elements with a pre-stressed state. In this method, the discretized nonlinear equations are given based upon the virtual work principle with a 3-node Timoshenko’s beam model. Finite element simulation is performed by using a 3-node BEAM189 element incorporating ANSYS nonlinear program. The pressure effect is equivalent included in our method by modifying beam element cross-section parameters related to pressure. A benchmark example, the bending case of an inflatable cantilever beam, is performed to verify the accuracy of our proposed method. The comparisons reveal that the numerical results obtained with our method are close to open published analytical and membrane finite element results. The method is then used to evaluate the whole buckling and the load-carrying characteristics of an inflatable support frame subjected to a compression force. The wrinkling stress and region characteristics are also shown in the end. This method gives better convergence characteristics, and requires much less computation time. It is very effective to deal with the whole load-carrying ability analytical problems for large scale inflatable structures with complex configuration.

Lihong Zhang, Anne Marie Habraken, Amine Ben Bettaieb and Laurent Duchêne, “Parametric study of metal/polymer multilayer coatings for temperature wrinkling prediction”, Journal of Materials Engineering and Performance, Vol. 22, No. 9, pp 2437-2445, September 2013, doi: 10.1007/s11665-013-0541-z ABSTRACT: This article presents an analytic model for the prediction of wrinkling occurring in metal/polymer coatings under particular conditions. Owing to different thermal expansion coefficients (TECs) of the substrate and the different coating layers, temperature variation can induce a compressive stress in the coating. The wrinkling is the material response to the instability caused by this compressive stress. In this study, a reference case was selected: a 0.27-mm-thick steel sheet with a 5-μm-thick polymer layer and, on top of it, a thin aluminum film of 50 nm in thickness. For this reference case, it was observed and predicted by the model that an increase in temperature yielded to the wrinkling of the thin aluminum film. The geometry of the multilayer coating and the properties of the constituent materials are factors able to promote or prevent the wrinkle. To better understand and predict their effects, a sensitivity analysis was carried out with the proposed analytic model. A special attention was devoted to the temperature when wrinkling occurs. The key parameters having a significant influence on the wrinkling temperature were identified. It is concluded that the elastic modulus of the thin aluminum film and that of the polymer, the TEC of the thin film, and the initial stress induced during the processing of the multilayer system all had a significant influence on the wrinkling temperature.
ABSTRACT: Compared with experiments, the J2 deformation theory of plasticity is known to predict plastic buckling with better accuracy than the more accepted incremental J2 flow theory. This paradox is commonly known as the ‘plastic buckling paradox’. In an attempt to analyse this discrepancy, the two mentioned constitutive models were implemented in a non-linear finite element code, along with a third non-associative J2 flow theory. The latter model incorporates a vertex-type plastic flow rule. Using these three constitutive models, the buckling behaviour of plate outstand elements was investigated. Comparisons between the buckling strengths derived are presented. The non-linear static buckling simulations show that the instability introduced by the alternative flow rule of the non-associative model has substantial influence on the buckling behaviour. The acceptance of only small departures from normality was shown to reduce the predicted ultimate capacity of the plates. Furthermore, for plates with small plate slendernesses it was found that the imperfection sensitivity was significantly reduced when using the non-associative flow rule.

ABSTRACT: In this paper the analysis of plastic collapse is executed for a complicated pressure vessel. It is shown that the collapse of the whole vessel depends on the collapse of its details, which are selected in such a way that their collapse takes place independently from each other. Two kinds of collapse modes of the details are recognized: by bulging and by a three-hinge mechanism. It is shown that the collapse of the latter cannot be approximated reasonably by elastic solutions. Following this approach, the collapse of the whole vessel need not be executed. It is shown that for a jacketed construction the jacket cannot be taken as a separate detail because its deformation depends on the stiffness of the component to which it is attached. The collapse of the jacket is pursued in detail. Allowable pressures with respect ot plastic collapse are calculated for a sample vessel.

ABSTRACT: All too often, mechanicists divide themselves into two camps, theoreticians and experimentalists. This unfortunate state of affairs denies us the essential two-sided, realistic view of important physical problems. We must realize that theory cannot exist without suitable experiments, and that experiments cannot be properly designed or used in engineering practice without some form of theory. Thoughtful, penetrating interaction between theoretician and experimentalist is crucial. The truly effective experimentalist must have a strong theoretical background. The truly effective theoretician must have at least a rudimentary, if not a strong, experimental background. Of course, the ideal mechanicist would be neither a theoretician nor an experimentalist, but both simultaneously! The important factor is cross-talk between the two points of view with the objective of achieving a unified view of a phenomenon and its model that can be used to treat behavior beyond that which was observed in experiments. This paper is about the elements that go into making up the
unified viewpoint. Those elements include appreciation of the actual characteristics of the phenomenon studied as determined by experimental techniques and how those characteristics help develop and refine every theory. The point is that experiment is the driving force behind theory.

ABSTRACT: Geometrically perfect plates that are restrained from in-plane expansion when slowly and uniformly heated generally develop compressive stresses and then buckle at a specific temperature. The equivalent mechanical loading concept is used to straightforwardly develop solutions to several fundamental thermal buckling problems involving simple laminated plate configurations and the most simple heating environment, namely uniform heating throughout the plate volume. The analysis is restricted to linear elastic stress-strain behavior and constant orthotropic lamina material properties at a specific temperature. Results are obtained for unidirectional and symmetric cross-ply laminated fiber-reinforced composite rectangular plates that are uniaxially restrained in their plane on two of the four edges, but have no edge rotational restraint on any edge. Those boundary conditions constitute two of the four possible types of simply supported edges that differ only in their in-plane conditions. The results are presented in the form of buckling temperature change from the stress-free temperature (at which no stress is generated against the restraint) versus plate aspect ratio curves festooned for different buckling mode shapes for all laminates. Anomalous examples include unidirectionally laminated plates that actually buckle upon cooling instead of heating and cross-ply laminated plates that do not buckle irrespective of whether they are heated or cooled. Those examples are of interest because of their intriguing possible design applications.

ABSTRACT: During the setup of an experiment, errors may occur. Sources of such errors may be due to several factors which sometimes accumulate and then cause erroneous results. An experimental investigation on buckling of GRP (glass-reinforced-plastic) cylindrical shells, subject to axial compression and/or external pressure loading, has been carried out. At the beginning of the experiment, the initial geometrical imperfections were measured. Because of the small size of these quantities and the great effect these imperfections had on buckling loads, any small errors in the measurement procedure may lead to unreasonable results. Attempts have been made to detect these errors, and to identify and minimize their effect on experimental results. Tables are provided to show a comparison between the final experimental results and the corresponding theoretical ones. References listed at the end of the paper:

ABSTRACT: Koiter's method for initial postbuckling and imperfection sensitivity analysis of elastic structures is conveniently formulated in terms of finite elements. Special care must, however, be taken in the computation of the postbuckling stresses and the postbuckling constant determining the initial curvature of the postbuckling path. The cause of the problem lies in the different degree of approximation of in-plane and lateral displacements and is inevitable in a standard compatible finite element formulation. It is shown that only a minor change in the computation of the postbuckling stresses is needed. The procedure is extended to cover Byskov and Hutchinson's method for cases with nearly simultaneous buckling modes.

ABSTRACT: Basic definitions and relations for stability of elastic discrete systems under one-parameter conservative loads are briefly presented. On the basis of the potential energy functional the incremental FEM equations are derived. Various methods of computation of paths of equilibrium are discussed. These methods are related to evaluation of a curvilinear path either in the configuration space $\mathbb{R}^N$ or in the load-configuration space $\mathbb{R}^{(N+1)}$. The best method seems to be related to computation in $\mathbb{R}^N$ if the arc-type parameter and vector tangent to the equilibrium path are used. This method enables to overcome easily the limit points.
Different stability criteria for computation of critical points are discussed. Tracing of a postbifurcation path of equilibrium is pointed out.

ABSTRACT: The paper is a continuation of Waszczyszyn et al. (in: R. Tadeusiewicz, L. Rutkowski, J. Chojcan (Eds.), Proceedings of the Third Neural Networks and their Applications, TU Czestochowa, Poland, 1997, p. 14), where back-propagation neural networks (BPNNs) were used for predicting the buckling loads for axially compressed cylindrical shells with initial geometrical (manufacturing) imperfections. The paper was based on the measured imperfections and tests on laboratory shell specimens, gathered in the Imperfection Data Bank at the Delft University of Technology (P. II, Report LR-559, TU Delft, Faculty of Aerospace Engineering, Delft, 1988). In the presented paper the idea of data compression is explored. The application of BPNN replicators enables us to significantly reduce the number of inputs so the master BPNN formulated for the buckling load prediction is considerably smaller than BPNNs discussed in Waszczyszyn et al. (1997). It is proved that the compression of imperfection parameters seems to be a new efficient tool for the analysis of experimental data of the problem considered.

ABSTRACT: In this paper a family of dilatant plasticity theories is introduced by considering yield surfaces which change according to a combination of isotropic expansion and kinematic translation. One limiting member of the family is Gurson's (1977) isotropic hardening model, and the other limiting member is a pure kinematic hardening version. The family of constitutive laws is constructed such that all versions coincide for proportional stressing histories. The differences between any two versions show up only under nonproportional stressing histories, such as those encountered in many plastic instability phenomena. Under nonproportional stressing, the kinematic version is significantly “less stiff” than Gurson's isotropic hardening model due to the relatively higher curvature of the kinematic yield surface. This effect is explored in some basic shear localization calculations and is found to have substantial influence on the localization predictions.

ABSTRACT: The results of finite element calculations for a hollow sphere micromodel are used to examine the underlying assumptions and the specific yield functions in the dilatant plasticity theories of Gurson (1977) and Mear and Hutchinson.
ABSTRACT: The effect of void nucleation is incorporated in a recently proposed material model that accounts for a combination of kinematic hardening and isotropic hardening of a porous ductile material. Since each of plastic dilatancy, void nucleation and yield surface curvature have a strong influence on predictions of plastic flow localization, the present material model can be used to study the interaction of these effects. Nucleation controlled by the plastic strain as well as nucleation controlled by the maximum normal stress on the particle-matrix interface are modelled. The predictions of the material model, for various combinations of parameters, are illustrated by analyses of shear band formation under plane strain or axisymmetric conditions, and by analyses of necking in biaxially stretched sheets.

ABSTRACT: Interaction of nearly simultaneous buckling modes in the presence of imperfections is studied. The investigation is concerned with axially stiffened cylindrical shells under axial compression. In these structures, two modes are of particular interest, namely an overall long-wave and a local shortwave buckling mode. Numerical results show that in some cases bending of the stringers in the local mode postbuckling solution plays an important role. Exclusion of this effect, as was done in a previous study by Byskov and Hutchinson, may lead to an overestimation of the carrying capacity of the shell. Furthermore, it is found that apparently reasonable approximations to the postbuckling fields associated with both the local and the overall mode, as well as with the overall mode alone, may lead to inexact values of the buckling load.

ABSTRACT: In some cases, asymptotic methods present an appealing alternative to full nonlinear analyses. In other cases, the value of an asymptotic analysis may merely be that, in a qualitative way, it can characterize the behavior of a structure. Whether an asymptotic method is applied for one or the other purpose it is of interest to attempt an estimation of its range of validity. The present paper addresses this question for an asymptotic method to predict imperfection sensitivity of elastic structures with mode interaction. The particular structure that is investigated possesses an infinity of nearly simultaneous local buckling modes. It is found that very few of these modes need to be taken into account.

ABSTRACT: A number of studies show that nonlinear interaction between a shortwave local panel buckling mode and a longwave overall shell buckling mode usually causes strong imperfection sensitivity in stiffened shells. Interaction is particularly strong for simultaneous or nearly simultaneous modes. Mode interaction
between two overall buckling modes, as well as interaction between two overall and one local mode, has received much less attention. The present study indicates that for certain imperfection combinations, such mode interactions are important. On the other hand, in most cases, interaction between one overall mode and one local mode governs.

ABSTRACT: Exact postbuckling stresses usually vary fairly smoothly. Unfortunately, finite element postbuckling stresses tend to be much less well behaved. The result is that second order postbuckling constants determined by the finite element method may be highly inaccurate. The reason is that in finite element solutions transverse displacements associated with the buckling fields furnish too rapidly varying postbuckling strain contributions, while the postbuckling axial or membrane displacements contribute strain components that are sufficiently smooth, thus creating an internal postbuckling strain and stress mismatch. The present study suggests a modified finite element method that handles the problem, which is a special example of membrane locking, by introducing the postbuckling strains as independent variables. In general, the method provides rather complicated finite element expressions. However, by a suitable choice of interpolating functions, the resulting finite element equations themselves may be found to be the usual ones, and yet provide smooth postbuckling stresses and therefore good values of the postbuckling constants.

ABSTRACT: The buckling load capacity of a form of cellular-walled circular cylindrical shell suggested by fossil shell remains is analyzed. Shells under combined loading of axial compression and external pressure are studied. In particular, the effect of high fluid pressure within the cells on the buckling behaviour of the shell is considered. This study demonstrates that shells of this type with pressurized cells exhibit significantly improved stability and thus appear to have potential in engineering applications, particularly in marine situations.

ABSTRACT: This paper presents an experimental study of the buckling load capacity of a form of cellular-walled circular cylindrical shell suggested by fossil shell remains. Five epoxy model shells were tested in axial compression, external pressure and pressure within the cells. The results confirmed predictions of buckling loads: that is, the shell stability can be significantly improved by pressurising the cells. Thus this form of shell has considerable potential as an engineering structure, particularly in marine situations.

ABSTRACT: A great deal of the behavior of thin-walled cylindrical shells loaded in axial compression can be explained by considering the Yoshimura buckle pattern as a three-dimensional space frame and observing the collapse of that space frame.

ABSTRACT: This paper presents the results of some tests that were conducted on stringer stiffened epoxy cylindrical shells. The object of the investigation was to determine if the Southwell technique for estimating buckling loads could reasonably be used for the nonlinear collapse of cylindrical shells. The results showed that the technique provides a useful estimate of the buckling load provided care is taken in interpreting the results. In some instances the estimate is likely to be greater than the actual load. Where two buckling modes are encountered at the same time the Southwell technique appears to predict the critical load associated with either mode depending on the deflection parameter being measured as well as on the interpretation of the results.

ABSTRACT: An analytical study has been carried out to determine the effect of axisymmetric shape imperfections on the compressive buckling strength of sandwich cylinders having isotropic facings and orthotropic, shear deformable cores. Buckling solutions are presented as a function of imperfection amplitude, wavelength and the core shear flexibility coefficients. Non-shear deformable cores have also been considered and results compared to isotropic cylinders based on an “equivalent” thickness parameter.

S. Krishnakumar and R. C. Tennyson (University of Toronto, Institute for Aerospace Studies, 4925 Dufferin Street, Downsview, Ontario M3H 5T6, Canada), Effect of impact delaminations on axial buckling of composite cylinders”, in Buckling of shell structures, on land, in the sea, and in the air, edited by J. F. Jullien, Spon Press, 1991, ISBN 1-85166-716-4

ABSTRACT: The development of delaminations induced by low velocity impact and their effect on the axial compressive buckling strength of thin laminated circular cylindrical shells was investigated experimentally. Image Enhanced Backlighting and Structureal Embedded Fiber Optic Sensors were employed for damage assessment. Buckling tests were also conducted on shells with implanted delaminations for comparison purposes and as a means for determining the influence of delamination area on the reduction in buckling strength.

ABSTRACT: The development of delaminations induced by low velocity impact and their effect on the axial compressive buckling strength of thin laminated circular cylindrical shells was investigated experimentally. Image Enhanced Backlighting and Structurally Embedded Fiber Optic Sensors were employed for damage assessment. Buckling tests were also conducted on shells with implanted delaminations for comparison purposes and as a means for determining the influence of delamination area on the reduction in buckling strength. Results are compared with finite difference solutions of the buckling equations and linear stability analysis using the ABSQUS finite element package.

PARTIAL INTRODUCTION: One of the major concerns involving the use of lightweight fibre-reinforced composites is their susceptibility to impact damage. Delamination (or interlaminar fracture), surface spallation and laminate penetration constitute various modes of failure resulting from impact loads. Low-velocity impacts are associated with delamination damage, especially that caused by blunt-headed projectiles. This inter-laminar debonding primarily reduces the local bending stiffness and thus can affect the bending and buckling behavior of the structure. In the latter case, local buckling can induce further delamination growth which can lead to overall global weakening of the structure….. As impact energy is increased, delamination coupled with surface spallation can occur, followed by penetration of the laminate…

ABSTRACT: This paper presents the results of hypervelocity impact tests conducted on graphite/PEEK laminates. Both flat plate and circular cylinders were tested using aluminum spheres of varying size, travelling at velocities from 2–7 km/s. The experiments were conducted at several facilities using light gas guns. Normal and oblique angle impacts were investigated to determine the effect of impact angle, particle energy and laminate configuration on the material damage and ejecta plumes. Correlations were established between an energy parameter and the impact crater size, spallation damage and debris cone angle. Secondary damage resulting from the debris plume on adjacent composite structures was studied using high-speed photography and witness plates. It was observed that for hypervelocity impacts, the debris plume particles have sufficient energy to penetrate adjacent structures and cause major structural damage as well.

ABSTRACT: Some basic problems in the analysis of nonlinear instability for multilayered composite cylindrical shells are discussed. These problems are: the influences of initial imperfections and geometrical nonlinearities of shells; the effects of physical nonlinearity caused by the material nonlinearity of shear modulus; the influences of transverse shearing deformation and the effects of prebuckling deformations on buckling and postbuckling behavior of laminated composite cylindrical shells under various boundary conditions. All these influences are studied under various loading conditions; e.g. axial compression,
hydrostatic pressure, and torsion. Of course, the interaction of these influences is an important and complicated problem. The synthetic analysis of these influences is reported, based on a series of investigated results in recent years on boron--epoxy composites.

ABSTRACT: The effects of prebuckling displacements on the buckling of laminated composite circular cylindrical shells are investigated. Both axial compression and pure torsion are considered for two shell geometries with length to thickness ratios usually associated with container vessels. A clamped prebuckling boundary condition is used for all analysis with four boundary conditions applied during the buckling process. The shell walls are made up of a 6 ply laminate with several symmetric ply orientations. The study was made using the STAGS computer code, utilizing the linear bifurcation branch with linear prebuckling displacements. The results are compared to the buckling loads determined when prebuckling displacements are neglected. It is shown that prebuckling deformations generally tend to decrease the buckling load of a composite shell. It is also shown that prebuckling displacements can cause shell buckling before failure of the fibers occurs.

ABSTRACT: This paper presents results for buckling of a stiffened cylindrical shell with cutouts and both isotropic and composite shells without cutouts acting under end bending moments. The STAGS-C program has been used in the analysis.

ABSTRACT: A finite element analysis is carried out on the buckling of composite cylindrical panels under shear loading. Deep panels are considered, thus requiring a higher order shell theory. A comparison is made with a Galerkin technique which incorporated the Donnell shell theory.

ABSTRACT: The paper presents an approach for a general laminated shell geometry describable by orthogonal curvilinear coordinates. The theory includes a through-the-thickness parabolic distribution of transverse shear stress. Additionally, a simplified approach that allows large displacements and rotations is incorporated. The theory is cast into a displacement-based finite element formulation and then specialized to a cylindrical shell geometry. The theory is then applied to the problem of a transversely loaded isotropic deep arch, and results show a slightly more flexible response compared with published results that are based upon inextensible
assumptions. This problem also indicates that the usual locking associated with shell elements is apparently eliminated.

ABSTRACT: The characteristics of dynamic buckling of a geometrically non-linear cylindrical laminated composite panel subjected to a transverse concentrated step load applied at the center is studied. Attention is focused on the dynamic stability of a finite element discrete structural system. The sufficient condition for dynamic buckling, from the energy transfer consideration, is defined as the smallest load for which an unbounded motion is initiated at one generalized displacement. In other words, the dynamic buckling load associated with that generalized coordinate can be predicted by the intersecting point on the static equilibrium curve and the zero potential energy curve. This dynamic buckling criterion can also be observed by the existence of an inflection point on the generalized displacement response curve. Considering the multi-degree-of-freedom for the entire structure without damping, the dynamic buckling criterion used in a single-degree-of-freedom model gives the lower-bound dynamic buckling estimate, which will be shown in the results of the dynamic buckling analysis for a laminated composite arch. The possibility of parametric resonance due to the transverse concentrated step load on a geometrically non-linear system is discussed. Furthermore, the dynamic effects for different loading rates of the applied concentrated load are examined. Finally, the study of the damping effect, which raises the dynamic buckling load, is included.

ABSTRACT: A versatile geometrically non-linear curved shell finite element formulation includes exact Green's strain displacement for the inplane strains and linear strain displacement for the transverse shear strains. Additional coupling results for membrane-bending and membrane-transverse shear due to non-linear curvature strain-displacement relations. Additional non-linear terms that are a function of the shell's radius of curvature are also present. The approach is applied to the bifurcation buckling of axially compressed flat plates and transversely pressure-loaded cylindrical shell panels. The method gives a more flexible result for the plates compared to von Kármán non-linearity. Additionally, larger buckling pressures are found for shell panels. The effects of transverse shear flexibility are evident.

ABSTRACT: Cylindrical shell panels subjected to external pressure are seen in thin semi-monocoque aerospace applications and in the thick-wall pressure hulls of deep-sea submersibles. Both cases are weight-sensitive designs, and therefore, laminated constructions due to their high strength and stiffness-to-weight ratios appear advantageous. In this paper, both linear bifurcation and nonlinear analyses are presented for a wide range of geometries. For shells of high curvature, i.e. a Batdorf parameter, Z, greater than 100, the bifurcation load predicts the onset of instability very accurately as compared to a nonlinear analysis. On the other hand, shallow shells indicate a bifurcation instability where none exists in the nonlinear analysis. The response for some curvatures is significantly altered where transverse shear flexibility apparently has a major influence.

ABSTRACT: A laminated shallow shell approach that includes von Karman geometric nonlinearity and parabolic transverse shear deformation is posed in differential operator form. Trigonometric series are assumed for each of the five shell displacement degrees freedom for the subsequent nonlinear galerkin solution resulting in 5n2 simultaneous algebraic equations where n is the number of displacement terms assumed in the series. The galerkin nonlinear solution is computationally intensive. The response of several laminate geometries subjected to transverse loadings are found. Thicker plates and shells generally exhibit more flexible response compared to thinner geometries in both linear and nonlinear analyses. The nondimensional shell response is examined by using the Batdorf-Stein shell parameter for laminated constructions. Quasi-isotropic shallow shells undergo significant transverse shear flexibility in the thicker geometries as given by the nondimensional shell crown deflection. However, the nondimensional crown deflection in the deeper shell response is not much influenced by shell thickness. For flat plates, geometric nonlinearity lessens the influence of transverse shear flexibility when compared to linear solutions due to membrane stretching resistance.

ABSTRACT: (Cannot cut and paste)

ABSTRACT: An asymptotic procedure is used to derive the nonlinear equations of motion governing the forced dynamic response of an arbitrarily laminated slightly compressible composite shell panel in cylindrical bending. A combination of the Galerkin procedure and the method of multiple time scales is used to construct a uniformly valid asymptotic expansion for the dynamic response of the panel under near-resonant external excitation, and in the presence of a two-to-one internal resonance condition. A qualitative analysis shows that there is a threshold value for the amplitude of excitation, above which the panel exhibits the saturation phenomenon in which the amplitude of the directly excited mode saturates and the coupled mode starts to respond nonlinearly and eventually dominates the response. The force-response curve also exhibits the jump phenomenon.

ABSTRACT: A geometrically non-linear dynamic shell theory presented by the authors in an earlier work is used to study the non-linear free vibrations of symmetrically laminated cylindrical shell panels. The theory accounts for arbitrary lamination constructions, anisotropy, and slight compression across the thickness. In this paper, this theory is used to derive the equation of motion of the panel with quadratic and cubic non-linearities and symmetric lamination schemes. The symbolic manipulator Mathematica™ is used to perform the Rayleigh-Ritz procedure and derive a single-mode approximation to the vibration of the panel. The Lindstedt-Poincare perturbation technique is used to analyze the resulting non-linear differential equation of motion and study the effects of non-linearities on the dynamics of free vibrations of the panel. A numerical example of a symmetrically laminated graphite/epoxy shell panel is used to demonstrate the procedure. The numerical example shows that non-linearities are of the hardening type and are more pronounced for smaller opening angles. Moreover, it shows that the larger-amplitude motions are dominated by the lower modes.

ABSTRACT: An analytical study was performed to determine the critical buckling loads and natural frequencies for composite cylindrical shells, including transverse shear effects and constant through-the-
thickness direct strain, epsilonz. A linearized form of Sander's shell equations are derived, including a parabolic transverse shear strain distribution. Higher order laminate constitutive relations are developed. Hamilton's Principle is applied to derive five partial differential equations of motion and the associated boundary conditions, which are then solved using the Galerkin technique. Ply layups of [0/90] and [45/-45] were investigated under three boundary conditions, simply supported, clamped, and a combination simple-clamped. Symmetric and nonsymmetric laminates were investigated. Curvature is shown to have an important effect on all panels investigated due to membrane and bending coupling. Buckling loads for deeper shells are significantly higher than for flat plates. The effect on frequencies is not as great. The behavior of the nonsymmetric laminates was somewhat unexpected. Some results indicate the nonsymmetric laminates to be stiffer than the corresponding symmetric layup.

ABSTRACT: This paper studies the non-linear free vibrations of simply supported curved orthotropic panels. The panels are modeled using the Donnell-Mushtari-Vlasov shell relationships. A combination of the Galerkin procedure and the Lindstedt-Poincaré perturbation technique is used to construct an approximate solution to the resulting non-linear equations of motion. Algebraic manipulations show that the panel exhibits a non-linear response only when both the involved axial and circumferential modes are axisymmetric. Numerical studies of a Graphite/Epoxy panel show that its response is softening, i.e. the non-linear natural frequency decreases as the amplitude of motion increases. They also show that the lower modes are more non-linear than the higher, mainly flexural modes. The presented results also show that for the studied panels, the non-linear effects are the strongest for shallow, thin, and short panels.

“Two Dimensional Laminated Shell Theory Including Parabolic Transverse Shear”, Final Report, USAFA-TR-89-6, October 1989, DTIC Accession Number: ADDA 213817
ABSTRACT: The report presents an approach for a general laminated shell geometry describable by orthogonal curvilinear coordinates. The theory includes a through the thickness parabolic distribution of transverse shear stress. Additionally, a simplified approach that allows large displacements and rotations is incorporated. The theory is cast into a displacement based finite element formulation and then specialized to a cylindrical shell geometry. Linear results are compared to exact elasticity solutions of a laminated cylindrical shell in cylindrical bending. The approach predicts displacement and stress for the unidirectional cases very well even for the very thick laminates.

ABSTRACT: A laminated shallow shell approach for circular cylindrical panels that includes von Kármán geometric nonlinearity and parabolic transverse shear deformation is posed in differential operator form. Trigonometric series are assumed for each of the five shell displacement degrees of freedom for the subsequent
nonlinear Galerkin solution resulting in $5n^2$ simultaneous algebraic equations where $n$ is the number of displacement terms assumed in the series. The responses of several laminate geometries subjected to transverse loadings are found. Thicker plates and shells generally exhibit more flexible nondimensional response compared to thinner geometries in both linear and nonlinear analyses. The nondimensional shell response is examined by using the Batdorf-Stein shell parameter for laminated constructions. Quasi-isotropic shallow shells undergo significant transverse shear flexibility in the thicker geometries as given by the nondimensional shell crown deflection. However, the nondimensional crown deflection in the deeper shell response is not much influenced by shell thickness. For flat plates, geometric nonlinearity lessens the influence of transverse shear flexibility when compared to linear solutions due to membrane stretching resistance.

ABSTRACT: The present shell research activities at the Aerospace Engineering Department of the TH Delft are directed towards the development of an improved shell design criteria, which incorporates the latest theoretical findings and makes efficient use of the currently available computational facilities. The establishment of an International Imperfection Data Bank is discussed. Characteristic initial imperfection distributions associated with different fabrication techniques are shown. It is demonstrated that the generation of reliability functions via the Monte Carlo Method, which displays the degrading effect of the expected initial imperfection distribution characteristic of a given fabrication process on the buckling load, offers the means of combining the Lower Bound Design Method with the notion of Goodness Classes. Thus shells manufactured by a process, which produces inherently a less damaging initial imperfection distribution, will not be penalized because of the low experimental results obtained with shells made by another process which produces a more damaging characteristic initial imperfection distribution.

ABSTRACT: This paper deals with the stability problem of axially compressed imperfect orthotropic cylindrical shells. The initial imperfections are represented by a double Fourier series. Approximate solutions are derived for a single axisymmetric, a single asymmetric, a 2-modes and a multimode imperfection model. The effect of boundary conditions is studied by reducing the stability problem to the solution of a 2-point nonlinear boundary value problem. A reliability based stochastic stability approach is described, which makes it possible to include the results of the Imperfection Sensitivity Theory directly into an Improved Shell Design Procedure.

ABSTRACT: The development of “DISDECO”, the Delft Interactive Shell Design Code is described. The purpose of this project is to make the accumulated theoretical, numerical and practical knowledge of the last 20 years readily accessible to users interested in the analysis of buckling sensitive structures. With this open ended, hierarchical, interactive computer code the user can access from his work-station successive programs of increasing complexity. Included are modules that contain Koiter's imperfection sensitivity theory extended to anisotropic shell structures under combined loading. The nonlinear Donnell-type anisotropic shell equations in terms of the radial displacement W and the Airy stress function F are used. The circumferential dependence is eliminated by Fourier decomposition. The resulting sets of ordinary differential equations are solved numerically via the “Shooting Method”. Thus the specified boundary conditions can be enforced rigorously not only in the pre-buckling but also in the buckling and post-buckling problem. Initial results indicate that in order to obtain reliable results for anisotropic shells rigorous enforcing of the edge restraint and of the boundary conditions is indeed a must.

ABSTRACT: The development of “DISDECO”, the Delft Interactive Shell Design Code, is described. The purpose of this project is to make the accumulated theoretical, numerical and practical knowledge of the last 20 years readily accessible to users interested in the analysis of buckling-sensitive structures. With the open ended, hierarchical, interactive computer code the user can access from his work-station successive programs of increasing complexity. Included are modules that contain Koiter’s imperfection sensitivity theory extended to anisotropic shell structures under combined loading. The nonlinear Donnell-type shell equations in terms of the radial displacement $W$ and the Airy stress function $F$ are used. The spatial dependence is eliminated by Fourier decomposition. The resulting sets of algebraic equations form a standard matrix eigenvalue problem. Initial results indicate that an interactive use of these simple modules can greatly facilitate the search for an optimal lay up of composite shells under combined loading.

ABSTRACT: Probabilistic methods are being applied to Koiter formulas in order to derive the reliability of imperfection-sensitive shells, on this occasion by taking into account the randomness of both parameters appearing in the formulas — the initial imperfection and the allowable load. The results indicate the importance of the loading randomness, implying a dramatic reduction in the reliability with respect to traditional derivations which consider only the randomness of the initial imperfections.

ABSTRACT: The establishment of an International Imperfection Data Bank is discussed. Characteristic initial imperfection distributions associated with different fabrication techniques are shown. Using a first-order, second-moment analysis, a stochastic method is presented, whereby the stability of isotropic, orthotropic and anisotropic nominally circular cylindrical shells under axial compression, external pressure and/or torsion possessing general nonsymmetric random initial imperfections can be evaluated. Results of measurements of initial imperfections are represented in Fourier series and the Fourier coefficients are used to construct the second-order statistical properties needed. The computation of the buckling loads is done with standard computer codes and includes a rigorous satisfaction of the specified boundary conditions. It is shown that the proposed stochastic approach provides a means to combine the latest theoretical findings with the practical experiences spanning about 75 years in an optimal manner via the advanced computational facilities currently available.
ABSTRACT: The reliability of imperfection-sensitive shells is derived. The Koiter (asymmetric case) formula is used to construct the failure criterion for the case where the imperfection surface is described by two terms of a double Fourier series with random amplitudes. The effect of the correlation between these variables is also investigated. In some cases exact solutions are derived, while in others, approximate derivations are obtained within the Hasofer-Lind method.

ABSTRACT: A rigorous solution is presented for the case of stiffened anisotropic cylindrical shells with general imperfections under combined loading, where the edge supports are provided by symmetrical or unsymmetrical elastic rings. The circumferential dependence is eliminated by a truncated Fourier series. The resulting nonlinear 2-point boundary value problem is solved numerically via the “Parallel Shooting Method”. The changing deformation patterns resulting from the different degrees of interaction between the given initial imperfections and the specified end rings are displayed. Recommendations are made as to the minimum ring stiffnesses required for optimal load carrying configurations.

ABSTRACT: A rigorous solution is presented for the case of stiffened anisotropic shells with general imperfections under combined axial compression, internal or external pressure and torsion. Donnell type equations are used to describe the behavior of the layered composite shell. The stiffeners are represented by smeared theory and for the discrete end rings, Cohen’s ring equations are used. The circumferential dependence is eliminated by a truncated Fourier series. The resulting 2-point boundary value problem is solved numerically via the “parallel shooting method”. The nonlinear collapse behavior is studied using different combinations of axisymmetric and asymmetric imperfections. Comparison with Koiter type imperfection predictions display the range of validity of the asymptotic results. It is shown that besides initial geometric imperfections also nonuniform harmonically varying boundary conditions can have severe degrading effect on the load carrying capacity of anisotropic shells.

ABSTRACT: The development of “DISDECO”, the Delft Interactive Shell DEsign COde, is described. The purpose of this project is to make the accumulated theoretical, numerical and practical knowledge of the last 20 years readily accessible to users interested in the analysis of buckling of sensitive structures. With this open ended, hierarchical, interactive computer code the use can access successively from his workstation programs of increasing complexity.
ABSTRACT: As a step towards developing a new design philosophy, one that moves away from the traditional empirical approach used today in design, towards a science-based design technology approach, a recent test series of 5 composite shells carried out by Waters [1] at NASA Langley Research Center is used. It is shown how the hierarchical approach to buckling load calculations proposed by Arbocz et al [2] can be used to perform an approach often called “high fidelity analysis”, where the uncertainties involved in a design are simulated by refined and accurate numerical methods. The Delft Interactive Shell Design Code (short: DISDECO) is employed for this hierarchical analysis to provide an accurate prediction of the critical buckling load of the given shell structure. This value is used later as a reference to establish the accuracy of the Level-3 buckling load predictions. As a final step in the hierarchical analysis approach, the critical buckling load and the estimated imperfection sensitivity of the shell are verified by conducting an analysis using a sufficiently refined finite element model with one of the current generation two-dimensional shell analysis codes with the advanced capabilities needed to represent both geometric and material nonlinearities.

ABSTRACT: Recent advances in structural analysis and design technology for buckling-critical shell structures are discussed. These advances include a hierarchical analysis strategy that includes analyses that range from classical analysis methods to high-fidelity nonlinear finite element analysis methods, reliability based design methods, the development of imperfection data bases, and the identification of traditional and nontraditional initial imperfections for composite shell structures. When used judiciously, these advances provide the basis for a viable alternative to the traditional and conservative lower-bound design philosophy of the 1960s. These advances also help answer the question of why, after so many years of concentrated research effort to understand the behavior of buckling-critical thin-walled shells, one has not been able to improve on this conservative lower-bound design philosophy in the past.
ABSTRACT: As a step towards developing a new design philosophy, one that moves away from the traditional empirical approach used today in design towards a science-based design technology approach, a test series of 7 isotropic shells carried out by Aristocrat and Babcock at Caltech is used. It is shown how the hierarchical approach to buckling load calculations proposed by Arbocz et al can be used to perform an approach often called 'high fidelity analysis', where the uncertainties involved in a design are simulated by refined and accurate numerical methods. The Delft Interactive Shell DEsign COde (short, DISDECO) is employed for this hierarchical analysis to provide an accurate prediction of the critical buckling load of the given shell structure. This value is used later as a reference to establish the accuracy of the Level-3 buckling load predictions. As a final step in the hierarchical analysis approach, the critical buckling load and the estimated imperfection sensitivity of the shell are verified by conducting an analysis using a sufficiently refined finite element model with one of the current generation two-dimensional shell analysis codes with the advanced capabilities needed to represent both geometric and material nonlinearities.

ABSTRACT: A procedure for deriving nondimensional parameters and equations for bifurcation buckling of anisotropic shallow shells subjected to combined loads is presented. First, the Donnell-Mushtari-Vlasov equations governing buckling of symmetrically laminated doubly curved thin elastic shallow shells are presented. Then, the rationale used to perform the nondimensionalization of the buckling equations is presented, and fundamental parameters are identified that represent measures of the shell orthotropy and anisotropy. In addition, nondimensional curvature parameters are identified that are analogues of the well-known Batdorf Z parameter for isotropic shells, and analogues of Donnell’s and Batdorf’s shell buckling equations are presented. Selected results are presented for shear buckling of balanced symmetric laminated shells that illustrate the usefulness of the nondimensional parameters.

ABSTRACT: The buckling and postbuckling behaviour of thin plates with a cut-out and made of advanced composite materials are research topics of great practical importance. For example, composite plate-like subcomponents with cut-outs are being considered for use in many types of aerospace structures owing to their high stiffness-to-weight and strength-to-weight properties. These properties could ultimately yield substantial weight savings for aircraft structures.

ABSTRACT: Results of buckling and nonlinear analyses of the Space Shuttle external tank superlightweight liquid-oxygen (LO2) tank are presented. Modeling details and results are presented for two prelaunch loading conditions and for two full-scale structural tests that were conducted on the original external tank. The results illustrate three distinctly different types of nonlinear response for thin-walled shells subjected to combined mechanical and thermal loads. The nonlinear response phenomena consist of bifurcation-type buckling, short-wavelength nonlinear bending, and nonlinear collapse associated with a limit point. For each case, the results show that accurate predictions of nonlinear behavior generally require a large-scale, high-fidelity finite-element model. Results are also presented that show that a fluid-filled launch-vehicle shell can be highly sensitive to initial geometric imperfections. In addition, results presented for two full-scale structural tests of the original standard-weight external tank suggest that the finite-element modeling approach used in the present study is sufficient for representing the nonlinear behavior of the superlight-weight LO2 tank.

ABSTRACT: A summary of the existing NASA design criteria monographs for the design of buckling-resistant thin-shell structures is presented. Subsequent improvements in the analysis for nonlinear shell response are reviewed, and current issues in shell stability analysis are discussed. Examples of nonlinear shell responses that are not included in the existing shell design monographs are presented, and an approach for including reliability-based analysis procedures in the shell design process is discussed. Suggestions for conducting future shell experiments are presented, and proposed improvements to the NASA shell design criteria monographs are discussed.

ABSTRACT: Results of linear bifurcation and nonlinear analyses of the Space Shuttle superlightweight (SLWT) external liquid-oxygen (LO2) tank for an important early booster ascent loading condition are presented. These results for thin-walled linear elastic shells that are subjected to combined mechanical and thermal loads illustrate an important type of response mode that may be encountered in the design of other liquid-fuel launch vehicles. Linear bifurcation analyses are presented that predict several nearly equal eigenvalues that correspond to local buckling modes in the forward ogive section of the LO2 tank. In contrast, the nonlinear response phenomenon is shown to consist of short-wavelength bending deformations in the forward ogive and barrel sections of the LO2 tank that grow in amplitude in a stable manner with increasing load. Imperfection sensitivity analyses are presented that show that the presence of several nearly equal eigenvalues does not lead to a premature general instability mode for the forward ogive section. For the linear bifurcation and nonlinear analyses, the results show that accurate predictions of the response of the shell generally require a large-scale, high-fidelity finite-element model. Results are also presented that show that the SLWT LO2 tank can support loads in excess of approximately 2.6 times the values of the operational loads considered.

ABSTRACT: An analytical, parametric study of the attenuation of bending boundary layers or edge effects in balanced and unbalanced, symmetrically and unsymmetrically laminated thin cylindrical shells is presented for nine contemporary material systems. The analysis is based on the linear Sanders-Koiter shell equations and specializations to the Love-Kirchhoff shell equations and Donnell’s equations are included. Two nondimensional parameters are identified that characterize and quantify the effects of laminate orthotropy and laminate anisotropy on the bending boundary-layer decay length in a very general and encompassing manner. A substantial number of structural design technology results are presented for a wide range of laminated-composite cylinders. For all laminate constructions considered, the results show that the differences between results that were obtained with the Sanders-Koiter shell equations, the Love-Kirchhoff shell equations, and Donnell’s equations are negligible. The results also show that the effect of anisotropy in the form of coupling between pure bending and twisting has a negligible effect on the size of the bending boundary-layer decay length of the balanced, symmetrically laminated cylinders considered. Moreover, the results show that coupling between the various types of shell anisotropies has a negligible effect on the calculation of the bending boundary-layer decay length in most cases. The results also show that, in some cases, neglecting the shell anisotropy results in underestimating the bending boundary-layer decay length and, in other cases, results in an overestimation. An example problem is included in an appendix that demonstrates how to perform the calculations that were used to generate the results of the present study.

ABSTRACT: The results of an analytical study of the elastic buckling and non-linear behavior of the liquid-oxygen tank for the new Space Shuttle superlightweight external fuel tank are presented. Selected results that illustrate three distinctly different types of non-linear response phenomena for thin-walled shells which are subjected to combined mechanical and thermal loads are presented. These response phenomena consist of a bifurcation-type buckling response, a short-wavelength non-linear bending response, and a non-linear collapse or “snap-through” response associated with a limit point. The effects of initial geometric imperfections on the response characteristics are emphasized. The results illustrate that the buckling and non-linear response of a geometrically imperfect shell structure subjected to complex loading conditions may not be adequately characterized by an elastic linear bifurcation buckling analysis, and that the traditional industry practice of applying a buckling-load knock-down factor can result in an ultra-conservative design. Results are also presented that show that a fluid-filled shell can be highly sensitive to initial geometric imperfections, and that the use a buckling-load knock-down factor is needed for this case.

Nemeth, M. P. (NASA Langley Research Center, Hampton, Virginia, USA), "Buckling Behavior of Long Anisotropic Plates Subjected to Fully Restrained Thermal Expansion," NASA TP-2003-212131, February 2003. ABSTRACT: An approach for synthesizing buckling results and behavior for long, balanced and unbalanced symmetric laminates that are subjected to uniform heating or cooling and that are fully restrained against thermal expansion or contraction is presented. This approach uses a nondimensional analysis for infinitely long, flexurally anisotropic plates that are subjected to combined mechanical loads and is based on useful nondimensional parameters. In addition, stiffness-weighted laminate thermal-expansion parameters are derived that are used to determine critical temperature changes in terms of physically intuitive mechanical buckling coefficients, and the effects of membrane orthotropy and membrane anisotropy are included. Many results are presented for some common laminates that are intended to facilitate a structural designer’s transition to the use of the generic buckling design curves that are presented in the paper. Several generic buckling design curves are presented that provide physical insight into the buckling response in addition to providing useful design data. Examples are presented that demonstrate the use of the generic design curves. The analysis approach and
generic results indicate the effects and characteristics of laminate thermal expansion, membrane orthotropy and anisotropy, and flexural orthotropy and anisotropy in a very general and unifying manner.

SUMMARY: Simple formulas for the buckling stress of homogeneous, specially orthotropic, laminated-composite cylinders are presented that are the counterpart of the classical buckling formula for an isotropic cylinder. The formulas are obtained by using nondimensional parameters and equations that facilitate general validation, and are validated against the exact solution for a wide range of cylinder geometries and laminate constructions. The buckling stress is found to be a product of a nondimensional coefficient, that involves only material properties of the wall, with the thickness-to-radius ratio of the cylinder and the effective modulus of the corresponding quasi-isotropic laminate. Unlike the corresponding isotropic-cylinder solution, that is represented by a single equation, two equations that depend on the laminate orthotropy, are needed to obtain the orthotropic-cylinder solution; one for axisymmetric and one for asymmetric buckling modes. Results are presented that establish the ranges of the nondimensional parameters and coefficients used. General results, given in terms of the nondimensional parameters, are presented that encompass a wide range of geometries and laminate constructions. These general results also illustrate a wide spectrum of behavioral trends. Design-oriented results are also presented that provide a simple, clear indication of laminate composition on critical stress, critical strain, and axial stiffness. The particular graphical form of these results that is used in the present study enables rapid trade studies for different design requirements. One conclusion found in the present study is that no buckling stress can be achieved for homogeneous specially orthotropic cylinders that is higher than the corresponding quasi-isotropic layup. Another conclusion is that the higher values of buckling stress are associated with higher values of axial strain. An example is provided to demonstrate the application of these results to thin-walled column designs.

SUMMARY: A detailed exposition on a refined nonlinear shell theory that is suitable for nonlinear limit-point buckling analyses of practical laminated-composite aerospace structures is presented. This shell theory includes the classical nonlinear shell theory attributed to Leonard, Sanders, Koiter, and Budiansky as an explicit proper subset that is obtained directly by neglecting all quantities associated with higher-order effects such as transverse-shearing deformation. This approach is used in order to leverage the existing experience base and to make the theory attractive to industry. In addition, the formalism of general tensors is avoided in order to expose the details needed to fully understand and use the theory in a process leading ultimately to vehicle certification.

The shell theory presented is constructed around a set of strain-displacement relations that are based on "small" strains and "moderate" rotations. No shell-thinness approximations involving the ratio of the maximum thickness to the minimum radius of curvature are used and, as a result, the strain-displacement relations are exact within the presumptions of "small" strains and "moderate" rotations. To facilitate physical insight, these strain-displacement relations are presented in terms of the linear reference-surface strains, rotations, and changes in curvature and twist that appear in the classical "best" first-approximation linear shell theory attributed to Sanders, Koiter, and Budiansky. The effects of transverse-shearing deformations are included in the strain-displacement relations and kinematic equations by using analyst-defined functions to describe the through-the-thickness distributions of transverse-shearing strains. This approach yields a wide range of flexibility to the analyst when confronted with new structural configurations and the need to analyze both global and local response phenomena, and it enables a building-block approach to analysis. The theory also uses the three-dimensional elasticity form of the internal virtual work to obtain the symmetrical effective stress resultants that appear in classical nonlinear shell theory attributed to Leonard, Sanders, Koiter, and Budiansky. The principle of virtual work, including "live" pressure effects, and the surface divergence theorem are used to obtain the nonlinear equilibrium equations and boundary conditions.

A key element of the shell theory presented herein is the treatment of the constitutive equations, which include thermal effects. The constitutive equations for laminated-composite shells are derived without using any shell-thinness approximations, and simplified forms and special cases are discussed that include the use of layerwise zigzag kinematics. In addition, the effects of shell-thinness approximations on the constitutive equations are presented. It is noteworthy that none of the shell-thinness approximations appear outside of the constitutive equations, which are inherently approximate. Lastly, the effects of "small" initial geometric imperfections are introduced in a relatively simple manner, and a resume of the fundamental equations are given in an appendix. Overall, a hierarchy of shell theories that are amenable to the prediction of global and local responses and to the development of generic design technology are obtained in a detailed and unified manner.

SUMMARY: Nonlinear and linear-bifurcation buckling equations for elastic, geometrically perfect, right-circular cylindrical shells subjected to combined loads is presented. The loads include compression, shear, and uniform external and hydrostatic pressure. The analysis includes constitutive equations that are applicable to stiffened or unstiffened cylinders made from isotropic or laminated-composite materials. Complete sets of equations are presented for the nonlinear boundary-value problem of shell buckling and the corresponding prebuckling and linear-bifurcation buckling problems that are based on Sanders’ shell theory for "small" strains and "moderately small" rotations. Based on these equations, a three-parameter approximate Rayleigh-Ritz solution and a classical solution to the buckling problem are presented for cylinders with simply supported edges. Extensive comparisons of results obtained from these solutions with published results are also presented for a wide range of cylinder constructions. These comparisons include laminated-composite cylinders with a wide variety of shell-wall orthotropies and anisotropies. Numerous results are also given that show the discrepancies between the results obtained by using Donnell’s equations and variants of Sanders’ equations. For some cases, nondimensional parameters are identified and "master" curves are presented that facilitate the concise representation of results.

ABSTRACT: A non-linear formulation for general, arbitrary, sandwich shells is presented. The formulation accounts for geometric and material non-linear behavior of the shell. The core plasticity is assessed. The first order shear deformation theory is presented as far as the kinematics are concerned. The analysis is based on the displacement formulation of the finite element method and uses the Ahmad shell element with five degrees of freedom per node. The approach is discussed, particularly with reference to a cylindrical shell subjected to transverse load that causes snap buckling.

ABSTRACT: In this work, a finite-element model is presented for geometric non-linear analysis of composite shell structures. It adopts a layered formulation of the Marguerre shell element. The material is assumed to have an orthotropic behaviour. The non-linear incremental equilibrium equations are set using a total Lagrangian displacement formulation of the finite element method and the solution is accomplished using the incremental/iterative Newton–Raphson method as well as a spherical formulation of the arc-length methods. The buckling behaviour of composite shells is analysed as a function of the material orientation and laminate stacking.

A.J.M. Ferreira, C.M.C. Roque and R.M.N. Jorge (Departamento de Engenharia Mecânica e Gestão Industrial, Faculdade de Engenharia da Universidade do Porto, Rua Dr. Roberto Frias, 4200-465 Porto, Portugal),

ABSTRACT: The higher-order shear-deformation theory of laminated orthotropic elastic shells of Vlasov–Reddy is a modification of Sanders’ theory and accounts for parabolic distribution of the transverse shear strains through the thickness of the shell. The Vlasov–Reddy shell theory allows the fulfillment of homogeneous conditions (zero values) at the top and bottom surfaces of the shell. This paper deals with a meshless solution of the Vlasov–Reddy higher-order shell theory. The meshless technique is based on the asymmetric global multiquadric radial basis function method proposed by Hardy and Kansa. This paper demonstrates that this truly meshless method is successful in the analysis of laminated composite shells.

Carla M.C. Roque, Antonio J.M. Ferreira and Renato M.N. Jorge (Department of Engineering Mechanics, University of Porto, Portugal), “Analysis of cylindrical sandwich shells using a meshless method and an optimization technique”, (publisher and date not given in the “pdf” file; most recent reference is dated 2006)

ABSTRACT: The purpose of this work is to use a meshless collocation method with multiquadric radial basis functions (RBFs), the higher order shear deformation theory presented by Khare et al. [1], and optimal values of the shape parameter in the RBFs to analyze static deformations of sandwich cylindrical shells. An optimization technique based on a statistical method is used to choose a shape parameter $c$ on the interpolating multiquadric radial basis function used by the meshless method. This parameter plays a decisive role in the quality of the solution of the boundary value problem and is usually chosen in a trial error basis. The optimization technique here presented allows to obtain a quasi user-independent shape parameter. Although the technique still requires some input by the user, results are encouraging, with the errors produced by the optimal shape parameter being lower than the ones produced by a user defined shape parameter.

“Nonlinear time-domain finite-element modeling of thin electromagnetic shells”, CEFC-ATHENS, PB1-10, 2008

ABSTRACT: A nonlinear time-domain extension of the classical linear frequency-domain thin-shell approach is presented. The interface conditions are expressed in terms of the average magnetic flux density throughout the shell thickness and a number of higher-order components. The method is elaborated in the frame of the magnetic vector potential formulation. The nonlinear system of algebraic equations is solved by means of the Newton-Raphson scheme. To validate the new formulation, we consider a magnetic plate placed above a double line carrying a sinusoidal current. Results are compared with those obtained with a fine finite-element model.

ABSTRACT: The paper summarises a part of the of activity of CEN/TC250 SC9 Committee, devoted to the preparation of Eurocode 9 “Design of Aluminium Structures”. The results of a wide imperfection sensitivity F.E.M. analysis, dealing with aluminium cylinders subjected to axial load, uniform external pressure and torsion, are discussed. Numerical simulations have been carried out by accounting for a wide geometrical imperfection spectrum, in order to consider the most dangerous distributions. Results of almost 6000 F.E.M. simulation runs have been used to delineate a numerical data-set for the definition of buckling curves for aluminium alloys shells, to be introduced into the new part prEN1999-1-5 of Eurocode 9. For the sake of homogeneity, the basic layout of prEN1993-1-6 has been referred to as a general framework. Nevertheless, it is shown that buckling curves given in EC3 can not be used for aluminium shells, but require proper modification.

“Plastic buckling of axially loaded aluminium cylinders: a new design approach”, CIMS 2004, Fourth International Conference on Coupled Instabilities in Metal Structures, Rome, Italy, 27-29 September, 2004

ABSTRACT: The results of a wide F.E.M. analysis on the imperfection sensitivity of axially loaded aluminium cylinders are used to investigate buckling modes occurring in case of relatively thick cylinders (R/t < 200 ÷ 250). The combined effect of geometrical imperfections, inelastic behaviour of material and boundary conditions is considered in order to set-up a refinement of rules given in prEN1993-1-6 dealing with steel shells. The proposal allows for a further exploitation of the cylinder buckling strength in plastic range, which is why it seems rather suited to applications in the field of civil engineering. To this purpose, a special requirement on the initial allowable imperfection level is defined, corresponding to a quality class higher than EC3 class A. Because of its features, the proposal presented herein could be profitably used for the new Part 1-5 “Supplementary rules for shell structures” of Eurocode 9 (prEN1999-1-5), presently under development, which is the very first codification issue at European level dealing with aluminium shell structures.

ABSTRACT: In order to simplify the problem, the equivalent-cylinder assumption has been adopted. The simplified governing equations of sandwich cones we obtain are different from the ones used in previous papers. They can be reduced into the equations of a corresponding sandwich cylinder if the buckle length parameter approaches zero. An analytical study has been carried out to determine the effect of axisymmetric
Shape imperfections on the compressive buckling strength of sandwich cones having isotropic facings and isotropic shear deformable cores. Buckling solutions are presented as a function of imperfection amplitude, wavelength, core shear flexibility coefficients and the small curvature ratio. The well known Koiter formula and circle have been obtained for the first time for sandwich cones.

No abstract is given.

ABSTRACT: Using Schieck and Stumpf’s superposition approach, the kinematics of buckling for continua has been investigated in the present paper. According to the properties of buckling phenomena the concept of “bifurcation configuration” has been introduced, and the total deformation gradient F can be expressed by pre-buckling deformation gradient, $F_{\text{sub-1}}$ and the post-buckling deformation gradient $F_{\text{sub-2}}$, i.e. $F = F_{\text{sub-2}} x F_{\text{sub-1}}$. As an extension, the elasto-plastic deformation has been investigated for the post-buckling stage using Lee and Liu’s multiplicative decomposition, $F = F_{\text{super-e}} x F_{\text{super-p}}$.

ABSTRACT: Buckling of a thin elastic cylindrical shell stiffened by rings of rectangular cross-sections are considered. The parameters of the shell of the minimal weight, having a given critical external pressure, are found. For the evaluating of the optimal parameters the asymptotic approach is used.
ABSTRACT: Wind loadings govern the design of most cooling towers. Until now, proof of sufficient safety against buckling under wind load has been a major concern for the designers of such shells. In this paper it is demonstrated that a typical cooling tower made of reinforced concrete would not buckle—at least not in the classical sense of the word. Failure would rather be initiated by rapid propagation of cracks in tensile zones followed by temporary stiffening and, finally, by yielding of the reinforcement. The theoretical part of this paper is restricted to a presentation of the constitutive model, discussion of the equation for incremental-iterative ultimate-load analysis and of the condition for instability. The numerical part contains a detailed study of a built hyperbolic cooling tower. It is shown that: (a), buckling loads resulting from linear and geometrically nonlinear prebuckling analyses are considerably larger than the ultimate load; and (b), results based on a certain form of ‘equivalent axisymmetric pressure’ are on the unsafe side of corresponding results from the ‘actual’ wind load. It is also demonstrated that the ‘crack load’, representing a lower bound to the ultimate load, can be estimated by means of a linear-elastic nonaxisymmetric analysis of the cooling tower.

ABSTRACT: The paper presents an optimization method for direct determination of the most unfavorable imperfection of structures by means of ultimate limit states. When analyzing imperfection sensitive structures it turns out that the choice of the shape and size of initial imperfections has a major influence on the response of the structure and its ultimate state. Within the optimization algorithm the objective function is constructed by means of a fully nonlinear direct and first order sensitivity analysis. The method is not limited to small imperfections and also allows the imposition of “technological” constraints on the shape of the imperfection, thus making it possible to avoid unrealistically low ultimate loads. When carefully constructed, the objective function and constraints remain linear enabling the use of numerically efficient and readily available linear programming algorithms. Imperfection analyses are shown for thin-walled girders and a cylinder to demonstrate the applicability and efficiency of the proposed method.

ABSTRACT: In certain structural applications, such as stiffened panels loaded in compression, a better exploitation of the properties of composite materials requires the development of design methodologies that allow the component to work in the post-critical range. This paper describes the results of a research activity with such an objective, carried out at the Department of Aerospace Engineering of the University of Pisa in collaboration with Alenia-Transport Aircraft Group. A group of tests has been carried out on 10 flat stiffened panels, made in composite material, and the results have been analysed with two computer codes, providing useful information concerning their capabilities.

ABSTRACT: This thesis deals with the analytical and experimental studies of the instability of geometrically composite shells of revolution. Different axisymmetric composite shells under uniform external pressure are studied analytically for their use as end-closures of submarine hulls or of pressure vessels. The composite shells studied here are (a) cap:cone end-closures (b) cup-cylinder end-closures and (c) dome-cylinder end-closures. In the cap-cone end-closures a spherical cap is attached to the smaller end of a conical frustum in such a way that the tangent at their junction maintains continuity. In the cup-cylinder end-closure, a spherical cup is attached at an end of a cylinder and in the dome-cylinder end-closure, a spherical dome replaces the spherical cup of the cup-cylinder end-closure. A computer program is developed and enclosed here in the appendix which can find both axisymmetric and asymmetric buckling load of shells of revolution under uniform external pressure. For the study of axisymmetric buckling, the program uses Reissner's theory of large deflection and interprets instability based on the two criteria of Thompson. The non-linear axisymmetric solutions of Reissner's theory are considered as prebuckling solution for asymmetric instability analysis based on eigen-value interpretation. Axisymmetric analyses of the cap-cone end-closure for varying cone height, cone angle (II) and thickness ratio show that increasing the cone angle or thickness ratio leads to decreasing the buckling load. In the case of varying height, the buckling load remains almost the same over a wide range of height and starts decreasing at a certain small height reaching a minimum at zero height when it is a simple spherical cap. The axisymmetric buckling load for cup-cylinder end-closures is found to be much higher than that of the dome-cylinder for the same thickness ratio, cylinder height and cup or dome angle. In the case of dome-cylinder end-closures, it is found that its buckling load is even lower than that of the cylinder. Circumferential stresses at the junction of a cup-cylinder end-closure at the axisymmetric critical load is so high that the failure of this end-closure would always be either due to yielding or asymmetric buckling. A new experimental technique has also been developed for testing the instability of axisymmetric shells. Electrodeposited cap-cone model specimens are tested for instability using this experimental technique. Results of the experiment show that the cap-cone models of tip ratio, r/R, about 0.80 can sustain the highest load and is least imperfection sensitive. The conical portion of the cap-cone end-closures were found to buckle asymmetrically with a number of circumferential lobes. Comparison of the analytical buckling load for both the axisymmetric as well as the asymmetric buckling with the experimental results show that the experimental results are in good agreement with asymmetric buckling load but the axisymmetric buckling loads are found to be about 10 to 15 times higher than the experimental results. At zero cone height, when it is a pure spherical cap with compatible angle (180°-11°), axisymmetric analytical results are found to agree with the experimental results. It is also found that the spherical cap models are highly sensitive to imperfections.

ABSTRACT: The instability under pressure of conical end caps with spherical tips when used as end closures to pressure vessels is studied in this paper. The spherical tip of the conical end cap was assumed to be attached in such a way that continuity of the slope at the cone/sphere junction was maintained. The geometrical parameters of the spherical-tip conical end closure are the ratio r/R; the apex angle of the conical frustum; and the thickness ratio R/h, where r and R are respectively the radius of the cone at the sphere/cone and vessel/cone junctions and h is the thickness of the shell. Governing nonlinear differential equations of axisymmetric deformation which ensure the unique states of lowest potential energy under given pressure have been solved by using the method of multisegment integration, developed by Kalnins and Lestingi. The results show that the critical pressure for the end closure decreases with increasing apex angle at constant values of R/h and r/R. At constant values of _® and R/h, the critical pressure remains constant over a considerable range of r/R and then decreases to a minimum value at r/R = 1Σ0 which corresponds to a purely spherical end cap without the conical extension.

Prashanta Dutta (1), Raisuddin Khan (2), Abdus Salam Akanda (3) and Wahhaj Uddin (1) (1) Mechanical Engineering Department, Bangladesh University of Engineering and Technology, Dhaka, Bangladesh (2) Mechanical Engineering Department, Bangladesh Institute of Technology, Chittagong, Bangladesh (3) Institute of Nuclear Science & Technology, Bangladesh Atomic Energy Commission, Dhaka, Bangladesh

ABSTRACT: The stability of a toroidal pipe-reducer system is determined here from the solution of non-linear governing equations of axisymmetric deformations of shells of revolution. Numerical solutions are obtained by a modified version of the computer program developed by Uddin for solving the governing equations of axisymmetric shells by the multisegment method of integration. The interpretation of instability of the toroidal reducers is based on Thompson's theorems I and II. Critical pressures for the toroidal reducers are calculated over useful ranges of the curvature ratio, the thickness ratio, and the diameter ratio. It has been found that the critical pressure of these reducers varies almost linearly with the diameter ratio and that the long toroidal reducers are prone to local instability near the larger end. But this critical zone occurs near either one of the two ends as the reducer becomes shorter. The results of stability and stress analysis of toroidal pipe-reducers are compared here with those of conical reducers obtained by Ali and parabolic reducers obtained by Rahman. Comparison shows that toroidal reducers develop uniform stresses of lower magnitude compared to the other two. Further, toroidal reducers are found to sustain higher critical pressure than parabolic reducers except at higher diameter ratio.

ABSTRACT: In this paper, a new experimental technique for the buckling test of shells under external pressure is presented. This technique is simple and determines buckling load very efficiently. It has already been used
extensively in the investigation of buckling load of electroformed spherically conical shells under uniform external pressure. In this method, instead of the conventional monitoring of load and linear displacement of points on a shell, load and change in internal volume of the shell are recorded. Internal volumetric change of a shell is found to be a better indicator of its instability compared to the change in displacements of points on its surface. Volumetric change, a function of all the displacements and rotations contributing to the total change in its configuration, is observed to be a highly magnified indicator of shell deformation encompassing the whole shell, primarily the buckling zones and imperfection locations.

References listed at the end of the paper:
interaction with instability is significant, in that imperfections associated with fabrication of shells reduce the load bearing capacity by a significant amount even when thickness is considerable. A specific buckling analysis is used to predict collapse failure of long pressure vessels and pipelines when they are subjected to external over-pressure. The problem of buckling for variable load conditions is relevant for the optimisation of several Nuclear Power Plant applications as, for instance, the IRIS (International Reactor Innovative and Secure) LWR integrated Steam Generator (SG) tubes. In this paper, we consider in addition to the usual assumptions of thin shell, homogeneous and isotropic material, also the tube geometric imperfections and plastic deformations that may affect the limit load. When all those conditions are considered at present, a complete theoretical analysis was not found in the literature. At Pisa University a research activity is being carried out on the buckling of thin walled metal specimen, with reference to several geometries and two different stainless steel materials. A test equipment (with the necessary data acquisition facility), suitable for carrying out many test on this issue, as well as numerical models implemented on the MARC FEM code, were set up. In this report, the results of the performed analyses of critical pressure load determination with different numerical and experimental approaches are presented. The numerical results obtained are compared with the experimental results, for the same geometry and loading conditions, showing a good agreement between these two approaches.

2008 VERSION ABSTRACT: The article presents a study about the buckling behavior of imperfect thin cylindrical shells under lateral pressure. It notes that the behavior of cylindrical shells under external pressure is very sensitive to geometric imperfections. Moreover, when thin shells are subjected to external pressure, the collapse is initiated by yielding. It also emphasizes that buckling phenomenon occurs when most of the strain energy can be converted to the bending energy which requires large deflections. In addition, it discusses the major factors which affect the collapse pressure of pipes such as the diameter-to-thickness ratio, the young's
modulus and the yield stress of the material in the circumference direction. Other details on the buckling behavior of cylindrical shells are discussed.

R. Lo Frano and G. Forasassi (Department of Mechanical, Nuclear and Production Engineering, University of Pisa, Italy), “Influence of the curved geometrical shape on the thin shell buckling phenomenon behavior”, Nuclear Engineering and Design, Vol. 239, No. 7, pp 1229-1236, 2009
ABSTRACT: The present paper deals with instabilities of long homogeneous and isotropic thin shells, characterized by geometrical non-linearities and imperfections, with reference to a bent helicoidally geometrical shape of particular interest for the helicoidal steam generators tube bundle. Apparently no data exist in the literature to describe the non-linear buckling behaviour of curved thin shells under external pressure, thus, the theoretical analyses based on the classical linear elastic theory, as expected, might be inadequate to evaluate the collapse load especially if the curvature is rather large. To the purpose of determining the buckling pressure load the effects of a pre-existing level of geometrical and technological imperfection, unavoidably caused by various manufacturing processes were also considered. A numerical analysis, based on detailed three-dimensional finite element (FE) code, was performed on curved thin shell subject to combined pressure and in-plane bending in order to take into account the non-linear geometrical and material properties as well as to assess and quantify their detrimental effects on the buckling phenomenon behaviour. Moreover, at Pisa University a rather intense experimental research activity is being carried out on the buckling of thin-walled tube specimens in the dimensional range suitable for the above mentioned applications. Collapse experiments have demonstrated that the detriment of the mechanical properties resulted in a reduction in the collapse pressure load of about 15% and the obtained results have highlighted also the dependence of the buckling
behaviour on the stress-initial defects/imperfection width (mainly on the diameter-to-thickness or tube/bending diameters ratios) relationship.

Rosa Lo Frano and Giuseppe Forasassi (Department of Mechanical, Nuclear and Production Engineering, University of Pisa, Italy), “Preliminary analysis of the structural effects due to dynamic loads of the isolated next generation lead cooled reactor”, 20th International Conference on Structural Mechanics in Reactor Technology (SMiRT 20), Espoo, Finland, August 9-14, 2009

ABSTRACT: The main purpose of this preliminary study deals with the evaluation of the structural effects due to the dynamic loads exerted and propagated through the lead coolant during a safety shut down earthquake with reference, as an example, to the isolated ELSY system configuration (CEE-7 Framework Project). Seismic base isolation is increasingly used to protect structures and their contents against dangerous ground motions as well as mitigate the structural effects, on the internals walls and reactor components of the induced dynamic load and of the coupling between coolant and vessel. An adequate predictive numerical modelling, by means a 3-D finite element model, was set up and a non-linear approach was used for the foreseen structural preliminary analyses and simulations of the plant and internals behaviours, in order to describe the interactions among the different subsystems. Moreover the fluid-structure interaction problem, due to the high density of the primary coolant has received a particular attention in relation to the possible hydrodynamic interaction, between lead and the surrounding internals, as well as the sloshing wave motion that may significantly influence the stress level in the reactor pressure vessel. As for the seismic analysis, isolation systems may influence the seismic capacity of as-built structure to reduce the intensity of the propagated seismic loads. Numerical results are presented and discussed highlighting the importance of the fluid-structure interaction effects as well as the isolation technique effectiveness, which is expected to be effective in raising the reliability of internals and vessel structures, during an earthquake event.

ABSTRACT: The current research seeks to demonstrate that an inverse solution approach, leveraging nonlinear finite element analysis with a divide and conquer type stochastic search algorithm, can identify the presence of localized denting imperfections in cylindrical shell structures. This imperfection field identification is achieved using rather sparse displacement measurements taken at safe, service loading conditions. Both the existence and nature of the imperfection field present in a given shell structure instance are determined. These inferred imperfections are subsequently used to make reasonably accurate predictions regarding the actual shell structure strength at ultimate loading.

ABSTRACT: It is now widely known that the presence of geometric imperfections in shell structures constitutes an important contribution to the discrepancy between theoretical and experimentally realizable ultimate loads governed by buckling. The present paper describes a method by which an actual initial imperfection field may be estimated using the service load response of a shell structure. The approach requires solving a stochastic inverse problem wherein uncertainty regarding initial imperfection predictions is expressed within the context of a Bayesian posterior distribution. The proposed approach could be applied to condition assessment and performance evaluation activities in practice.

ABSTRACT: The paper takes a phenomenological (topological) look at the Shanley model. Allowable loading sequences of a perfect system are first traced in closed form. By employing the smoothly-varying properties of an associated elastic potential function, comparisons are then made between the asymptotic predictions of a standard perturbation procedure, and a new scheme developed in accordance with the underlying topology. The new scheme is found to converge rapidly to the exact equilibrium paths, indicating compatibility in a global as well as a localized sense.

ABSTRACT: The recognized harmonic buckling modes for the elastic axially-loaded cylinder are by nature symmetric, equal and opposite amplitudes giving equal energy levels. On the other hand, in combination they account for considerable asymmetry, inwards deflection being fundamentally different from outwards; this asymmetry is also apparent in the underlying differential equations, and in the final large-deflection Yoshimura pattern. Taking the view that underlying symmetries are closely linked to the form of bifurcation experienced on buckling, and hence to the gross instability of the phenomenon, the paper thus explores a classic problem in a new light. The wellknown Donnell equations are first employed, the analysis being neatly written in terms of the two variables radial displacement w and stress function phi. An extension is then presented, derived from the full strain-displacement equations appropriate to genuinely large deflections. This makes use of a suite of computer programs, written for a small micro, which handle the required manipulations of multiplication and integration of harmonic functions in algebraic rather than numerical fashion.

ABSTRACT: The paper presents a selective review of modern bifurcation theory and its relationship to structural instability, with consequent implications for structural design. In particular, the complex non-linear analysis that is sometimes found in such work is avoided, by concentrating instead on easily recognizable symmetry properties. Simple spring and rigid-link models, such as the well-known Shanley model, are used to aid description...

ABSTRACT: Double-scale perturbation analysis of a long elastic cylindrical shell under axial compression reveals a second-order non-linear differential equation for the buckle-pattern amplitude in slow-space. Numerical solution then suggests that the most easily-triggered failure mode is localized along the length. The method is extended to include mode interaction, giving three coupled second-order non-linear differential equations in slow-space. Localized solutions are again found, by combining features of the Lagrangian function with a systematic numerical search procedure. The predicted extent of the localization, about one-and-a-half axial wavelengths when fully developed, compares well with published experiments on long cylinders. Moreover, in contrast to the associated periodic solutions, “square” waves at the minimum critical load are denied; the predominant waveform turns out to be long axially, again as seen experimentally.

ABSTRACT: Localization theory for long continuous structures is extended to the buckling of a thin elastic strut supported by a bilinear elastoplastic medium. It is demonstrated that the form of localization has much in common with the buckling of struts on linear and nonlinear elastic foundations in that the localized response, which is of the greatest practical significance, is accompanied by a myriad of associated less significant solutions including periodic ones. Special shooting techniques are developed to deal with the problem of finding the localized solutions from amongst all competing possibilities.

ABSTRACT: Buckling is investigated of a long thin cylindrical shell under longitudinal compression as modelled by the von Kármán–Donnell equations. Evidence is reviewed for the buckling being localized to some portion of the axial length. In accordance with this observed behaviour the equations are first approximated circumferentially by a Galerkin procedure, whereupon cross-symmetric homoclinic solutions of the resulting system of ordinary differential equations are sought in the axial direction. Results are compared with experimental and other numerical data. Excellent agreement with experiments is achieved with fewer approximating modes than other methods.

ABSTRACT: A structural system with an unstable post-buckling response that subsequently restabilizes has the potential to exhibit homoclinic connections from the fundamental equilibrium state to itself over a range of loads, and heteroclinic connections between fundamental and periodic equilibrium states over a different (smaller) range of loads. It is argued that such equilibrium configurations are important in the interpretation of observed behaviour, and govern the minimum possible post-buckling loads. To illustrate this, the classical problem of a long thin axially-compressed cylindrical shell is revisited from three different perspectives: asymptotic conjecture, analogy with nonlinear dynamics, and numerical continuation analysis of a partial spectral decomposition of the underlying equilibrium equations. The nonlinear dynamics analogy demonstrates that the structure of the heteroclinic connections is more complicated than that indicated by the asymptotics: this is confirmed by the numerics. However, when the asymptotic portrayal is compared to the numerics, it turns out to be surprisingly accurate in its Maxwell-load prediction of the practically-significant first minimum to appear in the post-buckling regime.

ABSTRACT: Experiments have shown that long cylinders buckle into localized patterns axially. It is argued that traditional linear or nonlinear analysis is unlikely to capture such modes, nor the effective buckling load at which such responses stabilize. However, the inherent translational indeterminacy of localized buckling is well captured by considering infinitely long cylinders and seeking homoclinic solutions of the von Kármán Donnell equations. This exploits the dynamical analogy of such structural problems, so that symmetry arguments and numerical techniques developed for dynamical systems may be used. The method is illustrated by successful application to a cylinder which has well documented experimental results.

ABSTRACT: This paper concerns numerical computation of localized solutions in partial differential equations (PDEs) on unbounded domains. The application is to the von Kármán--Donnell equations, a coupled system of elliptic equations describing the equilibrium of an axially compressed cylindrical shell. Earlier work suggests that axially localized solutions are the physically preferred buckling modes. Hence the problem is posed on a cylindrical domain that is unbounded axially and solutions are sought which are homoclinic in the axial variable and periodic circumferentially. The numerical method is based on a Galerkin spectral decomposition circumferentially to pose ordinary differential equations (ODEs) in the unbounded coordinate. Methods for location and parameter continuation of homoclinic solutions of ODEs are then adapted, making special use of the symmetry and reversibility properties of solutions observed experimentally. Thus a formally well-posed continuation problem is reduced to a rotational subgroup circumferentially and posed over a truncation of the
half-interval axially. The method for location of solutions makes use of asymptotic approximations where available. More generally, an adaptation of the "successive continuation" shooting method is used in the lowest possible number of circumferential modes, followed by additional homotopies to add more modes by continuation in the strength of nonlinear mode-interaction terms. The method is illustrated step by step to produce a variety of homoclinic solutions of the equations and compute their bifurcation diagrams as the loading parameter varies. Good agreement with experimental data is found. All computations are performed using AUTO. The techniques illustrated here for the von Kármán--Donnell equations are applicable to a wider class of PDEs.

ABSTRACT: We study the deformation of an elastic strut on a nonlinear Winkler foundation subjected to an axial compressive load P. Using multi–scale analysis and numerical methods we describe the localized, cellular, post–buckled state of the system when P is removed from the critical load P = 2. The solutions, and their modulation frequencies, differ significantly from those predicted by weakly nonlinear analysis very close to P = 2. In particular, when P approaches the Maxwell load PM , the localized solutions approach a large–amplitude heteroclinic connection between an unbuckled solution and a periodic solution. An asymptotic description of PM in terms of the system parameters is given. The agreement between the numerical calculations and the asymptotic approximations is striking.

ABSTRACT: A hypothesis for the prediction of the circumferential wavenumber of buckling of the thin axially-compressed cylindrical shell is presented, based on the addition of a length effect to the classical (Koiter circle) critical load result. Checks against physical and numerical experiments, both by direct comparison of wavenumbers and via a scaling law, provide strong evidence that the hypothesis is correct.

ABSTRACT: A personal view is presented of developments in the non-linear mechanics of structural buckling over more or less the past four decades. The era has been one of unprecedented change and development in the world of science as a whole, and this is acknowledged by describing ways in which the field has interacted strongly with other areas of study, including mathematics, non-linear dynamics and chaos and structural geology. A framework is provided through two key conferences that have emerged as pivotal moments in time when ideas seemed to take shape in a collective sense rather than just with individuals. Throughout most of the paper, the buckling of the axially compressed cylindrical shell is used to illustrate key features, including the breaking of hidden symmetry, localization and snaking solutions leading to a minimum energy periodic state that accords with a revitalized Maxwell stability criterion. The paper closes with some thoughts to the future, including the modelling of layered structures in geology and potential uses of modern composites.

ABSTRACT: Buckling-driven delamination is considered among the most critical failure modes in composite laminates. This paper examines the propagation of delaminations in a beam under pure bending. A pre-developed analytical model to predict the critical buckling moment of a thin sub-laminate is extended to account for propagation prediction, using mixed-mode fracture analysis. Fractography analysis is performed to distinguish between mode I and mode II contributions to the final failure of specimens. Comparison between experimental results and analysis shows agreement to within 5 per cent in static propagation moment for two different materials. It is concluded that static fracture is almost entirely driven by mode II effects. This result
was unexpected because it arises from a buckling mode that opens the delamination. For this reason, and because of the excellent repeatability of the experiments, the method of testing may be a promising means of establishing the critical value of mode II fracture toughness, $G_{IIc}$, of the material. Fatigue testing on similar samples showed that buckled delamination resulted in a fatigue threshold that was over 80 per cent lower than the static propagation moment. Such an outcome highlights the significance of predicting snap-buckling moment and subsequent propagation for design purposes.

ABSTRACT: Similarities and differences between the phenomena of kink banding in compressed layered structures and shear banding in compressed granular media are explored. Simple models are introduced for both, and the focus is directed onto how they can nucleate from the perfectly flat state. A convincing scenario is found for each in which a mode develops from an initial bifurcation into a periodic state, followed by rapid localization under falling load, while retaining decaying but wavy tails. At a certain lower critical load, the tails lose their waviness, and the expected form of the kink or shear band appears. In each case, good numerical evidence is provided for the existence of this form of behaviour. A second potential instability for the layered case is also explored, linked to the appearance of a critical force dipole that overcomes bending stiffness locally at some point along the length. This mode, which should appear with non-wavy decaying tails at the lower of the two critical loads mentioned earlier, proves somewhat elusive. Evidence is found for its existence in the linearized approximation to the layered model, but the search for numerical solutions to the underlying nonlinear equation is hindered by a shortage of suitable boundary conditions.

ABSTRACT: The two- and three-dimensional contact algorithms used in the finite element programs developed at the Lawrence Livermore National Laboratory are described in this paper. We are interested in both static contact and dynamic impact problems and, consequently, have pursued the development of two different algorithms. The first, based on the hydrocode technology of the sixties, is implemented in our two- and three-dimensional explicit finite element codes. The second, a symmetric penalty treatment, is used in our implicit codes and is optional in the explicit codes. The penalty methods are used to obtain solutions to almost all of our structural problems but we find that the hydrocode approach is vastly superior if pressures greatly exceed the yield strength. Examples are provided to show practical applications of both approaches.

ABSTRACT: In some of our applications we are interested in how a structure behaves after it buckles. When a structure collapses completely, a single surface may buckle enough that it comes into contact with itself. The traditional approach of defining master and slave contact surfaces will not work because we do not know a priori how to partition the surface of the structure. This paper presents a contact algorithm that requires only a single surface definition for its input.
ABSTRACT: This report provides a user's manual for NIKE3D, a fully implicit three-dimensional finite element code for analyzing the finite strain static and dynamic response of inelastic solids, shells, and beams. Spatial discretization is achieved by the use of 8-node solid elements, 2-node truss and beam elements, and 4-node membrane and shell elements. Over twenty constitutive models are available for representing a wide range of elastic, plastic, viscous, and thermally dependent material behavior. Contact-impact algorithms permit gaps, frictional sliding, and mesh discontinuities along material interfaces. Several nonlinear solution strategies are available, including Full-, Modified-, and Quasi-Newton methods. The resulting system of simultaneous linear equations is either solved iteratively by an element-by-element method, or directly by a factorization method, for which case bandwidth minimization is optional. Data may be stored either in or out of core memory to allow for large analyses.

ABSTRACT: In this article we discuss the treatment of contact—impact modeling in a large deformation explicit dynamic setting. Such problems are posed mathematically by demanding the usual satisfaction momentum balance equations and boundary conditions for each body separately, while imposing an additional set of constraints that govern the interaction of these bodies with each other. In applying such methods to contact problems we emphasize two requirements: first, that the treatment of contact should follow from the development of the local (weak) and global (strong) forms of the contact equations in the continuum setting. Algorithms developed from this framework are seen to readily handle the three-dimensional multi-body friction case. Second, and equally important especially in large applications is the practical aspect of computing the closest point projection for contact nodes, an essential component of defining the contact constraints. This calculation is global in nature, accounting for the fact that contact—impact involves multiple bodies interacting in unforeseeable ways. These requirements have guided the development of algorithms capable of treating contact—impact in PRONTO3D (M.W. Heinstein, S.W. Attaway, J.W. Swegle, F.J. Mello, A general purpose contact detection algorithm for nonlinear structural analysis codes, SAND92-2141, Sandia National Laboratories, Albuquerque, N-87185, 1992) are discussed in this paper.

CONCLUSIONS: Decisive factors, which have a considerable effect on the stability of cylindrical shells with exfoliations are the area of the region of the exfoliations, the location of the exfoliation region along the thickness and length of the shell, and the nature (discontinuity) of the exfoliation along the length of the shell. The strongest effect on the stability proves to be the exfoliations, equidistant from the annular reinforcing ribs and situated in the neighborhood of the middle surface of the shell. With the arrangement at the end of the shell, what is most dangerous is the discontinuous exfoliation, and in the middle part, continuous exfoliation. The nature of the exfoliation in the circumferential direction does not have a noticeable effect on the critical load of
the total stability of the shell. But we should expect a considerable reduction of the local stability (fracture by separation of the inner layers). The prediction and calculation of such a form of fracture is an independent problem, which has not been considered in the present study. An increase in the value of the opening of exfoliation, which has an effect on the bending stiffness and extension (compression) stiffness leads to a reduction in the critical load. The formulas presented for the critical load can be applied for normalization of the exfoliations. The calculation of such norms assumes the carrying out of a series of tests, as a result of which there should be agreement between calculated and experimental data, and margins of stability are introduced, ensuring reliable operation of shells with defects. The assumption of norms for the defects is economically profitable, since it enables us to use shells having exfoliations whose effects on the critical loads are no significant.

ABSTRACT: The effects of the presence of a delamination on the buckling load of composite laminates under compression are investigated. The linearized buckling analysis for two- and three-dimensional solid finite elements is proposed as an effective and practical tool for the prediction of the critical loads both for bi-dimensional and for tri-dimensional cases. The accuracy of the numerical procedure is assessed by comparing the results with existing analytical solutions obtained from the literature for simple bi-dimensional applications. A tri-dimensional analysis is then presented for the case of a square plate with a circular delamination. The effects of radius and depth of the delamination on the buckling load are also illustrated.

ABSTRACT: The post-buckling behaviour of compressed composite laminates in presence of a through-width delamination is considered. A 2D finite element procedure is proposed as an effective and practical tool for the nonlinear analysis of the examined structure. An incremental analysis is performed with the introduction of contact constrains to fully account for the real behaviour of the structure. Some illustrating examples are then presented which show the effect of the geometry of delamination on the post-buckling behaviour. Local and global buckled geometries of the deformed structures are also shown corresponding to different levels of the compressive loading.

ABSTRACT: The present study focuses on the determination of the buckling load and post-buckling behaviour of simply supported laminated composite rectangular panels loaded in shear. The nonlinear structural response is studied with a non-linear finite element approach. In order to determine the accuracy of the procedure, several tests have been performed comparing the finite element solutions for isotropic and laminated composite rectangular panels with existing ones, adopting different sequences of lamination and different length to width ratios. The analysis then considers the behaviour of laminates produced with innovative thermoplastic matrix composites developed in the frame of a national research program.

P Gaudenzi, P Perugini, A Riccio, Post-buckling behavior of composite panels in the presence of unstable delaminations, Composite Structures 51 (3), 301-309, 2001
ABSTRACT: The analysis of the non-linear behavior of delaminated composites panels under compression is considered. A modification to the incremental continuation method (by Riks) for the analysis of the non-linear behavior of damaged composites is proposed to improve the numerical treatment of the analysis of unstable delamination growth. The theoretical formulation of this modification is first presented in conjunction with a general formulation of the continuation method and the modified virtual crack closure technique (MVCCT) for the evaluation of delamination growth. Finally, numerical results for delaminated composite plates through the width and circular delaminations are presented and compared with existing experimental and numerical data.

ABSTRACT: The buckling and postbuckling behaviors of composite laminates with multiple delaminations under uniaxial compression are experimentally studied. The through-width multiple delaminations with triangular shape are used to simulate impact damage. A nonlinear buckling analysis from finite element method is also used to predict the buckling loads that are compared with experimental results. The critical delamination growth loads of multiple delaminations are obtained from postbuckling tests. The difference of single delamination and multiple delaminations on buckling behavior and postbuckling behavior is discussed. The results indicate that the buckling loads obtained by the nonlinear buckling analysis are in reasonable agreement with the experimental values. Experiments have proven that short delaminations distributed under the near-surface, long delamination have no effects on the buckling loads. The critical delamination growth loads of single-delamination specimens are much higher than those of multiple-delamination specimens, and the shape of the triangular multiple delaminations can affect the critical delamination growth loads.

ABSTRACT: Finite element procedures for the analysis of composite structures under compressive loads (buckling and post-buckling) generally are not deployed in books because they are still considered object of research whereas they are deemed as assessed by researchers that focus their papers on restricted audience topics. Therefore, regarding these procedures, a gap exists in literature between what researchers consider as well established and what has been already published. The aim of this paper is to contribute to close this gap by providing an insight in linear and non-linear buckling analyses and in their use with composite structures. Both modelling and analysis considerations are presented and discussed, focusing on what can be considered as best practice when dealing with this kind of problems. Applications (to a stiffened panel and to a wing box) are provided for demonstrating the effectiveness of the procedures presented.

ABSTRACT: An approximate method for analyzing the elastic buckling of Mindlin plates is proposed. The solutions of the differential equations of buckling of Mindlin plate are obtained in discrete forms by applying numerical integration. The discrete solutions give the transverse shear forces, twisting moment, bending moments, rotations and deflection at the all discrete points which are the intersections of the vertical and horizontal equally dividing lines on the plate. In order to confirm the convergency and accuracy of numerical solutions, the buckling loads of simply supported square Mindlin plates are calculated, and the results are compared with other published finite element solutions. As an application, the buckling loads and buckling modes of Mindlin plates with various types of mixed boundaries are calculated.

ABSTRACT: A discrete method is proposed for analyzing the natural vibration problem of rectangular plates with a line hinge. The fundamental differential equations and the solutions of these equations are derived for two parts of the plate, which are obtained by dividing the plate along the line hinge. By transforming these equations into integral equations, and using numerical integration and the continuous conditions along the line hinge, the solutions of the whole plate can be expressed by the unknown quantities on the boundary and the quantities of the rotation along the hinge. The Green function of the deflection problem is used to obtain the characteristic equation of the free vibration. The effects of the position of the line hinge, the aspect ratio, the thickness ratio and the boundary condition on the natural frequency parameters are considered. By comparing the numerical results obtained by the present method with those previously published, the efficiency and accuracy of the present method are investigated.

“Reference surface element modelling of composite plate/shell delamination buckling and postbuckling”,
ABSTRACT: A recently developed reference surface element technique is used to model the behaviour of
the buckling and postbuckling of delaminated plates and shells. The technique can be easily incorporated into any
finite element analysis programme for which the beam, plate and shell elements etc. satisfy the Reissner–
Mindlin assumption. In this paper, the reference surface element formulation of a four-node Co quadrilateral
membrane-shear-bending element (ZQUA24) is presented and numerical investigations are performed for
composite plates and shells with various delamination shapes. The numerical results show that the present
technique is simple, reliable and able to model delamination buckling and postbuckling behaviour of laminated
plates or shells. Observations of practical engineering significance are obtained from the study.

ABSTRACT: The subject of this paper is the buckling of laminated plates, with a pre-existing delamination,
subjected to in-plane loading. Each laminate is modelled as an orthotropic Mindlin plate. The analysis is carried
out by a combination of the finite element and asymptotic expansion methods. By applying the finite element
method, plates with general delamination regions can be studied. The asymptotic expansion method reduces the
number of unknown variables of the eigenvalue equation to that of the equation for a single Kirchhoff plate.
Numerical results for the critical buckling load are presented for several examples. The effects of the shape, size
and position of the delamination on the buckling load are studied through these examples.

ABSTRACT: The compressive strength of composite plates can be considerably reduced if they are damaged
by delaminations. To study the failure process buckling loads of laminates that contain rectangular, circular and
elliptical delaminations are calculated using two models based on the Rayleigh-Ritz and finite element method.
The influence of several parameters such as stacking sequence, flaw size, flaw location and flaw shape is
investigated and the results are plotted in diagrams. It can be distinguished between local buckling of the
debonded sublamine, buckling of the total plate and an interaction of both cases.
ABSTRACT: Delamination buckling of laminated composite structures with curvature, plays a critical role in affecting the compressive behavior as it may cause localized buckling and the high interlaminar shear and normal stresses at the edges of the buckled regions which often lead to delamination growth. Since an early contribution by Kachanov[1], the delamination buckling problems have received substantial attention in last decade. Chai et al.[2] modelled delamination buckling and crack growth of laminated plates using a simple one-dimensional beam theory. The energy release rate, was computed by evaluating the total potential energy of the plate and differentiating the result with respect to the variable length of delamination which determines the stability characteristics of delamination growth. Whitcomb[3, 4] who is among the first to use a nonlinear finite element method for analyzing local post-buckling of an embedded delamination in laminated plate considered the influence of crack tip mode dependence and contact at delamination buckling in a three-dimensional finite element formulation.

ABSTRACT: Location of delamination is a triggering parameter for structural instability of laminated composites. In this paper, a finite element method is employed to determine the effects of location of delamination on free vibration characteristics of graphite-epoxy cross-ply composite pre-twisted shallow conical shells. The generalized dynamic equilibrium equation is derived from Lagrange’s equation of motion neglecting Coriolis effect for moderate rotational speeds. The formulation is exercised by using an eight noded isoparametric plate bending element based on Mindlin’s theory. Multi-point constraint algorithm is utilized to ensure the compatibility of deformation and equilibrium of resultant forces and moments at the delamination crack front. The standard eigen value problem is solved by applying the QR iteration algorithm. Finite element codes are developed to obtain the numerical results concerning the effects of location of delamination, twist angle and rotational speed on the natural frequencies of cross-ply composite shallow conical shells. The mode shapes are also depicted for a typical laminate configuration. Numerical results obtained from parametric studies of both symmetric and anti-symmetric cross-ply laminates are the first known non-dimensional natural frequencies for the type of analyses carried out here.

ABSTRACT: This paper deals with the development of the linearized equation governing the buckling behavior of moderately thick, anisotropic, laminated, and sandwich cylindrical shell panels faced with fiber-reinforced plastic under uniform shear and normal membrane forces. The formulation takes into account the transverse shear flexibility. Two approaches for the approximate solution of the elastic stability equation are developed. The first approach is an analytical approach of the Galerkin type and rests upon the principle of virtual work. The second is a finite-element displacement approach. Some numerical results are presented and compared with other results from the open literature.

ABSTRACT: In a recent paper, the author has developed the equations governing the elastodynamic behaviour of moderately thick multilayered anisotropic plates by making use of a displacement field which allows a non-linear variation of the inplane displacements through the laminate thickness and fulfils a priori the static and geometric continuity conditions. In the present paper, the author specializes those results by developing a third-order shear deformation plate model with continuous interlaminar stresses. To show the accuracy and reliability of the proposed approach, closed-form solutions are given and compared with results from three-dimensional elasticity and other approximate bidimensional plate models with and without continuous interlaminar stresses. Based on the numerical investigation conducted, the proposed approach appears to work very well.

PARTIAL ABSTRACT: A theory of multilayered anisotropic plates featuring interlaminae imperfections in the form of interlayer slips is presented. The theory rests upon a representation of the displacement field which: i) fulfills a priori the transverse shear stress continuity conditions at each interface of the laminate and the free traction on the top and bottom external planes of the plate, ii) satisfies the requirement of continuous displacements at the perfectly bonded interfaces, and iii) allows for jumps in the in-plane displacements when slip-type interlayer imperfections are present. Numerical results illustrating their implications upon the linear and nonlinear static response of laminated plates are displayed and pertinent conclusions are…

ABSTRACT: The role of mesh design in the post-buckling analysis of delamination in composite laminates is addressed in this paper. The determination of the strain energy release rate (SERR) along the crack front is central to the analysis. Frequently, theoretical analysis is limited to treatment of the problem in two dimensions, since considerable complexity is encountered in extending the analysis to three dimensions. However, many practical problems of embedded delamination in composite laminates are inherently three-dimensional in nature. Although in such cases, the finite element (FE) method can be employed, there are some issues that must be examined more closely to ensure physically realistic models. One of these issues is the effect of mesh design on the determination of the local SERR along the delamination front. There are few studies that deal
with this aspect systematically. In this paper, the effect of mesh design in the calculation of SERR in two-dimensional (2D) and three-dimensional (3D) FE analyses of the post-buckling behavior of embedded delaminations is studied and some guidelines on mesh design are suggested. Two methods of calculation of the SERR are considered: the virtual crack closure technique (VCCT) and crack closure technique (CCT). The 2D analyses confirm that if the near-tip mesh is symmetric and consists of square elements, then the evaluation of the SERR is not sensitive to mesh refinement, and a reasonably coarse mesh is adequate. Despite agreement in the global post-buckling response of the delaminated part, the SERR calculated using different unsymmetrical near-tip meshes could be different. Therefore, unsymmetrical near-tip meshes should be avoided, as convergence of the SERR with mesh refinement could not be assured. While the results using VCCT and CCT for 2D analyses agree well with each other, these techniques yield different quantitative results when applied to 3D analyses. The reason may be due to the way in which the delamination growth is modeled. The CCT allows simultaneous delamination advance over finite circumferential lengths, but it is very difficult to implement and the results exhibit mesh dependency. Qualitatively, however, the two sets of results show similar distributions of Mode I and Mode II components of the SERR. This is fortunate, since the VCCT is relatively easy to implement.

“Delamination buckling and propagation analysis of honeycomb panels using a cohesive element approach”,

ABSTRACT: The cohesive element approach is proposed as a tool for simulating delamination propagation between a facesheet and a core in a honeycomb core composite panel. To determine the critical energy release rate (Gc) of the cohesive model, Double Cantilever Beam (DCB) fracture tests were performed. The peak strength (sigma c) of the cohesive model was determined from Flatwise Tension (FWT) tests. The DCB coupon test was simulated using the measured fracture parameters, and sensitivity studies on the parameters for the cohesive model of the interface element were performed. The cohesive model determined from DCB tests was then applied to a full-scale, 914 x 914 mm (36 x36 in.) debond panel under edge compression loading, and results were compared with an experiment. It is concluded that the cohesive element approach can predict delamination propagation of a honeycomb panel with reasonable accuracy.

ABSTRACT: An energy functional for a structure on a nonlinear softening foundation is worked into two different lagrangian forms, in fast and slow space respectively. The developments originate independently of the underlying differential equation, and carry some quite general features. In each case, the kinetic energy is an indefinite quadratic form. In fast space, this leads to an escape phenomenon with fractal properties. In slow space, kinetic energy is added to a potential contribution that is familiar from modal formulations. Together, and in conjunction with a recent set of numerical experiments, they illustrate the extra complexities of localized, as opposed to distributed periodic, buckling.

ABSTRACT: A long structural system with an unstable (subcritical) post-buckling response that subsequently restabilizes typically deforms in a cellular manner, with localized buckles first forming and then locking up in sequence. As buckling continues over a growing number of cells, the response can be described by a set of
lengthening homoclinic connections from the fundamental equilibrium state to itself. In the limit, this leads to a heteroclinic connection from the fundamental unbuckled state to a post-buckled state that is periodic. Under such progressive displacement the load tends to oscillate between two distinct values. The paper is both a review and a pointer to future research. The response is described via a typical system, a simple but ubiquitous model of a strut on a foundation which includes initially-destabilizing and finally-restabilizing nonlinear terms. A number of different structural forms, including the axially-compressed cylindrical shell, a typical sandwich structure, a model of geological folding and a simple link model are shown to display such behaviour. A mathematical variational argument is outlined for determining the global minimum postbuckling state under controlled end displacement (rigid loading). Finally, the paper stresses the practical significance of a Maxwell-load instability criterion for such systems. This criterion, defined under dead loading to be where the pre-buckled and post-buckled state have the same energy, is shown to have significance in the present setting under rigid loading also. Specifically, the Maxwell load is argued to be the limit of minimum energy localized solutions as end-shortening tends to infinity.

ABSTRACT: A variational model is formulated that accounts for the localization of deformation due to buckling under pure bending of thin-walled elastic tubes with circular cross-sections. Previous studies have successfully modelled the gradual process of ovalization of the cross-section with an accompanying progressive reduction in stiffness but these theories have had insufficient freedom to incorporate any longitudinal variation in the tube. Here, energy methods and small-strain nonlinear elastic theory are used to model the combined effects of cross-section deformation and localized longitudinal buckling. Results are compared with a number of case studies, including a nanotube, and it is found that the model gives rise to behaviours that correlate well with some published physical experiments and numerical studies.

Marc Fischer, David Kennedy (Cardiff School of Engineering, Cardiff University, PO Box 686, The Parade, Cardiff CF24 3TB, United Kingdom), “Local Postbuckling Analysis Of Curved Aerospace Structures”, ICAS 2000 Congress, no date or publisher given in the pdf file, 2000?

ABSTRACT: Minimum mass design of aerospace structures is greatly enhanced by allowing for their postbuckling reserve of strength, which is mainly due to stress re-distribution within the structure following buckling in a local mode. The paper first outlines a geometrically non-linear analysis for longitudinally compressed panels, in which the ratio of postbuckling to prebuckling axial stiffness is established by an iterative procedure, critical buckling loads and mode shapes being found by an ‘exact strip’ algorithm. The analysis is
illustrated by its application to a simply supported, curved, stiffened panel. The paper next describes an incremental approach to the local postbuckling analysis of longitudinally stiffened cylindrical shells loaded by longitudinal compression and/or a bending moment. The shell is modelled as a collection of skin/stiffener portions, for each of which the critical buckling load and stiffness ratio are determined. Next the axial loads in each portion due to the applied loads are calculated under linear elastic assumptions, so that it is possible to determine which portion will buckle first. Thereafter the buckled portion is modelled with a reduced stiffness, so that the location of the shell’s neutral axis changes and is found by an iterative improvement to a method originally developed by Bruhn.

“VICONOPT: Program for exact vibration and buckling analysis or design of prismatic plate assemblies”,

ABSTRACT: A summary is given of key features of the computer program VICONOPT, which covers prismatic assemblies of anisotropic plates exactly for buckling and vibration analysis and also for design subject to buckling constraints.

References listed at the end of the paper:

SUMMARY: The aim of this thesis is to investigate the local and global buckling behaviour of delaminated composite plates using exact stiffness analysis. Several attempts are made to model delamination with the accuracy of detailed 3D finite element analysis (FEA) but substantially improved computational efficiency. Investigation of local buckling behaviour is performed using the exact stiffness program VICONOPT, giving
good comparative results and substantially less solution times compared to those of FEA. Extending this approach to global buckling behaviour poses limitations and difficulties in retaining computational efficiency. Several techniques are introduced to study global buckling behaviour while requiring less solution time than FEA. The advantages and disadvantages of these techniques are discussed. Finally, an improved smeared stiffness method is derived which results from simplification of the total potential energy expression for the plate. This simplification avoids expensive computational effort while maintaining results of good accuracy (within 2%-3% of FEA results). This method can be employed for modelling delaminations of different shape and size located anywhere in the composite plate.

ABSTRACT: For a structure subjected to an intermediate velocity impact in which the duration of loading is in the order of milliseconds and in excess of the period of its first free vibration mode there is a relationship between impact duration and buckling load. Although this relationship results in higher buckling loads for shorter duration impacts, the precise nature of the correlation depends on a number of other factors, one of which is geometry. Since the design of many lightweight structures subject to dynamic loading in this intermediate range is based on the use of a static buckling load to which a load factor is then applied, it is essential that this factor accurately represents the relationship between the two and takes of account of any variations. Failure to do so will at least result in an over designed structure and at worst in catastrophic failure.

ABSTRACT: The critical buckling of composite plates with through-the-length delaminations is studied using exact stiffness analysis and the Wittrick–Williams algorithm. Computational efficiency is achieved by avoiding discretisation into elements, making the method suitable for preliminary aircraft design. Numerical results for longitudinal, transverse and shear loading show a transition from global to local buckling modes as the delamination width is increased. The critical buckling strength is dramatically reduced as the delamination is moved towards the plate surface, but is relatively insensitive to its widthwise location or to the edge conditions. The results are compared with finite element analysis.

ABSTRACT: Recent developments in optical techniques have allowed accurate representations of the geometry of test specimens to be obtained. These enable the nature of geometric imperfections resulting from manufacture or set-up to be captured in a form which allows them to be incorporated directly into models generated to predict the behaviour of the structure. This study examines the effect of such imperfections on the behaviour of a series of panels, simply supported along all four edges, and subject to uniaxial compressive in-plane loading. In each case, digital image correlation is used to determine the initial profile and set-up of the panel and to monitor its behaviour during test. The data are used to automatically generate a series of meshes representative of each of the specimens tested, suitable for finite element analysis. Comparison of the results obtained from these analyses with those found during the experiments modelled shows an improved correlation when compared with standard techniques for assessing imperfection sensitivity. Set-up is straightforward, and models can be obtained quickly based on the data collected.

ABSTRACT: The post-buckling behavior of a stiffened panel is investigated in this paper. Firstly, the buckling mode of the stiffened panel is obtained using the linear buckling eigenvalue method. Then, the collapsing strength of the stiffened panel is calculated using the ultimate strength method based on large deflection orthotropic plate theory. In addition, nonlinear finite element analysis is performed to predict the post-buckling behavior of the stiffened panel. By comparing the model prediction and the analytical results of ultimate strength, it is shown that good accuracy can be achieved, especially for the method referring to membrane stress in mid-thickness of equivalent orthotropic plate. It suggests that the proposed method can predict the ultimate strength of whole stiffened panel accurately and effectively.

ABSTRACT: Computer programs which model the static, dynamic and aeroelastic response of wing structures, and which permit optimisation of such structures, have been under development for more than 30 years. However, the industrial application of these programs remains small. This paper provides an overview of some of the existing optimisation methods which may be applied at various stages during the design of wing
structures. An indication of the variety of design variables, constraints and objective functions available within these methods is given. Some general conclusions are drawn, about both the limitations and potential application of such structural optimisation techniques.

ABSTRACT: The suitability of using the efficient, linear elastic design software VICONOPT for the analysis of a stiffened panel with a postbuckling reserve of strength is investigated. A longitudinally compressed panel, which initially buckled in a local skin mode, was analyzed with allowance being made for the effects of an initial overall imperfection. The panel was also analyzed using the nonlinear finite element package ABAQUS. and four laboratory specimens that represent the panel were tested to failure. The similarity of the experimental failure with the VICONOPT and ABAQUS predictions indicates that VICONOPT can give satisfactory analysis results for use in preliminary design.

ABSTRACT: Postbuckling results are presented for isotropic stiffened panels loaded in compression. Comparisons are made between single-bay and double-bay finite element (FE) models (where bay denotes a repeating portion, between supports, in the load/length direction) and a new strut model, following a Shanley-type approach, for single-bay and multibay panels. The strut model has been incorporated within the strip program VIPASA with CONstrains and OPTimization (VICONOPT) to design a multibay example panel with postbuckling reserve of strength in its skins, assuming linear elastic material properties. The panel has been shown by VICONOPT to have a stiffener buckling failure mode when an overall sinusoidal imperfection causing increased stiffener compression is present. The failure is confirmed by the double-bay FE model, which is shown to be an imperfect representation of the multibay case. Single-bay analysis using the strut model shows good agreement with the single-bay FE results. The VICONOPT code is able to design a metallic panel of realistic dimensions and loading using 50 strip elements (compared with the 9600 shell elements required by the finite element model) but cannot correctly account for material nonlinearity. The important phenomenological difference between postbuckling of single-, double-, and multibay panel models are indicated.

G. W. Hunt, B. Hu, R. Butler, D. P. Almond, J. E. Wright (University of Bath, Bath, BA2 7AY, UK),
ABSTRACT: A phenomenological overview of the buckling and postbuckling of fully and partially delaminated struts is developed using a simple four-degree-of-freedom nonlinear Rayleigh-Ritz formulation. Bifurcation analysis indicates that instability occurs in general at an asymmetric point of bifurcation. After bifurcation, realistic solutions are seen to follow the stable part of the postbuckling path, with the unstable branch being denied by contact between the contributing laminates. Depending on the geometry and position of
the delamination, thoroughly stable (thin-film), effectively neutral (overall), or potentially unstable (mixed-mode) buckling can occur in the postbuckling range. Numerically obtained equilibrium solutions of the model are found to compare well with those obtained using the finite element code ABAQUS. Critical delamination depths, where the response undergoes a change in form, are discovered at positions of secondary bifurcation. The multiplicity of equilibrium solutions that arise at such points are seen to cause possible problems of path selection for standard finite element routines.

ABSTRACT: The paper presents a bilevel strategy for the efficient optimum design of composite stiffened panels using VICONOPT, a fast-running optimization package based on linear eigenvalue buckling theory, and embracing practical composite design rules. Panel level optimization finds a minimum weight cross-sectional geometry based on a substitution of equivalent orthotropic plates for laminated plates. Optimization at the laminate level finds stacking sequences satisfying laminate design rules. VICONOPT models are validated with ABAQUS finite element models, and with experimental compressive testing of two blade-stiffened panels. The buckling and postbuckling behavior of the two panels, with initial buckling in the stiffeners and skin, respectively, is investigated in a high load and high strain range. The bilevel strategy is evaluated by the design of a relatively short Z stiffened panel which has been manufactured and tested, and also by design of a long wing cover panel with combined loads. The weight saving from the wing cover panel is 13% compared with an existing datum design. This demonstrated that the strategy is efficient, reliable, and extendable into the long panel range.

ABSTRACT: Composite stiffened panel optimization is typically a mixed discrete-continuous design problem constrained by buckling and material strength. Previous work applied a bi-level optimization strategy to the problem by decomposing the mixed problem to continuous and discrete levels to reduce the optimization search space and satisfy manufacturing constraints. A fast-running optimization package, VICONOPT, was used at the continuous optimization level where the buckling analysis was accurately and effectively performed. However, the discrete level was manually adjusted to satisfy laminate design rules. This paper develops the strategy to application on continuously long aircraft wing panels subjected to compression and lateral pressure loading. The beam-column approach used to account for lateral loading for analysis during optimization is reported. A genetic algorithm is newly developed and applied to the discrete level for automated selection of laminated designs. The results that are presented show at least 13% weight saving compared with an existing datum design.
References listed at the end of the paper:

ABSTRACT: The design of composite structures against buckling presents two major challenges to the designer. First, the problem of laminate stacking sequence design is discrete in nature, involving a small set of fiber orientations, which complicates the solution process. Therefore, the design of the stacking sequence is a combinatorial optimization problem which is suitable for genetic algorithms. Second, many local optima with
comparable performance may be found. Most optimization algorithms find only a single optimum, while often a designer would want to obtain all the local optima with performance close to the global optimum. Genetic algorithms can easily find many near optimal solutions. However, they usually require very large computational costs. Previous work by the authors on the use of genetic algorithms for designing stiffened composite panels revealed both the above strength and weakness of the genetic algorithm. The present paper suggests several changes to the basic genetic algorithm developed previously, and demonstrates reduced computational cost and increased reliability of the algorithm due to these changes. Additionally, for a stiffened composite panel considered in this study, we present designs lighter by about 4% compared to previously obtained results.

ABSTRACT: The present work develops an optimization procedure for a geometric design of a composite material stiffened panel with conventional stacking sequence using static analysis and hygrothermal effects. The procedure is based on a global approach strategy, composed by two steps: first, the response of the panel is obtained by a neural network system using the results of finite element analyses and, in a second step, a multi-objective optimization problem is solved using a genetic algorithm. The neural network implemented in the first step uses a sub-problem approach which allows to consider different temperature ranges. The compression load and relative humidity of the air are assumed to be constants throughout the considered temperature range. The mass, the hygrothermal expansion and the stresses between the skin and the stiffeners are defined as the optimality criteria. The presented optimization procedure is shown to yield the optimal structure design without compromising the computational efficiency.

ABSTRACT: Previously, the authors have developed a modelling methodology that establishes a threshold strain below which damage propagation will not occur in laminates subject to Compression After Impact (CAI). In order to validate this methodology, a number of quasi-istropic coupons each containing a circular artificial delamination have been tested in axial compression. These coupons had 0°, ±45° and 90° dominated thin sublaminates placed above the delamination in order to prove the applicability of the model to sublaminates with high anisotropy. Results indicate the model can predict both the strain at which delaminations in the coupons with 0° and ±45° dominated sublaminates propagate from their original sites and the stability with
which propagation occurred. Analysis of the coupon with a $90^\circ$ dominated sublamine was inconclusive due to an unexpected experimental propagation mode. For all coupons delamination propagation was in the direction of the dominant fibre direction in the sublamine. The established methodology is shown to be suitable for assessing the damage tolerance of composite laminates.

ABSTRACT: A Rayleigh–Ritz energy method application is proposed to calculate the buckling onset and bending behavior of flat rectangular anisotropic composite stiffened panels submitted to any combination of in-plane loads (biaxial compression and shear) and pressure. Panels may consist in any kind of anisotropic laminate. Thickness, lay-up and material property changes are allowed along both longitudinal and transverse directions and transverse shear effects are considered using a first order theory. Stiffeners, idealized as offset beams, can also be placed in both directions. Simply supported edges are the assumed boundary conditions for the panel. Nevertheless, additional restrictions can be added by means of the definition of certain torsional or flexural stiffness at the edges. Therefore, clamped conditions or any other condition between clamped and simply supported can be analyzed. The consideration of all these features, together with the potentially high computational performances of the Rayleigh–Ritz method compared with the classical finite elements analyses, enables a wide application in real aircraft structures, such as CFRP (composite fiber reinforced plastic) torque box covers and spars with elevated performances and accuracy. Comparisons with finite element methods and tests in real structures are shown.

ABSTRACT: An extensive experimental investigation of buckling of conical shells that are supported only along their lower edge and that are loaded by the weight of a liquid leads to diagrams and formulas which can be used directly in the design of such shells. The margin of safety to be applied, the influence of welding stresses and the limitations on the validity of the formulas for structures with different boundary conditions are discussed.

ABSTRACT: The major part of an investigation that began about 15 years ago consisted in testing 75 spherical model domes made of microconcrete. Some were subjected to rapidly increasing uniform radial pressure until they buckled, and some were subjected to a radial pressure held constant until they buckled (two of the latter specimens have not yet failed, ten years after the constant load was applied). Non-linear calculations reflecting the effects of the rapid loading and of the loading of long duration have been carried out and their results have been compared with the data obtained experimentally. The numerical results do not support GERARD’s and KOLLAR’s creep buckling hypothesis, while the set of experimental results of the long-term loading tests supports the hypothesis quite well in a statistical sense.

ABSTRACT: The main purpose of the paper is to confront the buckling failure of the conical steel tank of a water tower with buckling formulae resulting from experimental and theoretical research. The collapse corroborates those formulae, which had been published before. The designer of the water tower had relied on a solution to a different, somewhat similar buckling problem. The fact showed that solution to be unconservative for the shell as constructed. The shell buckling formula used by the designer was not accompanied by an imperfection limitation qualifying its applicability. On account of the adverse effect of shape defects of shells on their buckling strength, the writer believes the lack of such a limitation to be potentially dangerous.

ABSTRACT: Two aspects of the finite element analysis of mid-plane symmetrically laminated anisotropic plates are considered in this paper. The first pertains to exploiting the symmetries exhibited by anisotropic plates in their analysis. The second aspect pertains to the effects of anisotropy and shear deformation on the accuracy and convergence of shear-flexible displacement finite element models. Numerical results are presented which show the effects of increasing the order of approximating polynomials and of using derivatives of generalized displacements as nodal parameters.

ABSTRACT: A computational algorithm, based on the combined use of mixed finite elements and classical Rayleigh–Ritz approximation, is presented for predicting the nonlinear static response of structures; The fundamental unknowns consist of nodal displacements and forces (or stresses) and the governing nonlinear finite element equations consist of both the constitutive relations and equilibrium equations of the discretized structure. The vector of nodal displacements and forces (or stresses) is expressed as a linear combination of a small number of global approximation functions (or basis vectors), and a Rayleigh–Ritz technique is used to approximate the finite element equations by a reduced system of nonlinear equations. The global approximation functions (or basis vectors) are chosen to be those commonly used in static perturbation technique; namely a nonlinear solution and a number of its path derivatives. These global functions are generated by using the finite element equations of the discretized structure. The potential of the global–local mixed approach and its advantages over global–local displacement finite element methods are discussed. Also, the high accuracy and effectiveness of the proposed approach are demonstrated by means of numerical examples.

ABSTRACT: A two-stage global-local approach is presented for predicting the collapse behavior of shells. The first stage is that of spatial discretization wherein the shell is discretized by using finite elements (or finite differences) which cover the entire region of the shell. In the second stage the vector of unknown nodal
parameters is expressed as a linear combination of small number of global functions (or basis vectors). A Rayleigh-Ritz (or Bubnov-Galerkin) technique is then used to approximate the nonlinear equations of the discretized shell by a reduced system of nonlinear algebraic equations. For the case of loading applied by means of axial end shortening, a scalar function is introduced which measures the degree of nonlinearity of the structure. Also, a quantitative measure for the error of the reduced system of equations is proposed. The effectiveness of the proposed technique for predicting the collapse behavior of shells is demonstrated by means of a numerical example of the elastic collapse of a cylindrical shell with a rectangular cutout.

“Mixed models and reduced/selective integration displacement models for nonlinear shell analysis”,
doi: 10.1002/nme.1620181002
ABSTRACT: Simple mixed models are developed for the geometrically nonlinear analysis of shells. A total Lagrangian description of the shell deformation is used, and the analytical formulation is based on a form of the nonlinear shallow shell theory with the effects of transverse shear deformation and bending-extensional coupling included. The fundamental unknowns consist of eight stress resultants and five generalized displacements of the shell, and the element characteristic arrays are obtained by using the Hellinger-Reissner mixed variational principle. The polynomial interpolation (or shape) functions used in approximating the stress resultants are, in general, of different degree than those used for approximating the generalized displacements. The stress resultants are discontinuous at the element boundaries and are eliminated on the element level. The equivalence and ‘near-equivalence’ between the mixed models developed herein and displacement models based on reduced/selective integration of both transverse shear and extensional energy terms is discussed. The use of reduction methods in conjunction with the mixed models is outlined and the advantages of mixed models
over displacement models are delineated. Analytic expressions are derived for the rigid-body and spurious (or zero energy) models for the various mixed models and their equivalent displacement models. Also, the advantages of mixed models over equivalent displacement models are outlined. Numerical results are presented to demonstrate the high accuracy and effectiveness of the mixed models developed, and to compare their performance with other mixed models reported in the literature.

ABSTRACT: Status and some recent advances in the application of reduction methods to instability analysis of structures are summarized. The aspects of reduction methods discussed herein include: (a) multiple-parameter reduction methods for instability analysis of structures subjected to combined loads; (b) use of mixed models in conjunction with reduction methods for instability analysis; and (c) application of reduction methods to instability problems with displacement-dependent and nonconservative loadings. Numerical examples are presented to demonstrate the effectiveness of reduction methods in instability analysis. Also, research areas which have high potential for application of reduction methods are identified.

ABSTRACT: A multiple-parameter reduced basis technique and a problem-adaptive computational algorithm are presented for the bifurcation and post-buckling analyses of composite plates subjected to combined loadings. The computational algorithm can be conveniently divided into three distinct stages. The first stage is that of determining the stability boundary. The plate is discretized by using displacement finite element models and the analysis region is reduced by exploiting the special symmetries exhibited by the response of the plate. The vector of unknown nodal displacements is expressed as a linear combination of a small number of path derivatives (derivatives of the nodal displacements with respect to path parameters), and a Rayleigh-Ritz technique is used to approximate the finite element equations by a small system of algebraic equations. The reduced equations are used to determine the stability boundary of the plate. In the second stage, a nonlinear solution in the vicinity of the stability boundary is obtained by using a bifurcation buckling mode as a predictor, and a set of reduced equations is generated. In the third stage, the reduced equations are used to trace post-buckling paths corresponding to various combinations of the load parameters. The potential of the proposed approach is discussed and its effectiveness is demonstrated by means of a numerical example of laminated composite plate subjected to combined compressive and shear loadings.

ABSTRACT: Reduction method and computational procedures are presented for reducing the size of the analysis model and the number of degrees of freedom used in predicting the non-linear response of symmetric anisotropic panels. The two key elements of the method are (a) operator splitting, or decomposition of the
characteristic arrays of the finite element model into sums of orthotropic and non-orthotropic contributions, (b) application of a reduction method through the successive use of the finite element method and the classical Rayleigh-Ritz technique. The finite element method is first used to generate a small number of global approximation vectors (or modes). Then the amplitudes of these modes are computed by using the classical Rayleigh-Ritz technique. The global approximation vectors are selected to be those commonly used in single (or multiple) parameter perturbation techniques, namely a non-linear solution corresponding to zero non-orthotropic arrays and a number of its derivatives with respect to an anisotropic tracing parameter (and possibly, to a load or arc-length parameter in the solution space). The size of the analysis model used in generating the global approximation vectors is identical to that of the corresponding orthotropic structure. The effectiveness of the proposed reduction method is demonstrated by means of a numerical example, and its potential for solving quasi-symmetric non-linear problems of anisotropic panels is discussed.

ABSTRACT: An efficient preconditioned conjugate gradient (PCG) technique and a computational procedure are presented for the analysis of symmetric anisotropic structures. The technique is based on selecting the preconditioning matrix as the orthotropic part of the global stiffness matrix of the structure, with all the nonorthotropic terms set equal to zero. This particular choice of the preconditioning matrix results in reducing the size of the analysis model of the anisotropic structure to that of the corresponding orthotropic structure. The similarities between the proposed PCG technique and a reduction technique previously presented by the authors are identified and exploited to generate from the PCG technique direct measures for the sensitivity of the different response quantities to the non-orthotropic (anisotropic) material coefficients of the structure. The effectiveness of the PCG technique is demonstrated by means of a numerical example of an anisotropic cylindrical panel.

ABSTRACT: An efficient computational strategy is presented for reducing the cost of the stress and free vibration analyses of laminated anisotropic shells of revolution. The analytical formulation is based on a form of the Sanders-Budiansky shell theory including the effects of both the transverse shear deformation and the laminated anisotropic material response. The fundamental unknowns consist of the eight strain components, the eight stress resultant and the five generalized displacements of the shell. Each of the shell variables is expressed in terms of trigonometric functions (Fourier series) in the circumferential co-ordinate, and a three-field mixed finite element model is used for the discretization in the meridional direction. The shell response associated with a range of Fourier harmonics is approximated by a linear combination of a few global approximation vectors, which are generated at a particular value of the Fourier harmonic, within that range. The full equations of the finite element model are solved for only a single Fourier harmonic, and the response corresponding to the other Fourier harmonics is generated using a reduced system of equations with considerably fewer degrees of freedom.
ABSTRACT: An efficient procedure is presented for repetitive analysis of structures, with large numbers of degrees of freedom and design variables, as they are progressively modified during the automated optimum design process. The three key elements of the procedure are: (a) lumping of the large number of design variables into a single tracing parameter; (b) operator splitting or additive decomposition of the different arrays in the governing finite element equations of the modified structure into the corresponding arrays of the original structure plus correction terms; and (c) application of a reduction method through the successive use of the finite element method and the classical Bubnov-Galerkin technique. The reanalysis procedure is applied to the linear static and free vibration problems of framed structures. Changes in both the sizing and shape (configuration) design variables are considered. For static problems the similarities between the proposed procedure and the preconditioned conjugate gradient technique are identified and are exploited to provide a physical meaning for the preconditioned residual vectors. The effectiveness of the proposed procedure is demonstrated by means of numerical examples.

ABSTRACT: A review is given of recent advances in two aspects of the numerical simulation of the buckling and postbuckling responses of composite structures. The first aspect is exploiting non-traditional symmetries exhibited by composite structures; and strategies for reducing the size of the model and the cost of the buckling and postbuckling analyses in the presence of symmetry-breaking conditions (e.g. asymmetry of the material, geometry, and/or loading). The second aspect pertains to the prediction of onset of local delamination in the postbuckling range and accurate determination of transverse shear stresses in the structure. The accuracy and effectiveness of the strategies developed are demonstrated by means of a numerical example.

ABSTRACT: A study is made of the effects of variation in the lamination and geometric parameters of multilayered anisotropic (nonorthotropic) plates on the accuracy of the static and vibrational responses predicted by eight modeling approaches, based on two-dimensional shear-deformation theories. Two key elements distinguish the present study from previous studies reported in the literature: (1) the standard of comparison is taken to be the exact three-dimensional elasticity solutions, and (2) quantities compared are not limited to gross response characteristics (e.g. vibration frequencies, strain energy components, average through-the-thickness displacements and rotations), but include detailed through-the-thickness distributions of displacements, stresses and strain energy densities.

ABSTRACT: A computational procedure is presented for the geometrically nonlinear analysis of aircraft tires. The tire was modeled by using a two-dimensional laminated anisotropic shell theory with the effects of variation in material and geometric parameters included. The four key elements of the procedure are: (1) semianalytic finite elements in which the shell variables are represented by Fourier series in the circumferential direction and piecewise polynomials in the meridional direction; (2) a mixed formulation with the fundamental unknowns consisting of strain parameters, stress-resultant parameters, and generalized displacements; (3) multilevel operator splitting to effect successive simplifications, and to uncouple the equations associated with different Fourier harmonics; and (4) multilevel iterative procedures and reduction techniques to generate the response of the shell.

ABSTRACT: A study is made of the thermal postbuckling response of composite stiffeners subjected to prescribed edge displacement and a temperature rise. The flanges and web of the stiffeners are modeled by using two-dimensional plate finite elements. A mixed formulation is used with the fundamental unknowns consisting of the generalized displacements and the stress resultants of the plate. A reduction method is used in conjunction with mixed finite element models for determining the postbuckling response of the stiffeners. Sensitivity derivatives are evaluated and used to study the effects of variations in the different lamination and material parameters of the stiffeners on their postbuckling response characteristics. Numerical studies are presented for anisotropic stiffeners with Zee and channel sections.

ABSTRACT: Novel computational strategies are presented for the analysis of large and complex structures. The strategies are based on generating the response of the complex structure using large perturbations from that of a simpler model, associated with a simpler structure (or a simpler mathematical/discrete model of the original structure). Numerical examples are presented to demonstrate the effectiveness of the strategies developed.

ABSTRACT: A study is made of the effects of variation in the lamination and geometric parameters of multilayered composite cylinders on the accuracy of the static and vibrational responses predicted by eight modeling approaches, based on two-dimensional shear-deformation shell theories. The standard of comparison is taken to be the exact three-dimensional elasticity solutions, and the quantities compared include both the gross response characteristics (e.g. vibration frequencies, strain energy components, average through-the-thickness displacements and rotations): and detailed, through-the-thickness, distributions of displacements, stresses and strain energy densities. Based on the numerical studies conducted, a predictor -corrector approach, used in conjunction with the first-order shear-deformation theory (with five displacement parameters in the predictor phase), appears to be the most effective among the eight modeling approaches considered. For multilayered orthotropic cylinders the response quantities obtained by the predictor corrector approach are shown to be in close agreement with the exact three-dimensional elasticity solutions for a wide range of lamination and geometric parameters. The potential of this approach for predicting the response of multilayered shells with complicated geometry is also discussed.

ABSTRACT: A study is made of the postbuckling response of composite plates subjected to combined axial and thermal loadings. The analysis is based on a first-order shear deformation, von Kármán-type nonlinear plate theory. A mixed formulation is used with the fundamental unknowns consisting of the generalized displacements and the stress resultants of the plate. An efficient reduction method is used in conjunction with mixed finite element models for determining the stability boundary and the postbuckling response of the plate. Sensitivity derivatives are evaluated and used to study the sensitivity of the postbuckling response to variations in the different lamination and material parameters of the plate. Numerical results are presented showing the effects of variations in the material characteristics and fiber orientation of individual layers on the postbuckling response of the plate.

ABSTRACT: A study is made of the thermomechanical buckling and postbuckling responses of flat unstiffened composite panels. The panels are subjected to combined temperature change and applied edge displacement. The analysis is based on a first-order shear deformation, von-Karman type nonlinear plate theory. A mixed formulation is used with the fundamental unknowns consisting of the generalized displacements and the stress resultants of the plate. An efficient multiple-parameter reduction method is used in conjunction with mixed finite element models, for determining the stability boundary and postbuckling response. The reduction method is also used for evaluating the sensitivity coefficients which measure the sensitivity of the buckling and postbuckling responses to variations in the different lamination and material parameters of the panel. Numerical results are presented showing the effects of variations in the laminate stacking sequence, fiber orientation, number of layers and aspect ratio of the panels on the thermomechanical buckling and postbuckling responses and their sensitivity.

ABSTRACT: A study is made of the buckling and postbuckling responses of flat, unstiffened composite panels subjected to various combinations of mechanical and thermal loads. The analysis is based on a first-order shear deformation von Kármán-type plate theory. A mixed formulation is used with the fundamental unknowns consisting of the strain components, stress resultants and the generalized displacements of the plate. The stability boundary, postbuckling response and the sensitivity coefficients are evaluated. The sensitivity coefficients measure the sensitivity of the buckling and postbuckling responses to variations in the different
lamination and material parameters of the panel. Numerical results are presented for both solid panels and panels with central circular cutouts. The results show the effects of the variations in the fiber orientation angles, aspect ratio of the panel, and the hole diameter (for panels with cutouts) on the stability boundary, postbuckling response and sensitivity coefficients.

ABSTRACT: The research work presented here deals with the problems of geometrically nonlinear analysis of thin shell structures. The specific objective was to develop geometrically nonlinear formulations, using Discrete-Kirchhoff Curved Triangular (DKCT) thin shell elements. The DKCT elements, formulated in the natural curvilinear coordinates, based on arbitrary deep shell theory and representing explicit rigid body modes, were successfully applied to linear elastic analysis of composite shells in an earlier research work. A detailed discussion on the developments of classical linear and nonlinear shell theories and the Finite Element applications to linear and nonlinear analysis of shells has been presented. The difficulties of developing converging shell elements due to Kirchhoff's hypothesis have been discussed. The importance of formulating shell elements based on deep shell theory has also been pointed out. The development of shell elements based on Discrete-Kirchhoff's theory has been discussed. The development of a simple 3-noded curved triangular thin shell element with 27 degrees-of-freedom in the tangent and normal displacements and their first-order derivatives, formulated in the natural curvilinear coordinates and based on arbitrary deep shell theory, has been described. This DKCT element has been used to develop geometrically nonlinear formulation for the nonlinear analysis of thin shells. A detailed derivation of the geometrically nonlinear (GNL) formulation, using the DKCT element based on the Total Lagrangian approach and the principles of virtual work has been presented. The techniques of solving the nonlinear equilibrium equations, using the incremental methods has been described. This includes the derivation of the Tangent Stiffness matrix. Various Newton-Raphson solution algorithms and the associated convergence criteria have been discussed in detail. Difficulties of tracing the post buckling
behavior using these algorithms and hence the necessity of using alternative techniques have been mentioned. A detailed numerical evaluation of the GNL formulation has been carried out by solving a number of standard problems in the linear buckling and GNL analysis. The results compare well with the standard solutions in linear buckling cases and are in general satisfactory for the GNL analysis in the region of large displacements and small rotations. It is concluded that this simple and economical element will be an ideal choice for the expensive nonlinear analysis of shells. However, it is suggested that the element formulation should include large rotations for the element to perform accurately in the region of large rotations.

ABSTRACT: A combined numerical and experimental study is carried out for the postbuckling behavior of a stiffened composite panel. The panel is rectangular and is subjected to static in-plane compression on two opposite edges to the collapse level. Nonlinear - large deflection - plate theory is employed, together with an experimentally based failure criterion. It is found that the stiffened composite panel can exhibit significant postbuckling strength.

ABSTRACT: Some recent advances in the hierarchical modeling strategies are reviewed with special emphasis on applications to multilayered composite panels. Discussion focuses on the key elements of hierarchical adaptive modeling; multimodel predictor and corrector modeling procedures; potential for solving large complex problems; and the needed development to realize this potential. Numerical studies are presented for free vibrations of thermally-stressed multilayered composite panels and structural sandwiches with composite face sheets demonstrating the effectiveness of the multimodel predictor–corrector modeling approaches.

ABSTRACT: A computational procedure is presented for evaluating the sensitivity coefficients of the viscoplastic response of structures subjected to dynamic loading. A state of plane stress is assumed to exist in the structure, a velocity strain-Cauchy stress formulation is used, and the geometric non-linearities arising from large strains are incorporated. The Jaumann rate is used as a frame indifferent stress rate. The material model is chosen to be isothermal viscoplasticity, and an associated flow rule is used with a von Mises effective stress. The equations of motion emanating from a finite element semi-discretization are integrated using an explicit central difference scheme with an implicit stress update. The sensitivity coefficients are evaluated using a direct differentiation approach. Since the domain of integration is the current configuration, the sensitivity coefficients of the spatial derivatives of the shape functions must be included. Numerical results are presented for a thin plate with a central circular cutout subjected to an in-plane compressive loading. The sensitivity coefficients are generated by evaluating the derivatives of the response quantities with respect to Young's modulus, and two of the material parameters characterizing the viscoplastic response. Time histories of the response and sensitivity coefficients, and spatial distributions at selected times are presented.

ABSTRACT: A study is made of the effects of variation in the material and geometric parameters of curved sandwich panels on the accuracy of the static response predicted by nine different modeling approaches based on two-dimensional shell theories. The standard of comparison is taken to be the exact three-dimensional thermoelasticity solutions, and the quantities compared include gross response characteristics (e.g. strain energy components, average through-the-thickness displacements and rotations); detailed, through-the-thickness distributions of displacements and stresses; and sensitivity coefficients of the response quantities (derivatives of response quantities with respect to material and geometric parameters of the sandwich structure). Extensive numerical studies are conducted to assess the accuracy of both the global and detailed response characteristics and their sensitivity coefficients obtained by nine two-dimensional modeling approaches. For accurate determination of detailed through-the-thickness distributions such as transverse stresses, either high-order discrete three-layer models or predictor-corrector approaches are required. The potential of predictor-corrector approaches for predicting the thermomechanical response of sandwich panels and shells with complicated geometry is also discussed.

“THERMOMECHANICAL POSTBUCKLING OF MULTILAYERED COMPOSITE PANELS WITH CUTOUTS”, COMPOSITE STRUCTURES, VOL. 30, NO. 4, 1995, PP. 369-388, DOI: 10.1016/0263-8223(94)00055-7

ABSTRACT: The results of a study of the detailed thermomechanical postbuckling response characteristics of flat unstiffened composite panels with central circular cutouts are presented. The panels are subjected to combined temperature changes and applied edge loading (or edge displacements). The analysis is based on a first-order shear deformation plate theory. A mixed formulation is used with the fundamental unknowns consisting of the generalized displacements and the stress resultants of the plate. The postbuckling displacements, transverse shear stresses, transverse shear strain energy density, and their sensitivity coefficients are evaluated. The sensitivity coefficients measure the sensitivity of the post-buckling response to variations in the different lamination and material parameters of the panel. Numerical results are presented showing the effects of the variations in the hole diameter, laminate stacking sequence, fiber orientation, and aspect ratio of the panel on the thermomechanical postbuckling response and its sensitivity to changes in panel parameters.

PARTIAL INTRODUCTION: The physical understanding and numerical simulation of the buckling and postbuckling responses of laminated anisotropic plates have been the focus of intense efforts because of the extended use of fibrous composites in aerospace, automotive, shipbuilding and other industries, and the need to establish the practical limits of the load-carrying capability of structures made from these materials….
ABSTRACT: A detailed study is made of the buckling and postbuckling responses of composite panels with central circular cutouts subjected to various combinations of mechanical and thermal loads. The panels are discretized by using a two-field degenerate solid element with each of the displacement components having a linear variation through the thickness of the panel. The fundamental unknowns consist of the average mechanical strains through the thickness, and the displacement components. The effects of geometric nonlinearities and laminated anisotropic material behavior are included. The stability boundary, postbuckling response and the hierarchical sensitivity coefficients are evaluated. The hierarchical sensitivity coefficients measure the sensitivity of the buckling and postbuckling responses to variations in the panel stiffnesses, and the material properties of both the individual layers and the constituents (fibers and matrix). Extensive numerical results are presented for composite panels with central circular cutouts subjected to combined edge shortening, edge shear and temperature change. The results show the effects of variations in the hole diameter; the aspect ratio of the panel; the laminate stacking sequence and the fiber orientation on the stability boundary, postbuckling response and sensitivity coefficients.

ABSTRACT: The results of a detailed study of the nonlinear and postbuckling responses of curved unstiffened composite panels with central circular cutouts are presented. The panels are subjected to applied edge displacements and temperature changes. The analysis is based on a first-order shear-deformation Sanders-Budiansky type theory with the effects of large displacements, moderate rotations, transverse shear deformation and laminated anisotropic material behavior included. A mixed formulation is used with the fundamental unknowns consisting of the generalized displacements and the stress resultants of the panel. The nonlinear displacements, strain energy, transverse shear stresses, transverse shear strain energy density, and their hierarchical sensitivity coefficients are evaluated. The hierarchical sensitivity coefficients measure the sensitivity of the nonlinear response to variations in three sets of interrelated parameters; namely, the panel stiffnesses, the material properties of the individual layers, and the material properties of the constituents (fibers, matrix, interface and interphase). Numerical results are presented for cylindrical panels with central circular cutouts subjected to edge shortening and uniform temperature change, showing the effects of variations in the panel curvature, hole diameter, laminate stacking sequence and fiber orientation, on the nonlinear and postbuckling panel responses, and their sensitivity to changes in the various panel, layer and micromechanical parameters.

ABSTRACT: The results of a detailed study of the buckling and postbuckling responses of composite panels with central circular cutouts are presented. The panels are subjected to combined edge shear and temperature change. The panels are discretized by using a two-field degenerate solid element with each of the displacement components having a linear variation throughout the thickness of the panel. The fundamental unknowns consist of the average mechanical strains through the thickness and the displacement components. The effects of geometric nonlinearities and laminated anisotropic material behavior are included. The stability boundary,
postbuckling response and hierarchical sensitivity coefficients are evaluated. The hierarchical sensitivity coefficients measure the sensitivity of the buckling and postbuckling responses to variations in the panel stiffnesses, and the material properties of both the individual layers and the constituents (fibers and matrix). Numerical results are presented for composite panels with central circular cutouts subjected to combined edge shear and temperature change, showing the effects of variations in the hole diameter, laminate stacking sequence and fiber orientation, on the stability boundary and postbuckling response and their sensitivity to changes in the various panel parameters.

ABSTRACT: The results of a detailed study of the nonlinear and postbuckling responses of curved unstiffened composite panels with central circular cutouts are presented. The panels are subjected to uniform temperature change and an applied in-plane edge shear loading. The analysis is based on a first-order shear-deformation Sanders-Budiansky type theory with the effects of large displacements, moderate rotations, transverse shear deformation and laminated anisotropic material behavior included. A mixed formulation is used with the fundamental unknowns consisting of the generalized displacements and the stress resultants of the panel. The nonlinear displacements, strain energy, transverse shear stresses, transverse shear strain energy density, and their hierarchical sensitivity coefficients are evaluated. Numerical results are presented for cylindrical panels with central circular cutouts and are subjected to uniform temperature change and an applied in-plane edge shear loading. The results show the effects of variations in the panel curvature, hole diameter, laminate stacking sequence and fiber orientation, on the nonlinear and postbuckling panel responses, and their sensitivity to changes in the various panel, layer and micromechanical parameters.

ABSTRACT: The results of a detailed study of the buckling and postbuckling responses of composite panels with skewed stiffeners are presented. The panels are subjected to applied edge displacements and temperature changes. A first-order shear-deformation geometrically nonlinear shallow-shell theory that includes the effects of laminated anisotropic material behavior is used to model each section of the stiffeners and the skin. A mixed formulation is used in the analysis with the fundamental unknowns consisting of the generalized displacements and the stress resultants of the panel. The nonlinear displacements, strain energy, transverse shear stresses, transverse shear strain energy density, and their hierarchical sensitivity coefficients are evaluated. The hierarchical sensitivity coefficients measure the sensitivity of the buckling and postbuckling responses to variations in three sets of interrelated parameters; namely, the panel stiffnesses; the effective material properties of the individual layers; and the constituent material parameters (fibers, matrix, interface and interphase). Numerical results are presented for rectangular panels with open section I-stiffeners, subjected to edge shortening and uniform temperature change. The results show the effects of variations in the material properties of the skin and the stiffener on the buckling and postbuckling responses of the panel, as well as on the sensitivity coefficients.

ABSTRACT: The history, recent developments and trends in computational structures technology (CST) are summarized. Discussion focuses on development of CST software and goals of CST activities. Some recent advances in a number of CST areas are described, including discretization techniques and element technology; computational material modeling; modeling of composite, sandwich and smart structures; computational tools and methodologies for life management; transient response analysis; numerical simulation of frictional contact/impact response; articulated structural dynamics; non-deterministic modeling and analysis methods; qualitative analysis and simulation; neuro-computing; hybrid techniques; error estimation and adaptive improvement strategies; strategies for solution of coupled problems; sensitivity analysis; integrated analysis and design; strategies and numerical algorithms for new computing systems; model generation facilities; and application of object-oriented technology. Research areas in CST that have high potential for meeting the future technological needs are identified.

ABSTRACT: A two-phase approach and a computational procedure are presented for predicting the variability in the nonlinear response of composite structures associated with variations in the geometric and material parameters of the structure. In the first phase, hierarchical sensitivity analysis is used to identify the major parameters, which have the most effect on the response quantities of interest. In the second phase, the major parameters are taken to be fuzzy parameters, and a fuzzy set analysis is used to determine the range of variation of the response, associated with preselected variations in the major parameters. The effectiveness of the procedure is demonstrated by means of a numerical example of a cylindrical panel with four T-shaped stiffeners and a circular cutout.

ABSTRACT: A study is made of the variability in the nonlinear response of three stiffened composite panels associated with variations in their geometric and material parameters. The three panels have a cylindrical skin with either four or five T-shaped stiffeners. Two of the panels have a notch and the third panel has a circular cutout. Hierarchical sensitivity analysis is used to identify the major parameters at the micro-mechanical, layer, laminate and sub-component levels. The major parameters are then taken to be fuzzy parameters, and a fuzzy set analysis is used to determine the range of variation of the response associated with pre-selected variations in
the major parameters.

ABSTRACT: Research on the mechanics of composite structures at NASA’s Langley Research Center is discussed. The advantages and limitations of special purpose and general purpose analysis tools used in research are reviewed. Future directions in computational structural mechanics are described to address analysis shortcomings. Research results on the buckling and postbuckling of unstiffened and stiffened composite structures are presented. Recent investigations of the mechanics of failure in compression and shear are reviewed. Preliminary studies of the dynamic response of composite structures due to impacts encountered during crash-landings are presented. Needs for future research are discussed.

ABSTRACT: A study of thermal buckling of stiffened cylindrical shells with the proportions of a preliminary supersonic transport fuselage design (1970) is presented. The buckling analysis is performed using an axisymmetric shell-of-revolution code, BOSOR4. The effects of combined mechanical (axial loading) and thermal loading (heated skins) are investigated. Results indicate that the location of longitudinal eccentric stiffening has a very large effect on the thermal buckling strength of longitudinally stiffened shells, and on longitudinally stiffened shells with rings.

ABSTRACT: Simple experiments on self-weight buckling of thin, open-top, fixed-base, small-scale silicone rubber cylindrical shells are presented in this article. The buckling heights were found to be proportional to thickness raised to the power of approximately 1.5, compared to 1.0 as in the classical theory. A non-linear finite-element analysis of self-weight buckling showed that there is a ‘post-buckling plateau’ load corresponding to the experimental buckling loads. Moreover, the results of the present experiments showed very little ‘scatter’ in the buckling heights, compared to the large scatter in the experimental data from the literature on the buckling of thin cylindrical shells under axial compressive load (which also have buckling stress
proportional to thickness raised to the power of approximately 1.5), although there were measurable imperfections in terms of thickness variations. These observations somehow defy the accepted hypothesis of ‘imperfection-sensitivities’ in shell buckling. The most obvious explanation of the difference is that the open-topped shells of the present study are statically determinate, whereas the usual closed-ended shells of tests reported in the literature are statically indeterminate; the possibility of high initial stresses may explain the scatter in the experimental observations in the literature.

ABSTRACT: The Southwell plot is a well-known technique for determining experimentally the elastic critical load of a structure, without having to subject the structure to loading in the vicinity of critical. But several authors have suggested that when the structure is a beam which undergoes lateral-torsional buckling, a modified version of the Southwell plot is called for. In this paper we demonstrate that the modified form of the Southwell plot is not needed, and that the standard version is indeed satisfactory. We do this by plotting and re-plotting some experimental data; by drawing attention to some very clear work by Meck; and by explaining the practical coupling between the variables describing the lateral deflection and the rotation when lateral-torsional buckling occurs. Finally, we examine an argument based on symmetry which appears to support the idea that a modification of the standard Southwell plot is needed in the case of lateral-torsional buckling: but we show that a correct deployment of the argument from symmetry leads to the conclusion that the modified form of the Southwell plot is valid only for special, unrealistic cases.

Zia ul Rehman Tahir and Parthasarathi Mandal (School of Mechanical, Aerospace and Civil Engineering, University of Manchester, UK), “Effect of Asymmetric Meshing on the Buckling of Composite Laminated Cylindrical Shells”, ICAMS-2011: International Conference on Advanced Modeling and Simulation, November 28-30, 2011, Islamabad, Pakistan

ABSTRACT: This paper presents the details of a numerical study of buckling and post buckling behaviour of laminated carbon fiber reinforced plastic (CFRP) thin-walled cylindrical shell under axial compression using asymmetric meshing technique (AMT) by ABAQUS. AMT is considered to be a new perturbation method to introduce disturbance without changing geometry, boundary conditions or loading conditions. Asymmetric meshing affects both predicted buckling load and buckling mode shapes. Cylindrical shell having lay-up orientation \([0^\circ/45^\circ/-45^\circ/0^\circ]\) with radius to thickness ratio (R/t) equal to 265 and length to radius ratio (L/R) equal to 1.5 is used. A series of numerical simulations (experiments) are carried out with symmetric and asymmetric meshing to study the effect of asymmetric meshing on predicted buckling behaviour. Asymmetric meshing technique is employed in both axial direction and circumferential direction separately using two different methods, first by changing the shell element size and varying the total number elements, and second by varying the shell element size and keeping total number of elements constant. The results of linear analysis (Eigenvalue analysis) and non-linear analysis (Riks analysis) using symmetric meshing agree well with analytical results. The results of numerical analysis are presented in form of non-dimensional load factor, \(\Lambda\), which is the ratio of buckling load using asymmetric meshing technique to buckling load using symmetric meshing technique. Using AMT, load factor has about 2% variation for linear eigenvalue analysis and about 2% variation for non-linear Riks analysis. The behaviour of load end-shortening curve for pre-buckling is same for both symmetric and asymmetric meshing but for asymmetric meshing curve behaviour in post-buckling becomes extraordinarily complex. The major conclusions are: different methods of AMT have small influence on predicted buckling load and significant influence on load displacement curve behaviour in post buckling; AMT in axial direction and AMT in circumferential direction have different influence on buckling load and load displacement curve in post-buckling.

ABSTRACT: A numerical study is presented on buckling and post buckling behaviour of laminate d carbon fiber reinforced plastic (CFRP) thin-walled cylindrical shells under axial compression using asymmetric meshing technique (AMT). Asymmetric meshing technique is a perturbation technique to introduce disturbance without changing geometry, boundary conditions or loading conditions. Asymmetric meshing affects predicted buckling load, buckling mode shape and post-buckling behaviour. Linear (eigenvalue) and non-linear (Riks) analyses have been performed to study the effect of asymmetric meshing in the form of a patch on buckling behaviour. The reduction in the buckling load using Asymmetric meshing technique was observed to be about 15%. An isolated dimple formed near the bifurcation point and the size of which increased to reach a stable state in the post-buckling region. The load-displacement curve behaviour applying asymmetric meshing is quite similar to the curve obtained using initial geometric imperfection in the shell model.

ABSTRACT: AMT is a perturbation technique to introduce disturbance in the model without changing geometry, boundary conditions or loading conditions. Asymmetric meshing technique is employed in the form of a band along circumferential direction of the shell model. The elements size in the band is reduced as compared with the rest of shell to produce asymmetry in the meshing and four magnitudes of asymmetry in meshing are used. Asymmetric meshing affects predicted buckling load, buckling mode shape and post-buckling behaviour. The reduction in the buckling load using AMT was observed to be about 20%. An isolated dimple formed near the bifurcation point and the size of which increased to reach a stable state in the post-buckling region. The load-displacement curve behaviour applying asymmetric meshing is quite similar to the curve obtained by introducing initial geometric imperfection in the shell model.

ABSTRACT: Asymmetric meshing is a perturbation introduced in the numerical model without changing geometry, loading or boundary conditions. Asymmetric meshing is employed in the form of a band along axial direction of the shell model, the elements size in the axial band is reduced as compared with the rest of shell to produce asymmetry in the meshing and four amplitudes of asymmetry are used in a particular band. Asymmetric meshing affects predicted buckling load, buckling mode shape and post-buckling behaviour. The reduction in the buckling load using asymmetric meshing was observed to be about 18%, which depends mainly on area of asymmetric meshing and less on different magnitudes of asymmetry in the same area. The load-displacement curve behaviour using asymmetric meshing technique is quite similar to the curve obtained by introducing geometric imperfection in the shell model.

PARTIAL ABSTRACT: This paper describes an experimental and numerical study that is part of a research project aiming at improving the knowledge of buckling behaviour of composite shell structures. The experimental equipment and the methodologies for systematic data acquisition in buckling tests on composite cylindrical shells under axial compression and torsion, applied individually and in combination, are described. Typical results of the first tests performed on carbon-epoxy laminated cylinders are presented, in terms of diagrams, post-buckling patterns and two-dimensional Fourier analysis….

“Buckling of axially compressed fiber composite cylindrical shells due to impulsive loading”, in Spacecraft structures, materials and mechanical testing, Proceedings of a European Conference held at Braunschweig, Germany, 4-6 November 1998. Paris: European Space Agency (ESA), ESA-SP, Vol. 428, 1999,
PARTIAL ABSTRACT: Dynamic buckling of thin-walled CFRP shell structures due to impulsive loading is investigated. Computations for axially compressed cylindrical shells are performed by commercially available finite element codes. The effect of laminate set-up on the buckling load of cylindrical shells, the influence of boundary conditions and the sensitivity to geometric imperfections are analysed for static and dynamic buckling loads. The time history of impulsive loading with finite duration and constant in magnitude is varied, and the corresponding dynamic buckling loads are related to the quasi-static buckling loads.

ABSTRACT: This paper deals with the buckling and post-buckling behaviour of carbon fibre reinforced plastic cylindrical shells under axial compression. The finite element analysis is used to investigate this problem and three different types of analysis are compared: eigenvalue analysis, non-linear Riks method and dynamic analysis. The effect of geometric imperfection shape and amplitude on critical loads is discussed. A numerical–experimental correlation is performed, using the results of experimental buckling tests. The geometric imperfections measured on the real specimens are accounted for in the finite element model. The results show the reliability of the method to follow the evolution of the cylinder shape from the buckling to the post-buckling field and good accuracy in reproducing the experimental post-buckling behaviour.

ABSTRACT: To improve a helicopter design concept, which meets structural and crashworthiness requirements, a research program is undertaken to study the energy absorption capability of a subfloor structure. In particular, crash tests are performed on the subfloor structure and on the intersection elements, which are components of the structure and can create high deceleration peak loads at the cabin floor level causing dangerous inputs to the occupants. Then the structures are analysed by a commercial explicit finite element code, PAM-CRASH, using detailed geometrical models, suitable materials models and the appropriate definition of contact forces and rivets. The analysis shows that the load-shortening diagrams present a good correlation to the experimental data and that the structural collapse predictions correspond closely to the observed behaviour during the experimental tests. Consequently the finite element analysis can be used to aid the designers in evaluating the crashworthiness of different structural concepts and can therefore be an important mean of reducing development costs.

ABSTRACT: This paper deals with the definition of a post-buckling optimisation procedure for the design of composite stiffened panels subjected to compression loads. The optimised structures are then characterised by a
local skin buckling between the stiffeners and by a high ratio between the collapse load and the buckling load. To overcome too expensive analyses from a computational point of view, an optimisation procedure is developed. It is based on a global approximation strategy, where the structure response is given by a system of neural networks trained by means of finite element analyses, and on genetic algorithms, that results particularly profitable due to the presence of integer variables. The optimisation procedure reduces considerably the computational costs, offers a complete separation between the system modelling and the optimisation problem and shows that a local skin buckling between the stiffeners allows a weight reduction equal to 18%.

ABSTRACT: This paper describes an experimental investigation of the elastic dynamic buckling of carbon fiber reinforced plastic cylindrical shells subjected to pulse axial compression. The critical impulse is applied using a horizontal crash sled, so to obtain axial compression shape similar to a half-sine and duration of the impact load of approximately 0.1 s. The test results are reported and analyzed. The dynamic buckling load of the initially imperfect shell is related to its static buckling load and the ratio is less than unity. Since the common practice is to assume that dynamic buckling loads are higher than the static ones, which means that static design is safe, extra caution and careful design is recommended.

ABSTRACT: Experimental data obtained from buckling and post-buckling tests performed until collapse on three stiffened composite cylindrical shells are described. The shells, different in the skin and in the stiffeners lay-up, were expressly designed for working in the post-buckling field. The outer and inner surfaces are scanned before the tests, in order to determine the initial geometric imperfections and the thickness variations. After that, the shells are tested using a position control mode until collapse, two of them under axial compression and one under torque. The diagrams of axial load versus displacement and of torsion versus rotation are recorded in real time during the tests. To monitor the first buckling load and the evolution of the buckling shape, five laser displacement sensors are employed. The test results show the strength capacity of these structures to work in the post-buckling range. Indeed neither failure mechanisms nor any other hazards are visible in the post-buckling range. On the other hand, the collapse, due to the failure of the stringers, is sudden and destructive.

ABSTRACT: The paper deals with dynamic buckling due to impulsive loading of thin-walled carbon fiber reinforced plastics (CFRP) shell structures under axial compression. The approach adopted is based on the equations of motion, which are numerically solved using a finite element code (ABAQUS/Explicit) and using numerical models validated by experimental static buckling tests. To study the influence of the load duration, the time history of impulsive loading is varied and the corresponding dynamic buckling loads are related to the quasi-static buckling loads. To analyse the sensitivity to geometric imperfections, the initial geometric imperfections, measured experimentally on the internal surface of real shells, are introduced in the numerical models. It is shown numerically that the initial geometric imperfections as well as the duration of the loading period have a great influence on the dynamic buckling of the shells. For short time duration, the dynamic buckling loads are larger than the static ones. By increasing the load duration, the dynamic buckling loads decrease quickly and get significantly smaller than the static loads. Since the common practice is to assume that dynamic bucking loads are higher than the static ones, which means that static design is safe, careful design is
recommended. Indeed, taking the static buckling load as the design point for dynamic problems might be misleading.

ABSTRACT: First, the test equipment used for various types of buckling experiments in the Department of Aerospace Engineering at the Politecnico di Milano is presented. It can apply axial and torsion loading, separately and in combination, using displacement control. Then, the results of an experimental investigation on stiffened shells and curved panels, made from graphite-epoxy are presented. The experimental data acquired during the first non-destructive buckling tests and during the final destructive failure tests demonstrate clearly the strength capacity of these structures to work in the postbuckling range, allowing further weight savings. The results show that the structures are able to sustain load in the postbuckling range without any damage. On the negative side, the collapse is sudden and destructive. The measured data are also useful for the development and validation of analytical and numerical high-fidelity methods. These validated analysis tools can provide design criteria that are less conservative than the existing ones.

ABSTRACT: This work presents the buckling optimization of composite stiffened panels loaded in compression and shear. The procedure relies on the coupled use of an analytical formulation for the structural analysis together with an optimization based on genetic algorithms. The analytical formulation allows the assessment of the local buckling behavior of panels with blade, J, T and hat stiffener cross sections. The out-of-plane buckling deflections on the skin and the stiffener are represented by trigonometric shape functions, and the governing equations are derived referring to the minimum potential energy principle and the method of Ritz. The formulation is used to obtain optimal configurations in terms of skin and stiffener lay-ups, stiffener cross section and geometry. Constraints can be imposed on the structural response in terms of buckling load and prebuckling stiffness as well as on technological requirements. The optimal design is presented for the buckling load maximization of a flat hat stiffened panel loaded in compression and shear, and for the minimum weight under buckling constraints of a curved panel with open section stringers loaded in compression. Analytical results are then compared with finite element analyses.

ABSTRACT: The paper presents an analytical formulation for the post-buckling analysis of composite aeronautical panels with omega stiffeners loaded in compression and shear. The formulation relies on an energy principle and the method of Ritz. In the first step, the panel is an assembly of plate elements, and the buckling analysis is performed. In the second step, the panel is an elastically restrained skin, and the post-buckling behaviour is studied. The comparisons with finite element analyses and experimental results from the literature reveal the ability of the formulation to assess the post-buckling response.

References listed at the end of the paper:
DOI: 10.1142/9781786344335_0006
ABSTRACT: A semi-analytical method for the buckling and postbuckling analysis of composite-stiffened panels is presented. The method is formulated in the context of a variational framework and is based on the method of Ritz. Two levels of approximation are introduced, consisting of a plate assembly representation for the buckling analysis and an elastically restrained panel for the postbuckling assessment. Two aeronautical panels with open-section and closed-section stringer profiles are analyzed, illustrating the comparison with finite element predictions and with experimental data taken from the literature. The results indicate that accurate predictions can be obtained in terms of buckling loads, postbuckling reduction in stiffness, and out-of-plane deflections with an analysis time of the order of a few seconds.

ABSTRACT: An experimental and numerical investigation was conducted to study the skin-stiffener separation of single T-shape stiffener specimens in post-buckling condition. Three specimens were manufactured with a centrally located Teflon insert, and were loaded in compression until collapse. Deformation patterns and separation evolution were monitored during the tests. To measure the full-field displacements and the strain distributions of the specimens, digital image correlation system was used. Skin-stiffener separation was observed and measured with an ultrasound system. Finite element analyses were conducted to capture interlaminar damage mechanism based on Virtual Crack Closure Technique. The numerical analysis well predicted the post-buckling deformation and the skin-stiffener separation behaviour. The close correlation between the experimental and numerical results allows for further exploitation of strength reserve in post-buckling region and wider design options for the next generation of composite aircraft designs.

Carlos G. Davila and Chiara Bisagni, “Fatigue life and damage tolerance of postbuckled composite stiffened structures with indentation damage”, Journal of Composite Materials, 52(7):002199831771578, June 2017 DOI: 10.1177/0021998317715785
ABSTRACT: The fatigue life and damage tolerance of composite stiffened panels with indentation damage are investigated experimentally using single-stringer compression specimens. The indentation damage was induced to one of the two flanges of the stringer of every panel. The advantages of indentation compared to impact are the simplicity of application, less dependence on boundary conditions, better controllability, and repeatability of the imparted damage. The tests were conducted using advanced instrumentation, including digital image correlation, passive thermography, and in situ ultrasonic scanning. Specimens with initial indentation damage ranging between 32 and 56 mm in length were tested quasi-statically and in fatigue, and the effects of cyclic load amplitude and damage size were studied. A means of comparison of the damage propagation rates and collapse loads based on a stress intensity measure and the Paris law is proposed. The stress intensity measure provides the means to compare the collapse loads of specimens with different damage types and damage sizes, while the Paris law is used to compare the damage propagation rates in specimens subjected to different cyclic
loads. This approach enables a comparison of different tests and the potential identification of the effects that influence the fatigue lives and damage tolerance of postbuckled structures with defects.

ABSTRACT (From Alfano’s 2016 thesis): Cylindrical shells are widely used in primary structures of space launch vehicles. Due to the high imperfection sensitivity, buckling behavior of shells under axial compression exhibits a great discrepancy between theory and experiments. In order to meet the demand of aerospace industry for improved design criteria, a unified framework, the probability-based methodology, for probabilistic buckling analysis of axially-compressed shells is developed, illustrating it with application to two structures of Ariane 5 launcher. They are sandwich composite shells made of same material, but with different stacking sequence and geometric dimensions. One of them is also studied with the presence of three circular cut-outs. The methodology combines the Stress-Strength Interference Method and the Latin Hypercube Method to determine a probabilistic buckling factor, once the probability that shell withstands axial load without undergoing buckling is specified. Such a factor accounts for influence of manufacturing and in-service imperfections, but depends on required reliability, on sample size and on considered imperfections. Different sources of imperfections, modeled by literature, are introduced into the analysis independently and jointly. The main advantage of the methodology is the versatility as it can be used for buckling investigation of laminated composite shells and sandwich composite shells including different types of imperfections. In particular, the methodology allows for incorporating directly experimental data representative of shells of interest. To show this, buckling of an experimental shell is investigated by the probabilistic methodology using measured imperfections. An alternative method, the chaos approach, for buckling analysis of axially-compressed shells is derived using concepts of the chaos, with application to one of the studied shells. The goal is to obtain an erosion profile as function of increasing axial load. It illustrates concisely the degradation due to imperfections of the load-carrying capability of shells. The approach could be adopted when test-origination database of imperfections is not available to achieve a first assessment of the imperfection sensitivity of shells.

Chiara Bisagni and Michela Alfano, “Chaos theory applied to buckling analysis of composite cylindrical shell”, 30th Congress of the International Council of the Aeronautical Sciences, Daejeon, South Korea, June 2016

ABSTRACT: The durability and damage tolerance of postbuckled composite structures are issues that are not completely understood and remain difficult to predict due to the nonlinearity of the geometric response and its interaction with local damage modes. A research effort was undertaken to investigate experimentally the quasi-static and fatigue damage progression in single-stringer compression specimens. Three specimens were manufactured with a co-cured hat stringer, and an initial defect was introduced with a Teflon film inserted between one flange of the stringer and the skin. Pre-test finite element analyses were conducted using the virtual
crack closure technique to select the range of defect sizes to be considered and the load levels to be applied during the fatigue tests. The tests were monitored with digital image correlation, passive thermography, and ultrasound systems. After an initial opening and extension of the Teflon-induced embedded defect, the specimens sustained a high number of cycles. It was observed that when the skin/stringer separation develops in the opposite flange, it propagates rapidly within a small number of cycles and causes the collapse of the specimen. These test results contribute to a better understanding of the complex response phenomena exhibited by postbuckled stiffened structures subjected to fatigue loads in the postbuckling range.

Haim Abramovich (Technion – Israel Institute of Technology) and Chiara Bisagni (Delft University of Technology), “Behavior of curved laminated composite panels and shells under axial compression”, Progress in Aerospace Sciences 78, June 2015, DOI: 10.1016/j.paerosci.2015.05.008
ABSTRACT: The buckling and post-buckling behavior of curved cylindrical stringer-stiffened laminated composite and metal panels had been investigated both numerically and experimentally. The results were compared to those of cylindrical stringer-stiffened laminated composite shells to yield a way of determining the optimal structure to be used for axial compression loading. For the present tested structures, the composite panels showed the best load-weight ratio.

Thomas Ludwig, Mathias Doreille, Silvio Merazzi, Riccardo Vescovini and Chiara Bisagni, “Dynamic finite element simulations of composite stiffened panels with a transverse-isotropic viscoelastic energy dissipation model”, Progress in Aerospace Sciences 78, June 2015, DOI: 10.1016/j.paerosci.2015.06.001
ABSTRACT: This paper presents a methodology for predicting the damped response and energy dissipation of laminated composite structures, subjected to dynamic loads. Starting from simple coupon tests to characterize the material, the numerical simulation of damping properties is made possible by a novel linear viscoelastic model that has been developed and implemented in the finite element code B2000++. A nonlinear optimization procedure is adopted to fit experimental data and define the exponential Maxwell parameter model. To illustrate the potentialities of the method, the post-buckling analysis of a relatively complex aeronautical panel is presented, accounting not only for geometric nonlinearities, but also for viscoelastic effects. The results illustrate the effects due to material dissipation, their relation to the effects of inertia, and the influence of geometric imperfections on the response of the panel.

Chiara Bisagni (Delft University of Technology), “Overview of the DAEDALOS project”, Progress in Aerospace Sciences 78, June 2015, DOI: 10.1016/j.paerosci.2015.05.007
ABSTRACT: The “Dynamics in Aircraft Engineering Design and Analysis for Light Optimized Structures” (DAEDALOS) project aimed to develop methods and procedures to determine dynamic loads by considering the effects of dynamic buckling, material damping and mechanical hysteresis during aircraft service. Advanced analysis and design principles were assessed with the scope of partly removing the uncertainty and the conservatism of today's design and certification procedures. To reach these objectives a DAEDALOS aircraft model representing a mid-size business jet was developed. Analysis and in-depth investigation of the dynamic response were carried out on full finite element models and on hybrid models. Material damping was experimentally evaluated, and different methods for damping evaluation were developed, implemented in finite element codes and experimentally validated. They include a strain energy method, a quasi-linear viscoelastic material model, and a generalized Maxwell viscous material damping. Panels and shells representative of
typical components of the DAEDALOS aircraft model were experimentally tested subjected to static as well as dynamic loads. Composite and metallic components of the aircraft model were investigated to evaluate the benefit in terms of weight saving.

Chiara Bisagni (Delft University of Technology), Composite cylindrical shells under static and dynamic axial loading: An experimental campaign”, Progress in Aerospace Sciences 78, October 2015, pp 107-115
https://doi.org/10.1016/j.paerosci.2015.06.004
ABSTRACT: The results of an experimental investigation performed at the Politecnico di Milano inside the European project DAEDALOS on three composite cylindrical shells are here presented. At first, static buckling tests were performed under axial compression. Then, two types of dynamic tests were carried out: modal tests at different load levels before buckling and dynamic buckling tests applying an axial shortening of short duration. At the end, one shell was statically tested until final failure. The tests allow to understand the behavior of thin-walled cylindrical shells subjected to axial compression both in static and dynamic conditions. The results show the strength capacity of these structures to work in the post-buckling range with a capacity to sustain a load that is about 40% of the buckling load. The modal tests at different load levels allowed to observe that an increase of the load determines a reduction of the modal frequency and an increase of the damping. Large deformations are obtained before the final failure with out-of-plane displacements of almost 40 mm and a shortening equal to about 26 times the buckling shortening.

ABSTRACT: This paper describes the analysis and the minimum weight optimisation of a fuselage composite panel made from carbon/epoxy material and stiffened by five omega stringers. The panel investigated inside the European project MAAAXIMUS is studied using a fast tool, which relies on a semi-analytical procedure for the analysis and on genetic algorithms for the optimisation. The semi-analytical approach is used to compute the buckling load and to study the post-buckling response. Different design variables are considered during the optimisation, such as the stacking sequences of the skin and the stiffener, the geometry and the cross-section of the stiffener. The comparison between finite element and fast tool results reveals the ability of the formulation to predict the buckling load and the post-buckling response of the panel. The reduced CPU time necessary for the analysis and the optimisation makes the procedure an attractive strategy to improve the effectiveness of the preliminary design phases.

Chiara Bisagni (Delft University of Technology), “An analytical formulation for the prediction of buckling and post-buckling of composite panels and shells”, Third MIT Conference on Computational Fluid and Solid Mechanics, Boston, USA, June 2015
ABSTRACT: The paper gives an overview of some research activities regarding buckling of composite structures performed in Italy in the last years. In particular, the activities performed at Politecnico di Milano, at Politecnico di Torino and at Università di Pisa are here presented. Some investigations were performed on structures manufactured by Agusta/Westland and by Alenia Aeronautica, while other researches were funded by the Italian Ministry of Research, and other ones were funded by the European Commission within European Projects.

ABSTRACT: The present paper describes the results of an experimental and numerical investigation on a composite laminated helicopter tailplane, whose lower panels are subjected to buckling phenomena during its lifetime. The structure is made of woven carbon fibers, unidirectional carbon fibers, and honeycomb. Two different types of lower laminate composite panels are investigated: Z stringer-stiffened panels and L stringer-stiffened panels. During the tests, measurements are taken using a load cell, potentiometers, strain gauges, and moiré fringes. First, three Z stringer-stiffened and three L stringer-stiffened laminate composite lower panels are tested up to 85% of the target load. Then, the last L stringer-stiffened panel is tested until collapse. Buckling occurs at 63% of the target load, whereas the collapse happens at 90%. At the same time, the finite element analyses of the tailplane structures with both Z stringer-stiffened and L stringer-stiffened panels are performed, simulating the dynamic of a slow compression test, using LS-DYNA. The finite element results are compared with the experimental data, obtaining a good numerical-experimental correlation. Numerically, the collapse of the structure is predicted at 93% of the target load, whereas experimentally it happened at 90%.

ABSTRACT: This paper presents a fast tool that can be used during the preliminary design of isotropic and composite stiffened panels subjected to axial compression. It consists of two modules, one for the analysis and one for the optimization. The analysis is performed by implementing an analytical formulation to obtain the linearized buckling load and to study the nonlinear postbuckling field. In particular, closed-form solutions are derived for the linearized local and global buckling loads, and a semi-analytical procedure is implemented for the study of the nonlinear local postbuckling field. The optimization is based on genetic algorithms and allows
taking into account buckling and postbuckling requirements with reduced computational time. Two examples regarding the minimum weight optimization of an isotropic panel and a composite panel are discussed and verified by means of finite element eigenvalue and nonlinear analyses. The total time required for the analysis and the optimization is of the order of a few minutes, and the difference between the analytical and numerical results is below 9% for the buckling load and below 3% for the postbuckling stiffness.

ABSTRACT: This paper presents an analytical formulation for the study of linearized local skin buckling load and nonlinear post-buckling behaviour of isotropic and composite stiffened panels subjected to axial compression. The skin is modelled as a thin plate introducing Donnell-Von Kármán and Kirchhoff hypothesis and applying classical lamination theory, while the stiffeners are considered as torsion bars. The first part of the work deals with the study of linearized buckling load, and two analytical solutions are presented: one is based on Kantorovich method and the other one on Ritz method. The second part of the work regards the development of a semi-analytic This paper presents an analytical formulation for the study of linearized local skin buckling load and nonlinear al formulation for the study of the post-buckling field, using a variational approach and applying Ritz method. Results are compared with a serie of finite element analysis. It is shown that analytical buckling loads differ from numerical ones for less than 12%, and that force–displacement curves are well predicted. A computer program called stiffened panels analysis (StiPAn) is developed on the basis of the presented formulation. It allows quick analysis of stiffened laminated panels and is suited to be used in optimization routines for preliminary design.

ABSTRACT: Analysing the collapse of skin-stiffened structures requires capturing the critical phenomenon of skin-stiffener separation, which can be considered analogous to interlaminar cracking. This paper presents the development of a numerical approach for simulating the propagation of interlaminar cracks in composite structures. A degradation methodology was introduced in MSC.Marc, which involved the modelling of a structure with shell layers connected by user-defined multiple-point constraints (MPCs). User subroutines were written that employ the virtual crack closure technique (VCCT) to determine the onset of crack growth and modify the properties of the user-defined MPCs to simulate crack propagation. Methodologies for the release of failing MPCs are presented and are discussed with reference to the VCCT assumption of self-similar crack growth. The numerical results obtained by using the release methodologies are then compared with experimental data for a double-cantilever beam specimen. Based on this comparison, recommendations for the future development of the degradation model are made, especially with reference to developing an approach for the collapse analysis of fuselage-representative structures.

ABSTRACT: Advanced fibre-reinforced polymer composites have seen a rapid increase in use in aircraft structures in recent years. However, significant conservatism is applied in the design of composite aerospace structures, largely due to the inability of current analysis tools to accurately capture the effect of damage. In this work, the design of fuselage-representative composite structures for postbuckling applications is demonstrated, accounting for damage initiation and growth. An analysis methodology is applied that was developed to capture the critical damage mechanisms leading to collapse of these structures. The analysis methodology is used to investigate the effect of size and location of a pre-existing interlaminar damage region in a postbuckling composite structure design. A pre-damage configuration suitable for experimental investigation is selected. Experimental results are presented of the selected panel configuration tested to collapse in compression, and compared with numerical predictions.

ABSTRACT: Experimental and numerical investigations were conducted into the damage growth and collapse behaviour of composite blade-stiffened structures. Four panel types were tested, consisting of two secondary-bonded skin–stiffener designs in both undamaged and pre-damaged configurations. The pre-damaged configurations were manufactured by replacing the skin–stiffener adhesive with a centrally located, full-width Teflon strip. All panels were loaded in compression to collapse, which was characterised by complex post-buckling deformation patterns and ply damage, particularly in the stiffener. For the pre-damaged panels, significant crack growth was seen in the skin–stiffener interface prior to collapse, which caused a reduction in load-carrying capacity. In the numerical analysis of the undamaged panels, collapse was predicted using a ply failure degradation model, and a global–local approach that monitored a strength-based criterion in the skin–stiffener interface. The pre-damaged models were analysed with ply degradation and a method for capturing interlaminar crack growth based on multi-point constraints controlled using the Virtual Crack Closure Technique. The numerical approach gave close correlation with experimental results, and allowed for an in-depth analysis of the damage growth and failure mechanisms contributing to panel collapse. The successful prediction of collapse under the combination of deep post-buckling deformations and several composite damage mechanisms has application for the next generation of composite aircraft designs.

ABSTRACT: The European Commission Project COCOMAT (Improved MATerial Exploitation at Safe Design of Composite Airframe Structures by Accurate Simulation of COllapse) is a currently running four-year project that aims to exploit the large strength reserves of composite structures through a more accurate prediction of collapse. Accordingly, one of the COCOMAT work packages involves the design of test panels with a focus on investigating the progression of composite damage mechanisms. This paper presents the collaborative results of some of the partners for this task. Different design alternatives were investigated for fuselage-representative test panels. Non-linear structural analyses were performed using MSC.Nastran (Nastran) and ABAQUS/Standard (Abaqus). Numerical predictions were also made applying a stress-based adhesive degradation model, previously implemented into a material user subroutine for Abaqus. Following this, a fracture mechanics analysis using Nastran was performed along all interfaces between the skin and stiffeners, to examine the stiffener disbonding behaviour of each design. On the basis of the structural and fracture mechanics analyses, a design was selected as being the most suitable for the experimental investigation within COCOMAT. Though the COCOMAT panels have yet to be manufactured and tested, experimental data on the structural performance and damage mechanisms were available from a separate project for a panel identical to the selected design. This data was compared to the structural, degradation and fracture mechanics predictions made using non-linear finite element solutions, and the application of the design within the COCOMAT project was discussed.

ABSTRACT: The elastic buckling and postbuckling behaviour of eccentrically stiffened plates are evaluated analytically. The effects of lateral boundary conditions and of stiffener eccentricity relative to the plate plane are emphasized. Attention is confined to global buckling; local plate and local stiffener buckling effects are neglected. A simplified direct energy approach is used together with Marguerre's plate theory. Critical buckling loads are found which are generally higher than those obtained with a simple Euler column model. A simple closed-form solution is found for the postbuckling curve which for small imperfection levels coincides with the classical Koiter solution. The buckling behaviour is found to be asymmetric with loads generally in excess of the critical load in the advanced postbuckling region.

Eirik Byklum and Jørgen Amdahl (Department of Marine Structures, Norwegian University of Science and Technology, N-7491, Trondheim, Norway), “Nonlinear buckling analysis and ultimate strength prediction of stiffened steel and aluminium panels”, The Second International Conference on Advances in Structural Engineering and Mechanics, Busan, Korea, August, 2002

ABSTRACT: A computational model for buckling and postbuckling analysis of stiffened panels is developed. The model provides fast and accurate results for use in design of ships and offshore structures. The loads
considered are in-plane compression or tension, shear force, and lateral pressure. Deflections are represented by trigonometric functions, and the principle of minimum potential energy is applied. Geometrical nonlinearities are accounted for using large deflection plate theory. Material nonlinearity is not taken into account, since the onset of yielding is taken as the capacity limit. Various computations have been performed for verification of the proposed model, and comparisons are made with nonlinear finite element methods.

ABSTRACT: A computational model for analysis of local buckling and postbuckling of stiffened panels is derived. The model provides a tool that is more accurate than existing design codes, and more efficient than nonlinear finite element methods. Any combination of biaxial in-plane compression or tension, shear, and lateral pressure may be analysed. Deflections are assumed in the form of trigonometric function series. The deformations are coupled such that continuity of rotation between the plate and the stiffener web is ensured, as well as longitudinal continuity of displacement. The response history is traced using energy principles and perturbation theory. The procedure is semi-analytical in the sense that all energy formulations are derived analytically, while a numerical method is used for solving the resulting set of equations, and for incrementation of the solution. The stress in certain critical points are checked using the von Mises yield criterion, and the onset of yielding is taken as an estimate of ultimate strength for design purposes.

ABSTRACT: Direct application of geometrical non-linear plate theory is the main concept in the new Panel Ultimate Limit State (PULS) stiffened panel models recently recognized by Det Norske Veritas as part of the new rules and standards for ships and offshore constructions. The focus is on assessment of the ultimate capacity limit, rather than the more traditional elastic buckling limit. The method is streamlined for rules based on modern ultimate limit state design principles. The models are validated against non-linear FE analyses and laboratory experiments. Comparison against existing codes used by Classification Societies are included.

ABSTRACT: A computational model for global buckling and postbuckling analysis of stiffened panels is derived. The loads considered are biaxial in-plane compression or tension, shear, and lateral pressure. Deflections are assumed in the form of trigonometric function series, and the principle of stationary potential energy is used for deriving the equilibrium equations. Lateral pressure is accounted for by taking the deflection as a combination of a clamped and a simply supported deflection mode. The global buckling model is based on Marguerre’s nonlinear plate theory, by deriving a set of anisotropic stiffness coefficients to account for the plate stiffening. Local buckling is treated in a separate local model developed previously. The anisotropic stiffness coefficients used in the global model are derived from the local analysis. Together, the two models provide a tool for buckling assessment of stiffened panels. Implemented in the computer code PULS, developed at Det Norske Veritas, local and global stresses are combined in an incremental procedure. Ultimate limit state estimates for design are obtained by calculating the stresses at certain critical points, and using the onset of yielding due to membrane stress as the limiting criterion.

ABSTRACT: The buckling capacity of steel plates stiffened with T shape stiffeners was investigated experimentally and analytically. The test specimens, 2000 mm long, were fabricated with a 500×10 mm plate stiffened with a WT 125×12.5 stiffener. The experimental program was designed to investigate the effect of unloaded edges boundary restraint, combination of in-plane and out-of-plane load, and imposed plate damage on the buckling capacity of stiffened steel plates. The residual stresses were measured in a representative test specimen and initial imperfections were measured for each test specimen. The residual stresses and the measured initial imperfections were included in the finite element model. A large deformation and finite strain analysis was performed using the finite element code ABAQUS. The finite element analysis was found to predict very accurately both the behaviour and capacity of stiffened steel plate panels. Stiffener tripping and plate buckling modes were equally well predicted.

Joergen Amdahl, “Buckling and ultimate strength of marine structures”, Chapter 5, Buckling of Cylindrical Shells”, TMR4205, MTS-2005.01.18

PARTIAL INTRODUCTION: Stiffened and unstiffened cylindrical shells are important structural elements in offshore structures. They are very often subjected to compressive stresses and must be designed against buckling criteria. The buckling behaviour is usually more violent than it is for plate and column structures. ABSTRACT: The stability of plates stiffened with tee-shape stiffeners was investigated using a finite element model. Four series of stiffened plate panels were modeled using a finite strain four-node shell element. The model was validated using the results of tests on full-size stiffened plate specimens and was subsequently used to perform the study of various parameters presented in this paper. The parameters investigated are: the shape and magnitude of initial imperfections in the plate; residual stress magnitude and direction of applied uniform bending; plate slenderness ratio; plate aspect ratio; and plate to stiffener cross-sectional area ratio. The effect of the investigated parameters on the axial load carrying capacity and the mode of failure of stiffened plates is investigated both in the elastic and inelastic ranges. A comparison of these results with design guidelines formulated by Det norske Veritas and the American Petroleum Institute indicates that the guidelines are generally conservative for cases where initial imperfection magnitudes do not exceed the guidelines' prescribed maximum.

ABSTRACT: The stability of steel plates stiffened with tee-shape sections under uniaxial compression and combined uniaxial compression and bending was investigated using a finite element model. The emphasis of the work presented in this paper was to find the parameters that uniquely describe the strength and behaviour of stiffened steel plates. A finite element model, validated using the results of tests on full-size stiffened plate panels, was used to investigate the scale effect for five dimensionless parameters. The parameters investigated were: the transverse slenderness of the plate, the slenderness of the web and flange of the stiffener, the ratio of torsional slenderness of the stiffener to the transverse slenderness of the plate, and the stiffener-to-plate area ratio. Average magnitude residual stresses and initial imperfections were assumed for this study. A parametric study covering a wide range of dimensionless parameters indicated that stiffened steel plates do not fail by stiffener tripping unless a bending moment is applied to create flexural compressive stresses in the stiffener. Although plate buckling and overall buckling were found to lead to a very stable post-buckling behaviour, the interaction between these two buckling modes was found to give rise to a sudden loss of capacity following initial plate buckling. The plate transverse slenderness, the stiffener slenderness-to-plate slenderness ratio, and the stiffener-to-plate area ratio were found to have a significant effect on this behaviour. A comparison of the numerical analysis results with API and DnV design guidelines indicates that the guidelines predict stiffened steel plate capacity with various degrees of success, depending on the governing mode of failure. Neither guidelines address the potential interaction-buckling phenomenon.

ABSTRACT: This paper presents part of a series of investigations of the behaviour of steel plates stiffened with tee-shape stiffeners and loaded with axial compressive forces with or without bending moments. These elements typically form bridge decks, ship hulls, ship decks and heavy haul equipment walls. Earlier work by the authors validated a non-linear large deformation-finite strain elasto-plastic finite element model by comparison of the model with the results of sophisticated full-scale physical experimental trials under different load combinations. A parametric study carried out using the finite element model is presented in the following. The study deals with the response of stiffened plate elements under combined uniaxial compression and bending moment. The parameters investigated were the transverse slenderness of the plate, the slenderness of the web and flange of the stiffener, the ratio of torsional slenderness of the stiffener to the transverse slenderness of the plate, and the stiffener to plate area ratio. Average magnitude residual stresses and initial imperfections were assumed. The parametric study indicated that the plate transverse flexural slenderness is the most influential parameter affecting both the strength and behaviour of stiffened steel plates for all the failure modes observed under combined compression and bending. The ratio of stiffener torsional slenderness to plate transverse flexural slenderness, $\beta_4$, affected both the strength and behaviour of only the stiffened plates failing by stiffener tripping. A comparison of the numerical analysis results with American Petroleum Institute and Det Norske Veritas design guidelines indicates that the guidelines predict stiffened steel plate capacity with various degrees of success, depending on the governing mode of failure.

ABSTRACT: In this thesis a post processing tool for finite element analysis was developed to perform buckling checks on stiffened steel panels. The tool can perform buckling checks on rectangular, orthogonal stiffened plates including different panel sizes and openings. The procedure is completely automatic and is consequently conducive to reduction of engineering time. The tool detects geometrical and material properties from a finite element model and determines design loads based on stress results of a finite element analysis. The approach is in accordance with guidelines from design codes and therefore results can be considered to be verified according to the design code in question. The tool has been adapted to the American Bureau of Shipping guide for buckling and ultimate strength assessment for offshore structures. The tool is compared to the ABS plate buckling tool of the commercial software SDC Verifier. Results show that the developed tool does not need as fine finite element mesh as the ABS plate buckling tool of the SDC Verifier to predict accurate buckling factors. Furthermore for general cases up to 25% reduction of buckling factors can be obtained with the developed tool compared to the SDC Verifier.

Elisabeth Slettum (Faculty of Mathematics and Natural Sciences, University of Oslo), “A Semi-Analytical Model for Buckling of Stiffened Cylindrical Shells”, Master’s degree thesis, June 2013, (Supervisor Associate Professor Lars Brubak)

SUMMARY: Cylindrical shells are common configurations within the technology. The transition from the side to the bottom on a ship has the shape of a fourth of a cylindrical shell. Both ring and stringer stiffeners can be added to the shell for support. Buckling of this type of structure is an important area of interest. The main purpose of this thesis has been to make a semi-analytical model that can describe how a ring stiffened shell and stringer stiffened shell respond during buckling. A variety of loads have been subjected to the shell model. Simple analytical expressions do not exist for clamped shells or shells subjected to shear and numerical methods must be used. The development of the model has been done by use of linear buckling theory and an energy method, the Rayleigh Ritz method. The model has been programmed in Fortran. Eigenvalues and associated eigenmodes have been found. The semi-analytical model has been verified against the finite element analysis software Abaqus. The results from the models were in good agreement with each other. The apply of the semi-analytical model on a bilge structure showed a deviation in the results. A small difference in the boundary conditions, with the element model being stiffer due to the edges being held straight, was causing the deviation. The difference in the results from the semi-analytical model and the element model was smaller for the ring stiffened shell than for the unstiffened shell and the stringer stiffened shell. The buckling load calculated by the semi-analytical model were on the conservative side compared with the element model.

ABSTRACT: A total potential energy approach has been employed in conjunction with the Rayleigh-Ritz method to study the stability behaviour of generally laminated composite plates with all edges simply supported and subjected to in-plane loading conditions. Thorough comparison with exact solutions for some classes of laminated composite plates subjected to uniaxial compression and biaxial compression are presented to verify the theoretical prediction of the present analysis. Lastly parametric studies on the combination of the various in-plane loads, i.e. biaxial compression and uniaxial compression with shear, on practical laminated composite plates are presented. The buckling results for a symmetric angle-ply laminated composite plate are also discussed.

ABSTRACT: A closed-form expression to determine the effective flexural modulus for a laminated composite beam is derived and presented in this paper. An approach based on the established Euler—Bernoulli beam theory with the proposed effective flexural modulus to predict the buckling load of the laminated composite beam is also presented in detail. The problem of a laminated beam with no delamination and that with a single through-the-width delamination is analysed. The results obtained using the current expression are compared with those obtained using existing expressions found in the literature. Results from a non-linear finite-element analysis are also presented and included in the comparison. The parameters investigated include ply orientation, number of layers, delamination length, support conditions, and material property. The comparison of results showed that the current estimated effective flexural stiffness expression yields a good lower bound solution for predicting the buckling load of both the perfect and the delaminated laminated composite beam.

ABSTRACT: This article reports the structural responses of generally laminated composite columns subjected to uni-axial compression and transverse load. Closed-form expressions were developed and are presented in this contribution to analyse buckling and bending responses of generally laminated composite beams with various boundary supports. The expressions were developed using a combination of the Euler—Bernoulli beam and the classical lamination theory. In addition, the results of a complementary experimental study are presented and are used to validate the analytical models. The comparison of the analytical results with the experimental results shows good correlation in general. Some interesting preliminary results obtained in the analysis of the beam-column are also presented, noted, and discussed.

ABSTRACT: The post-buckling behaviour of anisotropic stiffened panels with initial imperfections is investigated. Since buckling of the skin between the stiffeners often occurs first, a non-linear analysis is developed for symmetric panels under biaxial compression in order to obtain the out-of-plane panel deflection in the post-buckling range. The non-linear differential equations are expressed in terms of the out-of-plane displacement and the Airy function. They are solved with the Galerkin method for various boundary conditions by imposing an edge displacement control. The theoretical and experimental results obtained by the present analysis show that the transverse load can greatly influence the buckling loads and halfwave number. Since no experimental results have been found in the literature, several tests have been carried out on graphite/epoxy blade stiffened panels 900 mm long and 620 mm wide applying simultaneously biaxial compression loads with several combined ratios. An eccentricity results between longitudinal and transverse load, because the longitudinal compression is applied along the centroidal axes of the stiffened section while the transverse compression is applied to the skin panel. The correlation between the experimental and analytical results has been quite good; the experimental results demonstrate the influence of eccentricity of the transverse load on panel deflection in the pre- and post-buckling range.

ABSTRACT: A systematic study of theoretical methods for predicting the ultimate hull girder strength of ships is carried out based on long-time theoretical and experimental work in authors group. An integrated framework of non-linear finite element analysis, a locally improved idealized structural unit method (ISUM), a simplified method (SM) in which average stress–strain relationship is derived using beam-column theory, along with an advanced analytical method (AM) which is coupled with an elastic-plastic method (EPM which is a combination of elastic large deflection analysis and rigid plastic analysis) of ultimate buckling strength of stiffened panels and suitable for biaxial bending and non-symmetric structures of damaged ship hulls, are used to perform a comparative study of ultimate hull girder strength of a 300,000 dwt large double hull tanker. The calculation results are also compared with single step procedure of common structural rules (CSR) for double hull tankers and comparative analysis of calculation methods of ultimate hull girder strength is carried out in many ways.

ABSTRACT: The new simple design equations for predicting the ultimate compressive strength of stiffened plates with initial imperfections in the form of welding-induced residual stresses and geometric deflections were developed in this study. A non-linear finite element method was used to investigate on 60 ANSYS elastic–plastic buckling analyses of a wide range of typical ship panel geometries. Reduction factors of the ultimate strength are produced from the results of 60 ANSYS inelastic finite element analyses. The proposed design equations have been developed based on these reduction factors. For the real ship structural stiffened plates, the most general loading case is a combination of longitudinal stress, transverse stress, shear stress and lateral pressure. The new simplified analytical method was generalized to deal with such combined load cases. The accuracy of the proposed equations was validated by the experimental results. Comparisons show that the adopted method has sufficient accuracy for practical applications in ship design.

ABSTRACT: An analytical method based on the modal expansion technique was developed to predict the vibro-acoustic response of both unidirectionally and bidirectionally stiffened flat panel. This paper presents the response to diffuse acoustic field (DAF) and turbulent boundary layer (TBL) excitations in terms of their joint acceptance. Numerical results for the dynamic and acoustic responses are compared with finite element method (FEM) and boundary element (BEM) results for stiffened panel with complex and eccentrically shaped stiffeners subject to point force excitation. A theoretical prediction of the transmission loss (TL) is also compared with laboratory measurements conducted on flat panels representing aircraft models as well as with hybrid statistical energy analysis (SEA)–FEM periodic model. The results confirm that the stiffened panel has the same acoustic response as the skin without stiffeners at frequencies where the structural wavelengths are equal to the spacing between the stiffeners. In addition, the transmission loss is lowered by the presence of the stiffeners at some particular region of frequencies below the critical frequency with respect to the unstiffened panel.

Knight, Norman F, Jr and Starnes, James H, Jr, “Postbuckling behavior of axially compressed graphite-epoxy cylindrical panels with circular holes”, American Society of Mechanical Engineers, Joint Pressure Vessels and Piping/Applied Mechanics Conference, San Antonio, TX; United States; 17-21 June 1984

ABSTRACT: The results of an experimental and analytical study of the effects of circular holes on the postbuckling behavior of graphite-epoxy cylindrical panels loaded in axial compression are presented. The STAGSC-1 general shell analysis computer code is used to determine the buckling and postbuckling response of the panels. The loaded, curved ends of the specimens were clamped by fixtures and the unloaded, straight edges were simply supported by knife-edge restraints. The panels are loaded by uniform end shortening to several times the end shortening at buckling. The unstable equilibrium path of the postbuckling response is obtained analytically by using a method based on controlling an equilibrium-path-arc-length parameter instead of the traditional load parameter. The effects of hole diameter, panel radius, and panel thickness on
postbuckling response are considered in the study. Experimental results are compared with the analytical results and the failure characteristics of the graphite-epoxy panels are described.

ABSTRACT: Results of an experimental and analytical study of the postbuckling behavior of selected graphite-epoxy cylindrical panels loaded in axial compression are presented. The postbuckling response and failure characteristics of the panels are described. The postbuckling response of each specimen is typical of axially-compressed cylindrical shells and curved panels in that a severe reduction in load occurs at buckling. Failure of all panels initiated near regions with severe local bending gradients. Analytical results from a nonlinear general shell finite element analysis computer code correlate well with typical experimental results up to buckling. Measured initial geometric imperfections were included in the postbuckling analysis. Analytically-determined stress distributions in the postbuckling response were used with failure criteria to identify the load level and the location of first-ply failure.

ABSTRACT: Factors influencing the nonlinear response prediction of composite panels are described. The role of these factors in performing test-analysis correlation for composite panels is discussed and demonstrated using selected configurations for which experimental data have been previously published. Advanced formulations and analysis methods are providing structural analysts with better tools to aid the development of understanding the complexities associated with composite structural design and analysis.

ABSTRACT: The prediction of the ultimate load-carrying capability for compressively loaded shell structures is a challenging nonlinear analysis problem. Selected areas of finite element technology research and nonlinear solution technology are assessed. Herein, a finite element analysis procedure is applied to four cylindrical shell collapse problems which have been used by computational structural mechanics researchers in the past. This assessment will focus on a number of different shell element formulations and on different approaches used to account for geometric nonlinearities. The results presented confirm that these aspects of nonlinear shell analysis can have a significant effect on the predicted nonlinear structural response. All analyses were performed using a single software system which allowed a convenient assessment of different element formulations with a consistent approach to solving the discretized nonlinear equations.

ABSTRACT: An improved 4-node quadrilateral assumed-stress hybrid shell element with drilling degrees of freedom is presented. The formulation is based on Hellinger–Reissner variational principle and the shape functions are formulated directly for the 4-node element. The element has 12 membrane degrees of freedom and 12 bending degrees of freedom. It has 9 independent stress parameters to describe the membrane stress resultant field and 13 independent stress parameters to describe the moment and transverse shear stress resultant field. The formulation encompasses linear stress, linear buckling and linear free vibration problems. The element is validated with standard test cases and is shown to be robust. Numerical results are presented for linear stress, buckling, and free vibration analyses.

ABSTRACT: The goal of this research project is to develop assumed-stress hybrid elements with rotational degrees of freedom for analyzing composite structures. During the first year of the three-year activity, the effort was directed to further assess the AQ4 shell element and its extensions to buckling and free vibration problems. In addition, the development of a compatible 2-node beam element was to be accomplished. The extensions and new developments were implemented in the Computational Structural Mechanics Testbed COMET. An assessment was performed to verify the implementation and to assess the performance of these elements in terms of accuracy. During the second and third years, extensions to geometrically nonlinear problems were developed and tested. This effort involved working with the nonlinear solution strategy as well as the nonlinear formulation for the elements. This research has resulted in the development and implementation of two additional element processors (ES22 for the beam element and ES24 for the shell elements) in COMET. The software was developed using a SUN workstation and has been ported to the NASA Langley Convex named blackbird. Both element processors are now part of the baseline version of COMET.

ABSTRACT: An improved smeared stiffener theory for stiffened panels is presented that includes skin-stiffener interaction effects. The neutral surface profile of the skin-stiffener combination is developed analytically using the minimum potential energy principle and statics conditions. The skin-stiffener interaction is accounted for by computing the bending and coupling stiffness due to the stiffener and the skin in the skin-stiffener region about a shift in the neutral axis at the stiffener. Buckling load results for axially stiffened, orthogrid, and general grid-stiffened panels are obtained using the smeared stiffness combined with a Rayleigh-Ritz method and are compared with results from detailed finite element analyses.
Knight, Norman F, Jr and Nemeth, Michael P (editors), “Stability Analysis of Plates and Shells”, NASA no. 19980019011. In: AIAA/ASME/ASCE/AHS/ASC Structures, Structural Dynamics, and Materials Conference ABSTRACT: This special publication contains the papers presented at the special sessions honoring Dr. Manuel Stein during the 38th AIAA /ASME/ASCE/AHS/ASC Structures, Structural Dynamics, and Materials Conference held in Kissimmee, Florida, Apdl 7-10, 1997. This volume, and the SDM special sessions, are dedicated to the memory of Dr. Manuel Stein, a major pioneer in structural mechanics, plate and shell buckling, and composite structures. Many of the papers presented are the work of Manny's colleagues and co-workers and are a result, directly or indirectly, of his influence. Dr. Stein earned his Ph.D. in Engineering Mechanics from Virginia Polytechnic Institute and State University in 1958. He worked in the Structural Mechanics Branch at the NASA Langley Research Center from 1943 until 1989. Following his retirement, Dr. Stein continued his involvement with NASA as a Distinguished Research Associate.

Norman F. Knight, Jr and Yunqian Qi (Department of Aerospace Engineering, Old Dominion University, Norfolk, VA 23529-0247, USA), “On a consistent first-order shear-deformation theory for laminated plates”, Composites Part B: Engineering, Vol. 28, No. 4, 1997, pp. 397-405, doi:10.1016/S1359-8368(96)00058-3 ABSTRACT: This paper systematically states the consistent first-order shear-deformation theory for laminated plates recently proposed by Qi and Knight. It assumes that only in an average sense does a straight line originally normal to the midplane remain straight and rotate relative to the normal of the midplane, and in a local sense a slight displacement perturbation around the average rotated line is also permitted after deformation. Since the curved line is very shallow, the present theory still approximates linear in-plane and constant transverse displacements through the thickness just as Reissner and Mindlin's first-order shear-deformation theory does. Reissner and Mindlin's theory leads to uniform transverse shear strain distributions by employing pointwise strain displacement relationships, and satisfies the transverse shear constitutive relationships only in an average corrected form. In contrast, Qi and Knight's theory accounts for variable transverse shear strain distributions by enforcing pointwise constitutive relationships, and relates transverse shear strains to kinematic unknowns only in a weighted-average form. Through-the-thickness transverse shear strains are thus consistent with the stress counterparts and their transverse-shear-stress-weighted-average values are just the nominal-uniform transverse shear strains which correspond to the average rotations. The new theory combines the advantages of several prevailing 2D laminated plate theories while overcoming their drawbacks. Numerical results for the cylindrical bending problem of orthotropic laminated plates exhibit excellent agreement between Qi and Knight's theory and Pagano's 3D exact elasticity results.

Norman F. Knight, Jr and Yunqian Qi (Department of Aerospace Engineering, Old Dominion University, Norfolk, Virginia 23529-0247, U.S.A.), “Restatement of first-order shear-deformation theory for laminated plates”, International Journal of Solids and Structures, Vol. 34, No. 4, February 1997, pp. 481-492, doi:10.1016/S0020-7683(96)00032-7 ABSTRACT: A restatement of the first-order shear-deformation theory of plates is offered and verified numerically by exact 3-D elasticity results. Based on a more appropriate physical assumption, the restated theory innovatively interprets its variables and applies elasticity equations in a more pertinent manner. It assumes physically that only in some average sense does a straight line originally normal to the midplane remain straight and rotate relative to the normal of the midplane after deformation. Hence the in-plane displacement is still approximated, in an average sense, as linear and the transverse deflection as constant through the plate thickness. The associated nominal-uniform transverse shear strain directly derived from these displacement field assumptions is identified as the weighted-average transverse shear strain through the plate
thickness, with the corresponding transverse shear stress as the weighting function, while the actual transverse shear strain is permitted to vary through the thickness and satisfies the constitutive law with its stress counterpart. Likewise, the average rotation of the line is identified as its weighted-average value, instead of the one evaluated from a linear regression of the inplane displacement with the least-square method. Examination of bending energy and transverse shear energy supports this interpretation. In addition, an effective transverse shear stiffness parameter is identified and proven appropriate. This restated first-order, shear-deformation theory yields accurate local as well as global response predictions without employing a shear-correction factor.

Knight, Norman F, Jr and Starnes, James H, Jr, “Developments in Cylindrical Shell Stability Analysis”, NASA no. 19980019015. Stability Analysis of Plates and Shells; UNITED STATES; 1998

ABSTRACT: Today high-performance computing systems and new analytical and numerical techniques enable engineers to explore the use of advanced materials for shell design. This paper reviews some of the historical developments of shell buckling analysis and design. The paper concludes by identifying key research directions for reliable and robust methods development in shell stability analysis and design.

“Optimal design of general stiffened composite circular cylinders for global buckling with strength constraints”, Composite Structures, Vol. 41, Nos. 3-4, March-April 1998, pp. 243-252,
doi:10.1016/S0263-8223(98)00020-8

ABSTRACT: A design strategy for optimal design of composite grid-stiffened cylinders subjected to global and local buckling constraints and strength constraints was developed using a discrete optimizer based on a genetic algorithm. An improved smeared stiffener theory was used for the global analysis. Local buckling of skin segments were assessed using a Rayleigh-Ritz method that accounts for material anisotropy. The local buckling of stiffener segments were also assessed. Constraints on the axial membrane strain in the skin and stiffener segments were imposed to include strength criteria in the grid-stiffened cylinder design. Design variables used in this study were the axial and transverse stiffener spacings, stiffener height and thickness, skin laminate stacking sequence and stiffening configuration, where stiffening configuration is a design variable that indicates the combination of axial, transverse and diagonal stiffener in the grid-stiffened cylinder. The design optimization process was adapted to identify the best suited stiffening configurations and stiffener spacings for grid-stiffened composite cylinder with the length and radius of the cylinder, the design in-plane loads and material properties as inputs. The effect of having axial membrane strain constraints in the skin and stiffener segments in the optimization process is also studied for selected stiffening configurations.

ABSTRACT: A buckling formulation for anisotropic variable-curvature panels is presented in this paper. The variable-curvature panel is assumed to consist of two or more panels of constant curvature where each panel may have a different curvature. Bezier functions are used as Ritz functions. Displacement (C0), and slope (C1) continuities between segments are imposed by manipulation of the Bezier control points. A first-order shear-deformation theory is used in the buckling formulation. Results obtained from the present formulation are compared with those from finite element simulations and are found to be in good agreement.

PARTIAL INTRODUCTION: The objectives of this paper are to present a brief overview of the finite element method, to review selected finite element analysis techniques as applied to determining the nonlinear postbuckling and collapse response of elastic structures, and to describe selected application problems. First, some of the fundamental concepts associated with finite element approximations are described. Second, the basic equations of nonlinear solid mechanics are given for the case of small strain, large elastic deformation including a brief discussion of laminate theory for composite structures. Third, different variational formulations are presented along with their finite element models. Then solution techniques for nonlinear systems (both static and dynamic) are discussed. The traditional approach of nonlinear finite element analysis using a Newton-Raphson approach is reviewed. Reduction methods for nonlinear problems such as the global function approach and the reduced basis approach are summarized. Next, selected applications are described, and finally some concluding remarks are made.

ABSTRACT: Three new buckling models have been incorporated into PANDA2, a program for minimum weight design of stiffened composite panels and shells: (1) buckling of unstiffened panels or unstiffened
portions of panels with use of double-trigonometric series expansions for buckling modal displacement components, u, v, w; (2) general buckling of cylindrical stiffened panels with both rings and stringers treated as discrete beams; and (3) inter-ring buckling of cylindrical panels based on a discretized single module model containing discretized ring segments and a discretized skin-smeared-stringer cylindrical surface to which the ring is attached. Examples are provided of buckling of certain isotropic and laminated composite flat and cylindrical unstiffened and stiffened panels and shells for which the predictions from the modified PANDA2, formerly unacceptably inaccurate, are compared with predictions from STAGS, a general-purpose finite element code. The new comparisons demonstrate that the modified PANDA2 is now well qualified for preliminary design in particular cases for which it previously yielded unreliable designs and designs that were overly conservative. The optimum design of a composite ring and stringer-stiffened cylindrical shell derived by PANDA2 is evaluated with the use of STAGS. The optimum design of an isotropic hydrostatically compressed internally T-ring stiffened cylindrical shell optimized by PANDA2 is evaluated with the use of the shell-of-revolution code BOSOR4. There is good agreement between PANDA2 predictions and STAGS and BOSOR4 predictions for buckling of the optimized designs.

ABSTRACT: Buckling loads of circular cylindrical laminated composite panels are obtained using Sanders–Koiter (e.g. Sanders, 1959; Koiter, 1959), Love (e.g. Love, 1927) and Donnell (e.g. Loo, 1957) shell theories with a first-order, shear-deformation approach and a Rayleigh–Ritz method that accounts for different boundary conditions and material anisotropy. Results obtained using Sanders–Koiter, Love, Donnell shell theories are compared with those obtained from finite element simulations, where the curved panels are modeled using nine-node quadrilateral continuum-based shell elements that are independent of any shell theory. Comparisons with finite element results indicate that Donnell’s theory could be in error for some lamination schemes and geometrical parameters.

ABSTRACT: Non-linear analyses are difficult simulations to perform and place increased demands not only on the computational systems but also on the analyst. The number of possible problems and/or difficulties increases significantly compared to those for linear elastic analyses. Combined material and geometric non-linearities challenge the analyst and the solution algorithms. Progressive failure and damage propagation for composite structures result in even more complexities due to the discrete, abrupt changes in local material stiffness. Analysts need to interrogate the computed solutions carefully based on their understanding of structural mechanics, material behavior, computational procedures and non-linear phenomena to distill correct physics from such simulations. This paper describes the computational strategy incorporated into the STAGS non-linear finite element analysis code with special emphasis on progressive failure analysis of laminated composite structures. Results for selected laminated composite structures are used to demonstrate the PFA

ABSTRACT: The design process is rapidly evolving as the twenty-first century begins. Advanced aerospace systems are becoming increasingly more complex, and customers are demanding lower cost, higher performance, and high reliability. Increased demands are placed on the design engineers to collaborate and integrate design needs and objectives early in the design process to minimize risks that may occur later in the design development stage. The Mars Sample Return/Earth Entry Vehicle has stringent design requirements imposed due to mission objectives. These requirements in turn necessitate the mitigation of uncertainties and risk associated with the system design and mission. Characterization of material response accounting for damage, delaminations, and manufacturing flaws, and understanding their influence on structural integrity to meet mission objectives are critical. Extreme environment loading conditions due to re-entry and impact on the earth’s surface using a passive impact energy management system require detailed mathematical models and advanced analysis tools based on verified constitutive models. The design process becomes a balancing process between risk and consequences. High-performance systems require better understanding of system sensitivities much earlier in the design process to meet these goals. This understanding is developed through enhanced concept selections, reduced uncertainty, and enhanced analytical tools. However, the cornerstone of the design process is the design engineer. The knowledge, skills, intuition, and experience of an individual design engineer will need to be extended significantly for the next generation of aerospace system designs. Then a collaborative effort involving the designer, rapid and reliable analysis tools and virtual experts representing the knowledge capture of technical disciplines, manufacturing processes, mission profile, and/or system performance will result in advanced aerospace systems that are safe, reliable, and efficient. This paper discusses the evolution, status, needs and directions for rapid modeling and analysis tools for structural analysis. First, the evolution of computerized design and analysis tools is briefly described. Next, the status of representative design and analysis tools is described along with a brief statement on their functionality. Then technology advancements to achieve rapid modeling and analysis are identified. Finally, potential future directions including possible prototype configurations are proposed.

ABSTRACT: Bearing-load response for a pin-loaded hole is studied within the context of two-dimensional finite element analyses. Pin-loaded-hole configurations are representative of mechanically connected structures, such as a stiffener fastened to a rib of an isogrid panel, that are idealized as part of a larger structural component. Within this context, the larger structural component may be idealized as a two-dimensional shell finite element model to identify load paths and high stress regions. Fastener modeling within these analysis models is often of low fidelity and limitations need to be assessed. Finite element modeling and analysis aspects of a pin-loaded hole are considered in the present paper including the use of linear and nonlinear springs to simulate the pin-bearing contact condition. For a repeating unit of a square domain with a center circular hole, the effects of hole diameter and degree of elastic restraint provided by material surrounding the hole are considered. These effects are found to affect the local response by changing it from a bearing-dominated response for small holes to a plane-stress-dominated ligament response for larger holes. For a T-shaped coupon specimen configuration, the pin-loaded-hole case resulted in higher local stresses around the hole, while the open-hole case generated high stresses along the majority of the free edge of the T-specimen web. Simulating pin-connected structures within a two-dimensional finite element analysis model using nonlinear spring or gap elements provides an effective way for accurate prediction of the local effective stress state and peak forces.

ABSTRACT: Experimental and analysis results for a curved, stiffened aluminum fuselage panel tested in a combined loads test machine with combined internal pressure, axial compression, and torsional shear loads are described. The experimental and analytical strain results for the panel with and without discrete source damage are presented. The effect of notch tip geometry on crack growth predictions is addressed. The crack growth trajectory predictions for the panel are presented for the applied loading conditions at failure. (Unfortunately, the pdf file does not permit cutting and pasting the 10 references listed at the end of the 4-page file.)

ABSTRACT: The results of an analytical and experimental study of the nonlinear response of thin, unstiffened, aluminum cylindrical shells with a long longitudinal crack are presented. The shells are analyzed with a nonlinear shell analysis code that accurately accounts for global and local structural response phenomena. Results are presented for internal pressure and for axial compression loads. The effect of initial crack length on the initiation of stable tearing and unstable crack growth in typical shells subjected to internal pressure loads is predicted using geometrically nonlinear elastic-plastic finite element analyses. The results of these analyses and of the experiments indicate that the pressure required to initiate stable tearing and unstable tearing in a shell subjected to internal pressure loads decreases as the crack length increases. The effects of crack length on the prebuckling, buckling and postbuckling responses of typical shells subjected to axial compression are also described. For this loading condition, the crack length is held constant. The results of the analyses illustrate the influence of crack length on shell buckling instabilities. The experimental and analytical results correlate well.

ABSTRACT: The results of an experimental and analytical study of the effects of initial imperfections on the buckling response of thin unstiffened graphite-epoxy cylindrical shells with and without a cutout, and with three different shell-wall laminates, are presented. Results that identify the individual and combined effects of traditional initial geometric shell-wall imperfections, and nontraditional shell-wall thickness variations, shell-end geometric imperfections, and variations in loads applied to the ends of the shells on the shell buckling and nonlinear responses, are included. The shells have been analyzed with a robust nonlinear finite-element analysis code for shells that accurately accounts for these effects on the buckling and nonlinear responses of the shells. The analysis results generally correlate well with the experimental results. The nonlinear analysis results are also compared with the results from a traditional linear bifurcation buckling analysis that is commonly used for...
shell design. The results suggest that the nonlinear analysis procedure can be used for determining accurate, high-fidelity, design knockdown factors for shell buckling and collapse. A discussion of how this high-fidelity nonlinear analysis procedure can be used to form the basis for a shell analysis and design approach that addresses some of the critical shell-buckling design criteria and design considerations for composite shell structures is included.

ABSTRACT: The results of a numerical study to assess the effect of skin buckling on the internal load distribution in a stiffened fuselage panel, with and without longitudinal cracks, are presented. In addition, the impact of changes in the internal loads on the fatigue life and residual strength of a fuselage panel is assessed. A generic narrow-body fuselage panel is considered. The entire panel is modeled using shell elements and considerable detail is included to represent the geometric-nonlinear response of the buckled skin, cross section deformation of the stiffening components, and details of the skin-stringer attachment with discrete fasteners. Results are presented for a fixed internal pressure and various combinations of axial tension or compression loads. Results illustrating the effect of skin buckling on the stress distribution in the skin and stringer, and fastener loads are presented. Results are presented for the pristine structure, and for cases where damage is introduced in the form of a longitudinal crack adjacent to the stringer, or failed fastener elements. The results indicate that axial compression loads and skin buckling can have a significant effect on the circumferential stress in the skin, and fastener loads, which will influence damage initiation, and a comparable effect on stress intensity factors for cases with cracks. The effects on stress intensity factors will influence damage propagation rates and the residual strength of the panel.

ABSTRACT: Results of a geometrically nonlinear finite element parametric study to determine curvature correction factors or “bulging factors” that account for increased stresses due to curvature for longitudinal and circumferential cracks in unstiffened pressurized cylindrical shells are presented. Geometric parameters varied in the study include the shell radius, the shell wall thickness, and the crack length. The major results are presented in the form of contour plots of the bulging factor as a function of two nondimensional parameters: the shell curvature parameter, Lambda, which is a function of the shell geometry, Poisson’s ratio, and the crack length; and a loading parameter, Eta, which is a function of the shell geometry, material properties, and the applied internal pressure. These plots identify the ranges of the shell curvature and loading parameters for which the effects of geometric nonlinearity are significant. Simple empirical expressions for the bulging factor are then derived from the numerical results and shown to predict accurately the nonlinear response of shells with longitudinal and circumferential cracks. The numerical results are also compared with analytical solutions based on linear shallow shell theory for thin shells, and with some other semi-empirical solutions from the literature, and limitations on the use of these other expressions are suggested.

ABSTRACT: Analysis methodologies for predicting fatigue-crack growth from rivet holes in panels subjected to cyclic loads and for predicting the residual strength of aluminum fuselage structures with cracks and subjected to combined internal pressure and mechanical loads are described. The fatigue-crack growth analysis methodology is based on small-crack theory and a plasticity induced crack-closure model, and the effect of a corrosive environment on crack-growth rate is included. The residual strength analysis methodology is based on the critical crack-tip-opening-angle fracture criterion that characterizes the fracture behavior of a material of interest, and a geometric and material nonlinear finite element shell analysis code that performs the structural analysis of the fuselage structure of interest. The methodologies have been verified experimentally for structures ranging from laboratory coupons to full-scale structural components. Analytical and experimental results based on these methodologies are described and compared for laboratory coupons and flat panels, small-scale pressurized shells, and full-scale curved stiffened panels. The residual strength analysis methodology is sufficiently general to include the effects of multiple-site damage on structural behavior.

ABSTRACT: The crack-tip-opening angle or displacement (CTOA/CTOD) fracture criterion is one of the oldest fracture criteria applied to fracture of metallic materials with cracks. During the past two decades, the use of elastic–plastic finite-element analyses to simulate fracture of laboratory specimens and structural components using the CTOA criterion has expanded rapidly. But the early applications were restricted to two-dimensional analyses, assuming either plane-stress or plane-strain behavior, which lead to generally non-constant values of CTOA, especially in the early stages of crack extension. Later, the non-constant CTOA values were traced to inappropriate state-of-stress (or constraint) assumptions in the crack-front region and severe crack tunneling in thin-sheet materials. More recently, the CTOA fracture criterion has been used with three-dimensional analyses to study constraint effects, crack tunneling, and the fracture process. The constant CTOA criterion (from crack initiation to failure) has been successfully applied to numerous structural applications, such as aircraft fuselages and pipelines. But why does the “constant CTOA” fracture criterion work so well? This paper reviews the results from several studies, discusses the issues of why CTOA works, and discusses its limitations.

ABSTRACT: This paper reviews some of the advances that have been made in stress analyses of cracked aircraft components, in the understanding of the fatigue and fatigue-crack growth process, and in the prediction of residual strength of complex aircraft structures with widespread fatigue damage. Finite-element analyses of
cracked structures are now used to determine accurate stress-intensity factors for cracks at structural details. Observations of small-crack behavior at open and rivet-loaded holes and the development of small-crack theory has lead to the prediction of stress-life behavior for components with stress concentrations under aircraft spectrum loading. Fatigue-crack growth under simulated aircraft spectra can now be predicted with the crack-closure concept. Residual strength of cracked panels with severe out-of-plane deformations (buckling) in the presence of stiffeners and multiple-site damage can be predicted with advanced elastic-plastic finite-element analyses and the critical crack-tip-opening angle (CTOA) fracture criterion. These advances are helping to assure continued safety of aircraft structures.

James H. Starnes, Jr and Cheryl A. Rose (NASA Langley Research Center), “Stable tearing and buckling responses of unstiffened aluminum shells with long cracks”, http://dl.acm.org/citation.cfm?id=887529 , 1998 NASA Technical Report (Number not given), NASA Langley Technical Report Server; Presented at the Second Joint DoD/FAA/NASA Conference on Aging Aircraft, Williamsburg, Virginia, August 31 – September 3, 1998 ABSTRACT: The results of an analytical and experimental study of the nonlinear response of thin, unstiffened, aluminum cylindrical shells with a long longitudinal crack are presented. The shells are analyzed with a nonlinear shell analysis code that accurately accounts for global and local structural response phenomena. Results are presented for internal pressure and for axial compression loads. The effect of initial crack length on the initiation of stable crack growth and unstable crack growth in typical shells subjected to internal pressure loads is predicted using geometrically nonlinear elastic-plastic finite element analyses and the crack-tip-opening angle (CTOA) fracture criterion. The results of these analyses and of the experiments indicate that the pressure required to initiate stable crack growth and unstable crack growth in a shell subjected to internal pressure loads decreases as the initial crack length increases. The effects of crack length on the prebuckling, buckling and postbuckling responses of typical shells subjected to axial compression loads are also described. For this loading condition, the crack length was not allowed to increase as the load was increased. The results of the analyses and of the experiments indicate that the initial buckling load and collapse load for shell subjected to axial compression loads decrease as the initial crack length increases. Initial buckling causes general instability or collapse of a shell for shorter initial crack lengths. Initial buckling is a stable local response mode for longer initial crack lengths. This stable local buckling response is followed by a stable postbuckling response, which is followed by general or overall instability of the shell.

ABSTRACT: The results of a numerical study of the nonlinear response of thin unstiffened aluminum cylindrical shells with a longitudinal crack are presented. The shells are analyzed with a nonlinear shell analysis code that accurately accounts for global and structural response phenomena. The effects of initial crack length on the prebuckling, buckling and postbuckling responses of a typical shell subjected to axial compression loads, and subjected to combined internal pressure and axial compression loads are described. Both elastic and elastic-plastic analyses are conducted. Numerical results for a fixed initial crack length indicate that the buckling load decreases as the crack length increases for a given pressure load, and that the buckling load increases as the internal pressure load increases for a given crack length. Furthermore, results indicate that predictions from an elastic analysis for the initial buckling load of a cracked shell subjected to combined axial compression and internal pressure loads can be unconservative. In addition, the effect of crack extension on the initial buckling load is presented.

ABSTRACT: A comparative study of different modeling approaches for predicting sandwich panel buckling response is described. The study considers sandwich panels with anisotropic face sheets and a very thick core. Results from conventional analytical solutions for sandwich panel overall buckling and face-sheet-wrinkling type modes are compared with solutions obtained using different finite element modeling approaches. Finite element solutions are obtained using layered shell element models, with and without transverse shear flexibility, layered shell/solid element models, with shell elements for the face sheets and solid elements for the core, and sandwich models using a recently developed specialty sandwich element. Convergence characteristics of the shell/solid and sandwich element modeling approaches with respect to in-plane and through-the-thickness discretization, are demonstrated. Results of the study indicate that the specialty sandwich element provides an accurate and effective modeling approach for predicting both overall and localized sandwich panel buckling response. Furthermore, results indicate that anisotropy of the face sheets, along with the ratio of principle elastic moduli, affect the buckling response and these effects may not be represented accurately by analytical solutions. Modeling recommendations are also provided.

ABSTRACT: A design strategy for optimal design of composite grid-stiffened structures with variable curvature subjected to global and local buckling constraints is developed using a discrete optimizer. An improved smeared stiffener theory is used for the global buckling analysis. Local buckling of skin segments is assessed using a Rayleigh–Ritz method that accounts for material anisotropy and transverse shear flexibility. The local buckling of stiffener segments is also assessed. Design variables are the axial and transverse stiffener spacing, stiffener height and thickness, skin laminate, and stiffening configuration. Stiffening configuration is herein defined as a design variable that indicates the combination of axial, transverse and diagonal stiffeners in the stiffened panel. The design optimization process is adapted to identify the lightest-weight stiffening configuration and stiffener spacing for grid-stiffened composite panels given the overall panel dimensions, in-plane design loads, material properties, and boundary conditions of the grid-stiffened panel or shell.

ABSTRACT: Experimental and analytical results are presented for progressive failure of stiffened composite
panels with and without a notch and subjected to in-plane shear loading well into the postbuckling regime. Initial geometric imperfections are included in the finite element models. Ply damage modes such as matrix cracking, fiber-matrix shear, and fiber failure are modeled by degrading the material properties. Experimental results from the test include strain full-field data from a video image correlation system in addition to other strain and displacement measurements. Results from nonlinear finite element analyses are compared with experimental data. Good agreement between experimental data and numerical results is observed for the stitched stiffened composite panels studied.

ABSTRACT: Progressive failure analyses results are presented for composite curved panels with and without a circular cutout and subjected to axial compression loading well into their postbuckling regime. Ply damage modes such as matrix cracking, fiber-matrix shear, and fiber failure are modeled by degrading the material properties. Results from finite element analyses are compared with experimental data. Good agreement between experimental data and numerical results are observed for most part of the loading range for the structural configurations considered. Modeling of initial geometric imperfections may be required to obtain accurate analysis results depending on the ratio of the cutout width to panel width.

“Intralaminar and interlaminar progressive failure analyses of composite panels with circular cutouts”, Composite Structures, Vol. 64, No. 1, April 2004, pp. 91-105, doi:10.1016/S0263-8223(03)00217-4
ABSTRACT: A progressive failure methodology is developed and demonstrated to simulate the initiation and material degradation of a laminated panel due to intralaminar and interlaminar failures. Initiation of intralaminar failure can be by a matrix-cracking mode, a fiber-matrix shear mode, and a fiber failure mode. Subsequent material degradation is modeled using damage parameters for each mode to selectively reduce lamina material properties. The interlaminar failure mechanism such as delamination is simulated by positioning interface elements between adjacent sublaminates. A nonlinear constitutive law is postulated for the interface element that accounts for a multi-axial stress criteria to detect the initiation of delamination, a mixed-mode fracture criteria for delamination progression, and a damage parameter to prevent restoration of a previous cohesive state. The methodology is validated using experimental data available in the literature on the response and failure of quasi-isotropic panels with centrally located circular cutouts loaded into the postbuckling regime. Very good agreement between the progressive failure analyses and the experimental results is achieved if the failure analysis includes the interaction of intralaminar and interlaminar failures.
ABSTRACT: Buckling of simply supported rectangular sandwich plate with multi-blade stiffeners is addressed herein. The main objective was to present and validate an approximate, semi-analytical computational model for such plates subjected to in-plane loading. The faceplates are modeled as shear-deformable plates using first-order shear deformation plate theory (SDPT). The core of the sandwich panel is treated as three-dimensional body. The stiffeners were added at the upper faceplates and modeled as simple beams with flexural stiffness only against out-of-plane bending. Nonlinear finite element analysis was used to verify the accuracy of the presented model. The results of the presented model are, in most cases, found to be in a good agreement with fully nonlinear finite element analysis results. The presented model allows for a very efficient analysis with relatively high numerical accuracy and low computational efforts compared to fully nonlinear finite element analysis results. A number of applications have been described, with the aim of demonstrating the capability and versatility of the presented approach.

ABSTRACT: Buckling of simply supported square orthotropic plates with multi-blade stiffeners is addressed herein. An approximate, semi-analytical model for such plates subjected to in-plane loading is derived. The optimal buckling load of simply supported laminated composite blade-stiffened panels with circular cutouts is predicted using Finite Element Analysis. In this optimization, the design variables were the cutout size, cutout location, fiber orientation angles, number and locations of stiffeners. Three types of in-plane loading were considered; namely, uniaxial, biaxial and shear loading. Based on the model studies, the total increase in the buckling load due to the presence of cutouts and stiffeners can reach up to 5 times in uniaxial loading, 7 times in biaxial loading and 2 times in shear loading compared to perfect plates. Several other imperative findings are identified based upon the various parameters influencing the buckling behavior. Guidelines for the optimal stiffeners' configurations and cutouts' proportioning are developed.

ABSTRACT: The vibrations of stiffened cylindrical shells having axisymmetric or asymmetric initial geometrical imperfections and axial preload are analyzed. The analysis is based on a solution of the von Kármán-Donnell non-linear shell equations, an “exact” solution of the compatibility equation, and a first order approximation by the Galerkin method of the equilibrium equation. The stiffeners are closely spaced and “smeared” stiffener theory is employed. The results of an extensive parametric study carried out on shells similar to those used in vibration and buckling tests at the Technion show that stiffening of the shell will lower the imperfection-sensitivity of its free vibrations, but the decrease depends on the type of stiffening (strings or rings), the mode shapes of the vibration and the imperfection, the stiffener strength and eccentricity. The imperfection-sensitivity decrease, caused by the stiffeners, is greater for vibration mode shapes with high imperfection-sensitivity than for other vibration mode shapes. The sensitivity differences between stringer and ring-stiffened shells depend especially on the vibration and the imperfection mode shapes, and on their coupling. Small imperfections change the natural frequencies of stiffened shells in the same directions as for isotropic shells, but to a smaller extent. The frequency dependence on the external load is also strongly affected by the imperfection mode shape. The results correlate well with earlier ones for isotropic shells.

ABSTRACT: Non-linear static deformation, combined with small vibrations in its vicinity, of an imperfect cylindrical panel under axial loading, is studied within a single-degree-of-freedom treatment. The frequency of the small vibrations vanishes at the limit load. This conclusion is proved to be valid for a system with any other non-linearity as well. Special emphasis is placed on the influence of initial imperfections on the vibration frequencies.

“Dynamics of a thin cylindrical shell under impact with limited deterministic information on its initial

ABSTRACT: This study deals with the dynamics and failure of a thin circular cylindrical shell with axisymmetric initial imperfections. In contrast to earlier studies, the uncertainty involved in the initial imperfections is described by convex modelling: a non-probabilistic, set-theoretical approach. This methodology is useful when only limited information is available on the distribution of the uncertain events. The most significant N Fourier coefficients are assumed to fall in an ellipsoidal set in N-dimensional Euclidean space. We evaluate the maximum total displacement as a function of the shape of the ellipsoid.

ABSTRACT: This paper is devoted to a fundamental problem of accounting for parameter uncertainties in random vibrations of structures. In contrast to the overwhelming majority of random vibration studies where perfect knowledge is assumed for the parameters of the excitation, this crucial conjecture is dispensed with. The probabilistic characteristics of the excitation are assumed to be given as depending on some parameters which are not known in advance. We postulate that some imprecise knowledge is available; namely, that these parameters belong to a bounded, convex set. In the case where this convex set is represented by an ellipsoid, closed form solutions are given for the upper and lower bounds of the mean-square displacement of the structures. For the first time in the literature the system uncertainty in the random vibrations is dealt with as an ‘anti-optimization’ problem of finding the least favorable values of the mean-square response. The approach developed here opens a new avenue for tackling parameter uncertainty which is often encountered in various branches of engineering.

ABSTRACT: Buckling of initial imperfection sensitive structure — column on a non-linear elastic foundation — is investigated. A criterion based on the concept of “modal buckling load” is proposed to determine which modes should be included in the analysis when the weighted residuals method is utilized to calculate the limit load — maximum load the structure can support — for a given initial deflection. For stochastic analysis, a random field model is suggested for the uncertain initial imperfection, and Monte Carlo simulations are performed to obtain the probability density of the buckling load and the reliability of the column. Finally, a non-stochastic convex model of uncertainty is employed to describe a situation when only limited information is available on uncertain initial deflection, and the minimum buckling load is obtained for this model. The results from both the stochastic and the non-stochastic approaches are derived and critically contrasted.

ABSTRACT: A refined second-order method is presented for structural reliability analysis. Exact and approximate reliability solutions are obtained for a circular shaft subject to random bending moments and a random torque. The comparison of the approximate results with exact ones shows that the first-order approximation is only applicable to the case where the failure surface is “far” from the origin, while the suggested second-order approximation yields quite accurate results even if the failure surface is “close” to the origin.

ABSTRACT: The present paper reviews recent developments in two major areas of structural sensitivity analysis: sensitivity of static and transient response; and sensitivity of vibration and buckling eigenproblems. Recent developments from the standpoint of computational cost, accuracy, and ease of implementation are presented. In the area of static response, current interest is focused on sensitivity to shape variation and sensitivity of nonlinear response. Two general approaches are used for computing sensitivities: differentiation of the continuum equations followed by discretization, and the reverse approach of discretization followed by differentiation. It is shown that the choice of methods has important accuracy and implementation implications. In the area of eigenproblem sensitivity, there is a great deal of interest and significant progress in sensitivity of problems with repeated eigenvalues. The paper raises the issue of differentiability and continuity that is inherent to the repeated eigenvalue case.

ABSTRACT: In many cases precise probabilistic data are not available on uncertainty in loads, but the magnitude of the uncertainty can be bound. This paper proposes a design approach for structural optimization with uncertain but bounded loads. The problem of identifying critical loads is formulated mathematically as an optimization problem in itself (called anti-optimization), so that the design problem is formulated as a two-level optimization. For linear structural analysis it is shown that the antioptimization part is limited to consideration of the vertices of the load-uncertainty domain. An example of a ten-bar truss is used to demonstrate that we cannot replace the anti-optimization process by considering the largest possible loads.

ABSTRACT: In this paper, we present a method for computing upper and lower bounds of the natural frequencies of a structure with parameters which are unknown, except for the fact that they belong to given intervals. These parameters are uncertain, yet they are not treated as being random, since no information is available on their probabilistic characteristics. The set of possible states of the system is described by interval matrices. By solving the generalized interval eigenvalue problem, the bounds on the natural frequencies of the structure with interval parameters are evaluated. Numerical results show that the proposed method is extremely effective.

ABSTRACT: This selective review (with emphasis on the word “selective”) gives only a taste of extensive research that has been conducted since 1759 when Leonhard Euler posed, apparently for the first time, a boundary value problem. Since then numerous studies have been conducted for rods, Bernoulli-Euler beams, Bresse-Timoshenko beams, Kirchhoff-Love and Mindlin-Reissner plates and shells and structures analyzed via finer, higher-order theories. This selective review classifies the solutions as belonging to either of three main classes: (1) direct problems, (2) semi-inverse problems, (3) inverse problems. In addition, some new closed-form solutions are reported, that have been obtained via posing an inverse vibration problem. Due to the huge body of literature, author limits himself with discussing classic theories of structures.

ABSTRACT: Hybrid optimization and antioptimization of the buckling load of composite cylindrical shells is conducted. The methodology, which has been developed in previous works, is applied to a set of cylindrical
composite shells, tested at the German Aerospace Center. Furthermore, the existing approach is enhanced to fit within the design-optimization scheme. The shells possess traditional imperfections in the form of Fourier series coefficients of their initial imperfection profile. Additionally, two nontraditional imperfections are included in the analysis. The available experimental data are enclosed by either 11-dimensional hyperrectangle or hyperellipsoid. The minimum buckling load of the ensemble of such shells is determined by the antioptimization procedure. Then, this minimum load is maximized by varying the laminate angle. It is shown that the proposed method is a viable and relatively simple alternative to probabilistic approaches and successfully supplements them. It is shown that the proposed method is a successful supplement to probabilistic methods and the deterministic single-buckle approach because it is deterministic in nature and thus could appeal to engineers and investigators alike, and it takes into account the actual scatter of input data.

ABSTRACT: This paper investigates the buckling mode localization in the periodic multi-span beam with disorder occurring in an arbitrary single span. The analytical finite difference calculus is used in conjunction with the conventional displacement method to derive the transcendental equations from which buckling load is calculated. The underlying treatment is general and the solution thus obtained is exact. Numerical results show that the buckling mode is highly localized in the vicinity of the disordered span of the beam.

ABSTRACT: This investigation deals with the buckling problem of a column with random geometric imperfection, resting on a nonlinear elastic foundation. In contrast to most of the earlier studies, it is assumed that the column is subjected to a random axial compression. The random initial imperfection is expressed in terms of buckling modes with coefficients obeying the truncated normal distribution. The external load is modeled as a random variable with the extreme-value distribution. An improved simulation technique with high computational efficiency is employed to obtain the probability of failure of the structure. Statistical analysis of the simulation data is proposed, and the final result is given in the form of confidence interval, which can be used directly in engineering design.

Isaac Elishakoff (Dept. of Mechanical Engineering, Florida Atlantic University, Boca Raton, Florida, USA), “Random vibration of structures: a personal perspective”, Applied Mechanics Reviews, VBoI. 48, No. 12, pp
Some topics in random vibration of structures are reviewed. For this occasion three topics are chosen: (a) effect of cross correlations in linear vibration of continuous structures, (b) effect of choice of deterministic theory describing the dynamic behavior of the structure, (c) new versions of stochastic linearization of nonlinear continuous structures. The essay attempts to partially answer a familiar but still nagging question “Now that I’m here, where am I?”

ABSTRACT: Stochastic approach and non-stochastic, convex modeling of uncertainty are critically contrasted. First some drawbacks of the probabilistic methods are discussed, attributable to lack of sufficiently accurate data; then the effect of human error in constructing a probabilistic model for input quantities is elucidated. Extensive quotations from pertinent works of Freudenthal, who is rightfully considered as an architect of modern reliability theory, are utilized to explain some doubts he himself experienced about probabilistic methods. His hints are realized in modern convex modeling of uncertainty, which the writer is advocating and advancing. A set-theoretical, convex description of uncertainty is discussed in detail. Uncertainty is described as a set of constraints unlike the classical probabilistic approach. Moreover, instead of conventional optimization studies, where the minimum possible responses are sought, here an uncertainty modeling is developed as an “anti-optimization” problem of finding the least favorable response under the constraints within the set-theoretical description. The question of how the output quantities of such an anti-optimization process vary when the global knowledge on the uncertainties increases is considered in detail. Response variability of viscoelastic structures is evaluated. Combined probabilistic-convex modeling is proposed for situations where the input quantities should be modeled as stochastic ones, but some of their probabilistic characteristics are unknown but bounded.

ABSTRACT: In this paper we present a closed-form solution for vibrational imperfection sensitivity-the effect of small imperfections on the vibrational frequencies of perturbed motion around the static equilibrium state of Augusti's model structure (a rigid link, pinned at one end to a rigid foundation and supported at the other by a linear extensional spring that retains its horizontality as the system deflects). We also treat a modified version of that model with attendant slightly different dynamics. It is demonstrated that the vibrational frequency decreases as the initial imperfections increase.

ABSTRACT: Buckling problems of two types of multi-span elastic plates with transverse stiffeners are considered using a method based on the finite difference calculus. The discreteness of the stiffeners is accounted for. It is found that the torsional rigidity of the stiffener plays an important role in the buckling mode pattern. When the torsional rigidity is properly adjusted, the stiffener can act as an isolator of deformation for the structure at buckling so that the deflection is only limited to a small area.

ABSTRACT: This paper elucidates that for rigorous analysis of many engineering structures, three seemingly unrelated concepts, namely probability, fuzziness and anti-optimization, ought to be utilized. This is in order to take into account the uncertainty in the actual values of the basic variables or on the models employed to evaluate the structure-expected behaviour. In this case, it is possible and reasonable to use the three paradigms in a combined manner. Some examples are given to illustrate these ideas.

ABSTRACT: Probabilistic and non-probabilistic, anti-optimization analyses of uncertainty are contrasted in this study. Specifically, the comparison of these two competing approaches is conducted for an uniform column, with initial geometric imperfection, subjected to an impact axial load. The reliability of the column is derived for the cases when the initial imperfections possess either (a) uniform probability density, (b) truncated exponential density or (c) generic truncated probability density. The problem is also analyzed in the context of an interval analysis. It is shown that in, the most important near-unity reliability range these two approaches tend to each other. Since the interval analysis constitutes a much simpler procedure than the probabilistic approach, it is argued that the former is advantageous over the latter in some circumstances.

ABSTRACT: In this paper we study axisymmetric buckling of radially graded circular plates. The flexural rigidity is considered to be a suitably varying function of the radial coordinate. The problem is posed as a semi-inverse one. The buckling mode is selected first, then the variation of the flexural rigidity consistent with the buckling mode is determined. Apparently for the first time in the literature, closed-form solutions are found. Such solutions allow the design of a circular plate whose buckling load is at least the pre-specified one. Such a design appears to find much applications in various fields of engineering.

ABSTRACT: The research explores the design and analysis of a thin marble shell that incorporates the latest developments in fabrication technology and computational analysis. Natural stone, one of the oldest and most traditional building materials, is used in innovative ways by manipulating it with a 6-axis robotic waterjet. The research studies techniques for the robotic perforation and surfacing of natural stone, with a particular focus on marble. The work was conducted in collaboration with Monica Ponce de Leon and Wes McGee at the Harvard Graduate School of Design (GSD). Small tests panels explore how transparency and translucency of stone can
be generated through robotic waterjet cutting. A prototypical stone shell is designed to further explore the design potential encountered in the small test pieces. The shell is post-tensioned and stiffened with metal stiffeners. Finite-element analysis (FEA) serves as a primary technique to conduct a detailed structural analysis of the shell.

Demetris Pentaras (Department of Mechanical Engineering, Florida Atlantic University, 777 Glades Road, Boca Raton, FL, USA; later Cyprus Institute of Technology), “Vibration, buckling and impact of carbon nanotubes”, Ph.D. dissertation, Isaac Elishakoff (advisor), College of Engineering and Computer Science, Florida Atlantic University, Boca Raton, Florida, April 2009

ABSTRACT: Natural frequencies of the double and triple-walled carbon nanotubes are determined exactly and approximately for both types. Approximate solutions are found by using Bubnov-Galerkin and Petrov-Galerkin methods. For the first time explicit expressions are obtained for the natural frequencies of double and triple-walled carbon nanotubes for different combinations of boundary conditions. Comparison of the results with recent studies shows that the above methods constitute quick and effective alternative techniques to exact solution for studying the vibration properties of carbon nanotubes. The natural frequencies of the clamped-clamped double-walled carbon nanotubes are obtained; exact solution is provided and compared with the solution reported in the literature. In contrast to earlier investigation, an analytical criterion is derived to establish the behavior of the roots of the characteristic equation. Approximate Bubnov-Galerkin solution is also obtained to compare natural frequencies at the lower end of the spectrum. Simplified version of the Bresse-Timoshenko theory that incorporates the shear deformation and the rotary inertia is proposed for free vibration study of double-walled carbon nanotubes. It is demonstrated that the suggested set yields extremely accurate results for the lower spectrum of double-walled carbon nanotube. The natural frequencies of double-walled carbon nanotubes based on simplified versions of Donnell shell theory are also obtained. The buckling behavior of the double-walled carbon nanotubes under various boundary conditions is studied. First, the case of the simply supported double-walled carbon nanotubes at both ends is considered which is amenable to exact solution. Then, approximate methods of Bubnov-Galerkin and Petrov-Galerkin are utilized to check the efficacy of these approximations for the simply supported double-walled carbon nanotubes. Once the extreme accuracy is demonstrated for simply supported conditions, the approximate techniques are applied to two other cases of the boundary conditions, namely to clamped-clamped and simply supported-clamped double-walled carbon nanotubes. For the first time in the literature approximate expression for the buckling loads are reported for these boundary conditions. The dynamic deflection of a single-walled carbon nanotube under impact loading is analyzed by following a recently study reported on the energy absorption capacity of carbon nanotubes under ballistic impact.

ABSTRACT: This review paper deals with two problems in structural engineering dynamics; one is deterministic, the other is of stochastic nature. One problem is linear, the other is nonlinear. Authors have a biased preferential view on these problems because of their active involvement in the discussed research topics.
Still, these two problems reflect, at least in a small manner, some developments in this vast and fascinating field. The first part deals with deterministic linear vibrations of double-walled carbon nanotubes either in classical or refined setting; the second part is devoted to the nonlinear random vibrations of structures.

ABSTRACT: Natural frequencies of triple-walled carbon nanotubes (TWCNTs) are determined both exactly and approximately. For the case of a TWCNT simply supported at its ends, closed-form solutions are obtained. It is shown that there are three series of natural frequencies corresponding to the cubic polynomial equation for natural frequency squares. For a TWCNT that has other boundary conditions approximate Bubnov–Galerkin and Petrov–Galerkin methods are used with simple polynomial functions. Each of these methods yields three natural frequencies corresponding to the lower end of each frequency spectrum.

ABSTRACT: This study deals with the Bubnov-Galerkin method applied to the buckling of clamped-free double-walled carbon nanotubes (DWCNTs) subjected to a concentrated compressive load at the free end. It was found that at least four comparison functions are needed in order to obtain accurate results.

failure mode associated with these structures is buckling. This failure mode is further subdivided into ‘local skin and/or stiffener buckling’, and ‘universal buckling’. In this paper buckling investigation of a grid stiffened composite cylinder is presented using analytical model, Finite elements model and experimentation. The cylinder under discussion has orthotropic stiffeners integrally made with an orthotropic shell. All the buckling analysis is based on a uniaxial compressive load condition.

ABSTRACT: Stiffened cylindrical shells are the major components of aerospace structures. In this study global buckling load for a generally cross and horizontal grid stiffened composite cylinder was determined. This was accomplished by developing an analytical model for determination of the equivalent stiffness parameters of a grid stiffened composite cylindrical shell. This was performed by taking out a unit cell and smearing the forces and moments due to the stiffeners onto the shell. Based on this analysis the extensional, coupling and bending matrices (A, B and D matrices, respectively) associated with the stiffeners were determined. This stiffness contribution of the stiffeners was superimposed with the stiffness contribution of the shell to obtain the equivalent stiffness parameters of the whole panel. Making use of the energy method the buckling load was solved for a particular stiffener configuration. Buckling test was also performed on a stiffened composite cylinder and compared with analytical results. Finally, using the analytical model developed, parametric analysis of some of the important design variables was performed and based on these results conclusions were drawn.

ABSTRACT: An improved smeared method is developed to model the buckling problem of an isogrid stiffened composite cylinder. In this model the stiffness contributions of the stiffeners is computed by analyzing the force and moment effect of the stiffener on a unit cell. The equivalent stiffness of the stiffener/shell panel is computed by superimposing the stiffness contribution of the stiffeners and the shell. The equivalent stiffness parameters are then used to calculate the buckling load of the stiffened cylinder. A 3-D finite-elements model is also built that takes into consideration the exact geometric configuration and the orthotropic properties of the stiffeners and the shell. Experimental analysis is also performed to compliment the two analytical methods used to determine the buckling load of the stiffened cylinder. Results of the three types of analyses methods are compared. Finally a parametric study is carried out and general conclusions are drawn regarding optimum configurations of the different parameters of the grid-stiffened cylinder.

ABSTRACT: In steel structures like vessels or offshore constructions shells are often not as thin as in aircraft and space constructions. The rather thick-walled shells which are stressed in the elastic-plastic range are of great importance. To take this fact into account the plastic range was introduced in the codes for shell buckling during the past years. Compared to the number of experiments in the elastic range there are unfortunately only a few tests performed in the plastic range. And these few ones are not even well documented. Especially there is a lack of exact values of the yield stresses of the materials being used.

ABSTRACT: The buckling and collapse behaviour of shells is a complex subject about which numerous books have been written. This chapter is intended to serve as a simple introduction to the behaviour and design of a restricted class of shells, namely cylindrical shells stiffened by ring or orthogonal stiffeners. The treatment is non-mathematical with an emphasis on explaining the behaviour of the components. This is demonstrated by reference to the results of numerical analyses. The geometries considered are typical of the main leg components of offshore rig legs and where specialist design rules are mentioned they are taken from the area of offshore design.

ABSTRACT: Offshore jacket structures are composed of tubular members. As offshore structures go deeper into the ocean, the water pressure on these tubular elements is increased. This paper discusses the effect of external and internal pressure on the buckling behavior of the circular cross section tubular elements or pipes. The linear and nonlinear buckling behaviors of the tubular members with circular cross section were considered. Material and geometry nonlinearities were included in the analysis. The nonlinear buckling was found to be significantly affected by the water pressure. The paper also introduces a parametric study on the change in buckling load with the change of different parameters.

ABSTRACT: A sequential linear programming method with a simple move-limit strategy is used to investigate the following three important buckling optimization problems of composite shells: (1) optimization of fiber orientations for maximizing buckling resistance of composite shells without cutouts; (2) optimization of fiber orientations for maximizing buckling resistance of composite shells with circular cutouts; and (3) optimization of cutout geometry for maximizing buckling resistance of a composite shell. From the results of optimization study, it has been shown that, given a structural geometry, loading condition and material system, the buckling resistance of a cylindrical composite shell is strongly influenced by fiber orientations, end conditions, the presence of cutout and the geometry of cutout.

ABSTRACT: A nonlinear material constitutive model, including a nonlinear in-plane shear formulation and a failure criterion for fiber-composite laminate materials is employed to carry out finite-element buckling analyses for composite shells under hydrostatic compressive loads. It has been shown that the nonlinear in-plane shear together with the failure criterion have significant influence on the buckling behavior of composite shells.

ABSTRACT: The buckling strengths of fiber-composite laminate shells with a given material system are maximized with respect to fiber orientations using a sequential linear programming method together with a simple move-limit strategy. While a modified Riks nonlinear solution algorithm is utilized to analyse the buckling and postbuckling behaviour of composite shells, both linear and nonlinear in-plane shear formulations are employed to form the finite-element constitutive matrix for fiber-composite laminate. Results of the optimization study for simply supported composite cylindrical shells using both linear and nonlinear in-plane shear formulations are presented.

ABSTRACT: The buckling resistance of fiber-reinforced laminated cylindrical panels with a given material system and subjected to uniaxial compressive force is maximized with respect to fiber orientations by using a sequential linear programming method together with a simple move-limit strategy. The significant influences of panel thicknesses, curvatures, aspect ratios, cutouts and end conditions on the optimal fiber orientations and the associated optimal buckling loads of laminated cylindrical panels have been shown through this investigation.

ABSTRACT: The fundamental frequencies of fiber-reinforced laminated cylindrical shells with a given material system are maximized with respect to fiber orientations by using the golden section method. The significant effects of shell thickness, shell length, cutout and end condition on the maximum fundamental frequencies and the associated optimal fiber orientations are demonstrated.

ABSTRACT: A nonlinear material constitutive model, including a nonlinear in-plane shear formulation and the Tsai- Wu failure criterion, for fiber-composite laminate materials is employed to carry out finite element buckling analyses for composite laminate skew plates under uniaxial compressive loads. The influences of laminate layup, plate skew angle and plate aspect ratio on the buckling resistance of composite laminate skew plates are presented. Comparing with the linearized buckling loads of the skew plates, one can observer that the
nonlinear in-plane shear together with the failure criterion have significant influence on the ultimate loads of the composite laminate skew plates with $[\pm \theta]_{10S}$ and $[\pm \theta/90/0]_{5S}$ layups but not the $[\alpha/0]_{10S}$ layup.

ABSTRACT: A procedure is presented for designing uniaxially stiffened panels made of composite material and subjected to combined inplane loads. The procedure uses a rigorous buckling analysis and nonlinear mathematical programming techniques. Design studies carried out with the procedure consider hat-stiffened and corrugated panels made of graphite-epoxy material. Combined longitudinal compression and shear and combined longitudinal and transverse compression are the loadings used in the studies. The capability to tailor the buckling response of a panel (i.e., design a panel so that it will have specified buckling loads at various buckling wavelengths) is also explored. Finally, the adequacy of another, simpler, analysis-design procedure is examined. The report demonstrates that a panel design procedure with a high-quality buckling analysis and with complete generality of constraints is practical. Such a procedure can be used to avoid failure from complex buckling modes and to determine mass and proportions of panels for multiple design load conditions and constraints.

ABSTRACT: A computer code denoted PASCO which can be used for analyzing and sizing uniaxially-stiffened composite panels is described. Buckling and vibration analyses are carried out with a linked-plate analysis computer code denoted VIPASA, which is incorporated in PASCO. Sizing is based on nonlinear mathematical programming techniques and employs a computer code denoted CONMIN, also incorporated in PASCO. Design requirements considered are initial buckling, material strength, stiffness, and vibration frequency. The capability of the PASCO computer code and the approach used in the structural analysis and sizing are described.

ABSTRACT: The stiffened composite structural panel analysis and sizing code designated 'PASCO' encompasses both the generality required for the exploitation of composite materials' design flexibility and an accurate buckling analysis for the detection of complex buckling modes. PASCO can accordingly design for buckling, frequency, material strength, and panel stiffness requirements. Attention is given to an additional thermal loading design capability. Design studies illustrate the importance of the multiple load condition capability when thermal loads are present.

ABSTRACT: Waffle panels are often used on fuselage structures such as that of the Space Shuttle. The waffle panel design is an efficient design for carrying biaxial, in-plane, and shear loads. The WAFFLE program was designed for application on waffle panels. The Panel Analysis and Sizing Code (PASCO) program was designed for analyzing and sizing uniaxially stiffened panels. The application of the PASCO program in conjunction with the WAFFLE program is discussed to account for both the fillet radius and the presence of stiffness in both directions. The results of the tests are used to verify that these adjustments are valid and necessary if accurate analysis of the waffle panel is to be achieved.

ABSTRACT: The circular cylindrical thin-walled shell is a fundamental building block of many structures, such as aircraft fuselages. When used with laminated composites, highly efficient structures can be designed. As a result, the analytical treatment of cylindrical shells has received significant attention over recent decades. However, most of the works carried out in this area concern isotropic materials or orthotropic laminates, that is, those with no couplings. The present analysis develops a closed-form, yet simple solution for the linear buckling of laminated circular cylindrical shell, from the Donnell's model, including all available couplings. Although the usefulness of a linear solution for predicting buckling loads is questionable, its worth is in initial sizing and layup selection during the early stages of design. The resulting model could be used to examine the usefulness of different couplings that are not yet well understood. It is found that extension/shear coupling results in torsional movement of the cylinder, which, when restricted, induces a secondary torsional loading on the cylinder, thus reducing its overall buckling load by up to 50%. When not restricted, extension/shear couplings generally increase buckling loads.

ABSTRACT: FASOR (Field Analysis of Shells of Revolution) is a user-oriented code for the analysis of stiffened, laminated axisymmetric shells. Very general shell geometries are allowed in that the reference surface meridian may form a branched, multi-circuit figure. Modes of response treated are linear asymmetric and geometrically nonlinear axisymmetric prebuckling, and asymmetric buckling and vibration under static axisymmetric loads. Bifurcation buckling under asymmetric loads is also treated by using a symmetrized prebuckling state based on the linear response of a user-specified meridian. For each mode of response, the user may specify any combination of orthotropic or anisotropic material properties with classical or transverse shear deformation shell theories. FASOR employs a numerical integration method (called the field method) whereby a numerically unstable linear boundary-value problem (all modes of response reduce to a sequence of such problems) is converted into two successive numerically stable initial-value problems. In this context, numerical stability means that round-off errors introduced at each step of the integration process tend to decay out. As a consequence, solution accuracy is controlled essentially by a single number, the truncation error tolerance, which is satisfied by automatically adjusting the size of each integration step. The field method thus eliminates
the need for mesh generation required by finite element and finite difference methods, and the associated problem of numerical convergence. It also provides for automatic determination of response storage points so as to obtain a uniformly valid discrete approximation of the continuous response. In this paper the field method is briefly described, basic aspects of the mathematical model are discussed, the organization of input data is presented, and input and plot output are given for specific examples.

ABSTRACT: An integrated computer program entitled Field Analysis of Shells of Revolution (FASOR) currently under development for NASA is described. When completed, this code will treat prebuckling, buckling, initial postbuckling and vibrations under axisymmetric static loads as well as linear response and bifurcation under asymmetric static loads. Although these modes of response are treated by existing programs, FASOR extends the class of problems treated to include general anisotropy and transverse shear deformations of stiffened laminated shells. At the same time, a primary goal is to develop a program which is free of the usual problems of modeling, numerical convergence and ill-conditioning, laborious problem setup, limitations on problem size and interpretation of output. The field method is briefly described, the shell differential equations are cast in a suitable form for solution by this method and essential aspects of the input format are presented. Numerical results are given for both unstiffened and stiffened anisotropic cylindrical shells and compared with previously published analytical solutions.

ABSTRACT: Critical in-plane normal and shear loads of rectangular anisotropic laminated plates are presented. These were calculated using the shell code FASOR, which includes the effect of transverse shear deformation. For simply-supported orthotropic laminates with midplane symmetry normal buckling loads are verified by a closed-form solution derived from transverse shear deformation plate theory. Results are compared to previously published solutions from three-dimensional elasticity theory and classical plate theory.

ABSTRACT: A computer program for the analysis of stress, nonlinear collapse and bifurcation buckling of hybrid bodies of revolution (BOSOR6) is used for the prediction of failure of axially compressed cylinders containing frangible joints. Plasticity and moderately large deflections are included in the analytical models. The structure in the immediate neighborhoods of the frangible joint notches is modeled with use of eight-node solid isoparametric finite elements of revolution and the rest of the structure is modeled with use of computationally efficient thin shell elements. Theoretical predictions are compared to test results. Certain aspects of the test specimens and boundary conditions remain unknown, and parameters in the analytical models are established and varied in order to reveal what these test conditions must have been. For reasonable values of these parameters, theoretical and experimental joint failure loads agree to within 2%.

ABSTRACT: The BOSOR5 computer program for elastic plastic buckling of shells of revolution is used for calculation of bifurcation buckling of cold bent and welded ring-stiffened cylinders under external pressure. Residual stresses and deformations from cold bending and welding are included in the model for buckling under service loads by introduction of these manufacturing processes as functions of a time-like parameter which ensures that the material in the analytical model experiences the proper sequence of loading prior to and during application of the service loads. The cold bending process is first simulated by a thermal loading cycle in which the temperature varies linearly through the shell wall thickness, initially increasing in time to simulate cold bending around a die and then decreasing in time to simulate springback to a final somewhat larger design radius. The welding process is subsequently simulated by the assumption that the material in the immediate neighborhoods of the welds is cooled below the ambient temperature by an amount that leads to weld shrinkage amplitudes typical of those observed in tests. Buckling loads are calculated for a configuration including and neglecting the cold bending and welding processes. These predictions are compared to values obtained from tests on two nominally identical specimens, one carefully machined and the other fabricated by cold bending the shell and then welding machined ring stiffeners to it.

ABSTRACT: The purpose of the many examples of buckling presented here is to give the reader a physical feel for shell buckling. Section 1 contains a brief description of two kinds of buckling, collapse and bifurcation. Section 2 concerns shell structures in which the cause of failure is nonlinear collapse due to either large deflections or to both large deflections and nonlinear material behavior. Section 3 gives examples of axisymmetric shells in which failure is due to bifurcation buckling. Section 4 provides examples that illustrate the effects of boundary conditions and eccentric loading on bifurcation buckling of shells of revolution. Section 5 is devoted to combined loading of cylindrical shells and nonsymmetric loading of shells of revolution. Section 6 is on bifurcation buckling and collapse of ring-stiffened shells with emphasis given to cylindrical shells. Section 7 contains several illustrations of buckling of prismatic shells and panels, that is, structures that have a cross section that is constant in one of the coordinate directions. Section 8 focuses on the sensitivity of predicted buckling loads to initial geometrical imperfections. Section 9 demonstrates axisymmetric collapse and bifurcation buckling of bodies of revolution that consist of combinations of thin shell segments and solid segments to which shell theory cannot be applied with sufficient accuracy.

ABSTRACT: A summary of previous work is first presented. Then an axisymmetric model is presented in which the bending of an infinite straight or curved pipe with external or internal pressure is simulated by thermal loading. The model includes geometric and material nonlinearity in the prebuckling analysis and bifurcation buckling from the nonlinear prebuckled state. Comparisons with tests on straight pipes and elbows are given. The calculations are performed with use of a slightly modified version of the BOSOR5 computer
program. Qualitative agreement with test results is demonstrated.

ABSTRACT: Results of nonlinear finite element analysis of several axially compressed, ring-stiffened, steel, cylindrical shells are presented, including comparisons with tests conducted at the Los Alamos National Laboratory. The specimens, all with radius-to-thickness ratio of about 450, have reinforced circular openings that cut across various numbers of ring stiffeners. The cylinders are loaded by enforced axial displacement applied to thick end plates halfway between the axis of revolution and the cylindrical shell wall. Measured imperfections are included in the analysis of a ring-stiffened specimen without any cutout. Inclusion of the imperfection field reduces the predicted collapse load by only eight per cent. Reinforced openings that cut one, two and three rings reduce the collapse load by 14, 21, and 22 per cent, respectively.

ABSTRACT: An analysis and an interactive computer program are described through which minimum weight designs of composite, elastic-plastic, stiffened, cylindrical panels can be obtained subject to general and local buckling constraints and stress and strain constraints. The panels are subjected to arbitrary combinations of in-plane axial, circumferential and shear resultants. Nonlinear material effects are included if the material is isotropic or has stiffness in only one direction (as does a discrete or a smeared stiffener). Several types of general and local buckling modes are included as constraints in the optimization process, including general instability, panel instability with either stringers or rings smeared out, local skin buckling, local crippling of stiffener segments, and general, panel and local skin buckling including the effects of stiffener rolling. Certain stiffener rolling modes in which the panel skin does not deform but the cross section of the stiffener does deform are also accounted for. The interactive PANDA system consists of three independently executed modules that share the same data base. In the first module an initial design concept with rough (not necessarily feasible or accurate) dimensions are provided by the user in a “conversational” mode. In the second module the user decides which of the design parameters of the concept are to be treated by PANDA as decision variables in the optimization phase. In the third module the optimization calculations are carried out. Examples are provided in which optimum designs obtained by PANDA are compared to those in the literature.

ABSTRACT: This paper opens with a general discussion of terms in an energy functional which might be the basis from which equations governing stress, stability, and vibration analyses are derived. The energy expression includes strain energy of the shell and discrete stiffeners, kinetic energy of the shell and stiffeners, constraint conditions with Lagrange multipliers, and other terms arising from the change in direction of applied loads during deformation. Brief discussions are included of the coupling effect between bending and extensional energy needed for the analysis of layered composite shells or elastic-plastic shells, nonlinear terms,
The form that the energy expression takes upon discretization of the structure. A section follows in which the energy formulation for stress, stability, and vibration analyses of an elastic curved beam is given, including thermal effects, moderately large rotations, boundary conditions, and distributed and concentrated loads. The matrix notation and type of discretization are introduced here which will later be used for the analysis of shells of revolution. Terms in the local element stiffness, mass, and load-geometric matrices are derived in terms of nodal point displacements, and it is shown how these local matrices are assembled into global matrices. The purpose of the section is to demonstrate the procedure for derivation of the analogous equations and quantities for shells of revolution or more complex structures. The next section is on elastic shells of revolution. It opens with a summary of what computer programs exist for stress, buckling, and stability analyses of such structures. The assumptions on which these programs are based are listed and the various components of the energy functional, such as strain energy of the shell and discrete rings, are identified and derived in terms of nodal point displacements. Included are a derivation of the constitutive law for anisotropic shell walls and a formulation of nonlinear constraint conditions, which are required for the treatment of segmented or branched shells with meridional discontinuities between segments or branches. Derivations of terms in the global stiffness and load-geometric matrices and the force vector are given, with tables tracing the origin of each term. The computational strategy for calculation of critical bifurcation buckling loads in the presence of prebuckling nonlinearities is given, with an example of buckling under axial compression of a very thin cylinder. This is a simple problem to formulate but a difficult one to solve numerically, owing to the existence of closely spaced eigenvalues corresponding to nonsymmetric buckling at loads close to the load corresponding to nonlinear axisymmetric collapse. A description of various pitfalls encountered in the search for the lowest bifurcation buckling load is given, including estimates of the critical number of circumferential waves in the buckling mode. Computerized formulations and run times are compared for various discretization methods, including finite difference energy models and standard finite element models, with an example showing comparisons of rate of convergence with increasing nodal point density and computer times required to form stiffness matrices. Hybrid bodies of revolution are discussed next. By “hybrid” is meant a body of revolution with both one-dimensionally and two-dimensionally discretized regions. The formulation is particularly useful for the stress, buckling, and vibration analyses of branched shells or ring-stiffened shells in which one is particularly interested in local effects within a distance equal to a shell wall thickness of a branch or ring. An appropriate strategy for the solution of nonlinear problems with simultaneous geometric nonlinearity and path-dependent material properties is described, including the development of the incremental constitutive law for the tangent stiffness method of treatment of elastic-plastic structures. The two-dimensionally discretized regions are modeled with use of 8-node isoparametric quadrilaterals of revolution. Details are presented on the formulation of constraint conditions for compatibility at junctions between rotationally symmetric shell segments (one-dimensionally discretized regions) and solid segments (two-dimensionally discretized regions). The paper closes with a summary of linear equations for general shells. Surface coordinates, the first and second fundamental forms, and the definition of a shell are introduced, and the assumptions corresponding to Love's first approximation are identified. The differences in commonly used or referenced formulations are listed, including differences with regard to kinematic relations, expressions for total strain anywhere in the thickness of the shell wall, and expressions for stress and moment resultants. Comments are offered on which theory is the most suitable for engineering estimates.

ABSTRACT: A theory based on minimum potential energy for the bifurcation buckling of elastic or elastic-plastic isotropic or elastic composite, flat or cylindrical, ring- and stringer-stiffened panels subjected to combined in-plane loads is derived. Equations are given for general instability, panel instability and local instability of panels with fully populated 6 x 6 thickness-integrated constitutive matrices. Also derived are equations for crippling and rolling of stiffeners. The theory has been implemented in user-friendly, interactive computer programs called PANDA and PANDA2 for the minimum-weight design of panels. These programs have been described in previous papers.

ABSTRACT: PANDA2 finds minimum weight designs of laminated composite flat or curved cylindrical panels or cylindrical shells with stiffeners in one or two orthogonal directions. The panels or shells can be loaded by as many as five combinations of in-plane loads and normal pressure. The axial load can vary across the panel. Constraints on the design include crippling, local and general buckling, maximum tensile or compressive stress along the fibers and normal to the fibers in each lamina, and maximum in-plane shear stress in each lamina. Local and general buckling loads are calculated with the use of either closed-form expressions or discretized models of panel cross sections. An analysis branch exists in which local post buckling of the panel skin is accounted for. In this branch a constraint condition that prevents stiffener popoff is introduced into the optimization calculations. Much of this paper represents a tutorial run through the PANDA2 processors for a hat-stiffened panel under combined axial compression, in-plane shear and normal pressure. Examples follow in which results from PANDA2 are compared with those in the literature and those obtained with the STAGS and EAL computer programs. Results of an extensive study are given for an optimized, blade-stiffened panel design so that it buckles locally at about 10% of the design load. The axially stiffened panel is subjected to pure axial compression, pure normal pressure, combined axial compression and normal pressure, and combined axial compression and residual stresses and deformations that arise from a simulated curing process. An example is provided of a design process applied to a ring and stringer stiffened cylindrical shell similar in geometry and loading to the 2/3 interstage of the ARIANE 4 booster.

ABSTRACT: A theory based on minimum potential energy for the nonlinear equilibrium of composite, stringer-stiffened, imperfect panels subjected to combined in-plane loads is derived. The normal displacement \( w(x, y) \) is assumed to have the form \( W(Y)\sin\left(\frac{x}{L}\right) \) in which \( x \) is the coordinate along the axis of the stringers, \( Y \) is the coordinate in the plane of the panel skin normal to \( x \), \( f_m \) is the slope of the nodal lines in the local buckling pattern in the panel skin, and \( L \) is the half-wavelength of the local bifurcation buckling mode. The function \( W(y) \) is obtained from a series expansion of the buckling modal normal displacement field obtained from a model in which the cross-section of a panel module is discretized as in the BOSOR4 analysis of shells of revolution. Nonlinear strain-displacement relations analogous to those developed in 1946 by Koiter for perfect panels are extended to handle panels with imperfections in the form of the critical local bifurcation buckling mode. The theory is incorporated into the PANDA2 computer program for minimum weight design. The nonlinear theory for the prediction of behavior of locally imperfect panels appears to be properly implemented in PANDA2, since there is excellent agreement between PANDA2 and STAGS for the case of a
uniformly axially compressed, imperfect, rectangular, isotropic panel loaded to four times the local bifurcation buckling load. The theory captures reasonably well the nonlinear modal interaction effect described in many papers published by Koiter, Hutchinson, Thompson, Tvergaard and others in the 1970s. There is good agreement between these previous theories, PANDA2 results and tests. Locally and globally imperfect panels can be automatically optimized with PANDA2, as demonstrated for the case of a blade-stiffened, imperfect, aluminum panel. The inclusion of local and global imperfections with amplitudes likely to occur in practice does not appear to affect dramatically the behavior nor the optimum design of axially stiffened panels that behave approximately as wide columns in the general instability mode of failure. Optimum designs of imperfect blade-, tee- and hat-stiffened panels are compared. Some recent modifications to the PANDA2 computer program are briefly described.

ABSTRACT: A number of struts or straps support a rigid, delicate mass (dewar) which must be successfully launched and maintained in orbit for a long time at a very low temperature. The support system must be designed so that the heat flow into the mass is minimized subject to constraints on minimum allowable natural frequency of the mass during launch, minimum natural frequency of the mass in orbit, maximum allowable stress in any support member during launch, and no buckling or slackening of any support member during launch. A user-friendly system of computer programs called DEWAR is described by means of which optimum designs can be obtained for a support system consisting of simple tension straps or simple tubes, or support systems with a passive thermal disconnect feature through which the thermal conductance is greatly reduced during the transition from the launch condition to the orbital condition. Most of the present paper consists of a sample case in which DEWAR is used in the tutorial mode.

ABSTRACT: The purpose of GENOPT (GEneral OPTimization) is to enable an engineer to create a user-friendly system of programs for analyzing and/or optimizing anything. The application of GENOPT is not limited to the field of structural mechanics. GENOPT is designed to handle problems with small data bases, not large finite element models, although it might well be used to provide a user-friendly “shell” within which any analysis could be done. GENOPT is ideal for generating programs for optimizing objects the behavior (stress, buckling, vibration, etc.) of which can be expressed by relatively simple tables or formulas such as those that appear in handbooks, or for optimizing objects the behavior of which has been previously encoded in existing subroutines. The optimizer used in GENOPT, created by Vanderplaats, is called ADS. Two examples are presented, one relatively simple, the other more complex.

ABSTRACT: The computer program PANDA2 for minimum weight design of composite, stiffened cylindrical
or flat panels made of composite material is described. The capability of PANDA2 has been expanded to handle truss-core sandwich panels. The new capability is demonstrated in this paper with an example: minimum weight design of a truss-core sandwich panel under axial compression, in-plane shear, and normal pressure. At the design load the panel is in a locally postbuckled state.

ABSTRACT: Local buckling and postbuckling of panels stiffened by stringers and rings and subjected to combined in-plane loads is explored with the use of a single module model that consists of one stringer and a width of panel skin equal to the stringer spacing. The cross-section of the skin-stringer module is discretized and the displacement field is assumed to vary trigonometrically in the axial direction. Local imperfections in the form of local buckling modes and overall initial axial bowing of the panel are included in the numerical model. The local postbuckling theory, based on early work of Koiter, is formulated in terms of buckling modal coefficients derived from integrals of products of the discretized displacement field and its derivatives. The principle of minimum potential energy is used to derive nonlinear algebraic equilibrium equations in terms of four unknowns, the amplitude f of the postbuckling displacement field, a postbuckling ‘flattening’ parameter a, the slope m of the nodal lines in the postbuckling displacement field, and an axial wavelength parameter N. The nonlinear equations are solved by Newton's method. An elaborate strategy is introduced in which the incidence of non-convergence is minimized by removal and re-introduction of the unknowns f, a, m, N on a one-by-one basis. This nonlinear theory has been implemented in the PANDA2 computer program, which finds minimum-weight designs of stiffened panels made of composite materials. PANDA2 is used to find the minimum weight of a cylindrical panel made of isotropic material with rectangular stringers mounted on thickened bases. The panel is optimized for three load sets, axial compression with negative axial bowing, axial compression with positive axial bowing, and combined axial compression and in-plane shear with no axial bowing. The optimum design is loaded well beyond local buckling for each load set. Critical margins of the optimized design include maximum allowable effective stress, bending-torsion buckling and general instability. The optimum design is evaluated by application of a general-purpose finite element program, STAGS, to finite element models generated by PANDA2 for each of the three load sets. The agreement of results between PANDA2 and STAGS is good enough to qualify PANDA2 as a preliminary design tool.

ABSTRACT: A minimum-weight design of a T-stiffened panel is found with the PANDA2 program. The panel, subjected to axial compression, in-plane shear, and normal pressure, is designed for service in its locally postbuckled state. A program called STAGSMODEL has been written for transforming output from PANDA2 to input for STAGS, a general-purpose nonlinear finite element code. STAGS is then used to evaluate the optimum design. Agreement between results obtained with PANDA2 and STAGS is reasonable for this very complex, very nonlinear problem. Therefore, PANDA2 qualifies as a preliminary design tool for panels operating in their locally postbuckled states.

ABSTRACT: Minimum-weight designs of T-stiffened and hat-stiffened panels made of laminated composite material are found with the PANDA2 program. The panels, subjected to axial compression, in-plane shear, and normal pressure, are designed for service in their locally postbuckled states. A program called STAGSMODEL is used for transforming output from PANDA2 to input for STAGS, a general-purpose nonlinear finite element code. STAGS is then used to evaluate the optimum designs. Agreement between results obtained with PANDA2 and STAGS is reasonable for these very complex, very nonlinear problems. Therefore, PANDA2 appears to qualify as a preliminary design tool for composite panels operating in their locally postbuckled states.

ABSTRACT: PANDA2 is a computer program for the minimum weight design of stiffened, composite, flat or cylindrical, perfect or imperfect panels and shells subjected to multiple sets of combined in-plane loads, normal pressure, edge moments, and temperature. The panels can be locally postbuckled. Recent additions to PANDA2 include implementation of: Sanders-type shell equations as a user-specified choice in addition to the Donnell equations, a 'global' optimizer processor, SUPEROPT, which in a single long run finds optimum designs from several different starting designs, and Arbocz' (1993) extension of Koiter's (1963) special theory for computation of buckling load factors for perfect anisotropic cylindrical shells and knockdown factors for axisymmetrically imperfect shells. Also incorporated are the ability to handle a new truss-core sandwich configuration and isogrid-stiffened panels and shells. Examples given.

ABSTRACT: The PANDA2 computer program for minimum-weight design of stiffened composite panels is expanded to handle optimization of ring and stringer stiffened cylindrical panels and shells with local, inter-ring, and general buckling modal imperfections in the form of buckling modes, any combination of which may be present: local (buckling between adjacent stringers and rings), inter-ring (buckling between rings with stringers bending with the panel skin), and general (buckling in which both stringers and rings bend with the panel skin). Stresses and buckling load factors of the imperfect panels are computed with use of the assumption that the amplitudes of the buckling modal imperfections grow hyperbolically with increasing load factor according to the formula AMP(i) = EIG(i)/(EIG(i) - 1), in which AMP(i) is a factor to be multiplied by the initial buckling modal imperfection and EIG(i) represents the critical load factor for the ith type of buckling mode (i = 1 = local buckling, i = 2 = inter-ring buckling, i = 3 = general buckling). Buckling load factors corresponding to local, inter-ring, and general buckling of the imperfect panel are computed with use of the maximum radius of curvature that develops in whatever portion of the panel (between stiffeners, inter-ring, overall) is being considered in the calculations and including redistribution of stress resultants over panel skin and stiffener cross-sections caused by prebuckling...
bending. Stress constraints in the optimization problem are computed including local, inter-ring, and general bending stresses generated by the growth of the initial local, interring, and general imperfections. These bending stresses are added to the stresses from other sources (thermal, in-plane loading, normal pressure, curing, redistribution of membrane stresses from overall prebuckling bending of the imperfect panel). Minimum-weight designs for various imperfect unstiffened and stiffened cylindrical shells derived by PANDA2 are evaluated with use of the STAGS general-purpose finite element code. The agreement of results from PANDA2 and STAGS appears to qualify PANDA2 for the preliminary design of imperfect, stiffened, composite cylindrical shells.

ABSTRACT: GENOPT, a program that writes user-friendly optimization code, and BOSOR4, a program for stress, buckling, and vibration analysis of segmented branched stiffened shells of revolution, are combined to create a capability to optimize specific classes of shells of revolution. GENOPT and BOSOR4 and recent improvements to them are described. An example is provided of an aluminum cylindrical shell with a wavy wall and with ring stiffeners. In the example the objective of the optimization is minimum weight, and the design constraints include stress, buckling, and modal vibration. In the report from which this paper is condensed an Appendix is provided in which a very simple example is employed to demonstrate in detail how a user can create a capability to optimize any shell of revolution.

ABSTRACT: The PANDA2 computer program has been modified to permit minimum weight design of imperfect panels with riveted Z-shaped stiffeners for service in a load regime in which the panel is in its locally postbuckled state. Perfect and imperfect panels optimized with PANDA2 are evaluated via nonlinear STAGS analyses. The agreement between predictions by PANDA2 and STAGS is sufficient to qualify PANDA2 as a preliminary design tool for panels with riveted Z-shaped stringers. Optimum designs for panels with Z-shaped stringers are compared to those with J-shaped and T-shaped stringers.

ABSTRACT: PANDA2 is a code for the minimum-weight design of perfect and imperfect elastic stiffened panels and shells made of composite laminates and subjected to multiple sets of in-plane loads, edge moments, normal pressure, and temperature. The scope of PANDA2 is increased to include global optimization and the capability to handle isogrid stiffening. The enhanced program is used to find global optimum designs of internally T-isogrid and internally T-ring stiffened perfect and imperfect isotropic cylindrical shells under uniform external pressure. For the cases studied, it is found that for the perfect optimized shells the isogrid stiffening is important but the rings are not, whereas the opposite holds for the optimized shells with an initial general buckling modal imperfection of amplitude equal to one per cent of the shell radius.

ABSTRACT: PANDA2, a computer program for the minimum-weight design of elastic perfect and imperfect stiffened cylindrical panels and shells under multiple sets of combined loads, is used to obtain optimum designs of uniformly axially compressed elastic internal T-ring and external T-stringer stiffened cylindrical shells with initial imperfections in the form of the general buckling mode. The optimum designs generated by PANDA2 are verified by STAGS elastic and elastic-plastic finite element models produced automatically by a PANDA2 processor called STAGSUNIT. Predictions from STAGS agree well with those from PANDA2. Improvements to PANDA2 during the past year are summarized. Seven different optimum designs are obtained by PANDA2 under various conditions. The most significant condition is whether or not PANDA2 is permitted automatically to make the initial user-specified amplitude of the general buckling modal imperfection directly proportional to the axial halfwavelength of the critical general buckling mode. A survey is conducted over (m,n) space to determine whether or not the critical general buckling modal imperfection shape computed by PANDA2 with (m,n)critical (m=axial, n=circumferential) halfwaves is the most harmful imperfection shape. It is found that indeed (m,n)critical is, for all practical purposes, the most harmful imperfection mode shape if PANDA2 is permitted automatically to make the general buckling modal imperfection amplitude directly proportional to the axial halfwavelength of the critical general buckling mode (inversely proportional to m). It is concluded that for axially compressed, stiffened, globally imperfect cylindrical shells the optimum designs obtained with the condition that PANDA2 is NOT allowed to change the initial user-specified imperfection amplitude are probably too heavy. One of the cases investigated demonstrates that the optimum design of a perfect shell obtained via the commonly used condition that a likely initial imperfection be replaced by an increase in the applied load by a factor equal to the inverse of a typical knockdown factor is too heavy. A new input index, ICONSV, is introduced into PANDA2 by means of which optimum designs of various degrees of conservativeness can be generated. Optimum designs are obtained with ICONSV = -1, 0, and +1, which represent increasing degrees of conservativeness in the PANDA2 model. It is concluded that, when obtaining optimum designs with PANDA2, it is best to allow PANDA2 to enter its branch in which local postbuckling...
behavior is determined, thereby avoiding the generation of designs that may be unsafe because of excessive local bending stresses in the panel skin and stiffener parts. In most cases both nonlinear static and nonlinear dynamic analyses are required in order to obtain collapse loads with STAGS. A table is included that demonstrates how to use STAGS to evaluate an optimum design obtained by PANDA2. In most cases the elastic STAGS models predict collapse in one of the ring bays nearest an end of the cylindrical shell. With the effect of elastic-plastic material behavior included in the STAGS models, collapse most often occurs in an interior ring bay where the finite element mesh is the most dense.

ABSTRACT: GENOPT, a program that can be used to optimize anything, and BIGBOSOR4, a program for stress, buckling, and vibration analysis of segmented, branched, stiffened, elastic shells of revolution, are combined to a capability to optimize a specific kind of shell of revolution: an internally isogrid-stiffened elastic ellipsoidal shell subjected to uniform external pressure. Optimum designs are obtained for isogrid-stiffened and unstiffened axisymmetrically imperfect and perfect titanium 2:1 ellipsoidal shells. The decision variables are the shell skin thickness at several user-selected meridional stations, the height of the isogrid stiffeners at the same meridional stations, the spacing of the isogrid stiffeners (constant over the entire shell), and the thickness of the isogrid stiffeners (also constant over the entire shell). The design constraints involve maximum stress in the isogrid stiffeners, maximum stress in the shell skin, local buckling of an isogrid stiffener, local buckling of the shell skin between isogrid stiffeners, general nonlinear bifurcation buckling, nonlinear axisymmetric collapse, and maximum normal displacement at the apex of the dome. Optimum designs first obtained by GENOPT are subsequently evaluated by the use of STAGS, a general-purpose finite element computer program. It is found that in order to obtain reasonably good agreement between predictions from BIGBOSOR4 and STAGS it is necessary to model the ellipsoidal shell as an "equivalent" ellipsoidal shell consisting of a spherical cap and a series of toroidal shell segments that closely approximates the true ellipsoidal meridional shape. The equivalent ellipsoidal shell is optimized with up to four axisymmetric buckling modal imperfections, each imperfection shape assumed to be present by itself. Computations include both plus and minus axisymmetric buckling modal imperfection shapes. At each design cycle and for the plus and minus version of each axisymmetric imperfection shape the following analyses are conducted: 1. linear general axisymmetric bifurcation buckling analysis (in order to obtain the axisymmetric linear buckling modal imperfection shapes), 2. nonlinear axisymmetric stress analysis at the design pressure, 3. nonlinear axisymmetric collapse analysis, and 4. nonlinear non-axisymmetric bifurcation buckling analysis. For each axisymmetric imperfection shape the design margins include an axisymmetric collapse margin, a general buckling margin, a margin involving the normal displacement of the apex of the shell, and local skin and stiffener stress margins and local skin and stiffener buckling margins within two approximately equal meridional regions of the equivalent ellipsoidal shell.

There is generally good agreement of the predictions from STAGS and from BIGBOSOR4 for the elastic behavior of the perfect stiffened and unstiffened optimized shells and for the behavior of the imperfect stiffened optimized shells with axisymmetric buckling modal imperfections. Optimization with the use of only axisymmetric buckling modal imperfections has a disadvantage in the case of the unstiffened imperfect shell under certain conditions: the optimum design of the axisymmetrically imperfect unstiffened shell evolves in such a way that, according to predictions from STAGS, a non-axisymmetric buckling modal imperfection with the same amplitude as an axisymmetric buckling modal imperfection causes collapse of the shell at an external pressure far below the design pressure. This disadvantage is easily overcome if, during optimization cycles, the
unstiffened shell wall in the neighborhood of the apex is forced to remain thick enough so that local axisymmetric buckling does not occur primarily at and near the apex but instead occurs primarily in the remainder of the shell. An extensive study of some of the previously optimized elastic shells is conducted with STAGS including elastic-plastic material properties. The effect on collapse pressure of initial imperfections in the form of off-center residual dents produced by load cycles applied before application of the uniform external pressure is determined and compared with the effect on collapse pressure of imperfections in the form of non-axisymmetric and axisymmetric linear buckling modes, especially the non-axisymmetric linear buckling modal imperfection with n=1 circumferential wave, which seems to be the most harmful imperfection shape for optimized externally pressurized ellipsoidal shells. For the optimized unstiffened shell it is found that a residual dent that locally resembles the n=1 linear buckling modal imperfection shape is just as harmful as the entire n=1 linear buckling modal imperfection shape.

ABSTRACT: GENOPT/BIGBOSOR4 is applied to the problem of an axially compressed perfect elastic cylindrical shell the wall of which is a composite truss-core sandwich. The truss-core sandwich is constructed of trapezoidal core tubes that are sandwiched between two face sheets. At the junction of the core webs and the face sheets are “noodle” regions that are filled with unidirectional composite material. The design constraints are local buckling, general buckling, and five stress constraints for each material. Local and general buckling are computed from BIGBOSOR4 models in which the "huge torus" prismatic representation of the cylindrical shell is employed. In both the local and general buckling models the "huge torus" representation of the cylindrical shell consists of a number of identical modules of the cross section of the truss-core sandwich wall that are strung together along the curved meridian of the "huge torus". The rather elaborate 22-segment module used for local buckling includes small curved and straight segments that occur at the corners of the trapezoidal tool around which the truss-core is wrapped during the fabrication process. The presence of "noodles" that fill the prismatic triangular-like gaps between adjacent trapezoids is accounted for.

ABSTRACT: GENOPT/BIGBOSOR4 is applied to the problem of perfect elastic spherical or cylindrical “shells” the complex inflatable wall of which is a webbed sandwich. The spherical or cylindrical “shell” is stabilized by uniform pressure applied between its inner and outer walls and subjected to uniform pressure applied to its outermost wall. This paper is analogous to [1]. The distance between the inner and outer walls of the optimized spherical balloons is smaller than that for the optimized cylindrical balloons. The pre-buckling behavior of the spherical balloons is “crankier” (more nonlinear) than that of the cylindrical balloons with the result that certain special strategies have to be introduced in order to permit the generation of optimum designs via the GENOPT processor called SUPEROPT. General buckling modes of the type observed in optimized cylindrical balloons have so far not been observed in any spherical balloons, optimized or not. Local buckling modes include both axisymmetric modes and non-axisymmetric modes with many circumferential waves. Since [1] was written new versions of the “balloon” software, behavior.balloon and bosdec.balloon, have been created by means of which both cylindrical and spherical balloons and balloons with either radial webs or truss-like
 webs can all be optimized and analyzed with use of the same “balloon” software. Since [1] was
produced a new behavioral constraint has been added that involves a load factor corresponding to the initial loss
of tension in any of the segments of the balloon wall. This new behavioral constraint is related to initial
wrinkling of the balloon, which is a type of buckling that pertains to both cylindrical and spherical balloons.
Optimum designs are found for balloons made of polyethylene terephthalate, which has a maximum allowable
stress of 10000 psi and weight density, 0.1 lb/in³, and for balloons made of a much stronger and lighter
fictitious carbon fiber cloth, which has much higher maximum allowable tensile and compressive stresses,
75600 psi and 59600 psi, respectively, and lower weight density, 0.057 lb/in³. The optimized weights of the
balloons made of the much stronger and lighter fictitious carbon fiber cloth are 15 to 20 times lighter than those
made of polyethylene terephthalate. A section is included showing optimized designs of cylindrical balloons
made of the fictitious carbon fiber cloth, which is not included as a material option in [1]. Some peculiarities of
the pre-buckling deformations and general buckling modes of optimized spherical and cylindrical balloons
made of fictitious carbon fiber cloth are displayed. These optimized balloons, which have much thinner walls
than the optimized balloons made of polyethylene terephthalate, exhibit significant spurious local “zig-zag”
components of pre-buckling and bifurcation buckling modal displacements. Convergence studies with respect to
the number of nodal points used for each segment of the balloons indicate that this spurious local “zig-zag”
characteristic does not have a major influence on the prediction of the overall behavior of the balloons.
Therefore, it appears that the optimized designs are valid despite the spurious local “zig-zag” characteristic,
which disappears with increasing numbers of nodal points used in each segment of a balloon wall.

ABSTRACT: The propellant tank is a shell of revolution completely filled with liquid hydrogen (LH2). This
propellant tank is to be launched into space. During launch it is subjected to high axial and lateral accelerations.
The tank is supported by a system of struts that consist mainly of tubes with laminated composite walls. This
strut-supported tank system is optimized via GENOPT/BIGBOSOR4 in the presence of two loading cases: (1)
10 g axial acceleration and 0 g lateral acceleration and (2) 0 g axial acceleration and 10 g lateral acceleration. In
addition to the g-loading the tank has 25 psi internal ullage pressure and the tank wall is 200 degrees cooler than
the wall of the launch vehicle from which it is supported by the struts. In the BIGBOSOR4 modal vibration
model the mass of the propellant is "lumped" into the tank wall, a conservative model. The tank/strut system is
optimized in the presence of the following constraints: (1) the minimum modal vibration frequency must be
greater than a given value; (2) five stress components in each ply of the laminated composite wall of the strut
tubes shall not exceed five specified allowables; (3) no strut tube shall buckle as a column; (4) no strut tube
shall buckle as a thin cylindrical shell; (5) the maximum effective (vonMises) stress in the tank wall shall not
exceed a specified value; (6) the tank wall shall not buckle; (8) the maximum force in a strut during the launch-
hold phase of a mission shall not exceed a specified value. The objective to be minimized is in general a
weighted combination of the normalized mass of the empty tank plus the normalized conductance of the support
system: Objective= W x (normalized empty tank mass) + (1-W) x (normalized strut conductance), in which W
is a user-selected weight between 0.0 and 1.0. Two propellant tank/strut systems are optimized: (1) a long tank
with two "rings" of struts, an aft ring and a forward ring, and (2) a short tank with only one "ring" of struts. It is
emphasized that the tank/strut combination is optimized as a single system. The flexibility of the propellant tank
is accounted for and found to be significant for optimized tank/strut systems. The flexibility of the launch vehicle to which the tank/strut system is attached is neglected: the ends of the supporting struts attached to the launch vehicle are assumed to be attached to rigid "ground". Parameter studies are conducted in which optimum designs are obtained as a function of the number of strut pairs attached to the tank. During optimization linear theory is used throughout. Predictions for certain of the optimized tank/strut designs obtained here are compared with those from the general-purpose finite element code, STAGS. The agreement between the predictions of GENOPT/BIGBOSOR4 and STAGS qualifies the use of GENOPT/BIGBOSOR4 for preliminary design in the particular cases studied here.

David Bushnell, Fellow, AIAA, semi-retired, Palo Alto, CA 94303 USA, Michael S. Jacoby, Senior Staff Engineer, Lockheed Martin Missiles and Space, Palo Alto, CA 94304, AIAA Member, and Charles C. Rankin, Rhombus Consultants Group, Inc., 1121 San Antonio Road, Palo Alto, CA 94303, AIAA Associate fellow, “Optimization of Propellant Tanks Supported by One or Two Optimized Laminated Composite Skirts”, AIAA Paper 2013-1480, AIAA 54th Structures, Structural Dynamics and Materials Meeting, April 8-12, 2013, Boston, Massachusetts

ABSTRACT: The propellant tank is a shell of revolution completely filled with liquid hydrogen (LH2). This propellant tank is to be launched into space. During launch it is subjected to high axial and lateral accelerations. The tank is supported by one or two conical skirts each of which consists of five segments: two short segments near each end of the skirt and a central long segment that has a laminated composite wall. Each of the short segments nearest the ends of the skirt has an isotropic one-layered wall with tapered thickness. Each short segment next to each short end segment is multi-layered with the extreme layers consisting of tapered isotropic material and the remaining internal, contained layers consisting of the same laminated composite wall as the long central segment. This tank/skirt system is optimized via GENOPT/BIGBOSOR4 in the presence of two loading cases: (1) 10 g axial acceleration and 0 g lateral acceleration and (2) 0 g axial acceleration and 10 g lateral acceleration. In addition to the g-loading the tank has 25 psi internal ullage pressure, the tank wall is 200 degrees cooler than the wall of the launch vehicle from which it is supported by the conical skirt(s), and there exists axisymmetric meridionally non-uniform cooling of the skirts. In the BIGBOSOR4 modal vibration model the mass of the propellant is "lumped" into the tank wall, a conservative model. The tank/skirt system, a multi-segment branched shell of revolution, is optimized in the presence of the following constraints: (1) the minimum modal vibration frequency of the tank/skirt(s) system must be greater than a given value; (2) five stress components in each ply of the laminated composite wall of the conical skirt(s) shall not exceed five specified allowables; (3) the conical skirt(s) shall not buckle; (4) the maximum effective (von Mises) stress in the tank wall shall not exceed a specified value; (5) the tank wall shall not buckle. The objective to be minimized is in general a weighted combination of the normalized mass of the empty tank plus the normalized conductance of the support system: Objective = W x (normalized empty tank mass) + (1-W) x (normalized strut conductance), in which W is a user-selected weight between 0.0 and 1.0. Two propellant tank/skirt systems are optimized: (1) a long tank with only one supporting skirt joined to the tank at the midlength of the tank and (2) the same long tank with two supporting skirts, an aft skirt and a forward skirt. It is emphasized that the tank/skirt(s) combination is optimized as a single branched shell of revolution. The flexibility of the launch vehicle to which the tank/skirt(s) system is attached is neglected: the ends of the supporting skirt(s) attached to the launch vehicle are assumed to be attached to rigid "ground". Linear theory is used throughout. Predictions for the optimized tank/skirt designs obtained here are compared with those from the general-purpose finite element code, STAGS. The agreement between the predictions of GENOPT/BIGBOSOR4 and STAGS qualifies the use of GENOPT/BIGBOSOR4 for preliminary design in the particular cases studied here.
ABSTRACT: We want to determine the minimum amount of material required to span a distance of width $= WIDTH$ for an axially compressed, unstiffened, prismatic metallic wall or panel of length $= LENGTH$. The prismatic panel has a complex “corrugated” cross section. The width of the complex “corrugated” panel is composed of a number of “major” cylindrical segments, each of which may be divided into a number of cylindrical “sub-segments”. Each segment and each sub-segment is a sector of a little cylindrical shell the generators of which run in the axial direction. In addition there exists an overall arching over the entire width of the panel. The several little cylindrical segments/sub-segments are joined generator to generator in series. The entire unstiffened “corrugated” panel can be fabricated without any welding. Half of the width of the panel is included in the BIGBOSOR4 model used for optimization, with symmetry and anti-symmetry conditions imposed at its mid-width, $WIDTH/2$. The GENOPT/BIGBOSOR4 system is used to build the model and to perform the optimization. The minimum weight of the panel is determined in the presence of the following behavioral constraints: 1. The panel shall not buckle locally, 2. The panel shall not buckle in a general mode that is symmetric at the plane of symmetry, 3. The panel shall not buckle in a general mode that is anti-symmetric at the plane of symmetry, 4. Each little cylindrical segment of the panel shall not buckle in a “classical” mode, and 5. The maximum stress in the wall of the panel shall be less than a specified value. The numerical analysis is extended to flat or curved panels of any width with repeating complex cross sections. An optimized cross-section profile with reflected and multiple repeating complex sections is mapped onto a cylindrical surface, and the buckling characteristics and weight of this complexly corrugated cylindrical shell are compared with those of an optimized “equivalent” cylindrical shell with external T-shaped stringers, an “equivalent” optimized cylindrical shell with a truss-core sandwich wall, and an optimized “equivalent” cylindrical shell with uniform corrugations. It is found that the optimized complexly corrugated cylindrical shell weighs less than these other three optimized “equivalent” cylindrical shells that have different wall constructions. Optimized complexly corrugated panels with cylindrical segments the geometry of which varies across its width weigh about 12-14 per cent less than optimized uniformly corrugated panels, such as a standard corrugated panel. The existence of sub-segments does not lead to panels that weigh less than panels without sub-segments. The gradient-based optimizer used in the GENOPT/BIGBOSOR4 system (“ADS” by Vanderplaats) has difficulty finding “global” optimum designs for panels with many cylindrical segments. Several of the optimized designs determined with GENOPT/BIGBOSOR4 are verified by comparison with predictions from the general-purpose computer program STAGS. The agreement between the predictions of GENOPT/BIGBOSOR4 and STAGS qualifies the use of GENOPT/BIGBOSOR4 for optimization in the particular cases studied here. The behavior of optimized configurations with “corners” (discontinuous slope in the “width-wise” direction) between major cylindrical segments are compared with that of configurations in which these “corners” have been smoothed by the introduction of transitional fairing segments. A program called HUGEBOSOR4 is developed to handle cases with up to 2950 segments.

ABSTRACT: The content of this volume is related to the choice of knockdown factors to be used in the design of containment vessels. The presently used design recommendations are based on experimental results pertaining to shells subjected to uniform static loading. Relatively few experiments have been performed on fabricated shells typical of civil engineering structures. A variety of factors have some effect on the imperfection sensitivity of shell structures, such as ratios between basic dimensions, degree of stiffening, inelastic deformation, duration and uniformity of loading. Therefore, it is hardly possible to collect sufficient empirical information to allow for the development of truly satisfactory design procedures. It is suggested here that the situation can be greatly improved if numerical experimentation based on computer analysis of shells with random imperfections is used to enlarge the basis for the procedures. A distinction is made between more or less deterministic imperfections inherent in the manufacturing process and truly random imperfections. The utilization of numerical results to verify or modify code recommendations is demonstrated for ring stiffened inelastic shell segments. Some effects on buckling of nonuniformity in loading are discussed.

ABSTRACT: A semiimplicit dynamic relaxation technique for solution of the nonlinear structural equilibrium equation is presented. A previously presented basic transient response analysis algorithm is employed, permitting use of one solution method and one software module for both static and dynamic analyses. A theoretical comparison of the method with explicit dynamic relaxation techniques shows that it offers a substantially improved convergence property without additional computational overhead.

ABSTRACT: A new corotational procedure is developed which enables existing finite element formulations to be used in problems that contain arbitrarily large rotations. Through the use of a nonsingular large rotation vector, the contribution of the rigid body motion of the element to the total displacement field is removed before element computations are performed, with the result that almost any element can be easily upgraded to handle large rotations. This paper contains a derivation of the theory, an outline of the implementation into the STAGS code, and a demonstration of performance for problems involving large rotations and moderate strains. (Referenced by other researchers 144 times as of August 2011)

ABSTRACT: A new approach for enforcing invariance to rigid body motion is introduced. This invariance property is derived in terms of a projection matrix, P, which depends on the rigid body modes and acts on nodal forces, f, independent of the element formulation. The invariance property takes the form $f = P^{\text{transpose}}f$. Moreover, the same transformation enforces equilibrium of the element internal force vector when it is not initially satisfied. An equivalent transformation using P is also derived for the element stiffness matrix. This approach has been applied to a number of established elements, and is used to solve two text examples that expose deficiencies of elements. Numerical results indicate marked improvement in the performance of the elements tested.

ABSTRACT: The solution of bifurcation problems with closely-spaced critical points is achieved by first separating the singular part of the equation system encountered during a Newton iteration and carrying the Taylor expansion of the reduced system out to higher order. This separation is accomplished by transforming the equation system into an equivalent system in which some of the original unknowns are replaced with an equal number of modal amplitude coefficients. This method was used to continue the analysis of two significant example problems well past multiple bifurcation points, allowing a detailed examination of postbuckling behavior in the presence of modal interaction.

ABSTRACT: A systematic procedure is presented that may be used to extend the capabilities of an existing linear finite element to accomodate finite rotation analysis. This procedure is a generalization of the work presented in Computers and Structures, Volume 30, pp. 257–267. The basis of our approach is the element-independent co-rotational algorithm, where the element rigid body motion (translations and rotations) is separated from the deformational part of its total motion. The variation of this co-rotational relation results in a projector matrix, with the property that a consistent internal force vector is invariant under its action. The consistent tangent stiffness matrix is shown to depend on this invariance condition through the derivative of the projector. This results in an unsymmetric tangent matrix whose anti-symmetric part depends on the out-of-balance force vector. In this paper we prove that using the symmetric part of the tangent matrix, the Newton
iteration retains its quadratic rate of convergence. This approach has been used to solve a number of large rotation test example problems. The results demonstrate that it is possible to analyze structures undergoing large rotations within a general co-rotational framework, using simple and economical finite elements. The resulting improvements in the performance of these simple elements are brought about through the use of convenient software utilities as pre- and post-processors to the element routines.

“The numerical simulation of the collapse process of axially compressed cylindrical shells with measured imperfections”, Delft University Aerospace Engineering Report LR-705, 1992, uuid: c94a0f5d-7d62-4e07-9eda-bd22ff66b5e2
ABSTRACT: A numerical computation of the collapse process of a cylindrical shell under prescribed edge displacement is discussed. The shell chosen for the computational experiment was manufactured, measured, and tested some twenty years ago. The purpose of the study is to compute the static, pre-collapse loading path and the subsequent snap (dynamic process) to the post buckling state. The test specimen is an integrally machined stringer stiffened cylindrical shell. The wave pattern in the pre-collapse state was observed to be dominated by a mode of one half wave in the axial direction and 9 waves in the circumferential direction. In the post buckling state after the snap, one half wave in the axial direction and ten full waves in the circumferential direction were observed. The simplifications applied in the model concern the adaptation of symmetry in the imperfection pattern and deformation after the load is applied.

ABSTRACT: A finite element procedure is presented for the analysis of the buckling and postbuckling behavior of cracks in plates loaded in tension. The procedure proposed is applied to the problem of the centrally cracked plate in tension where the loading direction is perpendicular to the crack faces. The results of the analysis show that the buckling deformations can cause a considerable amplification of the stress intensity around the crack tip. This effect, which is due to a redistribution of the stress field in the plate, increases with the length of the crack.

ABSTRACT: A method for computing the energy release rate for cracks of varying length in a typical stiffened metallic fuselage under general loading conditions is presented. Reliable analytical methods that predict the structural integrity and residual strength of aircraft fuselage structures containing cracks are needed to help to understand the behavior of pressurized stiffened shells with damage, to determine the safe life of such a shell. The models used in the simulation are derived from an extensive analysis of a fuselage barrel section subjected to operational flight loads. Energy release rates are computed as a function of the length of the crack, its location, and the crack propagation mode.

ABSTRACT: This paper is an investigation into the merits of an hybrid procedure for the numerical simulation of transient buckling problems. The procedure consists of the combination of a classical path-following method with a transient integration method where the first method is used for the quasi static (stable) parts of the simulation and the second method for the parts of the simulation that belong to the transient domain. It is shown that the success of the procedure is guaranteed by a proper formulation of the so-called matching conditions that define the transition from one mode of operation to the other. The chosen strategy turns out to be very robust and it has as an added advantage that it can be applied with relative ease. The power of the approach is demonstrated with the presentation of two simulations: The mode jumping problem of a plate strip and the collapse of a thin-walled composite cylinder in compression.

ABSTRACT: The discussion in this presentation is restricted to mechanical systems that are conservative or quasi-conservative. By quasi conservative we mean that the notion of conservatism holds as long as the changes of state occur infinitely slow. If changes of state occur with a finite rate of deformation, dissipative forces may
come into play.
Classic elastic stability theory studies the behavior of engineering structures under the influence of their service loads with a special focus on the determination of the (maximum) load these structures can carry. This maximum load is determined by geometrical effects that result from the state of deformation and not (in the first place) by material failure mechanisms. It is important to realize that the classical theory is restricted to quasi static loading conditions. The load carrying capacity in this setting is reached at the deformation state at which any further increase of the loading will result in the destruction of the structure. The state where this change is about to occur is called the collapse state, the limit state, or the state of loss of stability. The theory categorizes these states also as (proper) limit points and unstable bifurcation points.

In early applications of the theory, the actual collapse process -- called snap through or snap buckling -- was not deemed to be of particular interest and simply not considered. It should be added that the analytical tools in those days were not capable of solving the nonlinear partial differential equations of motion so that this transient phenomenon could be calculated. In fact, most applications remained restricted to the solution of the quasi-nonlinear buckling equations that arise when the pre-buckling state can be taken to be a linear function of the load intensity.

Thus before the age of “computational mechanics”, in the beginning of the 20th century, applications of stability theory remained restricted to problems that exhibited an initially linear pre-buckling state. This state of affairs did not change with the appearance of the perturbation theory of elastic stability conceived by Koiter. A milestone in the development of the concept of buckling, this development offered a considerable gain in understanding of the way stability is lost or maintained at a bifurcation point. It explained the consequences of these properties for the behaviour of structures loaded into the neighborhood of such a point. It also provided a systematic derivation of an ordered sequence of linearized equations that determine the shape of the most important bifurcations that can be encountered. However, with the analytical means available at that time, these equations were no more accessible to computation than the well established linearized buckling equations. As a consequence, applications of Koiter’s general theory remained also restricted to problems with a linear pre-buckling state. It was the advent of the computer and the surge of the numerical treatment of the classical theories of solid mechanics that gradually offered possibilities in computation that nobody would or could have dreamed of before. This revolution opened an approach in the solution of nonlinear equations that removed the necessity to restrict the analysis to initial linear behavior. It also removed the restriction to “static analysis only”. This means that the traditional assessment of the load carrying capacity on the basis of a quasi static loading process can presently be amended by transient analysis and even replaced by it. Moreover, these advances have now also paved the way to consider non classical definitions of stability loss. In particular, buckling induced by transient loading of short duration is presently studied as a possible potential critical loading case for certain buckling problems that are encountered in practice.

ABSTRACT: Reliable analytical methods that predict the structural integrity and residual strength of aircraft fuselage structures containing cracks are needed to help to understand the behavior of pressurized stiffened shells with damage, so that it becomes possible to determine the safe life of such a shell. Of special importance is the ability to determine under what conditions local failure, once initiated, will propagate. In this paper we shall present a reliable and efficient method for computing the energy release rate for cracks of varying length in a typical stiffened metallic fuselage under general loading conditions. The models used in the simulation are derived from an extensive analysis of a fuselage barrel section subjected to operational flight loads. Energy
release rates are computed as a function of the length of the crack, its location, and the crack propagation mode.

ABSTRACT: PANDA2 is a computer program for the minimum weight design of stiffened composite, flat or cylindrical, perfect or imperfect panels and shells subject to multiple sets of combined in-plane loads, normal pressure, edge moments and temperature. STAGS is a general nonlinear finite element code that is specifically designed to analyze especially difficult stability problems in shell structures. Weight optimization of stiffened panels can be particularly troublesome when local buckling is allowed to occur in the precollapse state. For these systems, designs may be affected by interaction between local modes, a mechanism that manifests itself as mode jumping and is difficult to characterize. In this paper we describe how in PANDA2 mode jumping is detected and suppressed in optimized panels. Two axially compressed blade stiffened panels optimized by PANDA2 for service in the far postbuckling regime were numerically tested by STAGS. Mode jumping was permitted to occur below the design load in the first panel and suppressed in the second. Results obtained by STAGS are in reasonably good agreement with predictions by PANDA2. The first panel exhibits mode jumping well below the design load. Application of STAGS to this panel reveals that even though the mode jump involves little change in potential energy it generates large amplitude oscillating stresses with significant stress reversal that might well cause fatigue and delamination.

ABSTRACT: This paper concerns the theory and implementation of a numerical procedure that is capable of solving the collapse process of a structure when it is loaded past its ultimate carrying strength. The procedure is a combination of two generally available methods: A path following method for the quasi static part of the solutions and a transient method for the dynamic part. The simulation of a compression test on a thin walled cylindrical shell with a local imperfection is provided to demonstrate the effectiveness of the strategy employed.

ABSTRACT: Oblique line contact algorithms are developed in this research to simulate local buckling around a crack due to crack edges contacting. The contact algorithms are based on a large-displacement and geometrically nonlinear response. A penalty function in terms of the minimum distance between two contacting lines is introduced in the proposed method to determine the contact conditions. The STAGS finite element code is employed to show the results of two cantilevered beams that experience line-to-line contact.

ABSTRACT: The finite strip method has successfully been applied for the calculation of the buckling load of stiffened panels in wing box structures. This article describes an implementation of the finite strip method that extends the scope of the analysis of the determination of the post-buckling stiffness of these panels.

ABSTRACT: Although the first known solution of a buckling problem was given by the outstanding Swiss ‘natural philosopher’ Leonhard Euler (1744), buckling theory as an engineering subject is an outgrowth of a development that was established during the last century. The overview of the present knowledge regarding the computational analysis of buckling problems is here given in the context of the theory's most important historical developments.

ABSTRACT: The buckling behaviour of complete spherical shells and spherical caps is explained and test results are extensively reviewed. The development of the theory up to the point where theoretical and experimental results agree is presented. The treatment is confined to completely elastic material.

ABSTRACT: Explicit analyses of flexural-torsional buckling of open thin-walled FRP beams, local buckling of rotationally restrained orthotropic composite plates subjected to biaxial linear loading and associated
applications of the explicit solution to predict the local buckling strength of composite structures (i.e., FRP structural shapes and sandwich cores), and delamination buckling of laminated composite beams are presented. Based on nonlinear plate theory, of which the shear effect and beam bending-twisting coupling are included, the buckling equilibrium equations of flexural-torsional buckling of pultruded FRP composite I- and channel beams are established using the second variational principle of total potential. The critical buckling loads for different span lengths are measured through experiments and compared with analytical solutions and numerical finite element results. A parametric study is conducted to evaluate the effects of the load location, fiber orientation, and fiber volume fraction on the buckling behavior.

The first variational formulation of the Ritz method is used to establish an eigenvalue problem for local buckling of composite plates elastically restrained along their four edges and subjected to a biaxial linear load, and the explicit solution in terms of rotational restraint stiffness is presented with a unique harmonic shape function. A parametric study is conducted to evaluate the influences of the biaxial load ratio, rotational restraint stiffness, aspect ratio, and flexural-orthotropy parameters on the local buckling stress resultants of various rotationally-restrained plates. The applicability of the explicit solutions of restrained composite plates is illustrated in the discrete plate analysis of two types of composite structures: FRP structural shapes and sandwich cores.

The delamination buckling formulas are derived based on the rigid, semi-rigid, and flexible joint deformation models according to three corresponding bi-layer beam theories (i.e., conventional composite, shear-deformable bi-layer, and interface-deformable bi-layer, respectively). Numerical simulation is carried out to validate the accuracy of the formulas, and the parametric study of the shear effect is conducted to demonstrate the improvement of flexible joint model. The explicit buckling solutions developed facilitate design analysis and optimization of FRP composite structures and provide simplified practical design equations and guidelines for buckling analyses.

ABSTRACT: This paper considers the elastic unilateral buckling of rectangular mild steel plates that are restrained elastically and subjected to bending and axial actions. A variational formulation of the Ritz method using linear combinations of harmonic functions for the buckling deformations is used to establish an eigenproblem to determine the plate local buckling coefficients. The motivation for the study is the retrofit of reinforced concrete beams by gluing and then bolting steel plates to the sides of the beam. Such plates, when acting compositely with the concrete beam, are subjected to predominantly bending and axial actions which may cause unilateral local buckling. Whereas the bolts provide complete restraint against buckling at discrete points, the glue may also inhibit local buckling between these nodal points since it acts as a continuous elastic restraint. The influence of the glue stiffness, support conditions and plate proportions on the unilateral buckling of such plates are assessed.

Summary: Aircraft structures, both metallic and composite, are often stiffened with thin-walled sections of
various shapes to resist compression loads efficiently. Analysis of these structures can be challenging, and empirical methods are often used for design purposes. Since initial buckling is not necessarily indicative of structural failure, the analysis must be carried into the post-buckling range, where geometric and material nonlinearities are present. Final failure in this context is called crippling, which corresponds to the maximum load carried by the section.

In this paper, the nonlinear capabilities of MSC Nastran SOL 400 are used to perform post-buckling analysis of graphite/epoxy composite I-section stiffeners. After performing an eigenvalue buckling analysis, initial imperfections in the shape of the buckling modes are applied to the model to start the large displacement analysis. Composite material failures are modeled using the Progressive Failure Analysis (PFA) feature of SOL 400. Results are plotted as load-displacement curves, and crippling failure is defined as the maximum load carried. Results are compared to published test data as well as MIL-HDBK-17 design equations.

Bonanni (Survivability, Structures and Materials Directorate, Naval Surface Warfare Center (formerly David Taylor Research Center), Bethesda, Maryland, USA), “Stability analysis of thick-section composite cylinders under hydrostatic pressure including three-dimensional effects and nonlinear material response”, ASTM STP1185, January 1994

ABSTRACT: Recent studies of thick-section laminated composite materials and structures have suggested that there is a need for three-dimensional (3-D) structural analysis methods which include the nonlinear material response of the constituents. The work described in this paper integrates a 3-D micromechanics-based nonlinear constitutive model for laminated composite materials into 3-D structural analyses performed with the ABAQUS general purpose finite element code. The nonlinear model and its incorporation into ABAQUS are described. The method is demonstrated through 3-D stability analyses of thick, unstiffened AS4/3501-6 carbon/epoxy circular cylinders under external hydrostatic pressure. The results of two-dimensional (2-D) shell finite element analyses of these cylinders are also presented for comparison. The cylinders analyzed are geometrically identical and are subjected to the same loading and boundary conditions. Five different ply layups are considered, including cross-ply, quasi-isotropic, and [±45°]. Modeling the nonlinear material response is found to reduce the predicted cylinder collapse load by up to 50% when layers oriented at ±45° to the cylinder axis are present in the laminate. The role of material nonlinearity in the plane of the laminate versus through-thickness nonlinearity is discussed for the cylinders analyzed.

ABSTRACT: Postbuckling analysis is essential to predict the capacity of composite plates carrying considerable additional load before the ultimate load is reached, and manufacturing-induced geometric imperfections often reduce the load-carrying capacity of composite structures. A higher-order finite strip method based on the higher-order shear deformation plate theory is developed for postbuckling analysis of laminated composite plates with initial geometric imperfection subjected to progressive end shortening. The arbitrary nature of initial geometric imperfection induced during manufacturing is accounted for in the analysis. Nonlinear equilibrium equations are solved by a Newton-Raphson procedure. Examples of postbuckling analyses of unsymmetric cross-ply, angle-ply, and arbitrary laminates are presented, and the accuracy and performance of the method are examined. The numerical higher-order finite strip method presented can be used as an accurate and efficient tool for postbuckling analysis of imperfect composite plates.

“Lightweight design for thin-walled cylindrical shell based on action mechanism of bamboo node”, ASME
ABSTRACT: Lightweight design is needed for many engineering structures, but conventional design methods cannot always meet requirements. Natural organisms have developed many types of structures with excellent properties and ingenious construction, and they can provide many new design ideas. In this paper, a thin-walled cylindrical shell, one of the most common structures, is designed to resist buckling based on the study of bionics. First, the structure and function of bamboo node are described, and a statistical analysis of internode length-to-diameter ratio in bamboo is performed to investigate structural characteristics of bamboo node. Then, through buckling analysis of three relevant experimental models, the action mechanism of bamboo node is investigated, and two rules for application of this structure in engineering are proposed. Finally, a bionic design method is introduced, and a lightweight design for a thin-walled cylindrical shell based on this method is presented. A comparison between the bionic shell and a conventional one shows that the weight was reduced by as much as 20.5%.

ABSTRACT: An explicit elastic stability analysis for local buckling of fiber-reinforced plastic (FRP) structural shapes is presented. Flange of pultruded FRP wide-flange sections is modeled as a discrete panel with elastic restraint at one unloaded edge and free at the other unloaded edge [restrained-free (RF) condition] and subjected to uniform distributed axial in-plane force along simply supported loaded edges. By considering a linear combination of simply supported-free and clamped-free boundary displacement fields as an interpolation function of the RF buckling, a variational formulation of the Ritz method is used to establish an eigenvalue problem, and a flange critical local buckling coefficient is determined. An explicit solution is obtained for local compressive buckling strength of orthotropic panels with the RF condition and is expressed in term of the coefficient of elastic restraint based on the flexibility of flange-web connection. The explicit predictions are in good agreements with experimental data, exact transcendental solutions, and finite-element analyses for local buckling of FRP wide-flange columns. The formulation developed in this paper is the first attempt in the literature for explicit buckling analysis of orthotropic plates with RF condition and can facilitate the local buckling analysis and design of open FRP structural profiles (e.g., I and channel shapes).

ABSTRACT: A combined analytical and experimental study of flexural–torsional buckling of pultruded fiber-reinforced plastic (FRP) composite cantilever I-beams is presented. An energy method based on nonlinear plate theory is developed for instability of FRP I-beam, and the formulation includes shear effect and bending–twisting coupling. Three different types of buckling mode shape functions of transcendental function, polynomial function, and half simply supported beam function, which all satisfy the cantilever beam boundary conditions, are used to obtain the eigenvalue solution, and their accuracy in the analysis are investigated in relation to finite element results. Four different geometries of FRP I-beams with cantilever beam configurations and with varying span lengths are experimentally tested under tip loads to evaluate their flexural–torsional buckling response. The loads are applied at the centroid of the tip cross-sections, and the critical buckling loads are obtained by gradually adding weight onto a loading platform. A good agreement among the proposed analytical solutions, experimental testing, and finite element method is obtained, and simplified explicit
formulas for flexural–torsional buckling of cantilever beams with applied load at the centroid of the cross-section are developed. The effects of vertical load position through the cross-section, fiber orientation and fiber volume fraction on buckling behavior are also studied. The proposed analytical solutions can be used to predict the flexural–torsional buckling loads of FRP cantilever beams and to formulate simplified design equations.

Suhir (Physical Sciences and Engineering Research Division, Bell Laboratories, Murray Hill, NJ 09074 Department of Electrical Engineering, University of California, Santa Cruz, CA 95064 Department of Mechanical Engineering, University of Maryland, College Park, MD 20742 Department of Electronic Materials, Technical University, Vienna, Austria ERS Co., Los Altos, CA 94024), “Elastic stability of a cantilever beam (rod) supported by an elastic foundation, with application to nano-composites”, J. Appl. Mech., Vol. 79, No. 1, 011009, December 2011, DOI: 10.1115/1.4005190

ABSTRACT: A simple analytical (“mathematical”) predictive model is developed with an objective to establish the condition of elastic stability for a compressed cantilever beam (rod) of finite length lying on a continuous elastic foundation. Based on the developed model, practical guidelines are provided for choosing the adequate length of the beam and/or its flexural rigidity and/or the spring constant of the foundation, so that the beam remains elastically stable. The obtained solution can be used, perhaps with some additional assumptions and modifications, for the assessment of the critical force for high-modulus and low-expansion fibers (including nano-fibers) embedded into a low-modulus and high-expansion medium (matrix). Composite systems are often fabricated at elevated temperatures and operated at lower temperature conditions. It is imperative that an embedded fiber remains elastically stable, i.e., does not buckle as a result of the thermal contraction mismatch of its material with the material of the matrix. If buckling occurs, the functional (e.g., thermal) and/or the structural (“physical”) performance of the composite might be compromised.

ABSTRACT: Ring and stringer stiffened perfect and imperfect angle-ply cylindrical shells under combined axial compression and in-plane shear are optimized with a program called PANDA2 for the minimum weight design of stiffened panels, and the optimum designs are then evaluated with use of a general purpose finite element code called STAGS. The good agreement between PANDA2 and STAGS predictions for the nonlinear collapse of imperfect stiffened shells justifies the use of PANDA2 for preliminary design. A new PANDA2 processor called STAGSUNIT automatically generates STAGS input files for cylindrical panels and shells with both stringers and rings that have various open cross sections such as Blades, Zees, Jays, Tees and Is. In STAGSUNIT the edge conditions are formulated so that STAGS models of subdomains of a long cylindrical shell with many stiffeners can be constructed that do not have artificial prebuckling stress concentrations near the edges that might significantly affect predictions of bifurcation buckling and nonlinear collapse of the subdomain. Many STAGS models of optimized shells and subdomains of shells with Blade, Zee, and Tee stiffening are generated and explored, both with respect to linear bifurcation buckling and nonlinear collapse. The behavior of shells with an initial imperfection in the form of a general buckling mode of the imperfect shell is described from a physical point of view. Some difficulties encountered during this project are described.

ABSTRACT: The PANDA2 computer program generates minimum-weight designs of ring and stringer stiffened flat or cylindrical composite panels subjected to multiple sets of load combinations. PANDA2 is described with emphasis on the many different stress and buckling constraints that can affect the evolution of a design during optimization cycles, on the way that imperfections are treated, on certain difficulties that
imperfections may cause during optimization cycles, and on difficulties encountered during attempts to evaluate optimum designs with the use of the STAGS general purpose finite element program. Details are given on how PANDA2 determines the effect of an initial buckling modal imperfection on the load bearing capability of a ring and stringer stiffened cylindrical shell. Numerical results pertain to a metallic cylindrical shell with external T-shaped stringers and external T-shaped rings subjected to combined axial compression, external pressure and in-plane shear (torque). The maximum allowable stress is set very high so that stress constraints do not affect the evolution of the global optimum design in this example. Minimum-weight designs are determined for this shell with an initial imperfection in the form of the critical general buckling mode. Modifications to PANDA2 are described which overcome some of the difficulties associated with the determination of a global optimum design in the presence of an initial general buckling modal imperfection. Further modifications to PANDA2 are described which lead to less conservative global optimum designs than was previously the case. The optimum designs obtained by PANDA2 are evaluated by comparisons with predictions from STAGS for various finite element models generated automatically with a PANDA2 processor called STAGSUNIT. The agreement between PANDA2 and STAGS predictions for a global optimum design obtained by PANDA2 is good enough to qualify PANDA2 for the optimum design of imperfect stiffened cylindrical panels and shells under combined loads.

ABSTRACT: The results of an analytical study of the nonlinear response of stiffened fuselage shells with long cracks are presented. The shells are modeled with a hierarchical modeling strategy and analyzed with a nonlinear shell analysis code that maintains the shell in a nonlinear equilibrium state while the crack is grown. The analysis accurately accounts for global and local structural response phenomena. Results are presented for various combinations of internal pressure and mechanical loads, and the effects of crack orientation on the shell response are described. The effects of combined loading conditions and the effects of varying structural parameters on the stress-intensity factors associated with a crack are presented.

ABSTRACT: Advanced modeling and analysis capabilities of a state-of-the-art general purpose finite element code, developed for nonlinear structural analysis of launch vehicles, are described. In particular, the application of these capabilities to nonlinear analyses of the new Space Shuttle superlightweight external liquid-oxygen tank are presented that can be used as a guide for conducting similar analyses on future launch vehicles. A typical prelaunch loading condition with combined thermal and mechanical loads is considered, and applications of the advanced modeling and analysis capabilities to linear bifurcation buckling and nonlinear static analyses are presented. The results for this problem illustrate a localized short-wavelength bending response, and show that a high-fidelity model is required to represent the behavior accurately. A mesh refinement strategy is presented that is based on the linear bifurcation buckling analyses and does not require respecification of the shell wall properties and load. Specifically, mesh refinement is simplified by using user-written subroutines to describe the spatial distribution of complex shell wall properties and loading conditions.

ABSTRACT: Finite element models of sandwich structures are often based on classical sandwich theory which reduces the essentially three-dimensional composite — a combination of two high strength faces separated by a light weight core — to a two-dimensional, deformable reference surface to which certain appropriate stiffness properties against stretch, bending and transverse shear are attached. The simplification introduced in this way is well established, but it suffers from a number of drawbacks that restricts its range of applicability rather severely. The drawbacks concern among others, the kinematic and dynamic boundary conditions that prohibit a realistic application of the loading along the edges. They also concern the inability of this model to study local effects such as buckling of the faces. In the present paper, we demonstrate how, with a relatively simple means, a sandwich model can be introduced that does not suffer from the deficiencies mentioned above. Moreover, this improved model provides the possibility to study the detrimental effect of delamination of the faces, and/or, decohesion zones between the core and faces, on the buckling strength of sandwich compression panels. The modification proposed here makes use of existing shell finite elements that are standard in many finite element codes. These shell elements are used to model the deformation of the faces of the sandwich, while the coupling between the two shell components is carried out by applying an appropriate penalty function that represents the deformation of the core. In this paper, we describe this model in some detail and solve an example problem involving the buckling of a sandwich plate with a partially debonded face plate.

P.J. Denrijer and E. Riks, “A finite element analysis of cracks in a thin walled cylinder under internal pressure”, (no publisher or date given by ProQuest-CSA, 1987?)
ABSTRACT: Finite element models for the analysis of the behavior of longitudinal cracks in a pressurized thin
walled cylindrical shell were defined with the STAGSC-1 finite element code and used to study the possibilities of an analysis of cracks present in stiffened cylinders. In contrast to the problem of a crack in a flat plate in tension, the problem of a crack in a cylinder is governed by geometrical nonlinear effects from the onset. This is clearly brought out by the analysis results. They show that for cracks with a large aspect ratio, the linear theory grossly overestimates the intensity of the crack tip singularity. The results also show that the finite element method holds considerable promise in this area of crack mechanics. This is illustrated by the solution of a problem which concerns a centrally cracked plate loaded in the post buckling range.

ABSTRACT and PARTIAL INTRODUCTION:
This paper discusses some computational tools, recently developed, that are useful in the assessment of the residual strength of fuselage shells damaged by through cracks.

1. Introduction
Fuselages can accumulate damage in the form of through cracks in the outer containment shell. The prediction of the way these cracks propagate under service loads is therefore an important issue in the assessment of the residual strength of such a shell. This paper is focused on some of the tools of analysis recently developed that are capable to assess the effect of this type of damage.

A through crack in a pressurized shell is known to be dominated by the following influence factors: (i) the curvature, which is the principal reason the crack faces bulge out; (ii) a geometrically nonlinear effect that usually, but not always, alleviates crack tip loading; and, (iii) the ductility of the material, so that a plastic zone develops in front of the crack tip and absorbs a part of the energy that must be supplied to force the crack to advance.

ABSTRACT: The capability of the computer program PANDA2 to generate minimum-weight designs of stiffened panels and cylindrical shells is enhanced to permit the adding of substiffeners with rectangular cross sections between adjacent major stringers and rings. As a result many new buckling margins exist that govern buckling over various domains and subdomains of the doubly stiffened panel or shell. These generally influence the evolution of the design during optimization cycles. The substiffeners may be stringers and/or rings or may form an isogrid pattern. The effects of local, inter-ring, and general buckling modal imperfections can be accounted for during optimization. Perfect and imperfect cylindrical shells with external T-shaped stringers and T-shaped rings and with and without substrings and subrings and under combined axial compression, external pressure, and in-plane shear are optimized by multiple executions of a "global" optimizer called SUPEROPT. It is found that from the point of view of minimum weight there is little advantage of adding substiffeners. However, with substiffeners present the major stringers and rings are spaced farther apart at the optimum design than is so when there are no substiffeners. The weight of a cylindrical shell with substiffeners is much less sensitive to the spacing of the major T-shaped stringers than is the case for a cylindrical shell without substiffeners. The optimum designs obtained by PANDA2 are evaluated by comparisons with buckling loads obtained from a general-purpose finite element program called STAGS. Predictions from STAGS agree well with those from PANDA2.

ABSTRACT: (Cannot cut and paste)

ABSTRACT: Results of a geometrically nonlinear finite element parametric study to determine curvature correction factors or “bulging factors” that account for increased stresses due to curvature for longitudinal and circumferential cracks in unstiffened pressurized cylindrical shells are presented. Geometric parameters varied in the study include the shell radius, the shell wall thickness, and the crack length. The major results are presented in the form of contour plots of the bulging factor as a function of two nondimensional parameters: the shell curvature parameter, Lambda, which is a function of the shell geometry, Poisson’s ratio, and the crack length; and a loading parameter, Eta, which is a function of the shell geometry, material properties, and the applied internal pressure. These plots identify the ranges of the shell curvature and loading parameters for which the effects of geometric nonlinearity are significant. Simple empirical expressions for the bulging factor are then derived from the numerical results and shown to predict accurately the nonlinear response of shells with longitudinal and circumferential cracks. The numerical results are also compared with analytical solutions based on linear shallow shell theory for thin shells, and with some other semi-empirical solutions from the literature, and limitations on the use of these other expressions are suggested.

ABSTRACT: The results of an experimental and analytical study of the effects of initial imperfections on the buckling and postbuckling response of unstiffened thin-walled compression-loaded graphite-epoxy cylindrical shells are presented. The shells considered in the study have four different shell-wall laminates and two different shell-radius-to-thickness ratios. The shell-wall laminates include two different orthotropic laminates and two different quasi-isotropic laminates. The shell-radius-to-thickness ratios include shell-radius-to-thickness ratios equal to 100 and 200. The results identify the effects of traditional and nontraditional initial imperfections on the nonlinear response characteristics and buckling loads of the shells. The traditional imperfections include the geometric shell-wall mid-surface imperfections that are commonly discussed in the literature on thin shell buckling. The nontraditional imperfections include shell-wall thickness variations, local shell-wall ply-gaps associated with the fabrication process, shell-end geometric imperfections, nonuniform applied end loads, and variations in the boundary conditions including the effects of elastic boundary conditions. A high-fidelity nonlinear shell analysis procedure that accurately accounts for the effects of these traditional and nontraditional imperfections on the nonlinear response characteristics and buckling loads of the shells is described. The analysis procedure includes a nonlinear static analysis that predicts the stable response characteristics of the shells, and a nonlinear transient analysis that predicts the unstable response characteristics. The results of a local shell-wall stress analysis used to estimate failure stresses are also described.

ABSTRACT: A parametric study of the effects of test-fixture-induced initial prestress and elastic edge restraints on the prebuckling and buckling responses of a compression-loaded, quasi-isotropic curved panel is presented.
The numerical results were obtained by using a geometrically nonlinear finite element analysis code with high-fidelity models. The results presented show that a wide range of prebuckling and buckling behavior can be obtained by varying parameters that represent circumferential loaded-edge restraint and rotational unloaded-edge restraint provided by a test fixture and that represent the mismatch in specimen and test-fixture radii of curvature. For a certain range of parameters, the panels exhibit substantial nonlinear prebuckling deformations that yield buckling loads nearly twice the corresponding buckling load predicted by a traditional linear bifurcation buckling analysis for shallow curved panels. In contrast, the results show another range of parameters exist for which the nonlinear prebuckling deformations either do not exist or are relatively benign, and the panels exhibit buckling loads that are nearly equal to the corresponding linear bifurcation buckling load.

Overall, the results should also be of particular interest to scientists, engineers, and designers involved in simulating flight-hardware boundary conditions in structural verification and certification tests, involved in validating structural analysis tools, and interested in tailoring buckling performance.

ABSTRACT: The development of DISDECO, the Delft Interactive Shell DEsign COde is described. The purpose of this project is to make the accumulated theoretical, numerical and practical knowledge of the last 25 years or so readily accessible to users interested in the analysis of buckling sensitive structures. With this open ended, hierarchical, interactive computer code the user can access from his workstation successively programs of increasing complexity. The computational modules currently operational in DISDECO provide the
prospective user with facilities to calculate the critical buckling loads of stiffened anisotropic shells under combined loading, to investigate the effects the various types of boundary conditions will have on the critical load, and to get a complete picture of the degrading effects the different shapes of possible initial imperfections might cause, all in one interactive session. Once a design is finalized, its collapse load can be verified by running a large refined model remotely from behind the workstation with one of the current generation 2-dimensional codes, with advanced capabilities to handle both geometric and material nonlinearities.

ABSTRACT: A FORTRAN IV, large capacity, computer program has been developed to determine collapse loads and bifurcation loads for linear and nonlinear prebuckling behavior for fiber-reinforced, laminated, rectangular plates and panels under general loading systems and boundary conditions. The program is based on the principle of total potential energy and uses finite-differences in the discretization process. Whole-station spacing has been used to calculate the strain energy associated with an area-element and an orthogonal finite-difference grid that provides for variable spacings in perpendicular directions is incorporated. Numerical results are presented that compare favorably with results obtained via the general computer program STAGS. Other numerical results are presented that illustrate the types of boundary conditions, applied loads, cut-outs and initial geometric imperfections that can be handled by the present program. A brief study of the effect of panel construction and initial geometric imperfections on the buckling behavior of fiber-reinforced panels is presented.

ABSTRACT: Attention is given to the structural efficiencies obtainable with optimally designed graphite/epoxy wing rib panel configurations that are potentially economically manufacturable. Some ribs are commonly used as fuel cell closeout panels, and are accordingly subjected to out-of-plane pressure loads in addition to the in-plane axial compressive and shear loads resulting from the wing loading. The present minimum-weight panel designs satisfy buckling and strength constraints for wing rib panels subjected to a wide range of combined load conditions.

ABSTRACT: Development of an algorithm to perform the optimal sizing of buckling resistant, imperfect, anisotropic ring-stiffened cylinders subjected to axial compression, torsion, and internal pressure is presented. An axisymmetric, geometrically nonlinear prebuckling equilibrium configuration is assumed and both stress and stability constraints are considered. The enforcement of stability constraints is treated in a way that does not require any eigenvalue analysis. Case studies performed using a combination of penalty function and feasible direction optimization methods indicate that the presence of the axisymmetric initial imperfection in the cylinder wall can significantly affect the optimal designs. Weight savings associated with the addition of two rings to the unstiffened cylinder and/or the addition of internal pressure is substantial when torsion makes up a significant fraction of the combined load state.

ABSTRACT: An automated procedure for designing minimum-weight composite panels subject to a local damage constraint under tensile loading was developed. A finite element program based on linear elastic fracture mechanics for calculating stress intensity factors (SIF) was incorporated in the design cycle. Panel fracture toughness was obtained by using a strain based criterion. A general purpose mathematical optimization algorithm was used for the weight minimization. Analytical sensitivity derivatives of the SIF employing the adjoint variable technique was used to enhance the computational efficiency of the procedure. Design results for both unstiffened and stiffened plates are presented.

ABSTRACT: An experimental and analytical study was carried out to investigate the buckling and failure characteristics of stiffened compression-loaded panels with holes, and to assess the validity of analytical models used for the design of such panels. Graphite-epoxy panels with four equally spaced blade stiffeners were fabricated with a laminate stacking sequence optimally designed for stiffened panels without holes. Panels with different hole sizes and panels without holes were tested. Failure of all panels initiated at or near the stiffeners, in regions with severe local bending gradients. Finite element analysis using a quarter-panel model with boundary conditions to simulate the experiment was used to predict the prebuckling and buckling behavior. Analytical results correlate well with experimental results.

ABSTRACT: Derivatives of buckling loads of stiffened panels with respect to ply thicknesses are easy to calculate. Consequently, such derivatives are often available in computer programs that calculate buckling loads of composite structures. These derivatives can be used to construct approximations of the dependence of the buckling load on ply thicknesses. The present work demonstrates the use of derivatives of buckling loads with respect to ply thicknesses to approximate the effects of changes in stacking sequence and ply orientations on buckling load of a laminate. Examples of unstiffened and stiffened panels are used to demonstrate the effectiveness of the proposed approximation.

ABSTRACT: Buckling and postbuckling analyses of circular laminated composite plates with delaminations are presented. An axisymmetric finite element model based on a layer-wise laminated composite plate theory is developed to formulate the problem. Geometric nonlinearity in the sense of von Kármán and imperfections in the form of initial global deflection and initial delamination openings are included. A simple contact algorithm which precludes the physically inadmissible overlapping between delaminated surfaces is proposed and incorporated into the analysis. Numerical results are obtained addressing the effects of the initial imperfections, the number of delaminations and their sizes on the critical buckling load and buckling mode shapes, as well as postbuckling responses.

ABSTRACT: Results of an analytical and experimental study to characterize the structural response of two compression-loaded variable stiffness composite panels are presented and discussed. These variable stiffness panels are advanced composite structures, in which tows are laid down along precise curvilinear paths within each ply and the fiber orientation angle varies continuously throughout each ply. The panels are manufactured from AS4/977-3 graphite-epoxy pre-preg material using an advanced tow placement system. Both variable stiffness panels have the same layup, but one panel has overlapping tow bands and the other panel has a constant-thickness laminate. A baseline cross-ply panel is also analyzed and tested for comparative purposes. Tests performed on the variable stiffness panels show a linear prebuckling load-deflection response, followed by a nonlinear response to failure at loads.

References listed at the end of the paper:
The introduction of advanced tow-placement machines has made it possible to fabricate novel variable-stiffness composite structures where the fiber orientation angle varies continuously within each ply and throughout the structure. This manufacturing capability allows designers of composites to use the fiber orientation angle as design variable in their analysis, not only for each ply as with conventional composites, but at each point within a ply. Consequently, beyond the improvements that can be accomplished with traditional composites with straight fibers, the directional material properties of composites can be fully exploited to improve the laminate performance. In this paper, design tailoring for the pressure pillowing problem of a fuselage panel bounded by two frames and two stringers is addressed using tow-placed steered fibers. The panel is modeled as a two-dimensional plate loaded by out-of-plane pressure and in-plane loads. A Python-ABAQUS script is developed to perform the linear and geometrically nonlinear finite element analyses of variable-stiffness panels. The design objective is to determine the optimal fiber paths within each ply of the laminate for maximum load carrying capacity and for maximum buckling capacity. Simulated-annealing algorithm is used to solve the optimization problems. Optimal designs are obtained for different loading cases and boundary conditions. As a basis of comparison, a practical constant-stiffness quasi-isotropic design is used. Numerical results indicate that by placing the fibers in their optimal spatial orientations within each ply, the load carrying capacity and the buckling load of the structure can be substantially improved compared with traditional straight fiber designs. It is shown that laminates optimized for maximum failure load have buckling loads that are higher than those for quasi-isotropic laminates. On the other hand, laminates optimized for maximum buckling load fail at load levels lower than laminates optimized for maximum failure load. However, the failure loads of those laminates may still be higher than those for their quasi-isotropic counterparts.

ABSTRACT: There is a renewed interest in grid-stiffened composite structures; they are not only competitive with conventional stiffened constructions and sandwich shells in terms of weight but also enjoy superior damage tolerance properties. In this paper, both global and local structural instabilities are investigated for grid-stiffened composite panels using homogenization theory. Characteristic cell configurations with periodic boundary constraints are employed for orthogrid- and isogrid-stiffened shells in order to smear the stiffened panel into an equivalent unstiffened shell. Homogenized properties corresponding to classical lamination theory are obtained by matching the strain energy of the stiffened and equivalent cells. Global buckling analysis is carried out based on the homogenized shell properties. Bloch wave theory is adopted to calculate the local buckling load of grid-stiffened shells, where the interaction of adjacent cells is fully taken into account. Moreover, instead of considering skin buckling and stiffener crippling separately, as is commonly done, the skin and stiffeners are assembled together at the level of the characteristic cell. The critical instabilities can be captured whether they are related to the skin or stiffener or their interaction. The proposed combination of global/local models can also be used to predict the material failure of a structure. Numerical examples of orthogrid- and isogrid-stiffened isotropic panels show that the local buckling loads predicted by the proposed method match finite element calculations better than semi-analytical methods based on assumptions and idealisations. The proposed method is further validated using typical configurations of flat composite panels and circular composite cylinders.

ABSTRACT: The model problem proposed to study the buckling of stratified geological layers consists of a linearly elastic plate, capable of accommodating finite rotations, resting over an inviscid and buoyant fluid. The Lyapunov–Schmidt–Koiter decomposition is applied to construct the bifurcated equilibrium solutions. The asymptotic analysis of the post-buckling reveals a decrease in the magnitude of the lateral compressive force during an overall shortening of the stratified structure. Buckling and post-buckling are not influenced by the presence of a vertical stress gradient in the elastic plate.

ABSTRACT: The aim of this work is to investigate the influence of axial load uncertainties on the nonlinear vibrations of simply-supported cylindrical shells. The axial load is composed by both harmonic deterministic and random terms; the random term depends on the parameters of the harmonic deterministic load. Donnell’s nonlinear shallow shell equations in terms of the in-plane and transversal displacements are used to study the nonlinear vibrations of the shell. To discretize the partial differential equations of motion, first, a general expression for the transversal displacement is obtained by a perturbation procedure which identifies all modes that couple with the linear modes through the quadratic and cubic terms in the equations of motion. Then, a particular solution is selected which ensures the convergence of the response up to very large deflection. Finally, the in-plane displacements are obtained as a function of the transversal displacement by solving the in-plane equations analytically. So, the proposed solution satisfies all boundary, continuity and symmetry conditions. Substituting the modal expansion of the transversal displacement into the equation of motion and applying the Galerkin’s method, a discrete system in time domain is obtained. Several numerical strategies are used to study the nonlinear behavior of the shell under an axial load with uncertainties. Special attention is given to the influence of the random term on the parametric instability and escape loads.

ABSTRACT: Cylindrical shells exhibit a dense frequency spectrum, especially near the lowest frequency range. In addition, due to the circumferential symmetry, frequencies occur in pairs. So, in the vicinity of the lowest natural frequencies, several equal or nearly equal frequencies may occur, leading to a complex dynamic behavior. So, the aim of the present work is to investigate the dynamic behavior and stability of cylindrical shells under axial forcing with multiple equal or nearly equal natural frequencies. The shell is modelled using the Donnell nonlinear shallow shell theory and the discretized equations of motion are obtained by applying the Galerkin method. For this, a modal solution that takes into account the modal interaction among the relevant modes and the influence of their companion modes (modes with rotational symmetry), which satisfies the boundary and continuity conditions of the shell, is derived. Special attention is given to the 1:1:1:1 internal resonance (four interacting modes). Solving numerically the governing equations of motion and using several tools of nonlinear dynamics, a detailed parametric analysis is conducted to clarify the influence of the internal resonances on the bifurcations, stability boundaries, nonlinear vibration modes and basins of attraction of the structure.

ABSTRACT: In recent papers, the authors have presented Generalized Beam Theory (GBT) formulations specifically designed for performing efficient (i) linear analyses of steel-concrete composite bridges [1] and (ii) elastoplastic collapse analyses of thin-walled steel members [2, 3]. This paper presents an extension of these previous formulations that includes non-linear reinforced concrete material behaviour, aiming at analysing, accurately and efficiently, steel-concrete composite beams. In particular, steel beam and rebar plastification is implemented, together with concrete cracking(crushing and shear-lag effects. Several illustrative examples are
presented and discussed. For validation and comparison purposes, results obtained with shell/solid finite element models are provided.

ABSTRACT: This paper presents the design guide based on analytical, numerical and experimental investigation of Steel-concrete-steel (SCS) sandwich structural members comprising a lightweight concrete core with density ranging from 1300 to 1445 kg/m³ subjected to static, impact and blast loads. The performance of lightweight sandwich members is also compared with similar members with normal weight concrete core and ultra high strength concrete core (f_c = 180 MPa). Novel J-hook shear connectors were invented to prevent the separation of face plates from the concrete core under extreme loads and their uses are not restricted by the concrete core thickness. Flexural and punching are the primary modes of failure under static point load. Impact test results show that the SCS sandwich panels with the J-hook connectors are capable of resisting impact load with less damage in comparison than equivalent stiffened steel plate panels. Blast tests with 100 kg TNT were performed on SCS sandwich specimens to investigate the key parameters that affect the blast resistance of SCS sandwich structure. Plastic yield line method is proposed to predict the plastic capacity and post peak large deflection of the sandwich plates. Finally, an energy balanced model is developed to analyze the global behavior of SCS sandwich panels subjected to dynamic load.

ABSTRACT: This paper deals with optimization of the buckling load for laminated composite structures. A new methodology has been developed where thermal residual stresses introduced in the manufacturing process are included in the buckling analysis. The thermal effects are also included in the calculation of the buckling load sensitivities, and it is therefore possible to “tailor” the thermal residual stresses in order to increase the buckling load. Rectangular plates and circular cylindrical shells subjected to axial compression are considered. The structures are optimized twice; the first time the thermal residual stresses are ignored in the optimization, and the second time the thermal residual stresses are included in the optimization. These two sets of optimizations give two important results. Firstly, it is possible to increase the buckling load for the structures significantly when the thermal residual stresses are taken into account. Secondly, structures which have been optimized ignoring the effects of thermal residual stresses, may have a buckling load which is much less than expected when the effects of the thermal residual stresses are included.

PARTIAL INTRODUCTION: When considering a structural system, perhaps one of the crucial problems facing the designer is the identification of those phenomena that are important. For example, there are quite different concerns if the predominant loads are compressive rather than tensile; compressive loads may lead to crushing, whereas tensile load may lead to necking phenomena. If materials are ductile or brittle there are different concerns; questions of yielding and flow may dominate for ductile materials, whereas flaw sensitivity may dominate for brittle materials. This is the context within which buckling or stability considerations should be taken. The conditions that always give the warning when a stability analysis may be necessary can be summarized quite easily: the structure must be subjected to compressive loads, and the structure must be thin. As contradictory as it may seem, these criteria are very precise and yet often ambiguous. Although thinness is absolutely essential for buckling, how “thin” is thin may be debatable. In a similar manner, identifying compressive loading situations may seem straightforward. However, some care must be exercised because a variety of loading situations may lead to compression. For example, shear buckling is quite common; in terms of principal stresses a pure shear results in a biaxial stress state with tensile and compressive principal normal stresses. It is the compressive component that causes buckling….

ABSTRACT: The optimal design of composite sandwich plates in which the facesheets are composed of a carbon fiber/epoxy net is considered. The objective of the work is to obtain minimum mass designs while maintaining constraints on the first natural frequency and selected facesheet stress components. The facesheets are assumed to be composed of an orthotropic net of unidirectional composite fiber strips and the optimal
design (the least mass design) is achieved by changing the strip widths and the spacings between them. It is demonstrated that varying the spatial fiber strip distribution can lead to significant structural advantages; in the example presented, a 32% facesheet mass reduction is achieved.

ABSTRACT: Buckling around an interfacial crack in a clamped sandwich plate is studied. The layers of the plate are assumed to be linearly viscoelastic, isotropic, and homogeneous. The investigations are carried out within the framework of a piecewise homogeneous body model with the use of a three-dimensional linearized theory of stability. The corresponding boundary value problems are solved numerically by employing the FEM and the Laplace transform. The calculated critical times are presented for various problem parameters. In this case, the upper and lower layers are assumed to be viscoelastic and are described by Rabotnov operators, whereas the midlayer is regarded as purely elastic. The influence of rheological parameters on the critical time is also analyzed.

SUMMARY: A thin solid film or coating bonded to a solid substrate may be in a state of residual stress due to mismatch in thermal expansion coefficient between the film and the substrate or other effects. If the residual stress is compressive, the tendency for film buckling is suppressed by the relatively high stiffness of the substrate. However, at a flaw in the interfacial bonding between the film and substrate, buckling of the film can and does occur. The focus here is on the process of delamination buckling under these circumstances, including dynamic effects. For an interfacial defect of a certain size, the compressive force in the film may exceed the buckling load, in which case the buckling process is inherently dynamic. Both cases of plane strain and axially symmetric deformation are considered, and propagation of the buckle is permitted provided that an energy balance separation condition is satisfied. Post-bifurcation response of the film is described by means of the von Karman plate theory. Hamilton’s principle is applied to obtain an approximate representation of the deformation in terms of two generalized coordinates, namely, the midpoint deflection of the buckled region and the size of the buckled region. Dynamic effects included are the transient deformation from the bifurcation state to the post-buckling configuration and the possibility of buckle nucleation due to waves impinging on the film from within the substrate. Histories of transient buckle deflection and buckle width are determined for representative material parameters.

ABSTRACT: We present the mechanics of folding surface-layer wrinkles on a soft substrate, i.e. inter-touching of neighbouring wrinkle surfaces without forming a cusp. Upon laterally compressing a stiff layer attached on a finite-elastic substrate, certain material nonlinearities trigger a number of bifurcation processes to form multi-mode wrinkle clusters. Some of these clusters eventually develop into folded wrinkles. The first bifurcation of the multi-mode wrinkles is investigated by a perturbation analysis of the surface-layer buckling on a pre-stretched neo-Hookean substrate. The post-buckling equilibrium configurations of the wrinkles are then trailed experimentally and computationally until the wrinkles are folded. The folding process is observed at various stages of wrinkling, by sectioning 20–80 nm thick gold films deposited on a polydimethylsiloxane substrate at a stretch ratio of 2.1. Comparison between the experimental observation and the finite-element analysis shows that the Ogden model deformation of the substrate coupled with asymmetric bending of the film predicts the folding process closely. In contrast, if the bending stiffness of the film is symmetric or the substrate follows the neo-Hookean behaviour, then the wrinkles are hardly folded. The wrinkle folding is applicable to construction of long parallel nano/micro-channels and control of exposing functional surface areas.

ABSTRACT: The aim of this chapter is to review the studies on buckle delamination in compressively stressed thin films over substrates by pulling together experimental and theoretical analysis. The general phenomena shown in delamination buckles of compressively stressed films were discussed from the onset to propagation over the substrates. The experimental observations were characterized by the delamination conditions and buckle morphologies. Then, the related mechanics for buckle delamination were provided with a theoretical solution for simple buckle configurations and a numerical solution for nonlinear buckle. Based on the experimental and theoretical analysis, the buckle configuration was applied to fluidic channels by precisely controlling buckle width within the desired area by adjusting interface adhesion.

K.G. Muthurajan, K. Sankaranarayanasamy, S.B. Tiwari and B. Nageswara Rao, 2006. Post-buckling of a Thin Film Strip Delamination in a Composite Laminate. Trends in Applied Sciences Research, 1: 48-60. ABSTRACT: Studies are made to understand the delamination growth of general laminates with general loading conditions. Post-buckling solutions are obtained for a laminate with clamped ends applicable to thin film strip delamination in a base laminate under uniform membrane loads. The strain energy release rate at the crack-tip (G) is derived in terms of the critical equivalent base laminate strain at the onset of the buckling ($\epsilon^*_{cr}$) and the applied equivalent strain ($\epsilon^*$). It is also expressed in terms of the maximum amplitude ($W_{max}$) of the delaminated layer. A Griffith-type fracture criterion with constant specific fracture energy ($G_c$) of the material is used to govern the delamination growth. The stability characteristics of the delamination growth are discussed. The maximum amplitude ($W_{max}$) of the delaminated layer increases with the applied load without enhancement in the length of the delamination for the values of G less than $G_c$. Initiation of the delamination growth can be expected when the value of G is very close to $G_c$. References listed at the end of the paper:

Haitao Han, Zixing Lu and Jordan Zhen Zhang (School of Aeronautic Science and Engineering, Beijing University of Aeronautics and Astronautics, 100191, Beijing, People’s Republic of China), “Solutions of beam-shaped-function for analysis of composite plates with embedded delaminations”, Archive of Applied Mechanics, Vol. 82, No. 4, pp 573-589, April 2012

ABSTRACT: Based on beam-shaped-function, the analytical solution for composite plates with arbitrary embedded delaminations is presented. The deflection function of the delaminated plate is composed by those of beams with the corresponding loading and support conditions, which can be easily and accurately derived from the beam analysis, and the deflection amplitude is derived by the minimum potential energy principle. The closed form solutions of displacements, stresses, and energy release rate of a composite plate containing an arbitrarily embedded rectangular delamination are obtained and compared with the three-dimensional finite element results to validate the accuracy of this present method. Furthermore, the influences of delamination depth, length, central position, and modulus mismatch ratio ($E_1/E_2$) of the upper and lower sublamine on the energy release rate are discussed.

References listed at the end of the paper:

ABSTRACT: Taking the longitudinal deformation into consideration, a two-dimensional beam theory is proposed, and a new layered beam model is established subsequently for composite laminates with multiple through-the-width delaminations. The undelaminated portion is regarded as separate beams along the layer interfaces, and the interface continuities are satisfied using the generalized variational principle. Comparisons of the present analytical solutions with three-dimensional finite element results and classical beam model solutions are made to verify the accuracy and efficiency of the present model. The effects of the geometrical parameters of the delamination on the deflection and the energy release rate are discussed.

ABSTRACT: Results related to the buckling delamination of elastic and viscoelastic composite plates are reviewed and analyzed. They have been obtained during the last fifteen years by the author and his students. The plates contain cracks whose faces have initial infinitesimal imperfections. The evolution of the imperfections under compression of the plates is studied, and the values of critical parameters are determined from a criterion of initial imperfection. The study is performed with the use of 3D geometrically nonlinear field equations. In the present paper, the historical background of the problems is outlined considered, general remarks about the field equations and solution method are made, and problems related to the plane strain state are reviewed.

ABSTRACT: In this paper, the formation of buckling and delamination of sandwiched stacking of Ti/Cu/Si thin film are investigated. The crystallization structures, the composition of the Cu/Ti thin films, and the surface morphology are measured during annealing. The results show that the solid-phase reaction between Cu and Ti occurs at the interface. Buckling is initiated in the thin film annealed at 600°C. The volume expansion promotes the buckling and further produces microcracks. With increasing volume expansion, there are cavities formed in the middle layer when the annealing temperature is up to 700°C. Finally, thin film is delaminated from the substrate.

ABSTRACT: Instability failure mode of nearly cylindrical sandwich shell was investigated by theoretical calculation. Finite Element Analysis and finally verified by two test specimens. During the test, information regarding snap-through, buckling mode and post buckling behaviour were collected. These indications were obtained by using the F/S method.

PARTIAL INTRODUCTION: The instability and the failure mode of nearly cylindrical sandwich shells, loaded in torsion, were investigated by theoretical calculation, Finite Element Analysis and verified by three parametric test specimens. Limited studies on composite wing boxes have been reported (Ref. 1-3), but they are all for solid laminate skins and none for thin composite sandwich shell skins. The purpose of this work was to develop a method for the analysis for the prediction of instability (buckling) and collapse (failure) of lightweight sandwich shells. The results are to be used in the design of GA (general aviation) structures.

ABSTRACT: The paper describes a design study for the structural optimization of a typical bay of a blended wing body transport. A hat stiffened laminated composite shell concept is used in the design. The geometry of the design is determined with the PANDA2 program, but due to the presence of varying axial loads, more accurate analysis procedure is needed. This is obtained by combining the STAGS finite element analysis program with response surface approximations for the stresses and the buckling loads. The design procedure results in weight savings of more than 30 percent, albeit at the expense of a more complex design. The response surface approximations allow easy coupling of the structural analysis program to the optimization program in
the widely available Microsoft EXCEL spreadsheet program. The response surface procedure also allows the optimization to be carried out with a reasonable number of analyses. In particular, it allows combining a large number of inexpensive beam-analysis stress calculations with a small number of the more accurate STAGS analyses.

ABSTRACT: A combined analytical and experimental study of a blade-stiffened composite panel subjected to axial compression was conducted. The study first examined the effects of the differences between a simple model used to design the panel and the actual experimental conditions. It was found that the large imperfection used in the design process compensated for the simplifying assumptions of the design model, and the experimental failure load was only 10% higher than the design load. Next, finite element analyses were performed in order to correlate analytical and experimental results. The buckling loads from finite element analyses agreed well with the experimental failure loads. However, substantial differences were found in the out-of-plane displacements of the panel. Finite element simulations of nonuniform load introduction with general contact definitions improved correlation between the measured and predicted out-of-plane deformations.

ABSTRACT: This paper explores reliability-based designs of isogrid stiffened panels. Uncertainties in material properties and geometric manufacturing uncertainties are represented by random variables. Due to the multiple failure modes in the stiffened panels, polynomial response surface approximation are fit to the most critical safety margins in the panel. Probability of failure is calculated by Monte Carlo simulation using the polynomial response surfaces. A probabilistic sufficiency factor approach is employed to facilitate the design optimization.

ABSTRACT: The design of reusable launch vehicles is driven by the need for minimum weight structures. Preliminary design of reusable launch vehicles requires many optimizations to select among competing structural concepts. Accurate models and analysis methods are required for such structural optimizations. Model, analysis, and optimization complexities have to be compromised to meet constraints on design cycle time and computational resources. Stiffened panels used in reusable launch vehicle tanks exhibit complex buckling failure modes. Using detailed finite element models for buckling analysis is too expensive for optimization. Many approximate models and analysis methods have been developed for design of stiffened panels. This dissertation investigates the use of approximate models and analysis methods implemented in PANDA2 software for preliminary design of stiffened panels. PANDA2 is also used for a trade study to compare weight efficiencies of stiffened panel concepts for a liquid hydrogen tank of a reusable launch vehicle. Optimum weights of stiffened panels are obtained for different materials, constructions and stiffener geometry. The study investigates the influence of modeling and analysis choices in PANDA2 on optimum designs. Complex structures usually require finite element analysis models to capture the details of their response. Design of complex structures must account for failure modes that are both global and local in nature. Often, different analysis models or computer programs are employed to calculate global and local structural response. Integration of different analysis programs is cumbersome and computationally expensive. Response surface approximation provides a global polynomial approximation that filters numerical noise present in discretized
analysis models. The computational costs are transferred from optimization to development of approximate models. Using this process, the analyst can create structural response models that can be used by designers in optimization. It allows easy integration of analysis models in optimization. The dissertation investigates use of response surface approximations for integrating structural response obtained from a global analysis in the local optimization of stiffened panels. In addition, response surfaces are used for correcting structural response predictions from a low fidelity model with a few expensive detailed finite element analyses.

ABSTRACT: Preliminary sizing of structural components in the conceptual design phase of new aerospace vehicles requires a large number of structural optimizations. Use of detailed finite element models for global optimization of stiffened shell structures is not affordable. Designers have to compromise between the complexity in the structural analysis model (e.g. small models or linear analysis) and that of the optimization method (local versus global optimization). When designing new concepts where good initial designs are not available, global design optimization needs to be performed, and this is not currently possible with complex models. In this paper, we discuss the use of simple analysis methods for performing global optimization of stiffened shell structures. We demonstrate the efficiency of using approximate analysis models by using PANDA2 for a practical design trade study. Often approximate models are based on assumptions that are not satisfied throughout the design space. Hence, such models require constraints that will keep the designs in regions where the analysis assumptions are valid. We illustrate with examples situations where such design constraints result in sub-optimal designs. We conclude that performing global optimization using approximate methods can permit a greater exploration of the design space than the use of local optimization with complex models.

ABSTRACT: Rapid increases in computer processing power, memory and storage space have not eliminated computational cost and time constraints on the use of structural optimization for design. This is due to the constant increase in the required fidelity (and hence complexity) of analysis models. Anecdotal evidence seems to indicate that analysis models of acceptable accuracy have required at least six to eight hours of computer time (an overnight run) throughout the last thirty years. This poses a severe challenge for global optimization or reliability-based design. In this paper, we review how increases in computer power were utilized in structural optimization. We resolve problem complexity into components relating to complexity of analysis model, analysis procedure and optimization methodology. We explore the structural optimization problems that we can solve at present and conclude that we can solve problems with the highest possible complexity in only two of the three components of model, analysis procedure or optimization. We use examples of optimum design of composite structures to guide the discussion due to our familiarity with such problems. However, these are supplemented with other structural optimization examples to illustrate the universality of the message.

ABSTRACT: Nonlinear problems such as transient dynamic problems exhibit structural responses that can be discontinuous due to numerous bifurcations. This hinders gradient-based or response surface-based
optimization. This paper proposes a novel approach to split the design space into regions where the response is continuous. This makes traditional optimization viable. A convex hull approach is adopted to isolate the points corresponding to unwanted bifurcations in the design space. The proposed approach is applied to a tube impacting a rigid wall representing a transient dynamic problem. Since nonlinear behavior is highly sensitive to small variations in design, reliability-based design optimization is performed. The proposed method provides the designer an optimal design with a prescribed dynamic behavior.

“A convex hull approach for the reliability-based design optimization of nonlinear transient dynamic problems”,
ABSTRACT: Nonlinear transient dynamic problems exhibit structural responses that might be discontinuous due to numerous critical points. The discontinuous behavior hinders classical gradient-based or response surface-based optimization. However, these discontinuities help to classify the system’s responses and identify regions of the design space corresponding to distinct dynamic behaviors. In this paper, data mining techniques are employed to group the responses into clusters. The regions of the design space corresponding to the clusters of unwanted behaviors are delimited with convex hulls. This allows an explicit definition of the boundaries of the failure region in terms of the design variables. In addition, the identification of response clusters, within which the responses might be considered continuous, enables the use of traditional response surface approximation for optimization. The proposed approach is applied to the reliability-based design of a tube impacting a rigid wall, which is optimized for a prescribed dynamic behavior.

ABSTRACT: Buckling of thin walled welded structures is one of the most common failure modes experienced by these structures in-service. The study of such buckling, to date, has been concentrated on experimental tests, empirical models and the use of numerical methods such as the Finite Element Method (FEM). Some researchers have combined the FEM with Artificial Neural Networks (ANN) to study both open and closed section structures but these studies have not considered imperfections such as holes, weld seams and residual stresses. In this paper, we have used a combination of FEM and ANN to obtain predictive models for the critical buckling load and lateral displacement of the center of the profile under compressive loading. The study was focused on ordinary Rectangular Hollow Sections (RHS) and on the influence of geometric imperfections while taking residual stresses into consideration.

ABSTRACT: Spatial variability in material properties and in the coefficient of thermal expansion (CTE) in particular can have detrimental effects on thermally induced buckling by lowering the buckling load. Worst-case effects of this variability were studied by anti-optimization on a plate subjected to thermal loading for up to 20% variation in CTE around a fixed mean. Finite element analyses were used to construct a response surface approximation of the buckling eigenvalues as function of the spatial variations of the CTE. Optimizing the spatial variations for lowest buckling eigenvalue led to worst-case CTE distributions with respect to the thermal buckling studied. It was found that for the same CTE mean these distributions could lead to up to 10% lower eigenvalues. Such anti-optimal distributions tend to lead to higher than average CTE along the centerline of the plate, which increases the pre-buckling stresses in those area which from the buckling point of view are the most sensitive to high stresses. For composites, CTE variations were also assumed to be caused by variations in fiber volume fraction, which would also affect moduli and Poisson ratio. The worst distribution of fiber volume fraction led to a reduction in eigenvalues of only about 4.3%, meaning that fiber volume fraction induced CTE variations have much milder effects on thermal buckling than independent CTE variations, due to the effects of individual material properties variations partially cancelling each other out.

ABSTRACT: An experimental program to determine the response of thin-walled steel projectiles to the impact with concrete targets was recently conducted. The projectiles were fired against 41-MPa concrete targets at an impact velocity of 290 m/s. This article contains an outline of the experimental program, an examination of the results of a typical test, and predictions of projectile deformation by classical shell theory and computational simulation. Classical shell analysis of the projectile indicated that the predicted impact loads would result in circumferential buckling. A computational simulation of a test was conducted with an impact/penetration model created by linking a rigid-body penetration trajectory code with a general-purpose finite element code. Scientific visualization of the resulting data revealed that circumferential buckling was induced by the impact conditions considered.

ABSTRACT: The vibrational behavior of geometrically imperfect single and multilayered composite double-curved shallow panels subjected to a system of tangential compressive/tensile edge loads in the pre- and postbuckling ranges is investigated. The effects of transverse shear deformations, lamination, the character of in-plane boundary conditions, and of transverse normal stress are incorporated and their influence is emphasized. Numerical illustrations enabling one to compare the obtained results based on higher order and first order shell theories with their classical counterparts, based on the Love-Kirchhoff model are presented and conclusions related to their range of applicability are outlined.

ABSTRACT: The paper presents a new technique for the prediction of buckling loads of structural elements with postbuckling unstable characteristics such as cylindrical shells. The technique introduced is based on the cubic parametric curve defined by the Hermite form, which is described in the paper. The technique requires as input the data obtained from vibration tests carried out on structural elements under compressive loading, specifically, the values of the applied load and the square of the measured corresponding natural frequency of vibration. The proposed technique is applied to a simplified cylindrical shell model and two cylindrical shells. A comparison between the predicted and the exact values of the buckling loads is presented for each case discussed in the paper, highlighting the accuracy of the proposed technique.

Abstract: A Hermite reproducing kernel Galerkin meshfree approach is proposed for buckling analysis of thin plates. This approach employs the Hermite reproducing kernel meshfree approximation that incorporates both the deflectional and rotational nodal variables into the approximation of the plate deflection and the $C^1$ continuous approximation requirement for the Galerkin analysis of thin plates can be easily achieved herein. The strain smoothing operation is consistently introduced to construct the smoothed rotation and curvature fields which appear in the weak form governing the thin plate buckling. The domain integration of the weak form is carried out by the method of sub-domain stabilized conforming integration with the smoothed measures of rotation and curvature, as leads to an efficient discrete meshfree formulation for the eigenvalue problem of thin plate buckling. A series of benchmark buckling problems are presented to assess the proposed algorithm and the results uniformly demonstrate the present approach is very effective and it performs superiorly compared to the conventional Galerkin meshfree formulations whose domain integration are performed by Gauss quadrature rules.

ABSTRACT: A higher-order, geometrically nonlinear theory of transversely isotropic symmetrically laminated composite plates is formulated and their post-buckling behavior is analysed. The numerical illustrations emphasize the role played by transverse shear deformation, transverse normal stress, higher-order effects and the character of in-plane boundary conditions. The results obtained within the present higher-order theory are compared with those of first-order transverse shear deformation and classical (Kirchhoff) theory, and conclusions on their range of applicability and the influence of various parameters are outlined.

The results obtained within the present higher-order theory are compared with those of first-order transverse shear deformation and classical (Kirchhoff) theory, and conclusions on their range of applicability and the influence of various parameters are outlined.

ABSTRACT: This paper discusses the thermally-induced geometrically nonlinear response of symmetrically laminated composite plates. The plate response is due to a temperature increase that is uniform in the plane of the plate but has a slight gradient through the thickness. The case of a completely uniform temperature increase but with an initial out-of-plane imperfection in the plate is also considered. Because they are closely allied
problems, thermal buckling and postbuckling are discussed. Using variational methods in conjunction with a Rayleigh-Ritz formulation, these responses are investigated for two laminates, a \((\pm 45/0/90)\) s and a \([+45/-45/0/2]s\) under two different simple support conditions, fixed and sliding. The effects of the principal material axes not being aligned with the edges of the plate, referred to here as material axis skewing, are also investigated. The study concludes that while differences between buckling temperatures for the two support conditions are small, support conditions can have a large influence on the thermally-induced nonlinear response. In general, plates with fixed simple supports deflect out-of-plane more than plates with sliding simple supports. In addition, support conditions can influence modal interaction. Skewing of the material axes decreases the buckling temperatures of both laminates and, like fixed support conditions, causes increased deflections. Skewing also influences modal interaction.

ABSTRACT: This study discusses the results of a layer-by-layer analysis of a thick-walled cross-ply graphite-epoxy cylinder subjected to external hydrostatic pressure. The analysis, which is valid away from the ends of the cylinder and is based on a generalized plane deformation elasticity solution for each layer, considers inter- and intralaminar stresses. Cylinders with 102 layers and radius to wall thickness ratios of 5 and 10 are studied. The influence of curing stresses are evaluated. For possible application to testing, the response of a thick laminated ring is compared to the response of a cylinder. The idea of smearing the 102 layers into an equivalent single layer is discussed and the results of a smeared analysis are compared with the layer-by-layer analysis. Finally, the responses of glass-epoxy and metallic cylinders are compared with the response of the graphite-epoxy cylinder. The primary findings of the study are: (1) the radial strain distribution through the thickness of the graphite-epoxy cylinder changes from extension at the inner radius to compression at the outer radius. This is different than the radial strain distributions through the glass-epoxy and metallic cylinders. The radial strains for these cylinders are everywhere extensional. (2) The magnitude of the curing stresses are much smaller than the stresses due to hydrostatic pressure. (3) The smearing technique works very well, the response predicted by the single-layer analysis being indistinguishable from the response predicted by the layer-by-layer analysis. (4) The high level of orthotropy of the graphite-epoxy causes a higher fiber loading than occurs for glass-epoxy. This effect could amplify any imperfections, e.g., fiber waviness, in the compressively loaded fibers and could lead to premature failure.

ABSTRACT: This paper explores the gains in buckling performance that can be achieved by deviating from the conventional straightline fiber format and considering the situation whereby the fiber orientation in a layer, or a group of layers, can vary from point to point in the plane of the plate. The particular situation studied is a simply-supported square plate with a centrally located hole loaded in compression. By using both a sensitivity analysis and a gradient-search technique, fiber orientation in a number of regions of the plate are selected so as to increase the buckling load relative to baseline straightline designs. The sensitivity analysis is used to determine which regions of the plate have the most influence on buckling load, and the gradient search is used to find the design that is believed to represent the absolute maximum buckling load for the conditions prescribed. Convergence studies and sensitivity of the final design are discussed. By examining the stress resultant contours, it is shown how the curvilinear fibers move the load away from the unsupported hole region of the plate to the supported edges, thus increasing the buckling capacity. The tensile capacity of the improved buckling design is investigated, and it is shown that both tensile capacity and buckling capacity can be improved with the curvilinear fiber concept.

ABSTRACT: The geometrically nonlinear Donnell shell theory is applied to the problem of stable bending of thin-walled circular cylinders. Responses are computed for cylinders with a radius-to-thickness ratio of 50 and length-to-radius ratios of 1 and 5. Four laminated composite cylinders and an aluminum cylinder are considered. Critical moment estimates are presented for short cylinders for which compression-type buckling behavior is important, and for very long cylinders for which the cross-section flattening, i.e., Brazier effect, is important. A finite element analysis is used to estimate the critical end rotation in addition to establishing the range of validity of the prebuckling analysis. The radial displacement response shows that the character of the boundary layer is significantly influenced by the geometric nonlinearities. Application of a first ply failure analysis using the maximum stress criterion suggests that in nearly all instances material failure occurs before buckling. Failure of the composite cylinders can be attributed to fiber breakage. Striking similarities are seen between the prebuckling displacements of the bending problem and axial compression problem for short cylinders.

ABSTRACT: A numerical and experimental investigation of the bending behavior of six eight-ply graphite-
epoxy circular cylinders is presented. Bending is induced by applying a known end-rotation to each end of the cylinders, analogous to a beam in bending. The cylinders have a nominal radius of 6 inches, a length-to-radius ratio of 2 and 5, and a radius-to-thickness ratio of approximately 160. A (+/- 45/0/90)S quasi-isotropic layup and two orthotropic layups, (+/- 45/0 sub 2)S and (+/- 45/90 sub 2)S, are studied. A geometrically nonlinear special-purpose analysis, based on Donnell's nonlinear shell equations, is developed to study the prebuckling responses and gain insight into the effects of non-ideal boundary conditions and initial geometric imperfections. A geometrically nonlinear finite element analysis is utilized to compare with the prebuckling solutions of the special-purpose analysis and to study the buckling and post buckling responses of both geometrically perfect and imperfect cylinders. The imperfect cylinder geometries are represented by an analytical approximation of the measured shape imperfections. Extensive experimental data are obtained from quasi-static tests of the cylinders using a test fixture specifically designed for the present investigation. A description of the test fixture is included. The experimental data are compared to predictions for both perfect and imperfect cylinder geometries. Prebuckling results are presented in the form of displacement and strain profiles. Buckling end-rotations, moments, and strains are reported, and predicted mode shapes are presented. Observed and predicted moment vs. end-rotation relations, deflection patterns, and strain profiles are illustrated for the post buckling responses. It is found that a geometrically nonlinear boundary layer behavior characterizes the prebuckling responses. The boundary layer behavior is sensitive to laminate orthotropy, cylinder geometry, initial geometric imperfections, applied end-rotation, and non-ideal boundary conditions. Buckling end-rotations, strains, and moments are influenced by laminate orthotropy and initial geometric imperfections. Measured buckling results correlate well with predictions for the geometrically imperfect specimens. The postbuckling analyses predict equilibrium paths with a number of scallop-shaped branches that correspond to unique deflection patterns. The observed postbuckling deflection patterns and measured strain profiles show striking similarities to the predictions in some cases. Ultimate failure of the cylinders is attributed to an interlaminar shear failure mode along the nodal lines of the postbuckling deflection patterns.

ABSTRACT: A numerical and experimental study of the behavior of unstiffened thin-walled graphite-epoxy cylindrical shells subjected to bending loads is presented. Eight-ply quasi-isotropic and orthotropic shells were subjected to bending in a special test fixture. The experimental prebuckling, buckling, and postbuckling responses are compared to predictions from geometrically nonlinear analyses. It is found that a geometrically nonlinear boundary layer behavior characterizes the prebuckling responses. Discrepancies between predicted and observed strain amplitudes indicate that shape imperfections and other localized imperfections influence the prebuckling responses, causing a reduction in the predicted buckling resistance. Ultimate failure is attributed to excessive postbuckling deformations.

ABSTRACT: The geometrically nonlinear Donnell shell theory is used to determine the prebuckling response of short thin-walled laminated circular cylinders in bending. Bending is induced by a known rotation of the clamped cylinder ends. The equilibrium equations and strain-displacement equations are manipulated so the governing partial differential equations are in first-order form. Using the separation of variables technique, along with a harmonic expansion in the circumferential direction, these first-order partial differential equations are converted to first-order ordinary differential equations. These equations are solved numerically using a finite-difference procedure and prebuckling responses are computed for cylinders with a radius: thickness ratio of 160 and length: radius ratios of 2 and 5. The range of validity of the prebuckling solution is limited by the critical, or previous term buckling, next term end rotation, which is estimated by the simple classical method. The use of the classical estimate is justified by comparing it with more rigorous approaches. Three laminated composite cylinders are considered: an axially stiff [−0/45/0]s layup, a circumferentially stiff [−45/0/90]s layup, and a quasiisotropic [0/45/90]s layup. The displacement response is discussed for each cylinder as a function of axial and circumferential location, with particular emphasis on the character of the radial displacement and the boundary layer associated with the nonlinear response. Comparisons with a geometrically linear analysis are made. An analog with the axial compression problem is developed and valuable information about boundary layer length as a function of laminate material properties and applied end rotation is presented. In addition, the role of the laminate Poisson's ratio ν(xθ) on the displacement behavior is discussed.

ABSTRACT: The results from semianalytical predictions and experiments are used to study the response of composite cylinders with elliptical cross sections haded with internal pressure. The results for ellipses are contrasted to the case of circular cylinders. The semianalytical approach is based on the methods of Marguerre, Rayleigh-Ritz, and Kantorovich, the radius of curvature end the displacements being approximated by expansions in harmonic series in the circumferential arc-length coordinate, and the coefficients of the displacement series being unknown functions of x that are solved for using the finite-difference method. The experiments are described and results for a circular and an elliptical quasi-isotropic cylinder loaded to 1 atm internal pressure are compared with predictions. Correlations between the predictions and the experiments are, in general, quite good.

ABSTRACT: A computationally efficient analysis capability for the geometrically non-linear response of compressively loaded prismatic plate structures was developed. Both a "full" finite strip solution procedure and a "reduced" solution procedure were implemented in a FORTRAN 90 computer code, and comparisons were
made with results available in the technical literature. Both the full and reduced solution procedures were demonstrated to provide accurate results for displacement and strain quantities through moderately large post-buckling loads. The full method is a non-linear finite strip analysis of the semi-analytical, multi-term type. Individual finite strips are modeled as balanced and symmetric laminated composite materials which are assumed to behave orthotropically in bending, and the structure is loaded in uniaxial or biaxial compression. The loaded ends of the structure are assumed to be simply supported, and geometric shape imperfections may be modeled. The reduced solution method makes use of a reduced basis technique in conjunction with the full finite strip analysis. Here, the potentially large set of non-linear algebraic equations produced by the finite strip method are replaced by a small set of system equations. In the present implementation, the basis vectors consist of successive derivatives of the non-linear solution vector with respect to a loading parameter. Depending on the nature of the problem....

ABSTRACT: Results of a numerical parametric study of the prebuckling and postbuckling response of tailored composite stiffened panels with axial-shear coupling are presented. In the stiffened panels, axial-shear stiffness coupling is created by rotating the stiffener orientation and tailoring the skin laminate anisotropy. The panels are loaded in axial compression and the effects of stiffener orientation and skin anisotropy on the panel stiffness, buckling parameters, and axial-shear coupling response are described. Results are obtained from a nonlinear general shell finite element analysis computer code. The prebuckling and postbuckling responses can be affected by both the stiffener orientation and skin laminate anisotropy, and the effects are different and load dependent. The results help identify different mechanisms for axial-shear coupling, and show that a load-dependent structural response can be controlled by selecting appropriate stiffener and skin parameters.

ABSTRACT: This paper briefly discusses the influences of through-thickness thermal expansion, a misaligned ply, and a resin-rich slightly thicker ply on the deformations of a curved composite laminate during cool down from the cure temperature. Both two-dimensional and three-dimensional level finite-element analyses are used. The deformations are categorized as to radial and tangential deformations and twist, and for each of the three influences, these deformations are quantified. An additional outcome of the study is an indication of the level of analysis needed to study each of these three influences.

ABSTRACT: The response characteristics of composite cylinders constructed in four circumferential segments are discussed. Two cylinder configurations, referred to as axially stiff and circumferentially stiff cylinders, are studied. Numerical results from STAGS finite element analyses are presented and include predicted radial displacements and selected stress resultants. Compressive loading into the postbuckling range by an axial endshortening is considered. The results show that, as the endshortening increases toward the buckling value, some segments of the cylinders begin to develop axial wrinkles, whereas other segments remain relatively unwrinkled. For the two cylinders considered here, the wrinkling of the segments is correlated with the level of axial stress resultant supported in the segment. Load drops of 20 and 57% for the axially stiff and circumferentially stiff cylinders, respectively, are predicted for levels of endshortening beyond the buckling values. The postbuckled cylinders are characterized by regions of large localized inward dimples and outward ridges in the radial displacement pattern. These regions are sites of large-magnitude axial and transverse shear stress resultants.

ABSTRACT: By varying the thickness of the cylinder wall with circumferential position, the axial buckling capacities of homogeneous, isotropic cylindrical shells with elliptical cross sections are improved. The classic buckling stress relation for a uniform-thickness homogeneous, isotropic circular cylindrical shell is applied to cylinders with elliptical cross sections. It is assumed that this relation can be used to design the wall thicknesses
of elliptical cylinders as a function of circumferential location to compensate for the negative effects of the variation of the radius of curvature with circumferential location. Three variable-thickness elliptical cylinder designs are proposed, and analytical expressions for the thickness variation, cross-sectional area, axial buckling stress, axial buckling stress resultant, and axial buckling load for each design are derived. Predictions from the analytical development are then compared with finite element analyses of the three designs. So-called small and large cylinders with three values of eccentricity are considered. The comparisons between the finite element results and the analytic predictions are quite good. It is shown that considerable improvement in axial buckling capacity can be achieved with the thickness-tailoring technique, and in some cases the axial capacity of the circular cylinder with the same circumference is achieved.

ABSTRACT: A novel re-defining of the orthotropic material properties in terms of a so-called associated geometric mean isotropic (GMI) material is used to develop a thorough buckling analysis of an axially-loaded orthotropic circular cylinder. A membrane prebuckling condition is assumed and an expression for the buckling stress is derived in terms of cylinder geometry, orthotropic material properties, and the number of waves in the buckling deformation pattern in the axial and circumferential directions. By assuming the number of waves in each direction are real-valued variables, as opposed to integers, conditions which result in stationary values of the buckling stress are sought, and once found, examined for their character as regards representing minima, maxima, or saddle points. Three quite different buckling characteristics are predicted, the particulars depending on the shear modulus of the orthotropic material relative to that of the associated GMI material. It is shown that if the shear modulus of the orthotropic material is greater than the shear modulus of the associated GMI material, the cylinder buckles into a unique axisymmetric deformation pattern. If the shear modulus of the orthotropic material is less than the shear modulus of the associated GMI material, the cylinder buckles into a unique nonaxisymmetric deformation pattern. If the shear modulus of the orthotropic material is exactly equal to the shear modulus of the associated GMI material (this is the situation for an isotropic cylinder), the cylinder can buckle into either axisymmetric or nonaxisymmetric deformation patterns. Moreover it is shown that, in this case, there exists a number of deformation patterns, all at essentially the same stress level. Closed-form lower-bound expressions for the buckling stress are developed using the adopted notation, the value of the shear modulus relative to the shear modulus of the GMI material determining which expression is applicable. The results of this analysis are applied to a circular cylinder constructed of a lattice structure consisting of helical and circumferential ribs, a so-called orthogrid lattice cylinder, where it is assumed that the ribs of the lattice structure are dense enough to be able to represent the elastic properties of the lattice with an equivalent homogenized orthotropic material. An isogrid cylinder, where the helical rib angle is 30° relative to the axial direction, is a special case. The orthotropic cylinder analysis is reformulated in terms of the material properties of the ribs and the angle of the helical ribs. For this situation the isogrid case is the GMI material, and the rib angle determines whether the shear modulus of the equivalent orthotropic material is greater than or less than the GMI material. This translates into the character of the buckling deformations depending directly on the rib angle.

ABSTRACT: The equations for the free vibration of an elliptic cylindrical shell of constant thickness were derived using a Ritz approach. A higher order shell theory is employed that includes the effects of shear deformation, rotary inertia, and symmetric and antisymmetric thickness stretch deformations. The frequency-wavenumber spectrum has seven branches: flexural, extensional, torsional, two thickness shear, and two thickness stretch. The resulting seven coupled algebraic equations are symmetric and positive definite. The shell has a constant thickness, $h$, finite length, $L$, and is “simply supported” at its ends, $(z = 0, L)$, where $z$ is the axial coordinate. The elliptic cross-section is defined by the shape parameter, $a$, and the half-length of the major axis, $I$. The modal solutions are expanded in a doubly infinite series of comparison functions in terms of circular functions in the angular and axial coordinates. Numerical results for the natural frequencies were obtained for two values of $h/I$ and $L/I$, and various shape parameters, including the limiting case of a simply supported cylindrical shell ($a \approx 100$).

ABSTRACT: Accurate analysis concerning static instability and reliable appointment of the buckling loads is important for safe design of thin-walled shell structures. Real shells contain geometric imperfections and other deviations from nominal values which have to be considered, as for buckling analyses on the basis of ideal
conditions extreme discrepancies between prediction and test data can result. This thesis deals with the buckling behaviour of thin-walled, unstiffened cylinders under pure axial compression because of their extraordinary sensitivity to imperfections in the shell geometry. The parameters required for an application of real imperfections in a buckling analysis are difficult to be specified. And measured values of real imperfections for the design of any new cylinder shell are hardly available. In the absence of such data in most cases buckling patterns are used that result for perfect geometry and whose buckling patterns can be described with harmonic displacement functions. For safe shell design that imperfection shape is significant which yields the minimum buckling load. But, in general neither the geometry nor the amplitudes of the buckling patterns which contribute to the most damaging imperfection shape are known a priori. In addition, the monotone wavelike dimples forming the buckling patterns of perfect cylinders enclose the entire shell surface, and hence localized irregularities like single dents or bulges of different amplitude are insufficiently included. Consequently, due to the lack of adequate imperfections parameters, cylindrical shells still have to be designed by use of reduction factors to be applied to the analytical buckling loads for perfect cylinders. These reduction factors consider smallest empirical values and therefore provide critical loads which appear to be rather conservative. Moreover, such instructions exist for steel and other isotropic shell materials but not for laminated composite cylinders, for instance.

For these reasons the thesis on hand focusses on cylinders having localized imperfections in form of local inward or outward dimples. To investigate the influences of a single initial dimple on the instability behaviour of such cylinders, and separate from any effect of other irregularities, discrete parametric dents or bulges were added to FE models of unstiffened circular cylinders of otherwise perfect geometry. The chosen shape of a parametric dimple allowed to investigate the influence of its initial amplitude, its initial axial height, its initial circumferential width, and its axial position systematically and independently of other parameters. With regard to the absence of practical design recommendations for laminated composite cylinders the thesis on hand covers analyses of isotropic as well as of laminated CFRP shells.

Several parameter studies were conducted for a number of cylinders having dimples of different initial amplitude but fixed initial circumferential width and axial height. In addition, for a few cylinders and for some predefined initial amplitudes the initial axial height and circumferential width to the dimple was searched which reduce the axial cylinder stability the most. Finally the influence of the relative position of a second identical dent to the load carrying capacity was investigated. These series of analyses aimed at investigating whether there are single, localized initial dimples which reduce the nominal axial buckling load of an unstiffened circular cylinder more than imperfections derived from classical buckling patterns of ideal shells, and whether there is a worst geometry of such a single dimple imperfection. Further: is the instability behaviour the same for isotropic shells as for laminated composite shells having such a localized dimple imperfection? And, is there an important interaction between two initial dimples?

The dimple-parameter studies required a large amount of static and transient dynamic FE analyses. Most of the calculations performed were nonlinear buckling analyses, i.e. nonlinear static stress analyses under consideration of large displacements and rotations using Updated Lagrangian formulations with additional linear eigenvalue calculations, conducted after a selected number of small loading steps to determine the stability of pre-buckling states of stress and deformation. To manage the large number of shells with different bucking loads and behaviour considered, the nonlinear buckling analysis was adapted for an adaptive load step control which utilizes the intermediately extracted eigenvalues. For a selection of cylinders and dimples additional nonlinear transient dynamic analyses were conducted in order to research into the particular deformation processes of such shells under axial loading. Because of the relatively slow compression velocities assumed the implicit "single-step Houbolt" method for time integration was preferred to the more common explicit operators. To reduce the number of time increments needed for stepwise convergence significant inertia damping was introduced.
In a classical analysis, for ideal, thin-walled unstiffened isotropic circular cylinders of medium length under pure axial compression the load-carrying capacity can be predicted analytically by means of simple equations. These equations follow from solving the coupled partial differential equations for equilibrium and compatibility in simply-supported cylinder with harmonic functions. There are also closed-form solutions of the Donnell-type shell equations available for thin-walled orthotropic composite cylinders. Such a classical analysis, however, is applicable exclusively for perfect cylinder geometry.

For the imperfection shapes and sizes considered no test results were available against which the FE analysis results could have been benchmarked. Instead, they are supported by convincing results of such calculations for similar cylinders with perfect geometry and for laminated CFRP cylinders with their measured imperfections included. The results of the ideal cylinders could be compared with values achieved with classical analyses, whereas for the analysis results of the CFRP shells with measured imperfections test data was available for comparisons.

The asymmetrically laminated CFRP cylinders analysed stem from a preceding European project which focused on the correlation of measured buckling loads of test cylinders with analytical and numerical buckling load predictions. The FE analyses of these shells have shown that for such cylinders calculated buckling loads close to test values may be attained if measured imperfections are included in the analysis. It was further found that the consideration of imperfections requires the use of FE analysis methods which take geometric nonlinearity into account. The nonlinear buckling and transient dynamic FE analyses of these CFRP cylinders with perfect geometry and with measured imperfections applied finally provided the basis for the FE analyses of such cylinders having a single localized dimple.

The FE analyses of cylinders with an initial local dent or bulge yielded particular deformation processes including different local buckling phenomena which were hardly known from unstiffened circular cylinders with neither perfect geometry nor with imperfections distributed over the entire shell surface. Nevertheless, by means of systematic parameter variation some interrelationships between the results and the nominal dimensions of the cylinder and the dimple could be derived.

The initial circumferential curvature of a shell in the dimple plays a decisive role in the deformation process of the cylinders and in the run of their FE analyses. The differences in the behaviour pattern and the initial curvature led to a distinction between "shallow" and "deep" dents. Shallow dents with an initial amplitude smaller than a certain marginal depth provoke a distinct local buckling with a sudden snapping inwards of the dent to form a local flattened shell strip of reduced geometric axial stiffness. Deep dents, in turn, result in a continuous local flattening of the shell without any dynamic local-buckling incident prior to the total cylinder collapse.

Localized, shallow dents of particular initial circumferential width and axial height reduce the buckling load as much as axisymmetric inward dimples of identical initial amplitude. And a non-axisymmetric, shallow dent of adequate initial width and height may be as damaging as an imperfection-pattern that is given by a classical buckling mode of initial amplitude that is half the initial amplitude of the dent. Further, localized non-axisymmetric bulges impair the load carrying capacity less than localized dents of the same absolute initial amplitude, width, and height. Finally, the buckling load of a cylinder with single localized dent is only little different from that of a cylinder having two dents of identical size.

For isotropic cylinders the initial axial heights of dimples that reduces the buckling load the most for a preselected initial depth is close to the wavelength for classical axisymmetric buckling of a perfect cylinder. The initial circumferential widths of the worst dent is between two to three times the initial height, whereas the worst bulge is always axisymmetric.

The studies yielded that the cylinder length is also decisive for the local deformation processes of the shell in and in the adjacency of the initial dimples (local buckling) observed. The design recommendations in standards and literature considered for thin-walled, unstiffened isotropic cylinders under axial compression are
conservative if the nominal radius and wall-thickness as well as the nominal cylinder length are taken into account.

For the laminated cylinders investigated accurate and general predictions of minimal buckling loads and of critical dimple dimensions could not be derived on basis of the cylinder geometry alone as the buckling behavior patterns of such shells depend strongly on the laminate stacking. However, there was no indication that any laminated cylinder with any non-axisymmetric dimple results in a lower buckling load than anisotropic cylinder of identical radius, length and wall thickness also having a non-axisymmetric dimple.

ABSTRACT: The implementation of the element free Galerkin method (EFG) for spatial thin shell structures is presented in this paper. Both static deformation and free vibration analyses are considered. The formulation of the discrete system equations starts from the governing equations of stress resultant geometrically exact theory of shear flexible shells. Moving least squares approximation is used in both the construction of shape functions based on arbitrarily distributed nodes as well as in the surface approximation of general spatial shell geometry. Discrete system equations are obtained by incorporating these interpolations into the Galerkin weak form. The formulation is verified through numerical examples of static stress analysis and frequency analysis of spatial thin shell structures. For static load analysis, essential boundary conditions are enforced through penalty method and Lagrange multipliers while boundary conditions for frequency analysis are imposed through a weak form using orthogonal transformation techniques. The EFG results compare favorably with closed-form solutions and that of finite element analyses.

Maurizio Paschero, “Improvement of the axial buckling capability of elliptical cylindrical shells”, Dissertation submitted to Virginia Polytechnic Institute and State University, March 2008 (See also, AIAA Journal, Vol. 47, No. 1, 2009, pp. 142-156)
ABSTRACT: A rather thorough and novel buckling analysis of an axially-loaded orthotropic circular cylindrical shell is formulated. The analysis assumes prebuckling rotations are negligible and uses a unique re-defining of the orthotropic material properties in terms of a so-called geometric mean isotropic (GMI) material. Closed-form expressions for the buckling stress in terms of cylinder geometry and orthotropic material properties are presented, the particular closed form depending on the specific character of the orthotropic material relative to the GMI material. With the formulation, the specific character of the buckling deformations - e.g., axisymmetric or nonaxisymmetric, the number of axial and circumferential waves - can be established. By using the maximum radius of curvature of an elliptical cross section in this formulation, the analysis is used to demonstrate the detrimental effects of an elliptical cross section on axial buckling capacity when compared to a circular cross section with the same circumference. Using the circumferentially-varying radius of curvature of an elliptical cross section, the analysis is then further used as the basis for developing two methods for improving the axial buckling capacity of elliptical cylinders. The first approach involves varying the wall thickness of an isotropic elliptical cylinder with circumferential position. Uniformly stable elliptical cross sections which preserve the same critical stress, critical load, or volume of an axially loaded circular cylinder of the same circumference are designed with the formulation. The second approach involves maintaining a
uniform wall thickness but varying the orthotropic material properties with circumferential position. This approach is applied to a cylindrical lattice structure where it is assumed that the ribs are dense enough to be able to describe the lattice structure by means of an equivalent homogenized material. The orthotropic properties of the homogenized material are varied by varying the lattice rib angle with circumferential position. Considerable recovery of the axial buckling capacity of the variable-rib-angle design elliptical cylinder compared to the same cylinder constructed in isogrid fashion is demonstrated. In fact, recovery relative to an isogrid circular cylinder of the same circumference is demonstrated. For both approaches confirming finite element models are used to verify the findings. The two different approaches are compared, and finally the two approaches are recognized as special cases of a more general design philosophy.

“Experimental study of nonlinear vibrations of thin-walled cylindrical shells”, ICAS 2000 Congress

ABSTRACT: Large amplitude vibration tests of thin-walled aluminum cylindrical shells were performed to validate results of theoretical analysis. The tests were carried out on four shells with practically clamped-clamped boundary conditions, two of them were perfect and the other two with built-in imperfections. The vibration behaviors of shell responses at large amplitudes of interest are the dependence of resonant frequency on the response levels and the possibility of response in the form of traveling waves. Parameters of the study were axial loads, geometric imperfections of the shell, excitation levels and direction of excitation frequency sweep. Comparison between the experimental and the theoretical results showed good agreements qualitatively.

ABSTRACT: Curved panels constructed of laminated graphite-epoxy composite material are of potential interest in airframe fuselage applications. An understanding of structural response at elevated temperatures is required for anticipated future high speed aircraft applications. This study concentrates on the response of unstiffened, curved composite panels subjected to combinations of thermal and mechanical loading conditions. Mechanical loading is due to compressive end-shortening and thermal loading is due to a uniform temperature increase. Thermal stresses, which are induced by mechanical restraints against thermal expansions or contractions, cause buckling and postbuckling panel responses. Panels with three different lamination sequences are considered, including a quasi-isotropic laminate, an axially soft laminate, and an axially stiff laminate. These panels were chosen because they exhibit a range of stiffnesses and a wide variation in laminate coefficients of thermal expansion. The panels have dimensions of 10 in. by 10 in. with a base radius of 60 in. The base boundary conditions are clamped along the curved ends, and simply supported along the straight edges. Three methods are employed to study the panel response, including a geometrically nonlinear Rayleigh-Ritz solution, a finite element solution using the commercially available code STAGS, and an experimental program. The effects of inplane boundary conditions and radius of curvature are studied analytically, along with consideration of order of application in combined loading. A substantial difference is noted in the nonlinear load vs. axial strain responses of panels loaded in end-shortening and panels loaded with uniform temperature change, depending on the specific lamination sequence, boundary conditions, and radius of curvature. Experiments are conducted and results are presented for both room temperature end-shortening tests and elevated temperature tests with accompanying end-shortening. The base finite element model is modified to include measured panel thicknesses, boundary conditions representative of the experimental apparatus, measured initial geometric imperfections, and measured temperature gradients. With these modifications, and including an inherent end displacement of the panel present during thermal loading, good correlation is obtained between the experimental and numerically predicted load vs. axial strain responses from initial loading through postbuckling.

ABSTRACT: The buckling and postbuckling responses of unstiffened cylindrically curved composite panels are studied using the finite element code STAGS and a geometrically nonlinear Rayleigh–Ritz solution. Loading is either through axial end-shortening at a fixed spatially uniform temperature, or it is temperature-induced due to the thermal stresses that arise when the spatially uniform temperature is increased while axial end displacement is restrained to be zero. Comparisons are made between two sets of boundary conditions and three laminates. Buckling and postbuckling responses are found to be strongly dependent on material orthotropy and are substantially affected by the amount of circumferential restraint along the straight edge boundaries.

ABSTRACT: A parametric study of the buckling behavior of infinitely long symmetrically laminated anisotropic plates that are subjected to linearly varying edge loads, uniform shear loads, or combinations of these loads is presented. The study focuses on the effects of the shape of linearly varying edge load distribution, plate orthotropy, and plate flexural anisotropy on plate buckling behavior. In addition, the study examines the interaction of linearly varying edge loads and uniform shear loads with plate flexural anisotropy and orthotropy. Results obtained by using a special purpose non-dimensional analysis that is well suited for parametric studies of clamped and simply supported plates are presented for [±theta]s thin graphite-epoxy laminates that are representative of spacecraft structural components. Also, numerous generic buckling-design charts are presented for a wide range of nondimensional parameters that are applicable to a broad class of laminate constructions. These charts show explicitly the effects of flexural orthotropy and flexural anisotropy on plate buckling behavior for linearly varying edge loads, uniform shear loads, or combinations of these loads. The most important finding of the present study is that specially orthotropic and flexurally anisotropic plates that are subjected to an axial edge load distribution that is tension dominated can support shear loads that are larger in magnitude than the shear buckling load.

ABSTRACT: When structures made of composite materials are designed to be used in load bearing applications, a primary consideration is the evaluation of their load carrying capacity in compression. To this end, a vast number of research investigations, whose main objective is linked to ascertaining the compressive strength of a composite structure has been carried out and/or is currently being performed. Apart from its practical significance, the complexity associated with the task of predicting compression strength is the main reason for the overt attention this problem is receiving. One such difficulty has been associated with testing. When laboratory tests are carried out to determine compression strength, structural instabilities dictated by the geometry of the structure may interfere with material strength dictated by the mechanical properties of the constituents and their alignment and geometry (needed to describe the microstructure of the material). In addition stress concentrations may occur at undesirable locations. In Part I, issues pertaining to compression testing and micromechanical failure theories are reviewed.

ABSTRACT: In Part I of this two part sequence, issues related to compression testing of composites and micromechanical failure models were reviewed. The present paper (Part II) is written with a focus on understanding experimental studies that have been carried out to illuminate those micromechanical influences that affect compression strength. The use of model composites to study compression failure is discussed. The advantages and disadvantages of the many different experimental techniques to measure fiber strengths are presented. Many suggestions for future investigations are given.

ABSTRACT: Thin-walled cylinders, used in a variety of engineering applications, are often subjected to situations where the applied loading is not limited to a single loading type. The introduction of multiple loads alters the stability characteristics of the system in a manner that must be understood to maintain structural integrity and abide by safety regulations. The present study investigates the elastic buckling response of thin-walled cylindrical shells under a combination of torsional loads and circumferentially-varying thermal loads. ABSTRACT: The stability theories energetically associated with different finite strain measures are equivalent if the tangential moduli are transformed as a function of the stress. However, for homogenized soft-in-shear composites, they can differ greatly if the material is in small-strain and constant elastic moduli measured in small-strain tests are used. Only one theory can then be correct. The preceding variational energy analysis showed that, for sandwich columns and elastomeric bearings, respectively, the correct theories are Engesser’s and Haringx’s, associated with Green’s and Almansi’s Lagrangian strain tensors, respectively. This analysis is reviewed, along with supporting experimental and numerical results, and is then extended to arbitrary multiaxially loaded homogenized soft-in-shear orthotropic composites. It is found that, to allow the use of constant shear modulus when the material is in small strain, the correct stability theory is associated with a general Doyle–Ericksen finite strain tensor of exponent m depending on the principal stress ratio. Further it is
shown that the standard updated Lagrangian algorithm for finite element analysis, which is associated with Green’s Lagrangian finite strain, can give grossly incorrect results for homogenized soft-in-shear structures and needs to be generalized for arbitrary finite strain measure to allow using constant shear modulus for critical loads at small strain.

ABSTRACT: The previous energetic variational analysis of critical loads and of the choice of finite strain measure for structures very weak in shear, remaining in a state of small strain, is extended to the initial postcritical behavior. For this purpose, consideration of the transverse deformation is found to be essential. It is shown that imperfection sensitivity of such structures, particularly laminate-foam sandwich plates, can arise for a certain range of stiffness and geometric parameters, depending on the proper value of parameter m of the Doyle–Ericksen finite strain tensor, as determined in the previous analysis. The bifurcation is symmetric and Koiter’s 2/3-power law is followed. The analytical predictions of maximum load reductions due to imperfection sensitivity are verified by finite element simulations. The possibility of interaction between different instability modes, particularly lateral deflection and bulging, is also explored, with the conclusion that lateral deflection dominates in common practical situations.

ABSTRACT: The dynamic axial crush response of circular cell polycarbonate honeycombs was studied for 3-cell and 7-cell specimens experimentally and through finite-element (FE) simulation. The experiments were conducted using two loading methods: (i) the wave loading device (WLD) method and (ii) the direct impact method (DIM). The specimens were subjected to crush velocities of about 12000 mm per second in the WLD method and 5000 mm per second in the DIM. The two methods were used to obtain a fairly wide range of input velocities. The collapse sequence and displacement information of the specimens were captured using a high-speed camera. The mode of collapse was through progressive concertina-diamond fold formation over a fairly constant state of load, which is referred to as the crush load. The crushing was simulated using an explicit FE analysis using ABAQUS, with geometrically imperfect 3-cell and 7-cell honeycomb models that incorporated the rate-dependent properties of polycarbonate. The FE results were found to agree well with the experimental results in terms of overall force-displacement plots, thus providing a basis to extract energy absorption estimates from the models and to draw comparisons between the 3-cell and 7-cell response behaviour. Moreover, the dynamic crush results were compared against a quasi-static axial crush response to demonstrate the presence of rate effects.

ABSTRACT: A sandwich beam buckling problem is studied here using two-dimensional elasticity to model the beam constituents. The global and local instability of such a beam with orthotropic constituents under various boundary conditions are investigated. The face sheet and the core are assumed to be linear elastic orthotropic continua. General buckling deformation modes of the sandwich beam subjected to uniaxial compressive loading are considered. The appropriate incremental stress and conjugate incremental finite-strain measure for the instability problem of the sandwich beam, and the corresponding constitutive model are addressed. It is shown that a sandwich beam having a core with a negligible stiffness compared to the face sheets is prone to fail by edge buckling. The present analysis is compared with several previous analytical studies and corresponding experimental results. Finite-element analyses are carried out for comparison against the theoretical predictions. The formulation used in the finite-element code is discussed in relation to the formulation adopted in the theoretical derivation.

"On the importance of work-conjugacy and objective stress rates in finite deformation incremental finite element analysis", Journal of Applied Mechanics, Vol. 80, 041024-1-9, July 2013, DOI: 10.1115/1.4007828

ABSTRACT: This paper is concerned with the elastic stability of a sandwich beam panel using classical elasticity. An exact solution for the buckling problem of a sandwich panel (wide beam) in uniaxial compression is presented. Various formulations that correspond to the use of different pairs of energetically conjugate stress and strain measures for the infinitesimal elastic stability of the sandwich panel are discussed. Results from the present two-dimensional analyses to predict the global and local buckling of a sandwich panel are compared with previous theoretical and experimental results. A new finite element formulation for the bifurcation buckling problem is also introduced. In this new formulation, terms that influence the buckling load, which have been omitted in popular commercial codes are pointed out and their significance in influencing the buckling load is identified. The formulation and results presented here can be used as a benchmark solution to establish the accuracy of numerical methods for computing the buckling behavior of thick, orthotropic solids.

Conclusion and suggestions for further work:

An analytical method for predicting global and wrinkling instabilities of a sandwich beam is presented. The sandwich beam is modeled as a 2D-linear elastic continuum. Field equations representing a solid slightly deformed from a state of initial stress and under conditions of plane strain is adopted in the analysis. The results obtained yield the buckling stress and the associated wavelength. The results have shown that the buckling stress for the anti-symmetrical deformation mode is always lower than that of the symmetrical one. The buckling behavior of the two modes is parameterized according to the ratio of core thickness to the face sheet thickness. The results are compared with previous experimental results, theoretical analyses, and a finite element analysis prediction. Since the present analysis has fewer assumptions than previous analyses, the limitations of previous investigation are discussed for different combination of geometry and material properties. The results presented here, which have been verified by finite element analysis and compared against experimental results, reproduce the buckling behavior accurately for a wide range of material and geometric parameters. The results that have been presented here are a good prediction of the overall behavior of a sandwich beam in a uniaxial compressive load environment regardless of the core modulus and thickness ratio. In particular, for thick face sheets and for relatively stiff cores, the present model is found to be more accurate than previous models that assume beam like behavior for the face sheets and neglect the axial load carrying capability of the core. The results from finite element analysis have verified the findings of the present analytical model. In addition the correct formulation of the 2D elastic sandwich column problem has been presented along with a FE formulation of the problem. The latter has revealed deficiencies in the formulation adopted by popular commercial codes (for example ABAQUS). An analytical prediction of dynamic buckling is also presented in this thesis. Dynamic buckling of a structure under uniaxial impact compression is studied. Fully coupled equations of inplane and out-of-plane motions are solved to find the condition of the onset of dynamic buckling. There exists a critical time for the axial strain to satisfy the emergence of the buckling deformation. The bifurcation condition is derived for the simple Euler-Bernoulli beam as well as the sandwich beam. Experimental studies are also performed to investigate the failure mechanism of the sandwich structure under axial impact loading. The sequential responses of the sandwich specimens reveal that the structure initially experiences the axial deformation only until the buckling deformation emerges at a certain load value corresponding to the critical time. FE analysis is also performed to simulate the dynamic response and it is found that there exist a sudden increase of the bending deformation after numerous superpositions of axial strain waves. The dynamic buckling analysis presented here has numerous potential applications in various fields. The analysis is not dependent on the beam response, but is derived quantitatively so that it is adaptable to various engineering applications. The dynamic buckling analysis can be extended further for better understanding of more complex material under dynamic loading. The analysis can be improved considering inelastic behavior of the material, orthotropic material, shear deformation, and various combinations of material and geometric properties for the sandwich structure. The analysis combined with fracture mechanics can be used to explain the failure mechanism of the sandwich structure under axial loading. The latter is suggested for future work. In addition, extension of the Euler-Bernoulli model to a Timoshenko beam model is suggested for the impact buckling problem, so that shear deformation effects can be accounted for. Adopting the work of Von Karman [34], the effects of column plasticity on the “critical time to buckle” can be captured and this is also suggested for future work. Finally, it is
possible to develop a sandwich beam FE model that includes cohesive zone models for the face sheet-core interface. Such a model in conjunction with an explicit FE code can be used to obtain a comprehensive response model for the sandwich beam impact problem.

ABSTRACT: This paper is concerned with the 2D elasticity solution for the buckling of a thick orthotropic ring under external hydrostatic pressure loading. The bifurcation buckling problem is first formulated using two methods, distinguished by the manner in which the external work done by the pressure loading during the buckling transition is treated. In doing so, the correct buckling equations and associated traction boundary conditions are derived. The resulting sets of equations and associated boundary conditions are then cast in a weak form, amenable to a numerical solution using the finite element method. The necessity of using the correct pairs of energetically conjugate stress and strain measures for the buckling problem is pointed out. Errors in using the incorrect traction boundary condition and terms that influence the buckling load and that have been omitted in popular commercial codes are pointed out and their significance in influencing the buckling load is identified. Results from the present two-dimensional analysis to predict the critical pressure are compared with previous theoretical results. The formulation and results presented here can be used as the correct benchmark solution to establish the accuracy in computing the buckling load of thick orthotropic composite structures, of contemporary interest, due to the increased use of thick-walled composite shell type structures in diverse engineering applications.

ABSTRACT: Results from a study of the effects of cutouts and laminate construction on the prebuckling and initial postbuckling stiffnesses, and the effective widths of compression-loaded laminated-composite and aluminum square plates are presented. An effective-width concept is derived for plates with and without cutouts, and experimental and nonlinear finite-element analysis results are presented. Behavioral trends are compared for seven plate families and for cutout-diameter-to-plate-width ratios up to 0.66. A general compact design curve that can be used to present and compare the effective widths for a wide range of laminate constructions is also presented. A discussion of how the results can be used and extended to include certain types of damage, cracks, and other structural discontinuities or details is given. Several behavioral trends are described that initially appear to be nonintuitive. The results demonstrate a complex interaction between cutout size and plate orthotropy that affects the axial stiffness and effective width of a plate subjected to compression loads.

ABSTRACT: Results from a numerical study of the response of thin-walled compression-loaded quasi-isotropic laminated composite cylindrical shells with unreinforced and reinforced square cutouts are presented. The effects of cutout reinforcement orthotropy, size, and thickness on the non-linear response of the shells are described. A high-fidelity non-linear analysis procedure has been used to predict the non-linear response of the shells. The analysis procedure includes a non-linear static analysis that predicts stable response characteristics of the shells and a non-linear transient analysis that predicts unstable dynamic buckling response characteristics. The results illustrate the complex non-linear response of a compression-loaded shell with an unreinforced cutout. In particular, a local buckling response occurs in the shell near the cutout and is caused by a complex non-linear coupling between local shell-wall deformations and in-plane destabilizing compression stresses near the cutout. In general, reinforcement around a cutout in a compression-loaded shell can retard or eliminate the local buckling response near the cutout and increase the buckling load of the shell. However, results are presented that show how certain reinforcement configurations can cause an unexpected increase in the magnitude of local deformations and stresses in the shell and cause a reduction in the buckling load. Specific cases are presented that suggest that the orthotropy, thickness, and size of a cutout reinforcement in a shell can be tailored to achieve improved buckling response characteristics.

ABSTRACT: Results from a numerical and experimental study that illustrate the effects of laminate orthotropy on the buckling and failure response of compression-loaded composite cylindrical shells with a cutout are presented. The effects of orthotropy on the overall response of compression-loaded shells is described. In general, preliminary numerical results appear to accurately predict the buckling and failure characteristics of the shell considered herein. In particular, some of the shells exhibit stable post-local-buckling behavior accompanied by interlaminar material failures near the free edges of the cutout. In contrast another shell with a different laminate stacking sequence appears to exhibit catastrophic interlaminar material failure at the onset of local buckling near the cutout and this behavior correlates well with corresponding experimental results.

ABSTRACT: Results from a numerical study of the buckling response of two different orthogrid stiffened circular cylindrical shells with initial imperfections and subjected to axial compression are used to compare three different lower bound buckling load prediction techniques. These lower bound prediction techniques assume different imperfection types and include an imperfection based on a mode shape from an eigenvalue analysis, an imperfection caused by a lateral perturbation load, and an imperfection in the shape of a single stress-free dimple. The STAGS finite element code is used for the analyses. Responses of the cylinders for ranges of imperfection amplitudes are considered, and the effect of each imperfection is compared to the response of a geometrically perfect cylinder. Similar behavior was observed for shells that include a lateral perturbation load and a single dimple imperfection, and the results indicate that the predicted lower bounds are much less conservative than the corresponding results for the cylinders with the mode shape imperfection considered herein. In addition, the lateral perturbation technique and the single dimple imperfection produce response characteristics that are physically meaningful and can be validated via testing.

ABSTRACT: The problem of designing a cutout in a load bearing structural member in the form of a shell, such that the cut structure maintains its stress state with a minimal departure from the stress state of the uncut structure is addressed herein. Symmetrically laminated composite circular cylindrical shells under hydrostatic compression and axial pressure are considered. Shallow thin shell (Donnell shell theory) lamination theory is utilized. The original (uncut) stiffness of the shell structures is recovered considerably by appropriately designing an edge reinforcement around the cutout. The buckling load of the designed shells are analyzed via the finite element method. An experimental investigation has been carried out to verify some of the results obtained from the finite element analysis. In the work presented, the reinforcement is modeled as a one-dimensional rod/beam type structural element.

ABSTRACT: An analysis-based approach for developing shell buckling design factors for cylindrical shells that accurately accounts for the effects of initial geometric imperfections is presented. To develop this approach, measured initial geometric imperfection data from six laboratory-scale graphite-epoxy shells are used to determine a manufacturing-process-specific imperfection signature for these shells. This imperfection signature is then used as input into nonlinear finite element analyses. The imperfection signature represents a “first approximation” mean imperfection shape that is suitable for developing preliminary design data. Comparisons of test data and analytical results obtained by using several different imperfection shapes are presented for
selected shells. These imperfection shapes include the actual measured imperfection shape of the test specimens, a “first approximation” mean imperfection shape with plus or minus one standard deviation in the shape, and a linear-bifurcation-mode imperfection shape. In addition, buckling interaction curves for composite shells subjected to combined axial compression and torsion loading are presented that were obtained by using the various imperfection shapes in the analyses. A discussion on the development of experimentally validated nonlinear finite element analyses is also presented. Overall, the results indicate that the proposed analysis-based approach presented herein, for developing reliable preliminary design criteria, has the potential to provide improved, less conservative buckling load estimates, and to reduce the weight and cost of developing buckling-resistant shell structures.

“Buckling Behavior of Compression-Loaded Quasi-Isotropic Curved Panels With a Circular Cutout,”
doi:10.1016/S0020-7683(00)00114-1
ABSTRACT: Results from a numerical and experimental study of the response of compression-loaded quasi-isotropic curved panels with a centrally located circular cutout are presented. The numerical results were obtained by using a geometrically nonlinear finite element analysis code. The effects of cutout size, panel curvature and initial geometric imperfections on the overall response of compression-loaded panels are described. In addition, results are presented from a numerical parametric study that indicate the effects of elastic circumferential edge restraints on the prebuckling and buckling response of a selected panel and these numerical results are compared to experimentally measured results. These restraints are used to identify the effects of circumferential edge restraints that are introduced by the test fixture that was used in the present study. It is shown that circumferential edge restraints can introduce substantial nonlinear prebuckling deformations into shallow compression-loaded curved panels that can result in a significant increase in buckling load.

doi: 10.1002/9780470686652.eae178
ABSTRACT: Guidelines on the development of a successful test plan for large-scale, aerospace vehicle shell buckling tests with particular attention given to defining test objectives and requirements are presented. In addition, some of the more challenging aspects of test planning, test operations, test article, and test apparatus design are discussed, and recommendations on instrumentation and control system setup for buckling tests and including state-of-the-art measurement approaches and technologies are provided. In many cases, actual examples are given. This chapter is intended to provide the first time as well as the experienced test engineer or project manager with experiences and lessons learned from recent large-scale aerospace vehicle development test activities at NASA.

Structural Dynamics and Materials Meeting, Honolulu, Hawaii, April 2012

ABSTRACT: NASA’s Shell Buckling Knockdown Factor (SBKF) Project was established in the spring of 2007 by the NASA Engineering and Safety Center (NESC) in collaboration with the Constellation Program and Exploration Systems Mission Directorate. The SBKF project has the current goal of developing less conservative, robust shell buckling design factors (a.k.a. knockdown factors) and design and analysis technologies for light-weight stiffened metallic launch vehicle (LV) structures. Preliminary design studies indicate that implementation of these new knockdown factors can enable significant reductions in mass and mass-growth in these vehicles and can help mitigate some of NASA’s LV development and performance risks. In particular, it is expected that the results from this project will help reduce the reliance on testing, provide high-fidelity estimates of structural performance, reliability, robustness, and enable increased payload capability. The SBKF project objectives and approach used to develop and validate new design technologies are presented, and provide a glimpse into the future of design of the next generation of buckling-critical launch vehicle structures.

The complete non-linear strain equations are derived using two Equivalent Single-Layer Theories: the Classical Laminated Plate Theory and the First-order Shear Deformation Theory. The non-linear terms will be identified corresponding to Donnell’s, Sanders’ and Timoshenko and Gere’ assumptions, but the discussion will focus on Donnell’s and Sanders’ equations. The resulting strain- displacement equations will then be applied to the stationary conditions of the total potential energy in order to obtain the non-linear static equations and the eigenvalue problem that can be used to predict the instability behavior, the latter using the neutral equilibrium criterion.

The Ritz method is selected to solve the non-linear set of equations and a new set of appropriate approximation

ABSTRACT: The non-linear buckling of unstiffened laminated composite cones and cylinders will be investigated and new semi-analytical models capable to predict the static and the instability response of these shells under various loads and boundary conditions will be proposed. An introduction is given to the reader in order to present and discuss some of the main deterministic approaches currently used for the design of imperfection sensitive structures. From this introduction it will become clear the need for non-linear tools that are able to take into account both geometric and load imperfections, which are recognized to be among the main factors affecting the load carrying capacity of the shells under discussion.

The complete non-linear strain equations are derived using two Equivalent Single-Layer Theories: the Classical Laminated Plate Theory and the First-order Shear Deformation Theory. The non-linear terms will be identified corresponding to Donnell’s, Sanders’ and Timoshenko and Gere’ assumptions, but the discussion will focus on Donnell’s and Sanders’ equations. The resulting strain- displacement equations will then be applied to the stationary conditions of the total potential energy in order to obtain the non-linear static equations and the eigenvalue problem that can be used to predict the instability behavior, the latter using the neutral equilibrium criterion.

The Ritz method is selected to solve the non-linear set of equations and a new set of appropriate approximation
functions for the displacement field is proposed, in order to simulate axial compression, torsion, pressure, load asymmetry, any arbitrary surface or concentrated loads; and any load case combining these loads. Elastic constraints are used to produce a wide range of boundary conditions, covering the four types of boundary conditions commonly used in the literature.

Two methods to solve the non-linear static equations are discussed: Newton-Raphson with line search and Riks; both presented in the full form, where the tangent stiffness matrix is calculated at every iteration; and in the modified form, where the tangent stiffness matrix is updated at the beginning of each load increment (or arc-length increment) and kept constant along the iterations.

An analytical integration scheme is proposed for the linear stiffness matrices and a numerical integration scheme proposed for the non-linear stiffness matrices. The analytical integration schemes assume constant laminate properties over the whole conical/cylindrical surface. For conical shells a novel approximation is proposed in order to efficiently perform the analytical integration of the linear stiffness matrices.

Detailed convergence analyses are presented and the proposed models are verified with finite element results, models available from the literature and test results from the literature. All the developed tools and algorithms are presented in detail and made available to the reader online.

ABSTRACT: The important role of geometric imperfections on the decrease of the buckling load for thin-walled cylinders had been recognized already by the first authors investigating the theoretical approaches on this topic. However, there are currently no closed-form solutions to take imperfections into account already during the early design phases, forcing the analysts to use lower-bound methods to calculate the required knock-down factors (KDF). Lower-bound methods such as the empirical NASA SP-8007 guideline are commonly used in the aerospace and space industries, while the approaches based on the Reduced Stiffness Method (RSM) have been used mostly in the civil engineering field. Since 1970s a considerable number of experimental and numerical investigations have been conducted to develop new stochastic and deterministic methods for calculating less conservative KDFs. Among the deterministic approaches, the single perturbation load approach (SPLA), proposed by Hühne, will be further investigated for axially compressed fiber composite cylindrical shells and compared with four other methods commonly used to create geometric imperfections: linear buckling mode-shaped, geometric dimples, axisymmetric imperfections and measured geometric imperfections from test articles. The finite element method using static analysis with artificial damping is used to simulate the displacement controlled compression tests up to the post-buckled range of loading. The implementation of each method is explained in details and the different KDFs obtained are compared. The study is part of the European Union (EU) project DESICOS, whose aim is to combine stochastic and deterministic approaches to develop less conservative guidelines for the design of imperfection sensitive structures.

“Investigation of buckling behavior of composite shell structures with cutouts”, Applied Composite Materials,
ABSTRACT: Thin-walled cylindrical composite shell structures can be applied in space applications, looking for lighter and cheaper launcher transport system. These structures are prone to buckling under axial compression and may exhibit sensitivity to geometrical imperfections. Today the design of such structures is based on NASA guidelines from the 1960’s using a conservative lower bound curve generated from a database of experimental results. In this guideline the structural behavior of composite materials may not be appropriately considered since the imperfection sensitivity and the buckling load of shells made of such materials depend on the lay-up design. It is clear that with the evolution of the composite materials and fabrication processes this guideline must be updated and or new design guidelines investigated. This need becomes even more relevant when cutouts are introduced to the structure, which are commonly necessary to account for access points and to provide clearance and attachment points for hydraulic and electric systems. Therefore, it is necessary to understand how a cutout with different dimensions affects the buckling load of a thin-walled cylindrical shell structure in combination with other initial geometric imperfections. In this context, this paper present some observations regarding the buckling load behavior vs. cutout size and radius over thickness ratio, of laminated composite curved panels and cylindrical shells, that could be applied in further recommendations, to allow identifying when the buckling of the structure is dominated by the presence of the cutout or by other initial imperfections.

ABSTRACT: A preliminary design tool for metallic stiffened fuselage cylindrical panels subjected to longitudinal compression has been developed and validated by comparison to test results. Several methodologies for stiffened panel buckling and failure predictions were examined and evaluated. An appropriate level of analysis fidelity was determined for different failure modes and design details. Results from panel tests conducted to verify analytical methods used to design the Gulfstream V aircraft were presented. The panels were representative of four general skin/stringer configurations on the aircraft. Finite Element analyses and standard analytical methods were used to predict panel failure loads. The accuracy of the finite element analysis predictions was dependent upon the level of detail included in the model. The inclusion of such details as fasteners had a significant effect on the predicted failure load. The omission of such complexities from the finite element model led to unconservative failure predictions. Standard analytical methods were found to be more efficient than finite element methods and produced conservative panel failure loads. Improvements for a preliminary design tool were identified to reduce conservatism in failure predictions and thereby reduce structural weight.

Starnes, James H., Jr. ; Hillburger, Mark W., “Using High-Fidelity Analysis Methods and Experimental Results to Account for the Effects of Imperfections on the Buckling Response of Composite Shell Structures”, March 2003, http://handle.dtic.mil/100.2/ADP014170
ABSTRACT: The results of an experimental and analytical study of the effects of initial imperfections on the buckling response of unstiffened thin-walled compression-loaded graphite-epoxy cylindrical shells are presented. The analytical results include the effects of traditional and nontraditional initial imperfections and uncertainties in the values of selected shell parameters on the buckling loads of the shells. The nonlinear structural analysis results correlate very well with the experimental results. The high-fidelity nonlinear analysis procedure used to generate the analytical results can also be used to form the basis of a new shell design procedure that could reduce the traditional dependence on empirical results in the shell design process.

ABSTRACT: The results of an experimental and analytical study of the effects of initial imperfections on the buckling and postbuckling response of three unstiffened thin-walled compression-loaded graphite-epoxy cylindrical shells with different orthotropic and quasi-isotropic shell-wall laminates are presented. The results identify the effects of traditional and non-traditional initial imperfections on the non-linear response and buckling loads of the shells. The traditional imperfections include the geometric shell-wall mid-surface imperfections that are commonly discussed in the literature on thin shell buckling. The non-traditional imperfections include shell-wall thickness variations, local shell-wall ply-gaps associated with the fabrication process, shell-end geometric imperfections, non-uniform applied end loads, and variations in the boundary conditions including the effects of elastic boundary conditions. A high-fidelity non-linear shell analysis procedure that accurately accounts for the effects of these traditional and non-traditional imperfections on the non-linear responses and buckling loads of the shells is described. The analysis procedure includes a non-linear static analysis that predicts stable response characteristics of the shells and a non-linear transient analysis that predicts unstable response characteristics.

ABSTRACT: The results of an experimental and analytical study of the effects of initial imperfections on the buckling response and failure of unstiffened thin-walled compression-loaded graphite-epoxy cylindrical shells are presented. The shells considered in the study have six different shell-wall laminates two different shell-radius-to-thickness ratios. The shell-wall laminates include four different orthotropic laminates and two different quasi-isotropic laminates. The shell-radius-to-thickness ratios include shell-radius-to-thickness ratios equal to 100 and 200. The numerical results include the effects of traditional and nontraditional initial imperfections and selected shell parameter uncertainties. The traditional imperfections include the geometric shell-wall mid-surface imperfections that are commonly discussed in the literature on thin shell buckling. The nontraditional imperfections include shell-wall thickness variations, local shell-wall ply-gaps associated with the fabrication process, shell-end geometric imperfections, nonuniform applied end loads, and variations in the boundary conditions including the effects of elastic boundary conditions. The cylinder parameter uncertainties considered include uncertainties in geometric imperfection measurements, lamina fiber volume fraction, fiber and matrix properties, boundary conditions, and applied end load distribution. Results that include the effects of these traditional and nontraditional imperfections and uncertainties on the nonlinear response characteristics, buckling loads and failure of the shells are presented. The analysis procedure includes a nonlinear static analysis that predicts the stable response characteristics of the shells and a nonlinear transient analysis that predicts the unstable response characteristics. In addition, a common failure analysis is used to predict material failures in the shells.

ABSTRACT: An analysis-based approach for developing shell buckling design criteria for laminated-composite cylindrical shells that accurately account for the effects of initial geometric imperfections is presented. With this approach, measured initial geometric imperfection data from six graphite-epoxy shells are used to determine a manufacturing-process-specific imperfection signature for these shells. This imperfection signature is then used as input into nonlinear finite-element analyses. The imperfection signature represents a "first-approximation" mean imperfection shape that is suitable for developing preliminary-design data. Comparisons of test data and analytical results obtained by using several different imperfection shapes are presented for selected shells. These shapes include the actual measured imperfection shape of the test specimens, the "first-approximation" mean imperfection shape, with and without plus or minus one standard deviation, and the linear-bifurcation-mode imperfection shape. In addition, buckling interaction curves for composite shells subjected to combined axial compression and torsion loading are presented that were obtained by using the various imperfection shapes in the analyses. A discussion of the nonlinear finite-element analyses is also presented. Overall, the results indicate that the analysis-based approach presented for developing reliable preliminary-design criteria has the potential to provide improved, less conservative buckling-load estimates, and to reduce the weight and cost of developing buckling-resistant shell structures.

ABSTRACT: This study addresses the effect of thickness variation on the stability of the composite cylindrical shells under axial compression. Various lamination configurations and three commonly used composite materials are considered. Numerical results show that certain types of thickness variation patterns can greatly reduce the classical buckling load. Results indicate that the most detrimental effect of the thickness variation occurs when the wave number of the thickness variation is twice that of the classical buckling mode. For this case, an asymptotic formula is established by use of a computer algebra, which relates the buckling load reduction rate to the thickness variation parameter.

ABSTRACT: A nonlinear two-degree-of-freedom system is considered to simulate the peculiar behavior of stringer-stiffened cylindrical shells under nonuniform axial compression, which was observed in recent tests where the characteristic curves (eigenfrequency squared versus load) were nonmonotonic and decreasing steeply when approaching the critical load. Correlation is traced between the characteristic curves and equilibrium paths. It is shown that for particular nonzero values of load eccentricity, bifurcations are observed instead of the usual limit points. Nonunique stable post-buckling equilibrium paths are pointed out. The general properties of characteristic curves are discussed.

ABSTRACT: Eight curved blade stringer-stiffened composite panels were tested under axial compression to obtain the "first" buckling and postbuckling behavior till collapse. Except for one panel, used as a reference panel, all of the panels had stringers without dropoff layers. Four panels contained either artificial damage or
both artificial and impact-induced damage. Cyclic/repeated buckling was applied well in a relatively "deep" postbuckling region. It was demonstrated that neither repeated buckling, within the number of cycles applied in the present program, nor artificial damage and impact-induced damage, which were introduced into the panels, resulted in stiffness degradation of the panels. No premature failure of any of the tested panels was observed within their expected life cycle, i.e. exposure to a few hundred cycles deep in the postbuckling region, even in the presence of either type or a combination of the damage. All of the tested panels sustained repeated postbuckling loading till they were subjected to static loading aimed at determining their collapse loads. In spite of the present design, i.e. stiffeners with no dropoff plies aimed amongst others at providing a mechanism for initiating stiffener debonding, no skin-stringer separation was encountered till collapse of the panels. It was found that composite stringer-stiffened panels can be safely and repeatedly loaded in their deep postbuckling range with no degradation in their stiffness. Damage, due to either manufacturing or impact, which usually will result in rejection of a structural element, affected neither the load-carrying capacity nor the capability to withstand repeated loading in the relatively very deep postbuckling range within the present designed life cycle of the element. It was realized that manufacturing complexities and consequently costs can be reduced by employing a simplified design configuration where the use of a dropoff ply of the stringer base has been eliminated.

ABSTRACT: An extensive test series on circular cylindrical laminated composite stringer-stiffened panels subjected to axial compression, shear loading introduced by shear and combined axial compression and shear was carried out at the Technion, Israel. The test program was an essential part of an ongoing effort undertaken by the POSICOSS project (improved postbuckling simulation for design of fibre composite stiffened fuselage structures) aiming at design of low cost, low weight airborne structures that was initiated and supported by the Fifth European Initiative Program. The first part of this test series, dealing with panels PSC1–PSC9 (blade-stiffened), has already been summarized and published. The results of the tests with panels BOX1–BOX4 (blade- and J-stiffened) have also been reported and published. These tests dealt with two identical stiffened panels, combined together by two flat nonstiffened aluminum webs, to form a torsion box, thus enabling application of shear tractions, through introduction of torsion, and combined axial compression and shear. The present manuscript aims at describing test results and relevant numerical studies on the buckling and postbuckling behavior of another set of four panels, AXIAL1–AXIAL4, stiffened by J-type stringers. Based on the experimental studies carried out within the framework of the POSICOSS project and reported in the literature and on the present study design guidelines were formulated and presented. Accompanying supporting calculations were presented as well; they were performed with a “fast” calculation tool developed at the Technion, and based on the effective width method modified to handle laminated circular cylindrical stringer-stiffened composite panels.

“Effect of cyclic post-buckling loads on CFRP panels,” 2008 (publisher not given in the “pdf” file)

ABSTRACT: Experimental results obtained on four carbon fiber composite stiffened curved panels subjected to static and cyclic compression and shear loadings are discussed. Two of the four panels presented an initial delamination obtained with Teflon inserts between stringers and skin. Panels were assembled in two closed boxes using flat aluminum plates. This solution allows the application of shear on each panel by applying torque on the box. The first box was obtained using undamaged panels, while the second one assembling damaged panels. Results are described in terms of axial load vs. shortening curve, torque vs. rotation curve, deformed shape and strain measurements. Boxes were subjected to a cyclic post-buckling torque, allowing the investigation of the effect of cyclic buckling in terms of global and local behavior. The obtained results show that this kind of structures can well work in the post-buckling field even if during their operative life the buckling load is reached thousands of times.

PARTIAL ABSTRACT: Experimental results on the behavior of nine single panels and of four torsion boxes, each comprising of two stringer-stiffened cylindrical graphite-epoxy composite panels are presented. These were tested under axial compression, torsion and combined loading. The buckling and postbuckling behavior of these single panels and torsion boxes demonstrated consistent results. Prior to performing the buckling tests, the initial geometric imperfections of the panels and boxes were scanned and recorded. The tests were complemented by finite element calculations, which were performed for each panel and box. These detailed calculations have also assisted in identifying critical regions of the boxes and the boxes were reinforced accordingly to avoid premature failure. The investigation on the single panels revealed a good correlation between the predictions of the finite element codes and the experimental results…

ABSTRACT: In a number of applications, the actual boundary conditions at the ends of a cylinder are not taken into account properly when the structure is being designed against buckling. For example, in the design of submersibles the older theoretical treatments assume that bulkheads are present at the ends of the cylinders, whereas this form of construction is not always used. The purpose of the investigation described here is to study the effect of realistic boundary conditions on the elastic buckling pressure of unstiffened cylinders with torispherical or hemispherical end closures. In the present study only perfect, initially stress-free, structures are
considered and their theoretical buckling pressures are obtained from a variational finite-difference program written for the digital computer. The numerical results presented were obtained from a limited parametric survey of the problem. In the main, linear buckling theory was used. However, as is shown, this can sometimes lead to unsafe predictions. The buckling pressures for the cylinders with hemispherical end closures, as predicted by the variational finite-difference technique, are also compared with a modified von Mises formula with corrections for the end closures. The agreement between the two sets of predictions was good within the range of the survey.

ABSTRACT: Elastic and elastic-plastic buckling pressures for internally-pressurized 2:1 ellipsoidal shells with diameter-thickness ratios in the range 750 < D/t < 1500 are given in the paper. The effects of σ\textsubscript{m}, E and linear strain hardening on the buckling pressures were investigated and both flow and deformation theories utilized. Some experimental/theoretical correlations are also given. The elastic p\textsubscript{cr} \_s differ from some which have been published recently and the elastic-plastic p\textsubscript{cr} \_s are believed to be new. For steel shells, flow and deformation theories sometimes gave contradictory buckling predictions but this was not the case with the aluminum shells which were investigated.

ABSTRACT: The elastic-plastic buckling of internally pressurized torispherical shells is considered in some detail in the paper. The effects of geometric parameters (r/D, RS/D and D/t) and material properties (σ\textsubscript{m}, E and the strain-hardening coefficient) on the elastic-plastic internal buckling pressures were investigated using the BOSOR 5 program. Based on the results of the parametric study, approximate formulas for predicting the elastic-plastic internal buckling pressures are suggested. These should be useful to designers.

ABSTRACT: With the aid of the non-linear shell buckling computer program BOSOR 4, the internal pressures at which elastic circumferential buckling (or wrinkling) take place in thin torispherical shells have been calculated. The maximum equivalent (or effective) stresses in the shells in the axisymmetric pre-buckled state were also obtained…

ABSTRACT: Thin metallic torispherical shells are used frequently in many industries as end closures on cylinders subjected to internal pressure and, for those torispheres which have diameter/thickness ratios greater than 400, elastic–plastic internal pressure buckling may occur. As yet, however, code rules to assist the designer with this buckling problem are not available in either the UK or the USA and one of the aims of this paper is to help to correct this situation. Elastic–plastic internal buckling pressures, for a range of perfect torispherical geometries and obtained with the aid of a sophisticated computer program, are given in the first part of the paper. These pcr's are then utilized (a) to develop a relatively simple equation for predicting the internal buckling pressures of torispherical shells and (b) to assess the accuracy of another, even simpler, approximate buckling equation which was suggested recently.

ABSTRACT: The elastic-plastic buckling pressures of three (the ‘optimum’ and two others) 2:1 torispherical shells subjected to internal pressure are compared with the corresponding $p_r$ for the 2:1 ellipsoidal shell. This is done for $207 \text{ N/mm}^2 \leq \sigma_{yp} \leq 620 \text{ N/mm}^2$ and over the diameter-thickness range $750 < D/t < 1250$. The result of the comparison is that the 2:1 ellipsoidal shape appears to have about 25% more buckling resistance than the 2:1 torispherical shape. Whether one can rely on this 25% margin in practice depends on the accuracy of the shape verification procedure. Some examples are discussed to illustrate the problem.

SUMMARY: Some simple approximate equations for predicting the buckling pressures of internally-pressurised perfect torispheres are given and compared with experimental results obtained on (i) small machined aluminium alloy models and (ii) large ‘as-manufactured’ stainless steel heads. The agreement between theory and test was reasonably satisfactory. Based on these results, a possible procedure for the design of these ‘as-fabricated’ heads is outlined and evaluated. The axisymmetric plastic collapse mode in these heads is also discussed briefly.

ABSTRACT: Vertical liquid-filled cylindrical shells which are subjected to horizontal seismic loads can fail by buckling in shear. One example where this might arise in the nuclear industry is with the primary vessel in a fast breeder reactor (LMFBR) and design criteria are, therefore, needed to prevent its occurrence. In the present paper, the static analogue of the foregoing problem is considered and experimental results on the plastic buckling of short, steel cantilevered cylindrical shells subjected to transverse edge shearing loads are presented. In addition, a simple quadratic equation is suggested for predicting the plastic shear buckling loads. The agreement between the experimental shear loads at the inception of buckling and the predictions of the proposed design equation is excellent for the limited range of geometries investigated.

ABSTRACT: In the diameter-to-thickness range 250 < D/t < 1000, internally pressurized torispherical shells can fail either by plastic buckling or by axisymmetric yielding. However, the present Code rules cater only for the axisymmetric yielding mode and they also restrict the D/t ratios to being less than 500. The rules are based on limit analysis results and these can be conservative for this problem. With regard to internal pressure buckling, there are as yet no design rules in either the American or the British pressure vessel Codes to prevent its occurrence. To provide guidance for a more accurate formulation of design rules for both of these failure modes over the range 300 < D/t < 1500, the authors have made a series of calculations to determine the values of Pcr (the internal buckling pressure) and Pc (the axisymmetric yielding pressure) for perfect torispherical
shells. The availability of these results, obtained with a finite-deflection shell theory, enables curves to be drawn showing when buckling is the controlling failure mode and when axisymmetric yield controls. …

ABSTRACT: The buckling of welded steel cylindrical shells under the combined action of external pressure and axial compressive loads is of considerable interest to the offshore oil and nuclear industries. However, test results on this subject are scarce and some design rules which have been proposed recently have not been validated experimentally, especially in the plastic buckling region. In order to check these rules, and suggest others, interactive buckling tests were conducted at Liverpool University on cylindrical shells having R/t = 100. One series of tests consisted of 19 machined and stress-relieved steel models having L/R ratios of 0.33, 0.74 and 1.45. The results obtained on these near-perfect machined models were compared with theoretical predictions of the behaviour of perfect cylindrical shells and the agreement between the two was good. The other series consisted of 21 welded steel models and had geometric ratios which were similar to the machined ones. The linear interaction equation \( Sp + Sx = 1 \) was used to predict the failure loads of these welded steel models and the predictions were safe in all cases. However, for some combined loading cases the linear equation was rather conservative and, in consequence, some non-linear interaction equations were investigated. These seem promising for design purposes. Irrespective of whether a linear or a non-linear equation is chosen for design, more tests will be needed to establish the scatter bands of the interactive buckling curves for various values of R/t. Some tests were also carried out on (a) the effect of the loading path on the failure loads and (b) models with localized dents. Other topics discussed in the paper are: the effects of residual stresses and initial geometric imperfections, the general procedure adopted by Codes to predict buckling loads and some discrepancies between the predictions of various Codes.

ABSTRACT: Plastic buckling/collapse pressures for externally pressurized imperfect hemispherical shells were calculated for several values of the yield point, the radius-thickness ratio, and the amplitude of the initial imperfections at the pole. The well-known elastic-plastic shell buckling program, BOSOR5, was used in the calculations, and two axisymmetric initial imperfection shapes were studied, a localized increased-radius type and a Legendre polynomial….

ABSTRACT: The test results obtained on 24 externally-pressurised torispherical steel shells are given in this paper. The knuckle radius-to-diameter ratio of the domes varied from 0.06 to 0.18 and the spherical cap radius-to-thickness ratios were between 75 and 335. Initial shape and thickness measurements were carried out on all the torispheres and a summary of this information is given. The BOSOR5 shell buckling program was employed to predict the buckling/collapse pressures of all the domes; both perfect domes and those with axisymmetric imperfections were considered. The correlation between the theoretical predictions and the experimental results was, in general, very good. The main conclusions of the present investigation are: (i) that some of the experimental buckling pressures were lower than those obtained by multiplying the BS 5500 design values by a safety factor of 1.5, and (ii) that those torispheres with sharp knuckle radii failed by plastic collapse in the knuckle region and the collapse pressures were not very sensitive to initial geometric imperfections. It thus appears that the BS 5500 rules relating to the strength of shallow torispheres subjected to external pressure need to be amended, and that the tolerances on geometric shape for cases which are likely to be imperfection-insensitive should be reconsidered.

ABSTRACT (cannot cut and paste abstract)

ABSTRACT: Perfect clamped torispherical shells subjected to external pressure are analysed in the paper using the BOSOR5 shell buckling program. Various values of the knuckle radius-to-diameter ratio (r/D) and the spherical cap radius-to-thickness ratio (Rs/t) were studied, as well as four values of sigma_y, the yield point of the material. Buckling/collapse pressures, modes of failure and the development of plastic zones in the shell wall were determined. A simple diagram is presented which enables the failure mode in these shells to be predicted. The collapse pressures, pc, were also plotted against the parameter….

ABSTRACT: Various shell buckling problems have been studied in the Department of Mechanical Engineering at Liverpool over the past decade. The background to these problems, and the work carried out on them at Liverpool, is discussed briefly in this paper. The shell types which have been investigated are doubly-curved shells (torispheres and hemispheres) and cylinders (mainly unstiffened but some with ring stiffeners). The principal applied loading has been uniform pressure (internal or external) but transverse edge shear and axial compression loads on cylinders have also been studied.

ABSTRACT: Experimental and numerical results on seven 580 mm diameter, spun steel, hemispherical shells subjected to external pressure are discussed in the paper. The average wall thickness of the shells varied from 0.37mm to 2.5mm. Careful shape and thickness measurements on all the shells were obtained and utilised in several types of analysis (2-D Finite Element, best-fit axisymmetric, axisymmetric with a local fattening, etc.). None of the analysis techniques employed proved to be entirely reliable insofar as predicting the collapse strength of the spun steel hemispheres. For example, the ratios of the experimental to the 2-D FE numerical collapse pressures were between 0.56 and 1.21. The test results were also compared with the ECCS design curve and it is shown that one should use the minimum shell thickness for design purposes and not rely on the average wall thickness (three test results plotted below the design curve when the average wall thickness was used).

ABSTRACT: A recent innovation in the design of submersibles is the employment of a series of circular pipes to form part of the pressure hull. These pipes serve as storage for gaseous oxygen, which is mixed with fuel oil to drive a diesel engine in a closed-cycle mode. One of the structural design problems with these vessels is the calculation of the local buckling pressure of the hull and in this paper this is tackled by isolating a short section of the vessel. Two adjacent toroids were considered first, together with their connecting annular segments. Then three toroids were considered. The loading was external pressure on the external surface of the vessel plus the axial thrust caused by the pressure on the end closures. The stress distributions, elastic plastic buckling pressures and mode shapes were determined using the variational finite-difference BOSOR5 program. Factors investigated for the 2-torus case were: the shape of the connecting segments, the constraint conditions at the contact point between the toroids and the influence of the yield stress. The results of the investigation showed that: (i) the local buckling pressure of the 3-torus structure was almost the same as that of the 2-torus case; and
(ii) cylindrical connecting segments gave a higher buckling pressure than circular toroidal ones. A simple approximate method for calculating the local buckling pressure of the 2-torus shell structure was also checked. It turned out to be conservative, giving a buckling pressure which was about three-quarters of the BOSOR 5 value.

ABSTRACT: When perfect, externally pressurized complete circular toroidal shells buckle, the minimum buckling pressure pc occurs in the axisymmetric n = 0 mode, with pc for n = 2 being only slightly larger. In the present paper, the effects of axisymmetric initial geometric imperfections on reducing pc for the perfect shell are investigated. Various types of imperfection are studied, i.e. localized flat spots, smooth dimples, sinusoids and buckling mode shapes. The principal geometry investigated was R/b = 10, b/t = 100, although other geometries were also considered. The maximum decrease in buckling resistance….

ABSTRACT: It was predicted recently that some complete toroidal shells of elliptical cross-section would buckle when subjected to internal pressure. As yet there is no experimental evidence for this, so two independent shell buckling programs (BOSOR and INCA) were employed to calculate the internal buckling pressures for some test cases. The agreement between the results of the two programs is very good, with both programs predicting that buckling occurs. Calculations were also carried out by using BOSOR on complete toroids having cross-sections in the form of prolate (k=a/b>1.0) ellipses. The ranges of the parameters were: R/b=4 and 10, b/t=50, 100 and 200, and 1.3<k<2.5. The shells were assumed to be perfect, made from steel and to behave elastically. The buckling pressures and circumferential wavenumbers are given in tabular form and some are plotted graphically. The deformed shapes of some typical cross-sections prior to buckling are also illustrated, along with the buckling modes.

ABSTRACT: This paper summarizes the results of numerical studies into the effects of initial geometric imperfections on the elastic buckling behaviour of steel circular and elliptic toroidal shells subjected to follower-type external pressure. The types of initial imperfection studied are (a) axisymmetric localized ones and (b) sinusoidal buckling modes. The principal localized imperfections studied are (i) circular increased-radius "flat spots" and (ii) smooth dimples. The buckling pressures pc of circular toroidal shells were not very sensitive to initial imperfections. With elliptic toroids, whether the shell was sensitive to initial imperfections or not depended on the ratio k(a/b) of major to minor radii of the section. The shells on the ascending part of the pc versus k curve behaved like circular toroidal shells, i.e. they were not sensitive to initial imperfections. However, the behaviour of elliptic toroids on the descending part of the pc versus k curve was very different. The
numerical results quoted in the paper are for limited ranges of the geometric parameters. It would be useful to extend these ranges, to explore the effects of plasticity and to conduct model tests on imperfect steel models to verify the conclusions of the numerical studies.

ABSTRACT: Optimal meridional shape and thickness distributions in a filament wound dome closure were investigated in order to increase shell buckling strength under static external pressure. The meridional shape was sought amongst generalized ellipses. The variable thickness profile was obtained through appropriate stacking sequence of continuously wound pre-preg carbon in polar mode. Significant increases in the collapse pressures were obtained for some analysed configurations. The collapse strength of optimally wound domes was then compared with quasi-isotropic lay-up of woven and vacuum bagged closures having the same mass and meridional shape. The latter models were, in many cases, stronger than their wound counterparts. The complex method of Box was used as an optimizer. Bifurcation buckling, axisymmetric snap-through and first ply failure were included in the evaluation procedure.

J. Blachut and G. Galletly, “Progressive collapse of composite shells”, March 1994-October 1997 research project at the University of Liverpool, Engineering and Physical Sciences Research Council (EPSRC) Reference: GR/J14622/01
ABSTRACT: Progressive collapse of this externally-pressurised doubly-curved composite shells, from woven cloth, is to be investigated. This includes development of theoretical/numerical model(s) for the post first ply failure region. The numerical predictions of the difference in strength between the first-ply failure (FPF) and the last-ply failure pressures will be compared with experiments. The behaviour of composite shells in the post FPF region is of great practical importance. We aim here to capture the correct mechanisms of failure and reliable predictions of same backed by experiment.

ABSTRACT: The paper considers barreling of a mild steel cylindrical shell as a way of improving its load carrying capacity when subjected to static external pressure. Numerical results show that the load carrying capacity can be increased from 1.4 to 40 times above the load capacity of mass equivalent cylinders. The effect of end boundary conditions on the ultimate load is examined together with sensitivity of buckling loads to initial geometric imperfections.

ABSTRACT: An effort is made to parametrically establish the maximal compressive axial buckling load of a 'bowed out' shell whose wall thickness and shell volume are maintained constant. Buckling load increase is due to the change in the shell meridional curvature. While there is no dramatic increase in the buckling load, gains of up to 20 percent can be achieved through curvature shaping of the kind presently employed.

J. Blachut (Department of Mechanical Engineering, University of Liverpool, P.O. Box 147, Liverpool L69 3BX, U.K.), “Combined axial and pressure buckling of shells having optimal positive Gaussian curvature”,
ABSTRACT: The optimal curvature of a monocoque toroidal, clamped-clamped shell under axial compression and external pressure is sought under static stability constraints. The material is assumed to be either elastic or elastic-plastic and nonlinear prebuckling effects are included. The results of this parametric study are presented for length/radius ratios varying from 0.5 to 4.0 and radius/thickness varying from 100 to 1000.

Box 147, Liverpool L69 3BX, U.K.), “Optimally shaped torispheres with respect to buckling and their sensitivity to axisymmetric imperfections”, Computers & Structures, Vol. 29, No. 6, 1988, pp. 975-981, doi:10.1016/0045-7949(88)90323-9
ABSTRACT: A discrete version of dynamic programming is used to optimise elastic-plastic externally pressurised torispheres. Step-wise redistribution of mass along the meridian is allowed with an arbitrary number of segments. The optimally shaped torispheres seem to be sensitive to initial axisymmetric geometrical imperfections to the same extent as spherical caps/hemispheres—unlike torispheres with uniform thickness. The full advantage of 15–50% increase in buckling pressure requires shape control to a considerable degree of accuracy.

ABSTRACT: Parabolic and cubic splines together with circular arcs are used to approximate the meridional shapes of multisegmental, axisymmetric, externally pressurized domes. Bifurcation buckling, axisymmetric collapse and fibre first ply failure are considered as possible mechanisms of dome collapse. The objective is to maximize the lowest collapse pressure for a constant wall thickness, given the material and the through thickness lamination sequence. The optimization procedure is based on the complex method of Box and the geometrically nonlinear analysis uses the classical lamination theory. The largest increase in the failure load is obtained for segments made out of circular arcs. A generalized ellipse is also used as a possible meridional profile.

ABSTRACT: Sensitivity of bifurcation buckling, first-ply failure (FPF) and last-ply failure (LPF) to the different modelling methods of woven cloth is examined numerically for a range of torispherical shells. Axisymmetric and two two-dimensional models are used for externally pressurized multi-ply domes. In the first two-dimensional model, angles between warp and weft directions on torispheres are obtained through an optical projection of an initially orthogonal woven net. In the second type of modelling, a planar/orthogonal mapping is preserved on the torispherical geometry. Bifurcation buckling seems to be insensitive to the method of modelling. Results for FPF show that differences between axisymmetric and planar models can be as high as 50%, whilst the differences for optical and planar models can reach 30%. The magnitude of LPF pressures is also sensitive to the two-dimensional modelling method adopted. Ultimate collapse loads, associated with LPFs and based on optical modelling, are up to 30% higher than those obtained for planar modelling for carbon cloth.

ABSTRACT: The effect of knuckle size and length of the cylindrical flange on the buckling strength of externally pressurised torispheres with a sharp knuckle is examined numerically. Both elastic and elastic–perfectly plastic modelling is used. It is illustrated how sensitivity of the load-carrying capacity to the boundary conditions can be removed by the adoption of a large enough knuckle or a cylindrical flange of appropriate length. Experimental results available for the sharp knuckle domes are collected and 10 new tests are carried out on machined steel domes. Two tests on spun torispheres are also included. The tests demonstrate that the safety margin as used for externally pressurised hemispheres and deep torispheres is inadequate for sharp knuckle torispheres with a 6% knuckle.

ABSTRACT: This article contains a survey of some of the recent literature on the structural integrity of metallic and composite domed closures subjected to external or internal pressure. The article refers to other recent reviews and gives a general overview of recent and current research with which the author has been directly or indirectly concerned. For externally pressurized heads this includes correlation between experimental and numerical results, imperfection sensitivity, low buckling resistance of shallow torispheres, and modelling of wound and handdraped multi-ply composite domes. For internally pressurized heads, the topics include the plastic buckling paradox, plastic loads and first cycle shakedown pressures. Structural optimization of vessel closures is also mentioned in the article.

ABSTRACT: The paper presents results of a numerical study into the buckling resistance of geometrically perfect and imperfect steel toroidal shells with closed cross-sections. Elastic and elastic-plastic buckling analyses of shells subjected to uniform external pressure were carried out for a range of geometries, boundary conditions and material properties. Toroids with circular and elliptical cross-sections were investigated. Elastic-plastic analyses carried out for toroids with circular cross-sections allowed identifying shell configurations,
which fail by bifurcation buckling or by collapse. An appropriate equation is proposed for identification of configurations for which either bifurcation or collapse governs the shell’s stability. The proposed equation supplements Jordan’s long-standing design formula, which is applicable to elastic buckling only. The obtained results show that toroids with an elliptical cross-section can be much stronger than shells with a circular cross-section. Calculations identified geometries possessing the largest load carrying capacity. It was found numerically that on both sides of ‘the peak performance geometry’ there is a different failure mechanism which in turn, as it is discussed in the paper, leads to different imperfection sensitivity. A simple design curve is provided for the separation of these two regions. Within each region, the paper provides simple design equations for the elastic buckling strength of geometrically perfect toroids with elliptical cross-sections. Imperfection sensitivities of elastic and elastic-plastic buckling loads to initial, localised and global shape deviations from perfect geometry are given for typical shells with circular and elliptical cross-sections. Initial geometric imperfections in the form of the eigenmode, ‘a single wave’ extracted from the eigenmode and inward dimple modelled by a cosine function in both R-circumferential and r-meridional directions are studied.

J. Blachut (Department of Mechanical Engineering, Applied Mechanics Division, The University of Liverpool, Liverpool L69 3GH, UK), “Application of simulated annealing to optimal barreling of externally pressurised shells”, ICAAISE ’01 Proceedings of the eighth international conference on The application of artificial intelligence to civil and structural engineering computing, Civil-Comp Press, 2001

ABSTRACT: The load carrying capacity, of externally pressurised and optimally shaped metallic shell, has been increased by 40 % over the performance of an equivalent cylinder. The optimal geometry has been sought within a class of generalised ellipses by the application of simulated annealing algorithm. The optimal solution has been verified experimentally by collapsing two, nominally identical, CNC-machined, mild steel shells at about 17 MPa. The wall thickness of the optimal shell was about 2.6 mm, its height was about 100 mm and its diameter was 200 mm. The effect of initial geometric imperfections on the ultimate load is also discussed. The comparison of theoretical and experimental results is good.

ABSTRACT: Current interest in non-gradient optimization can be attributed to two, distinct developments. The first stems from studying natural processes and the second from fast progress in the computing environment. The first has resulted in new optimization techniques like simulated annealing, tabu search and genetic algorithms whilst the second has made many of the existing zero order methods computationally affordable. This chapter discusses simulated annealing, tabu search, dynamic programming, random methods and other heuristics. A variety of illustrative examples is provided together with practical examples drawn from structural mechanics.

Details of collapse tests of two cylindrical and four bowed out mild steel shells are provided. The diameter of the tested shells was about 200 mm, their length varied from 75 to 100 mm whilst the wall thickness was about 3 mm. Experimental buckling/collapse pressures varied from 8 to 22 MPa. Zero radial displacements and zero rotations have been implemented at both ends of all tested shells. The sensitivity of buckling/collapse pressures to the initial, eigenmode type geometric imperfections has been assessed for both cylindrical and bowed out geometries. It appears that barrelling does not necessarily increase the sensitivity of buckling pressure to shape deviations from perfect geometry. Good agreement has been obtained between experimental results on these computer numerically controlled (CNC)-machined models and numerical predictions. Results show that, on a like-for-like basis, barrels were able to support a pressure 85% higher than mass equivalent cylinders.

The paper discusses the load-carrying capacity of toroidal shells with closed circular cross section and loaded by static external pressure. Details about the manufacturing, pre-experiment measurements and testing of three, nominally different, steel toroids are provided. Two of them were manufactured from mild steel by spinning two halves and then welding them around the inner and outer equatorial perimeters. The third one has been assembled by welding four 90-deg stainless elbows. The outer diameter of these models was about 300 mm and the wall thickness varied from 2.0 to 3.0 mm. The hoop radius-to-thickness ratio, r/t, varied from about 15 to 30. The experimental collapse pressures were in the range from 4 to 8 MPa. Comparisons with numerical results are also provided.

The load carrying capacity, of externally pressurised and optimally shaped metallic shell, has been increased by 40% over the performance of an equivalent cylinder. The optimal geometry has been sought within a class of generalised ellipses by the application of simulated annealing algorithm. The optimal solution has been verified experimentally by collapsing two, nominally identical, CNC-machined, mild steel shells at about 17 MPa. The wall thickness of the optimal shell was about 2.6 mm, its height was about 100 mm and its diameter was 200 mm. The effect of initial geometric imperfections on the ultimate load is also discussed. The comparison of theoretical and experimental results is good.

This contribution details buckling tests and numerical results for shallow spherical caps subjected to static and uniform external pressure. Six mild steel caps were carefully CNC-machined from a solid billet. Three caps were designed to fail elastically with the remaining three failing within the plastic range. Caps’ shallowness parameter, λ, varied from 3.5 to 5.5, and radius-to-thickness ratio varied from 300 to 1800. References listed at the end of the paper:

ABSTRACT: Results of a parametric study into buckling and first ply failure of bowed out cylinders, subjected to static external pressure, are discussed. It is shown that substantial pressure increases can be achieved through barreling. This can be further enhanced by varying the lamination angles. The effect of imperfections in lamination angles, and the effect of top/bottom edge boundary conditions on the buckling strength are also discussed.

ABSTRACT: Results of a numerical and experimental study into buckling performance of multi-segment pressure hull subjected to uniform hydrostatic pressure are discussed. Constituents of multi-segment configurations are bowed-out cylindrical shells with, and without flanges. Details about five collapse tests of laboratory scale mild steel, CNC machined models are given. Segments were about 200 mm diameter, 100 mm long and had uniform wall thickness of 3 mm. Experimental collapse pressures were in the range from 12 to 20 MPa. Numerical collapse pressures agreed well with those obtained during experiments.

ABSTRACT: Details are given of a numerical and experimental study into buckling of steel ellipsoidal domes loaded by static external pressure. A range of geometries and thicknesses of domes is examined, as is the influence of different boundary conditions. Shells are examined on the basis of having the same mass. The main focus of the study is on prolate domes, i.e., those taller than a hemisphere of the same base radius. Numerical predictions are confirmed by pressurizing six laboratory scale prolate domes to destruction. Details are given of the manufacture and test procedure for the domes. The adverse effects of variations in shape and wall thickness are discussed, and finite element predictions are made for geometrically imperfect domes. Correlation between the two sets of results is good. Numerically and experimentally obtained results are related to the current design codes: ASME Boiler and Pressure Vessel Code, Sec. VIII, Division 2 (described hereon as ASME VIII), PD5500, and ECCS recommendations (ASME B&PV Code, 2004 ed., Sec. 8, Division 2, New York, NY; BSI 2003 “Published Document PD5500: Specification for Unfired Pressure Vessels,” BSI London; European
ABSTRACT: The paper details numerical and experimental study on elastic buckling of cylindrical shells, which at present make no provision for prolate domes. Suggestions are made for the possible inclusion of such domes into the standards.

ABSTRACT: The paper details numerical and experimental study on elastic buckling of cylindrical shells caused by external pressure, a horizontal edge force and combined action of both. The following three geometries of vertical cylinders are considered: (i) circular cylinders, (ii) concentric circular cylinders, and (iii) cylinders with elliptical cross-section. In total, test results on nineteen shells are given. The experimental data is benchmarked against the FE predictions of buckling loads. Good agreement has been obtained between the experimental results and numerical predictions for all tested shells except for buckling of the concentric cylinders loaded by the horizontal edge force. Possible reasons for discrepancies are discussed. The paper offers insight into buckling performance of vertical cylinders subjected to combined loading, and in the case of concentric cylinders, into the interaction between the inner and outer shells. Some of the interaction
features, not immediately obvious, are discussed.

ABSTRACT: The load bearing capacity has been computed for axially compressed mild steel cylinders with non-uniform axial length. The initial geometric imperfection had a sinusoidal shape along the compressed edge. Computations were carried out for the radius-to-thickness ratio, 165 less-than-or-equals, slant R/t less-than-or-equals, slant 1000, the length-to-radius ratio, L/R "a 2.4, and the ratio of axial amplitude of imperfections to the wall thickness, 0 less-than-or-equals, slant A/t less-than-or-equals, slant 6.0. The contact problem between a rigid plate and a deformable cylinder was successfully benchmarked against experimental data on axially-perfect aluminium cylinders and also against predictions of other proprietary software. Buckling strength showed an astonishing sensitivity to axial imperfections in cylinders. Within the studied range, this could be nearly five times more severe than in the case of geometric imperfections in the shell’s generator, modelled with eigenmode type shape deviations of the same amplitude. The usual sequence of failure modes seen in compressed cylinders, i.e. asymmetric bifurcation followed by axisymmetric collapse is also no longer the case for some geometrical configurations. In particular, asymmetric bifurcation buckling can appear on the post-collapse path. This in turn can lead to mode jumping, i.e. the shell might not reach collapse and instead it can snap to the asymmetric mode at a much lower load than the predicted collapse. This has not been reported for metallic shells but it has recently been actively pursued for composite shells.

ABSTRACT: Eighteen mild steel cylinders with the length-to-radius ratio, L/R ≈ 2.4 and with the radius-to-wall
thickness ratio, R/t ≈ 185 were collapsed by axial compression. Cylinders had variable length at one end of sinusoidal profile. The magnitude of axial imperfection-to-wall thickness ratio, 2A/t, was varied between 0.05 and 1.0. Experimental results show that buckling strength strongly depends on the axial amplitude of imperfection. On average imperfect cylinders, with 2A/t = 1.0, are able to support 49% of experimental buckling load obtained for geometrically perfect model. The largest sensitivity of buckling strength was associated with small amplitude of imperfection in axial length. For example, for axial length imperfection amounting to 25% of wall thickness the buckling strength was reduced by 40%. It appears that the number of sinusoidal waves in the imperfection profile plays a secondary role, i.e., its role in reducing the buckling strength is not a dominant factor. The paper provides experimental details and comparisons with numerical results.

ABSTRACT: This paper considers the determination of plastic instability pressure in toroidal shells under internal uniform pressure. Analytical and numerical approaches, as well as verification by experiments, are presented. This work is inspired by Mellor’s treatment (1983, Engineering Plasticity, Ellis Horwood Ltd., Chichester; 1960, “The Ultimate Strength of Thin-Walled Shells and Circular Diaphragms Subjected to Hydrostatic Pressure,” Int. J. Mech. Sci., 1, pp. 216–228; 1962, “Tensile Instability in Thin-Walled Tubes,” J. Mech. Eng. Sci., 4(3), pp. 251–256), which assumed that plastic instability occurs at the maximum load. A closed-form formula of plastic instability condition is derived analytically. This expression for toroidal shells turns out to be the general case of spherical and cylindrical shells given by Mellor. Then the corresponding pressure is obtained by semianalytical analysis for a material with the strain hardening characteristic, s = A(B+e)^n. For the numerical approach, plastic instability pressure is the maximum pressure at which a small pressure increment causes a very large deformation. This is identified by the slope of pressure—change of volume curve approaching zero. Both approaches predict the onset of instability at the inner equator point. Experimental results of two nominally identical stainless steel toroidal shells correlated well to both approaches in terms of the magnitude of pressure and failure location.

ABSTRACT: The paper provides results of a numerical and experimental investigation into static stability of externally pressurised hemispherical and torispherical domes. Hybrid wall of considered domes includes steel–aluminium, titanium–aluminium and copper–steel–copper configurations. Buckling-collapse tests were conducted on domes manufactured from copper–steel–copper layered material. Details are provided of manufacture of domes, pre-test measurements, testing, and the FE analysis of measured geometries of domes. Five pairs of laboratory scale domes were tested. Each pair had nominally identical geometry. Total wall thickness of copper–steel–copper domes was about 1.1 mm. Inner and outer layers were copper, each 0.05 mm thick. Both types of heads, i.e., hemispherical and torispherical were manufactured from flat sheets using spinning. The (radius-to-wall-thickness)-ratio, R/t, was in the range from 40 to 200. Two values of the (knuckle-radius-to-diameter)-ratio in torispheres were used, i.e., 10% and 17%. Single, quasi-static incremental loading was applied in all cases. The end of load carrying capacity was sudden and well defined. Values of experimental buckling pressures varied from 1.7 to 10 MPa.

ABSTRACT: This paper studies the static stability of metal cones subjected to combined, simultaneous action of the external pressure and axial compression. Cones are relatively thick; hence, their buckling performance remains within the elastic-plastic range. The literature review shows that there are very few results within this range and none on combined stability. The current paper aims to fill this gap. Combined stability plot, sometimes called interactive stability plot, is obtained for mild steel models. Most attention is given to buckling caused by a single type of loading, i.e., by hydrostatic external pressure and by axial compression. Asymmetric bifurcation bucklings, collapse load in addition to the first yield pressure and first yield force, are computed using two independent proprietary codes in order to compare predictions given by them. Finally, selected cone configurations are used to verify numerical findings. To this end four cones were computer numerically controlled-machined from a solid steel billet of 252 mm in diameter. All cones had integral top and bottom flanges in order to mimic realistic boundary conditions. Computed predictions of buckling loads, caused by external hydrostatic pressure, were close to the experimental values. But similar comparisons for axially compressed cones are not so good. Possible reasons for this disparity are discussed in the paper.

ABSTRACT: The paper considers the buckling of short, and relatively thick, mild steel conical shells subjected to the combined action of external pressure and axial compression. Past results on axially compressed cones and on cones subjected to hydrostatic external pressure are compared with fresh test results on equivalent, axially compressed cylinder and with the equivalent cylinder subjected to external hydrostatic pressure. The paper contains both numerical and experimental results. Details about experiments, numerical modelling and computed estimates of the load carrying capacity of analyzed shells are given. Results of this study suggest that the concept of equivalent cylinders is not applicable to short master-cones. Combined stability plots have also been derived for the master-cone and equivalent cylinders. They provide not only the failure envelopes but also the yield envelopes and spread of plastic zones. The paper also brings into the light a useful design tool proposed by Esslinger and van Impe [8], and applicable to elastic–plastic buckling of cones subjected to external hydrostatic pressure.

ABSTRACT: Five laboratory scale models have been machined from 250 mm steel billet. The nominal wall thickness was, t = 2 mm, the semi-vertex angle, beta = 14 deg. Their (large radius, r₂, to-wall-thickness)-ratio was r₂/t ≈ 50, and the (height, h, to large-radius)-ratio was h/r₂ ≈ 1.0. Under axial compression, two nominally identical cones collapsed at F_{coll} ≈ 230 kN. Further two models were subjected to lateral pressure, and one shell to hydrostatic pressure. The magnitudes of their bifurcation pressure were, p_{bif} ≈ 4.7 MPa. Experimental results compare very well with numerical estimates of collapse and asymmetric bifurcation buckling. But the goodness of the comparison strongly depends on the modeling strategy.

ABSTRACT: Buckling of shallow spherical shells subjected to external pressure has been exploited, for example, in pressure safety devices. Shallow spherical caps have also been used as mirrors and more recently they have been considered as energy concentrators in space applications. Hence there is a renewed interest in their static stability performance. This paper addresses two issues: (1) buckling performance of caps, with shallowness parameter, lambda, varying from 3.5 to 7.5, and (2) the effect of boundary conditions on the buckling strength. In the first case, for elastic buckling of caps, there is a sudden drop in the buckling strength for small magnitude of cap's geometrical parameter lambda, i.e., for lambda ≈ 4.0. This has recently been reconfirmed for steel caps. However, it is not clear whether this drop can be eliminated or reduced in caps made from composites mainly through the lamination sequence and also by appropriate supporting of the caps perimeter—as typically used in inflatable space antenna. The current paper examines spherical caps made from composites subjected to quasi-static external pressure. The effect of different lamination sequences on the buckling strength is examined for a range of the shallowness parameter. In the second part, it is proposed to use a closed toroidal shell as means of supporting the cap's perimeter. The supporting toroidal shells can be of different cross-section, i.e., circular or elliptical. The toroids can also be internally pressurized, differently laminated, etc. Additionally the point of attachment can be chosen in such a way that buckling load is as large as possible. The effect of some of these parameters on the buckling pressures is quantified. This is an entirely numerical study.

ABSTRACT: Three types of imperfections are analysed in the current paper, and they are: (i) Initial geometric imperfections, i.e., deviations from perfect geometry, (ii) Variations in the wall thickness distribution, and (iii) Imperfect boundary conditions. It is assumed that cones are subject to: (a) axial compression only, (b) radial pressure only, and (c) combined loading, i.e., axial compression and external pressure acting simultaneously. Buckling strength of imperfect cones is obtained for all of the cases above. It is shown that the buckling strength is differently affected by imperfections, when cones are subjected to axial compression or to radial external pressure. The response to imperfections along the combined stability envelope is also provided, and these results are first of this type. The finite element analysis, using the proprietary code is used as the numerical tool. Cones are assumed to be from mild steel and the material is modelled as elastic perfectly plastic. Geometrical imperfection profiles are affine to eigenshapes. A number of them are tried in calculations, as well as the effect
of them being superimposed. The results indicate that imperfection amplitude and its shape strongly affect the load carrying capacity of conical shells. Also, it is shown that the buckling loads of analyzed cones are more sensitive when subjected to combined loading as compared to their sensitivity under single load conditions. At the next stage, uneven thickness distribution along the cone slant was considered. Variation of wall thickness was assumed to vary in a piece-wise constant fashion. This appears to have a large effect on the buckling strength of cones under axial compression only as compared with that of cones subjected to radial external pressure only. Finally, the effect of variability of boundary conditions on failure load of cones was investigated for two loading conditions, i.e., for axial compression and for radial pressure, only. Results indicate that change of boundary conditions influences the magnitude of buckling load. For axially compressed cones the loss of buckling strength can be large (about 64% for the worst case (beta = 30 deg, the cone not restrained at small radius end). Calculations for radial pressure indicate that the loss of buckling strength is not as acute — with 34% for the worst case (beta = 40 deg, relaxed boundary conditions at the larger radius end). This is an entirely numerical study but references to accompanying experimental programme are provided.

ABSTRACT: This is the first study into elastic-plastic buckling of unstiffened truncated conical shells under simultaneously acting axial compression and an independent external pressure. This is both a numerical and experimental study. Domains of combined stability are obtained using the finite element method for a range of geometrical parameters. Cones are clamped at one end and free to move axially at the other end, where all the other degrees of freedom remain constrained. Shells are assumed to be from mild steel and the material is modeled as elastic perfectly plastic. The FE results indicate that the static stability domains remain convex. The failure mechanisms, i.e., asymmetric bifurcation and axisymmetric collapse are discussed together with the spread of plastic strains through the wall thickness. Also, the combined stability domains are examined for regions of purely elastic behavior and for regions where plastic straining exists. The latter is not convex and repercussions of that are discussed. The spread of plastic strain is computed for a range of the (radius-to-wall-thickness) ratios. Experimental results are based on laboratory scale models. Here, a single geometry was chosen for validation of numerically predicted static stability domain. Parameters of this geometry were assumed as follows: the ratio of the bigger radius, r2 , to the smaller radius, r1 , was taken as (r2 /r1 ) = 2.02; the ratio of radius-to-wall-thickness, (r2 /t), was 33.0, and the cone semiangle was 26.56 degrees, while the axial length-to-radius ratio was (h/r2 ) = 1.01. Shells were formed by computer numerically controlled machining from 252 mm diameter solid steel billet. They had heavy integral flanges at both ends and models were not stress relieved prior to testing. Details about the test arrangements are provided in the paper.

ABSTRACT: The paper provides details about tests on six steel cones. Test models were machined from 250 mm diameter billet. All cones had substantial and integral top and bottom flanges in order to secure well defined boundary conditions. Experimental data were obtained for: (i) two cones subjected to axial compression, (ii) two cones subjected to external pressure, and (iii) the remaining two models subjected to combined action of external pressure and axial compression. Apart from axisymmetric modeling of tested cones, true geometry with true wall thickness was also used in calculations. Theoretical failure loads were obtained for: (i) elastic perfectly plastic, (ii) engineering stress–strain, and (iii) true stress–true strain modeling of steel. The latter approach coupled with measured geometry and wall thickness secured safe predictions of the collapse loads in all cases. Comparisons of experimental collapse loads with estimates given by ASME and ECCS design codes are included. It is seen here that the ASME and ECCS rules provide a safety margin of about 100% against the collapse (except 50% for axial compression in the case of the ECCS).

ABSTRACT: The paper examines the influence of axisymmetric, bulge-type shape imperfections in conical shells on buckling strength. Mild steel cones are subjected to axial load, lateral pressure, and any combination of both. Imperfection sensitivity of buckling load along the entire interactive plot for (i) inward shape deviations, (ii) outward shape deviations and (iii) both inward and outward shape imperfections is examined numerically. For all three cases the worst possible scenario is sought through the application of structural optimization. The latter employs Tabu search algorithm coupled with the FE re-analysis tool. It is shown that both inward and outward imperfections can significantly reduce the load carrying capacity. But the largest shrinkage of the interactive diagram is obtained for the case of co-existing inward and outward initial shape imperfections.

Andreas Taras, “Contribution to the development of consistent stability design rules for steel members”, Ph.d dissertation, Technical University of Graz, Austria, 2010

ABSTRACT: This thesis is concerned with open questions relating to the accuracy and safety of buckling design rules for steel members. It identifies a series of inconsistencies in the current practice of design of these members against instability and comes up with novel solutions to overcome them. The accuracy of design rules is addressed for the buckling modes of lateral-torsional, torsional-flexural and in-plane beam-column buckling. It is shown that the load-carrying capacity of steel members for these modes can be assessed with great accuracy on the basis of simple, case-specific second order (Ayrton-Perry) equations. Thereby, it is of paramount importance that the proposed design equations are calibrated to accurately reflect the results of materially and geometrically non-linear GMNIA FEM calculations. For the purposes of determining how accurately a formulation reflects the true mechanical behaviour of a certain member in a buckling mode, these GMNIA calculations are inevitably of deterministic nature, but are conveniently carried out on “model members” that inherently reflect a certain,desired safety level through their assumptions regarding imperfections and geometry. By doing so, the same, consistent procedure was finally adopted for the development of design rules for these buckling modes as for the most-studied and best-understood benchmark
case of flexural column buckling. Accordingly, also the resulting design formulae are both formally and mechanically consistent with the benchmark case.

Aspects of safety were addressed both implicitly through the above-mentioned development procedure and explicitly by the use of reliability assessments on the basis of Monte Carlo simulations and First Order Reliability Methods. Random number generation and numerical tests were used to answer some questions related to the nexus between fabrication tolerances and specified imperfections for design. Specifically, the impact of changes to the curvature tolerances of compression members was quantified by the use of these methods. Additionally, the possibility was addressed to move away from “semi-deterministic” buckling rules calibrated onto “model member” GMNIA calculations, and to directly base the calibration of buckling rules on “constant reliability curves”. Such curvatures can be obtained from a combination of numerical GMNIA and probabilistic FORM calculations.

Finally, a systematic development procedure for buckling design rules for steel members is proposed, which allows for a consistent expansion of the findings of this thesis to other buckling modes.

ABSTRACT: This thesis is concerned with the study of the elastic-plastic buckling of short and relatively thick conical shells subjected to combined loading, i.e., axial compression and external pressure acting simultaneously. This is both numerical and experimental study. Within the context of numerical study, a
nonlinear finite element calculations were carried out in order to obtain: (i) the failure loads of cones under axial compression only, external pressure only and under combined loading, (ii) the spread of plastic strain and the effect of strain hardening of the material on failure loads, and (iii) the sensitivity of buckling loads to initial geometric imperfections or to structural defects under various loading conditions. The thesis provides results of extensive FE calculations. An experimental programme involved tests on thirteen conical specimens CNC machined with integral top and bottom flanges from 252mm diameter steel billet. The specimens were made from mild steel material with average yield stress of 230.6 MPa, Young's modulus of 21 0490 MPa and Poisson's ratio of 0.281. Prior to tests, the existing test rig had to be significantly modified and instrumented in order to accommodate independent/combined loadings. The test procedure has been developed and successfully implemented. Two models were subjected to axial compression, with further two subjected to external pressure. The remaining nine cones were subjected to combined action of axial compression and external pressure. Experimental results were compared with predictions of failure loads obtained from the existing design codes. For the case of axial compression an extension of the design rules is outlined in order to widen the range of applicability. For the case of external pressure, the test data compared well with the theoretical work by Esslinger and Van Impe, [40]. At the same time the test data highlighted how inadequate estimates of the load carrying capacity are given by the design codes. The case of combined loading, i.e., axial compression and external pressure is only covered by ASME code case 2286-2, [157], and experimental data does not exist. The current study provides the first and much needed test data. The thesis also looks into the concept of equivalent cylinder. Numerical results point out to the fact that this approach is unsuitable for combined stability scenario (axial compression and external pressure). Experimental data is also compared with predictions given by the Finite Element calculations. Details about various approaches to modeling material properties, shape, wall thickness distribution, and boundary conditions are discussed. The quality of FE models is assessed by comparing the FE predictions of the load carrying capacity with the test data.

ABSTRACT: This paper considers the buckling behaviour of commonly used shell structures in the offshore and oil industry. Three types of shells subjected to external pressure were examined, and they are: (i) torispheres, (ii) circular cylinders and (iii) truncated cones. It is assumed that shells are made from steel and the material is modeled as elastic material behaviour. Buckling strength for cases of different prebuckling/perturbation load and different edge support were obtained. In the case of transfer, results indicate that the magnitude of prebuckling/perturbation load has a significant effects on the bifurcation pressure. Whilst, changing the edge support has no effect on the buckling load. For the case of circular cylinder and cone, numerical calculation reveals that the magnitude of the prebuckling/perturbation load does not affect the bifurcation pressure. Whereas, in the case of different edge support, for a convergent solution to be obtained, the edge support must be either pinned or fully clamped at both ends. This is purely numerical study but the results of bifurcation pressure were compared with available data in open literature.

Abstract: Effect of torispherical head on the buckling of pressure vessels was investigated by finite element (FE) method. The FE method with use of nonlinear buckling analysis was applied to predict the critical buckling Load. The influences of geometrical parameter such as thickness, knuckle radius and diameter of cylindrical part, on the buckling of heads have been studied. The Arc Length method which can control the load level, the length of the displacement increment and the maximum displacement was been used. By verification performed with the European Convention for Constructional Steelwork (ECCS) code, it was confirmed that the nonlinear buckling analysis could assure accurate results for buckling strength. It was shown that geometrical imperfections had little effect on buckling strength.

ABSTRACT: In analysis of the removal of offshore jackets an important failure mode is buckling. In current practice, a buckling check involves manual determination of the buckling lengths of each frame member. It is estimated that 5 to 10% of the man-hours in structural analysis of removal projects is spend on checking and correcting buckling lengths. Fortunately, an alternative method is available that does not require determining buckling lengths. In this paper it is shown how this method can be derived from the NORSOK standard for tubular steel frame structures. The method is demonstrated in a removal analysis of an offshore jacket. It is concluded that this method can be successfully applied.

ABSTRACT: Finite element analysis has been carried on composite pipes of length-to-internal diameter ratio of 5 and internal diameter-to-thickness ratio of 20 to assess their strength when subjected to a combination of external pressure and axial compression. The effect of the winding angle of the fibre reinforcements on the buckling and first-ply failure loads of the pipes have been examined. It is shown that the optimum winding angle of the fibres varies according to the ratio of hoop-to-axial membrane stresses in the pipes. In the case of hydrostatic external pressure loading of the pipes, the optimum angle is close to 80° instead of 55° reported elsewhere for internal pressure loading.

ABSTRACT: The outline of a procedure to calculate the buckling and material failure loads of axisymmetric composite shells and cylinders subjected to uniform pressure is presented. It is shown that conventional axisymmetric shell analysis programs have to overcome the limitation of the uniform thickness and fibre orientation circumferentially. The procedure uses this limitation to useful effect by modelling a given problem as a series of shells having uniform thickness and material properties associated with the different meridians of the shell. It is thus possible to employ one-dimensional axisymmetric shell analysis to solve effectively three-dimensional shell problems. In order to demonstrate the viability of the proposed method, three hemispherical domes prepared from two, four and six layers of woven carbon rovings in epoxy resin matrix were tested to failure under the action of external pressure loading. The domes were selected to give both buckling and material modes of failure and their failure loads were compared with those predicted by the method described herein. It is shown that for the thinnest dome having only two layers, the failure mode is bifurcation buckling with a high number of circumferential waves. The mode of failure changes to snap-through axisymmetric collapse when the number of layers is increased to four. A further addition of two layers in the dome changes the failure mode to material collapse. Theoretical prediction of the failure loads based on geometrically perfect structures and average compression properties tended to vary in the range 1.37–1.83 of the experimental values. Thus there was a reasonable agreement between the two sets of results after allowing for the scatter in compressive properties of the material and the sensitivity to geometric imperfections of thin domes.

ABSTRACT: The necking of an elastic-plastic circular plate under uniform radial tensile loading is investigated both within the framework of the three-dimensional theory and within the context of the plane-stress approximation. Attention is restricted to axisymmetric deformations of the plate. The material behavior is described by two different constitutive laws. One is a finite-strain version of the simplest flow-theory of
plasticity and the other is a finite-strain generalization of the simplest deformation theory, which is employed as a simple model of a solid with a vertex on its yield surface. For an initially uniform plate made of an incompressible material, bifurcation from the uniformly stretched state is studied analytically. The regimes of stress and moduli where the governing axisymmetric three-dimensional equations are elliptic, parabolic or hyperbolic are identified. The plane-stress local-necking mode emerges as the appropriate limiting mode from the bifurcation modes available in the elliptic regime. In the elliptic regime, the main qualitative features of the bifurcation behavior are revealed by the plane-stress analysis, although three-dimensional effects delay the onset of necking somewhat. For the deformation theory employed here, the first bifurcation modes are encountered in the parabolic regime if the hardening-rate is sufficiently high. These bifurcations are not revealed by a plane-stress analysis. For a plate with an initial inhomogeneity, the growth of an imperfection is studied by a perturbation method, by a plane-stress analysis of localized necking, and by numerical computations within the framework of the three-dimensional theory. When bifurcation of the corresponding perfect plate takes place in the elliptic regime, the finite element results show that the plane-stress analysis gives reasonably good agreement with the numerical results. When bifurcation of the corresponding perfect plate first occurs in the parabolic regime, then a bifurcation of the imperfect plate is encountered, that is, the finite element stiffness matrix ceases to be positive definite.

ABSTRACT: The buckling behaviour is investigated for an axially compressed elastic-plastic cylindrical panel of the type occurring in stiffened shells. The bifurcation stress is determined analytically and an asymptotically exact expansion is obtained for the initial post-bifurcation behaviour in the plastic range. For panels with small initial imperfections the behaviour is analysed asymptotically on the basis of the hypoelastic theory that results from neglecting the effect of elastic unloading. The imperfection-sensitivity of an elastic-plastic panel is also computed numerically by a linear incremental method, and the results are compared with the results of the asymptotic analysis. For a low hardening material the panel is found to be imperfection-sensitive in the whole range of curvatures considered, whereas for a high hardening material the panel is only imperfection-sensitive if the curvature exceeds a certain value.

ABSTRACT: The creep buckling behaviour is investigated for simply supported rectangular plates under axial compression. In addition to creep also elastic and plastic deformations are accounted for. The initial creep buckling behaviour at small deflections is analysed by a perturbation method, and this solution is used to obtain a simple, rough estimate of the life time. Numerical solutions for the plate creep buckling are obtained by an iterative incremental method. Based on these results the effect of the creep exponent and various effects of plasticity are discussed. The failure times obtained numerically are compared with the time estimates based on a symptotic theory and with critical times predicted in earlier investigations.

Viggo Tvergaard (Department of Solid Mechanics The Technical University of Denmark, DK-2800 Lyngby, Denmark), “Plastic buckling of axially compressed circular cylindrical shells”, Thin-Walled Structures, Vol. 1,
ABSTRACT: For elastic-plastic cylindrical shells with initial axisymmetric imperfections bifurcation into a non-axisymmetric shape is analysed. The shell material is represented by a phenomenological plasticity theory that accounts for the formation of a vertex on subsequent yield surfaces. The influence of various geometric and material parameters is investigated for a wide range of radius-to-thickness ratios. It is shown that for the thicker shells bifurcation generally occurs beyond the maximum axial compressive load. A few analyses for shells with additional non-axisymmetric imperfections show the unstable post-bifurcation behaviour and the sensitivity to imperfections of more general shapes.

ABSTRACT: The influence of buckling pattern localization on the collapse mode of axially compressed elastic-plastic circular cylindrical shells is investigated. Initial imperfections are assumed to be axisymmetric and the possibility of bifurcation into a non-axisymmetric shape is analysed. For sufficiently thin-walled shells bifurcation occurs before the load maximum: but in more thick-walled shells the axisymmetric deformations are stable beyond the maximum load, at which localization into a single outward buckle takes place. It is found that localization delays bifurcation considerably, such that sufficiently thick-walled shells will collapse in an axisymmetric mode. The theoretical predictions are compared with a number of published experimental results.

ABSTRACT: Plastic buckling theory is presented, starting with the general theory of uniqueness and bifurcation for elastic-plastic solids. Also asymptotic procedures for estimating the initial post-bifurcation behaviour and the imperfection-sensitivity are presented, based on the classical elastic-plastic solid. The effect of other elastic-plastic constitutive descriptions on bifurcation and post-bifurcation behaviour is discussed. Several numerical analyses of the plastic buckling of plate — or shell structures are reviewed, and special attention is given to the localization of buckling patterns that often occurs as a secondary bifurcation. Finally, the effect of material strain-rate sensitivity on the prediction of plastic instabilities is discussed in some detail.

ABSTRACT: Localization of an initially periodic buckling pattern is investigated for an axially compressed elastic–plastic cylindrical panel of the type occurring between axial stiffeners on cylindrical shells. The phenomenon of buckling localization and its analogy with plastic flow localization in tensile test specimens is discussed in general. For the cylindrical panel, it is shown that buckling localization develops shortly after a maximum load has been attained, and this occurs for a purely elastic panel as well as for elastic–plastic panels. In a case where localization occurs after a load maximum, but where subsequently the load starts to increase
again, it is found that near the local load minimum, the buckling pattern switches back to a periodic type of pattern. The inelastic material behavior of the panel is described in terms of J2 corner theory, which avoids the sometimes unrealistically high buckling loads predicted by the simplest flow theory of plasticity.

ABSTRACT: Weld-induced residual stresses in shell structures tend to give earlier onset of plastic yielding and to reduce the critical buckling load. Geometrical imperfections may also have a detrimental effect on the load carrying capacity. The interaction between these two kinds of imperfections is studied here for various longitudinally welded cylindrical shell structures, with focus on short wave local buckling modes. It is found that structures with reduced bifurcation loads due to residual stresses show less sensitivity to geometrical imperfections, and after buckling mode deflections of the order of the shell thickness, the residual stresses play no role at all.

ABSTRACT: Free vibrations of turbine blades are analysed numerically by means of a general shell theory. The effect of centrifugal force is taken into account, and it is found possible to examine a wide class of blades. The continuous shell problem is discretized through a finite difference energy method, working on a simple rectangular grid mapped onto the blade surface by parameter functions. Three examples are shown, all of which are compared with previous investigations. One example considers an actual blade from the last stage of a steam turbine, while another considers a compressor blade.

ABSTRACT: This work presents a model to predict the flexural behavior of reinforced concrete slabs, combining the Mazars damage model for simulation of the loss of stiffness of the concrete during the cracking process and the Classical Theory of Laminates, to govern the bending of the structural element. A variational formulation based on the principle of virtual work was developed for the model, and then treated numerically according to the Finite Difference Energy Method, with the end result a program developed in Fortran. To validate the model thus proposed have been simulated with the program, some cases of slabs in flexure in the literature. The evaluation of the results obtained in this study demonstrated the capability of the model, in view of the good predictability of the behavior of slabs in flexure, sweeping the path of equilibrium to the rupture of the structural element. Besides the satisfactory prediction of the behavior observed as positive aspects of the model to its relative simplicity and reduced number of experimental parameters necessary for modeling. ABSTRACT: The derivation for the nonlinear bending response of finite length composite tubes exhibiting cross-sectional deformations associated with Brazier's flattening effect is presented using classical shell theory. Semi-membrane constitutive theory is used to simplify the analysis and local buckling on the compressive side of the tube is investigated based on the axial stress and local curvature on the compressive side of the cylinder. The nonlinear system is solved numerically and results are obtained for various combinations of material and geometric parameters as well as end conditions. Results of the present investigation are compared with published finite element solutions and approximate analytical solutions for the Brazier effect of finite length tubes.

ABSTRACT: An analytical method is proposed for the solution of geometrically nonlinear Brazier problem for thin-wall pipes with initial cross-sectional shape imperfection in the case of action of pressure. Geometrical equations relating displacement components to strains and equilibrium equations taking into account change in the curvature of pipe cross section and axis have been derived. A solution in a first approximation for dimensionless flexibility parameter is presented, the exactness of which is illustrated by numerous examples. For the case of joint action of external bending moment and pressure, a limit curve of the critical moment value
as a function of pressure value has been obtained.

PARTIAL ABSTRACT: An investigation of the possible performance improvements of thin circular cylindrical shells through the use of the variable stiffness concept is presented. The variable stiffness concept implies that the stiffness parameters change spatially throughout the structure. This situation is achieved mainly through the use of curvilinear fibers within a fiber-reinforced composite laminate, though the possibility of thickness variations and discrete stiffening elements is also allowed. These three mechanisms are incorporated into the constitutive laws for thin shells through the use of Classical Lamination Theory. The existence of stiffness variation within the structure warrants a formulation of the static equilibrium equations from the most basic principles. The governing equations include sufficient detail to correctly model several types of nonlinearity, including the formation of a nonlinear shell boundary layer as well as the Brazier effect due to nonlinear bending of long cylinders. Stress analysis and initial buckling estimates are formulated for a general variable stiffness cylinder. Results and comparisons for several simplifications of these highly complex governing equations are presented so that the ensuing numerical solutions are considered reliable and efficient enough for in-depth optimization studies. Four distinct cases of loading and stiffness variation are chosen to investigate possible areas of improvement that the variable stiffness concept may offer over traditional constant stiffness and/or stiffened structures.

ABSTRACT: The past developments on tow-placement technology led to the production of machines capable of controlling fibre tows individually and placing them onto the surface of a laminate with curvilinear topology. Due to the variation of properties along their surface, such structures are termed variable-stiffness composite panels. In previous experimental research tow-steered panels have shown increased buckling load capacity as compared with traditional straight-fibre laminates. Also, numerical analyses by the authors showed that first-ply failure occurs at a significant higher load level. The focus of this paper is to extend those analyses into the postbuckling progressive damage behaviour and final structural failure due to accumulation of fibre and matrix damage. A user-developed continuum damage model implemented in the finite element code ABAQUS is employed in the simulation of damage initiation and material stiffness degradation. In order to correctly predict the buckling loads of tow-steered panels under compression, it is of crucial importance to take into account the residual thermal stresses resulting from the curing process. Final failure of tow-steered panels in postbuckling is predicted to within 10% difference of the experimental results. Curvilinear-fibre panels have up to 56% higher strength than straight-fibre laminates and damage initiation is also remarkably postponed. Tow-steered designs also show more tolerance to central holes than traditional laminates.
ABSTRACT: Machines capable of individually controlling fibre tows and placing them onto the surface of a laminate with curvilinear topology are available nowadays. Due to the variation of properties along their surface, such structures are termed variable-stiffness composite panels. Experimental research demonstrated that properly designed tow-steered panels buckle at higher loads than traditional straight-fibre laminates. Also, numerical analyses by the authors demonstrated that first-ply failure of these designs is remarkably postponed.

The focus of this paper is to extend those analyses into the postbuckling progressive damage behaviour and final structural failure. A user-developed continuum damage model implemented in the finite element code ABAQUS is employed in the characterisation of damage initiation and propagation. As with damage initiation, failure of curvilinear-fibre panels is remarkably postponed as compared with straight-fibre laminates. Tow-steered panels also show to be more tolerant to notches than traditional laminates. By taking into account the residual thermal stresses, not only predicted and experimented buckling loads show remarkable agreement but also predicted final failure loads of tow-steered panels in postbuckling are within 12% of the experimental results.

“Variable stiffness composite panels: Effects of stiffness variation on the in-plane and buckling response”,

ABSTRACT: Descriptions of fiber orientation variation for flat rectangular composite laminates that possess variable stiffness properties are introduced. The simplest definition employs a unidirectional variation based on a linear function for the fiber orientation angle of the individual layers. Analyses of variable stiffness panels for in-plane and buckling responses are developed and demonstrated for two distinct cases of stiffness variations. The first case assumes a stiffness variation in the direction of the loading, and numerical results indicate small improvements in buckling load for some panel configurations due to favorable distribution of the transverse stresses over the panel planform. The second case varies the stiffness perpendicular to the loading, and provides a much higher degree of improvement due to the re-distribution of the applied loads. It is also demonstrated that the variable stiffness concept provides a flexibility to the designer for trade-offs between overall panel stiffness and buckling load, in that there exist many configurations with equal buckling loads yet different global stiffness values, or vice versa.

ABSTRACT: One of the primary advantages of using fibre-reinforced laminated composites in structural design is the ability to change the stiffness and strength properties of the laminate by designing the laminate
stacking sequence in order to improve its performance. This procedure is typically referred to as laminate tailoring. Traditionally, tailoring is done by keeping the fibre orientation angle within each layer constant throughout a structural component. Allowing the fibres to follow curvilinear paths within the plane of the laminates constitutes an advanced tailoring option that can lead to modification of load paths within the laminate to result in more favourable stress distributions and improve the laminate performance.

“Variable-Stiffness Composite Panels: Effects Of Stiffness Variation On The Buckling And Failure Responses”, 7th EUROMECH Solid Mechanics Conference J. Ambrosio et.al. (eds.) Lisbon, Portugal, 7–11 September 2009

ABSTRACT: The traditional approach to the problem of stress concentrations around cutouts in composite structures is to locally increase the laminate thickness in order to smooth out the stress peak. Often, this practice attracts more loads to the cutout region besides increasing part weight. A more effective solution is to avoid the stress concentrations altogether by using fibre-steered laminates. The production of composites in this format is practical nowadays due to capabilities of advanced fibre-placement technology. This paper shows that it is possible to design and manufacture composite panels whose buckling and failure responses are insensitive to the existence of a central hole. This cutout insensitivity does not involve an increase in structural mass, but only the steering of the fibres in the plane of the laminate, in order to promote the redistribution of the loading towards the supported edge sections of the panel.

ABSTRACT: A generalized reciprocal approximation is presented for design of variable-stiffness laminated composite panels for maximum buckling load. The buckling load is expanded in terms of the inverse of the stiffness tensor. For discretized panels such an approximation has the important property of being separable, which allows the maximization to be carried out at each discrete node separate from the others. This makes the algorithm particularly suited to parallel computations. The sensitivity analysis is performed exactly using an adjoint method, requiring only one back substitution using the already factored in-plane stiffness matrix with different right hand sides to compute the sensitivities for all design variables. A conforming CLPT finite element is used for the buckling analysis of rectangular plates and the proposed reciprocal approximation is used to update fiber orientation angles at each finite element node. Numerical results obtained for rectangular plates show that significant improvements can be gained in the buckling load by allowing the stiffness properties to vary spatially. The case of repeated eigenvalues is handled using a dual formulation.

ABSTRACT: Fiber-reinforced composite conical shells with given geometry and material properties are optimized for maximum fundamental frequency. The shells are assumed to be built using an advanced tow-placement machine, which allows in-plane steering of the fibers, resulting in a variable-stiffness structure. In this paper, different path definitions for variable-stiffness shells are provided and used to optimize conical shells for maximum fundamental frequency, while manufacturing constraints that apply for tow placement are taken into account in the process. The influence of manufacturing constraints on the performance is shown; and improvements of variable-stiffness conical shells over conventional, constant-stiffness shells are demonstrated.
ABSTRACT: A fiber-reinforced cylindrical shell with given geometry and material properties is optimized for maximum load-carrying capability under bending. The shell is assumed to be built using an advanced fiber-placement machine, which allows in-plane steering and overlapping of fibers, resulting in a so-called variable-stiffness shell. The design methodology for strength and stiffness variation in circumferential direction by means of fiber placement is explained and restrictions on the manufacturability are specified. Implementation in the commercially available finite element package ABAQUS® for structural analysis is described. Subsequently, the cylinder is optimized to carry a maximum buckling load under bending, while applying a strength constraint. Constraints on the global stiffness are imposed by means of comparison with a baseline quasi-isotropic shell, while a matrix dominated lay up is avoided at all locations in the laminate in order to ensure that the laminate is strong enough in all directions in case a hole is present. Optimization is done using a surrogate model in order to minimize the amount of finite element analyses. Improvements of up to 17% are obtained by changing the load path. The tension side is made stiffer and the compression side softer in longitudinal direction by changing the fiber orientation from near zero at the upper (tension) side to higher fiber angles at the lower (compression) side, such that load is relieved from the compression side. This results in a higher load-carrying capability of the cylinder.

ABSTRACT: Underwater vehicles that operate in deep waters require a pressure hull to maintain the sufficient strength and stiffness against external hydrostatic pressure. We investigated the validity of the finite element method (FEM) that is applied to a buckling analysis of the filament-wound composite cylinder, subjected to an external hydrostatic pressure. Two methods were suggested for the buckling analysis of a filament-wound thick composite cylinder under hydrostatic pressure: using the equivalent properties of the composite, and using stacking sequence. The hydrostatic pressure test was conducted to verify the FEA. Test results were compared with the previous results obtained by FEM on the buckling of a filament-wound composite cylinder under hydrostatic pressure. FEM analysis results were in good agreement with the test results. The difference between FEM results and the test results was approximately 1 to 5%.

“Buckling of filament-wound composite cylinders subjected to hydrostatic pressure for underwater vehicle applications”, Composite Structures, Vol. 92, No. 9, August 2010, pp. 2241-2251, Special Issue: Fifteenth International Conference on Composite Structures, doi:10.1016/j.compstruct.2009.08.005
ABSTRACT: The buckling and failure characteristics of moderately thick-walled filament-wound carbon–epoxy composite cylinders under external hydrostatic pressure were investigated through finite element analysis and testing for underwater vehicle applications. The winding angles were [±30/90]FW, [±45/90]FW and [±60/90]FW. ACOS, an in-house finite element program, successfully predicted the buckling pressure of filament-wound composite cylinders with 2 to 23% deviation from the test results. The analysis and test results showed that the cylinders do not recover the initial buckling pressure after buckling and that this leads directly to the collapse. Major failure modes in the test were dominated by the helical winding angles.

ABSTRACT: Progressive failure analysis based on the complete unloading method was conducted to investigate the crippling failure of carbon/epoxy composite stiffeners under axial compression. A modified arc-length algorithm was incorporated into a nonlinear finite element method to trace the equilibrium path after local buckling. For the validation of the finite element method, several carbon/epoxy Z-section stiffeners were tested in compression. The finite element results on the buckling and crippling stresses showed good agreement with the experimental results.

ABSTRACT: Increasing use of composite materials in aircraft structure aims in reducing the structural weight significantly. In order to exploit the advantage of composite materials especially to manufacture fuselage structure can be efficiently developed by Automatic Fiber Placement (AFP) technology. In this regard, design of composite materials for fuselage structure has been needed. In this study, stacking sequence of skin, stringer and frame has been designed. The skin and frame stacking sequence are designed as [45/90/-45/0/45/0/-45]s and [90/45/-45]s, respectively. The numbers of stringer have been decided on the basis of already published papers. Material selected for fuselage is T800/3900-2 tape lamina. The sizing of stringer (T-shape) and frame (C-shape) has been decided on the basis of Denis Howe’s methods. One ply thickness is taken as 0.1905 mm. The design is modeled in CATIA V5 and imported in FEM code MSC. Patran and Nastran. The meshing is critical near the joint, so, mesh transition between the skin and stringer and skin and frame has been matched. The analysis has been done for internal pressure, shear load, bending moment, torsional load and axial compressive buckling, respectively. It has been observed from the analysis that designed fuselage can withstand internal pressure 75.5 kPa, shear load 13.86x10^6 N, bending moment 8.05x10^6 N-m and axial compressive force 504.150 kN, individually.

ABSTRACT: This work is concerned with the finite element modeling of Nomex honeycomb core and carbon/epoxy composite laminate face sandwich panel structures. One objective is the identification of a material model for the honeycomb’s constituent material by model comparison with experimental test results. A detailed model of the panel structure, including the geometry of the honeycomb, was constructed. This model was loaded in the same fashion as corresponding 3-point flexure, 4-point flexure and compression experimental load tests. Linear isotropic and orthotropic Nomex material models were evaluated by comparing simulation results with test results. Both the isotropic and orthotropic linear material model can make the model agree reasonably well with 3-point flexion test results alone. When those 3-point flexion test identified material model parameters are used in the 4-point flexion and compression test models, they yield about 60% and 90% stiffer results than experiment, respectively. The modeling strategy used in this work along with the material models evaluated thus appears to provide unsatisfactory precision. In spite of this, the orthotropic material model gave the best fit to experimental results from the parameter sets evaluated.

ABSTRACT: Nomex honeycomb core composite sandwich panels are widely used in aircraft structures. Detailed meso-scale finite element modeling of the honeycomb geometry can be used to analyze sandwich inserts, vibration response, and complex combined loading cases. The accuracy of a meso-scale honeycomb modeling technique for static load cases was evaluated. A rectangular honeycomb core was modeled with perfect hexagon honeycomb cells. Compression and shear tests simulations with linear and non-linear solutions were performed for four core densities. The simulated moduli and buckling strengths were recorded. These results were compared to property data published by honeycomb manufacturers. The simulated maximum honeycomb wall stresses at the manufacturer predicted core strengths were also recorded. The honeycomb walls’ first compression deformation mode shape was observed. Sinusoidal small imperfections were then introduced in the honeycomb geometry based on that deformation mode shape. These imperfections provided a better match to manufacturer compressive modulus data while having a limited impact on the shear moduli. The
simulated properties did not exactly match manufacturers’ shear and compression data together for all the core densities. Modeling the honeycomb cells with rounded corners and with increased thickness at the cell junctions are potential strategies to improve the accuracy.

ABSTRACT: BIGBOSOR4 is used in an optimization loop in which the dimensions of a typical axially oriented weld land and the cross-section dimensions of reinforcing Tee-shaped stringers along the two straight edges (generators) of the weld land are decision variables. The optimization is carried out in a GENOPT context. Any number of equally spaced identical T-stiffened weld lands in a 360-degree cylindrical shell can be accommodated. The weld lands are embedded in an internally stiffened "acreage" cylindrical shell that has been previously optimized by PANDA2. The previously optimized "acreage" cylindrical shell has internal "acreage" stringers and internal "acreage" rings with rectangular cross sections. The spacings, heights, and thicknesses of the internal "acreage" stiffeners are not decision variables for the optimization problem in which the weld land and its reinforcing edge Tstringers are optimized. The design constraints for the cylindrical shell with the T-stiffened weld lands are: 1. general buckling, 2. inter-ring buckling, and 3. stress. The prebuckled state is assumed to be uniform end shortening, with the membrane axial compression in each segment of the structure proportional to the axial membrane stiffness of that segment. The prebuckled state is assumed to be a membrane state: no prebuckling bending. The entire shell structure is fabricated of the same material. In the model for general buckling the previously optimized "acreage" rings and stringers are smeared out and the cylindrical shell is simply supported at its ends. In the model for inter-ring buckling adjacent "acreage" rings are replaced by simple supports, that is, a length of shell equal to the ring spacing is analyzed, and the previously optimized "acreage" stringers are smeared out. The maximum stress in the weld-land-edge-stringer region is computed as if there were no prebuckling bending (membrane compression only). The cylindrical shell is modeled as a 180-degree segment of a huge torus, with symmetry conditions applied along the generators at zero and at 180 degrees. In the GENOPT examples studied here there are three identical T-stiffened weld lands spaced at 120 degree intervals. The adequacy of the optimized "acreage" cylindrical shell with and without the optimized T stiffened weld lands is evaluated with various STAGS finite element models. There is good agreement between predictions from the GENOPT/BIGBOSOR4 model and the various STAGS models.

ABSTRACT: The stability pattern of shells is governed by a set of nonlinear partial differential equations. The solution procedure can be simplified, and fast and accurate predictions of the critical buckling load obtained, with the aid of a multilevel approach. Under this approach the lower levels are implemented by means of the perturbation technique, with the nonlinear prebuckling deformation disregarded, and a linear set of equations solved for each state. It turns out, however, that in these circumstances the prediction may differ depending on the chosen formulation. In an attempt to find the reasons for these differences, the linear bifurcation buckling behavior of laminated cylindrical shells was examined via two well-known formulations, with u–v–w and w–F as the unknowns. A third, mixed formulation, was found the most reliable in predicting the buckling behavior.

ABSTRACT: The sensitivity of laminated conical shells to imperfection is considered, via the initial post-buckling analysis, on the basis of three different shell theories: Donnell’s, Sanders’, and Timoshenko’s. Unlike isotropic conical shells or laminated cylindrical shells, in the case of laminated conical shells the thickness and the material properties vary with the shell coordinates, which complicates the problem considerably. The main objective of the study is to investigate the influence of the variation of the stiffness coefficients on the buckling behavior and on the imperfection sensitivity of laminated conical shells. It is felt that by finding the various parameters that influence the shell’s imperfection sensitivity, it is possible to improve the behavior of the whole structure. A special Level-1 computer code ISOLCS (Imperfection Sensitivity of Laminated Conical Shells) had been developed. ISOLCS calculates the classical buckling load and the imperfection sensitivity via Koiter’s theory of laminated conical shells with consideration to the variation of the material properties in the shell’s coordinates. The range of validity of the Level-1 predictions by ISOLCS is verified by the Level-3 code STAGS-A.

ABSTRACT: The buckling behavior of a filament-wound laminated conical shell is thoroughly investigated by consideration of the variation of the stiffness coefficients. To date, all analyses of laminated conical shells have been undertaken with constant stiffness coefficients in the laminate constitutive relations, usually under the assumption of nominal material properties taken from the midlength of the cone. The main object of the study is to investigate the influence of the variation of the stiffness coefficients on the buckling behavior of laminated conical shells. An analytical and computational model was developed to calculate the variation of the stiffness coefficients under the assumption that, in the case of filament-wound truncated conical shells, the fiber orientation changes using a geodesic path. The model was added to the computer code STAGS-A to calculate the buckling behavior of the laminated conical shell.

ABSTRACT: A hierarchical high-fidelity analysis procedure is adopted for predicting the critical buckling load of filament wound laminated conical shells. This hierarchical procedure includes three levels of fidelity for the analysis. Level-1 assumes that the shell buckling load can be predicted by using simply supported boundary condition with a linear membrane prebuckling solution. Level-2 includes the effects of a nonlinear prebuckling solution and the effects of different boundary conditions. Level-3 includes the nonlinear interaction between nearly simultaneous buckling modes and the effects of boundary imperfections. For the Level-1 analysis a computer code BOLCS had been developed. BOLCS calculates the buckling load of laminated conical shells by a linear bifurcation analysis. The buckling behavior obtained by BOLCS is compared for various load cases with Level-3 solutions calculated by the two-dimensional nonlinear code STAGS-A. The effects of the assumptions and approximations used for the two solutions are discussed. In addition, the influence of the in-plane boundary condition on the buckling behavior of laminated conical shells under axial compression is investigated. It is found that the in-plane boundary condition at the large end of the shell has a major effect on the buckling behavior.

ABSTRACT: Optimum laminate configuration for minimum weight of filament-wound laminated conical shells is investigated subject to a buckling load constraint. In the case of a composite laminated conical shell, due to the manufacturing process, the thickness and the ply orientation are functions of the shell coordinates, which ultimately results in coordinate dependence of the stiffness matrices (A,B,D). These effects influence both the buckling load and the weight of the structure and complicate the optimization problem considerably. High computational cost is involved in calculating the buckling load by means of a high-fidelity analysis, e.g. using the computer code STAGS-A. In order to simplify the optimization procedure, a low-fidelity model based on the assumption of constant material properties throughout the shell is adopted, and buckling loads are calculated by means of a low-fidelity analysis, e.g. using the computer code BOCS. This work proposes combining the high-fidelity analysis model (based on exact material properties) with the low-fidelity model (based on nominal material properties) by using correction response surfaces, which approximate the discrepancy between buckling loads determined from different fidelity analyses. The results indicate that the proposed multi-fidelity approaches using correction response surfaces can be used to improve the computational efficiency of structural optimization problems.

ABSTRACT: The present study concentrates on the optimization of geometrically nonlinear shell structures using the multipoint approximation approach. The latter is an iterative technique, which uses a succession of approximations for the implicit objective and constraint functions. These approximations are formulated by means of multiple regression analysis. In each iteration the technique enables the use of results gained at several previous design points. The approximate functions obtained are considered to be valid within a current subregion of the space of design variables defined by move limits. A geometrically nonlinear curved triangular thin shell element with the corner node displacements and the mid-side rotations as degrees of freedom is used for the FE analysis. The influence of initial shape imperfections on the optimum designs is investigated. Imperfections are considered as a shape distortion proportional to the lowest buckling modes of the perfect structure. Displacement, stress, and stability constraints are taken into account. To prevent finite element solutions from becoming unstable during the optimization process, a simple strategy for avoiding passage of stability points is applied. Some numerical examples are solved to show the practical use and efficiency of the technique presented.

SUMMARY: In this thesis a curved triangular finite shell element is described based on the Kirchhoff-Love hypothesis. Using this element, thin shell structures can be analysed in the nonlinear field. The element has twelve degrees of freedom, namely, nine displacement components and three rotations about the element sides. The membrane strains and the changes of curvature, just like the tangential stress resultants and the tangential stress couples, are taken to be consant over the element. In addition to a comprehensive discussion of geometrical nonlinearities, it is also pointed out how to incorporate time independent plasticity in a consistent way. In Chapter 1 a general introduction is given, in which a number of finite element approaches to shell analysis are mentioned, while further some historical background of the present study is outlined. In Chapter 2 a short review of the usual nonlinear shell theory is presented. By introducing a number of error estimates, suitable expressions for a shallow part of a shell are derived. In Chapter 3 the just-mentioned expressions are applied to obtain the actual finite element formulation. A key role is played by a second-order interpolation for the initial geometry and the displacement component in the direction perpendicular to the plane determined by the vertices of the element. Furthermore, attention is paid to inter-element continuity of the displacements and the rotations of the normal to the shell middle surface, while the requirement that rigid body motions must be described correctly is also emphatically taken into consideration. Due to the way of calculating the changes of curvature, the incremental rotations have to remain moderate. In Chapter 4 a recapitulation of constitutive rate equations for time-independent small strain elastoplasticity is given, together with a discussion of possible solution strategies. The three-dimensional nature of the fraction model is illustrated and the implications of using a three-dimensional stress state instead of a two-dimensional one are taken into account. In Chapter 5 a number of demonstrative examples are shown. They deal with a variety of analysis types, from linear to both geometrically and physically nonlinear, including dynamics. All solutions are compared with semi-analytical or other finite element solutions known from the literature. In the Appendices A.1 and A.2 an alternative method for calculating the changes of curvature, which is also valid for finite rotational increments, and some aspects concerning the Tresca yield criterion are mentioned, respectively.

Van Keulen (Faculty of Mechanical Engineering and Marine Technology, Dept. of Engineering Mechanics, Delft University of Technology, The Netherlands), “A mixed element for geometrically and physically nonlinear shell problems”, (publisher and date not given in the pdf file; most recent citation is dated 1991)
ABSTRACT: A triangular element for geometrical and physical nonlinear shell problems is described. The degrees of freedom are 18 displacement components and 6 rotation-like scalars. A key role in the description is played by a flat reference triangle through the vertices of the element. The governing equations are derived by means of the principle of virtual work, using constitutive equations based on a layered model. The performance of the element is illustrated by two sample problems.

ABSTRACT: The objective of this article is to study the solvability of variational problems of both geometrically and physically nonlinear theory of thin non-sloping shells of zero Gaussian curvature with rigidly fixed edge. The characteristic property of this article is the fact that the solvability of problems is proved in a functional space which differs from spaces of displacements and forces. Solvability conditions of the problem are obtained without assumptions on smallness of components of the outer load. Similar problems for sloping shells were considered in [1]. The physically nonlinear problems for non-sloping shells whose middle surface is formed by rotation, a convex developable surface, were studied in [2], [3].

ABSTRACT: A structural optimization algorithm is developed for truss and beam structures undergoing large deflections against instability. The method combines the nonlinear buckling analysis using the displacement control technique, with the optimality criteria approaches. Several benchmark case studies illustrate the procedure and the results are compared with examples reported in the literature. It is shown that a design based on the generalized eigenvalue problem (linear buckling) highly underestimates the optimum mass or overestimates the buckling load for these types of structures, so a design based on the linear buckling analysis may result in catastrophic failure. The effect of geometrical nonlinearities and element imperfections has also been studied.

ABSTRACT: Optimum laminate configuration for the maximum buckling load of filament-wound laminated conical shells is investigated. In the case of a laminated conical shell, the thickness and the ply orientation (the design variables) are functions of the shell coordinates, influencing both the buckling load and the weight of the structure. Thus, optimization can be performed by maximization of the buckling load for a specific weight, or
by minimization of the weight of the structure under the constraint of applied buckling load. Due to the complex nature of the problem a preliminary investigation is made into the characteristic behavior of the buckling load with respect to the volume as a function of the ply orientation. The exact buckling load is calculated by means of the computer code STAGS-A (Structural Analysis of General Shells [Almroth BO, Brogan FA, Meller E, Zele F, Petersen HT. Collapse analysis for shells of general shape, user's manual for STAGS-A computer code. Technical report AFFDL TR-71-8; 1973]) by adding a user written subroutine WALL, see Ref. [Goldfeld Y, Arbocz J. Buckling of laminated conical shells taking into account the variations of the stiffness coefficients. AIAA J 2004; 42(3):642–649]. The optimization problem is solved using response surface methodology.

ABSTRACT: The sensitivity of laminated cylindrical shell to imperfection is considered, via the initial post-buckling analysis, on the bases of Sanders’ theory. A general code is developed and used in studying the effect of the stretching–bending coupling (B) and the flexural (D) stiffness matrices on the buckling and the post-buckling behavior of the shell, thereby improving its behavior.

doi: 214, 35400009945776.0160

ABSTRACT: Bifurcation buckling analysis of laminated cylindrical shells is presented on the basis of three different shell theories: Donnell's (Donnell, L. H., Stability of Thin-Walled Tubes under Torsion, NACA TR-479, 1933), Sanders's (Sanders, J. L., Jr., Nonlinear Theories of Thin Shells, Quarterly Journal on Applied Mathematics, Vol. 21, No. 1, 1963, pp. 21-36), and Timoshenko's (Timoshenko, S., Theory of Elastic Stability, McGraw-Hill, New York, 1961). Formulations in terms of the displacement components and of the Airy stress function and normal displacement are examined. The partial differential equations are derived via the variational principle and solved with variables expanded in Fourier series in the circumferential direction and presented as finite differences in the axial direction. The buckling behavior of an angle-ply laminated cylindrical shell under different modes of loading was investigated parametrically, showing-in contrast to its isotropic counterparts-a discrepancy between the two formulations.
ABSTRACT: Most of the previous research on buckling and stability of shell structures is confined to \( u-v-w \) or \( w-F \) formulation, which are limited either by accuracy or by the chosen kinematic theory. In this work, an alternative mixed formulation is proposed for general laminated shells of revolution and calculated for different shell theories. Its principle consists in choosing the set of unknown functions as the obtainable boundary conditions from the variational formulation. The main advantage of the mixed formulation is direct involvement of the stiffness matrices, without their derivatives. This quality is most important in complicated woven-fabric procedures when the derivative functions of the fiber orientations are not available or the constitutive functions have discontinuities. The proposed formulation is validated and demonstrated for filament-wound laminated conical shells with variable material properties.

ABSTRACT: A hierarchical high-fidelity analysis methodology for predicting the critical buckling load of compression-loaded thin-walled isotropic shells is described. This hierarchical procedure includes three levels of fidelity for the analysis. Level 1 assumes that the buckling load can be predicted by the classical shell solution with simply supported boundary condition, and with a linear membrane prebuckling solution. Level 2 includes the effects of a nonlinear prebuckling solution and the effects of traditional clamped or simply supported boundary conditions. Level 3 includes the nonlinear interaction between nearly simultaneous buckling modes and the effects of boundary imperfections and general boundary conditions. Various deterministic and probabilistic approaches are used to account for the degrading effects of unavoidable shell-wall geometric imperfections. The results from the three solution levels are compared with experimental results, and the effects of the assumptions and approximations used for the three solution levels are discussed. This hierarchical analysis approach can be used in the design process to converge rapidly to an accurate prediction of the expected buckling load of a thin-shell design problem.

ABSTRACT: A probability-based analysis method for predicting buckling loads of compression-loaded laminated composite shells is presented, and its potential as a basis for a new shell-stability design criterion is demonstrated and discussed. In particular, a database containing information about specimen geometry, material properties, and measured initial geometric imperfections for a selected group of laminated-composite cylindrical shells is used to calculate new buckling-load “knockdown factors.” These knockdown factors are shown to be substantially improved and hence much less conservative than the corresponding deterministic knockdown factors that are presently used by industry. The probability integral associated with the analysis is evaluated by using two methods; that is, by using the exact Monte Carlo method and by using an approximate first-order second-moment method, yields results that are conservative for the shells considered. Furthermore,
the results show that the improved, reliability-based knockdown factor presented always yields a safe estimate of the buckling load for the shells examined.

ABSTRACT: As a step towards developing a new design philosophy, one that moves away from the traditional empirical approach used today in design towards a science-based design technology approach, a test series of 5 lightly stiffened orthotropic shells carried out by Singer, Arbocz and Babcock at Caltech is used. In earlier publications a hierarchical high-fidelity analysis procedure for predicting the critical buckling load of compression-loaded thin-walled shells is described. This hierarchical procedure includes three levels of fidelity for the analysis, Level-1 assumes that the shell buckling load can be predicted by the classical solution with simply supported boundary condition, and with a linear membrane prebuckling solution. Level-2 includes the effects of a nonlinear prebuckling solution and the effects of boundary conditions. Level-3 is a two-dimensional analysis, which includes the nonlinear interaction between nearly simultaneous buckling modes. As a final step in the hierarchical analysis approach, in the present paper the Level-3 buckling load prediction based on the experimentally measured initial imperfections are verified by the experimental buckling loads. Since the simulated buckling loads yield a lower bound to the experimental buckling loads of all five shells tested, it is believed that the proposed hierarchical analysis procedure can be used in the design process to rapidly converge to an accurate prediction of the expected buckling load of a thin-shell design problem.

ABSTRACT: Multi-level high-fidelity analysis is recognized as a viable strategy for obtaining improved safe knock-down factors based on the so-called “manufacturing signature” of a fabrication process. This approach is implemented in the hierarchical interactive computer code, DISDECO, the Delft, Interactive Shell Design Code, which enables interactive investigation of the various aspects of the nonlinear response of thin-walled shells. The goal of the research reported in this paper is the development of accurate inheritance of computed results from low-level parametric analysis modules through intermediate approximate analysis levels to high-level large general purpose computer codes. Accurate fitting, interpolation and extrapolation of computed results as
well as reformulating to accommodate alternate computational methods are major requirements. The inheritance methods are demonstrated by the hierarchical analysis of the collapse behavior of a stringer stiffened cylindrical shell.

PARTIAL ABSTRACT: Because of their favourable strength over weight ratios thin-walled stiffened or unstiffened, metallic or composite shells are widely used structural elements in many applications in the aerospace, the off-shore, the maritime, the process-technology and other civil engineering fields. Unfortunately, thin-walled shells are also often very prone to buckling instabilities. In the 1960s, the engineering community in the United States was facing the urgent problem of having to devise reliable design procedures for both the ballistic missile program of the US Air Force and the launch vehicles of the NASA space program. ...

ABSTRACT: Energy distribution within the critical modes of a classical energy eigenvalue analysis for circular cylindrical seashells under external pressure shows that a significant contribution to the stability of the shell is derived from membrane stiffness. It is argued from physical reasoning that the unstable post-critical behavior is the result of the loss of this membrane stiffness. To account for the combined effect of mode coupling and imperfections in eroding this membrane stiffness, a simplified theoretical analysis is described in which appropriate terms in the membrane potential energy are neglected. It is shown, by comparison with the writers’ experiments, and with a collection of data found in the literature, that this reduced stiffness method provides lower bounds which, for shells with moderate imperfections, are reliable lower bounds of the experimental buckling pressures in the modes observed to trigger buckling. This lower boundedness combined with the conceptual and analytic simplicity of the reduced stiffness method make it a particularly attractive basis for the design.

ABSTRACT: A re-examination of some 240 past experiments on the general elastic buckling of axially loaded stringer stiffened cylinders suggests that the observed buckling behaviours exhibited a degree of imperfection sensitivity considerably higher than that so often ascribed to them. It is demonstrated how the underestimation of these experimental knock-downs may have resulted from the use of theoretical models insufficiently
representative of test conditions. By incorporating a more precise modelling of the test shells the present analyses show how, contrary to a widely held belief, the potential knock-down factors for general elastic buckling can approach those of the isotropic cylinder. Furthermore, despite the relatively perfect nature of many of the test shells, the recently described ‘reduced stiffness analysis’ method provides lower bounds of the observed experimental scatter that are sufficiently reliable to recommend this method as a basis for future design.

ABSTRACT: Re-examination of some 85 past experiments on the elastic buckling of axially loaded ring stiffened cylinders shows the existence of two distinctive behavioural regimes. Lightly stiffened cylinders, like isotropic cylinders, buckle into non-axisymmetric modes having long axial wavelengths at loads that are sensitive to the precise magnitudes of small initial imperfections. Heavily stiffened cylinders are characterised by snap buckling into axisymmetric modes which, for elastic behaviour at least, show only limited sensitivity to initial imperfections. Each of these characteristics is shown to be predicted by the recently developed ‘reduced stiffness analysis’ method, which, despite the relatively perfect nature of test specimens, predicts reliable lower bounds to the experimental scatter. Taken together with the previously demonstrated empirical validity of the reduced stiffness analysis for the prediction of buckling modes and lower bounds to buckling loads for both isotropic and stringer stiffened cylinders, the present comparisons provide further support to the recommendation that this method be considered as an alternative basis for future design.

ABSTRACT: This paper reports a study carried out on behalf of the U.K. Dept. of Energy to update its Guidance Notes relating to the buckling design of offshore steel structures. The results presented here refer to stringer and orthogonally stiffened cylinders and are compared with the predictions from various design codes. Conclusions are predictions from various design codes. Conclusions are drawn as to the validity and conservativeness of the code recommendations.

A.C. Walker, Y. Segal and S. McCall (Dept. of Mechanical Engineering University of Surrey, Guildford, UK), “The buckling of thin-walled ring-stiffened steel shells”, in Buckling of Shells, pp 275-304, 1995

SUMMARY: The buckling of thin-walled cylindrical shells subject to various types of combined loading is of current interest to engineers engaged in offshore engineering practice. This paper considers the inter-ring buckling of cylinders when subject simultaneously to pressure and axial loading. Some example results from an experimental research programme on steel models are presented and compared to the interaction diagrams proposed by other researchers.

ABSTRACT: A reduced stiffness theoretical analysis of imperfection sensitive elastic buckling for end supported cooling tower-type shells, provides lower bounds of experimentally recorded buckling pressures. Classical analysis of these shells with the same empirically realistic boundary support conditions, in contrast, provides unreliable upper bounds of test buckling pressures. By attempting to attribute this imperfection sensitivity to notionally weakened boundary conditions, past interpretations may have provided non-conservative advice for the estimation of design buckling pressures. The reduced stiffness method provides a simple, alternative basis for designing against imperfection sensitive buckling.

ABSTRACT: This paper shows how the analysis of minimum, quasi-static, buckle propagation pressures for subsea pipelines may be exactly formulated in terms of the characteristics of ring collapse. A simple mechanistic approach to ring collapse is described which enables the rational incorporation of the effects of material strain hardening. Theoretical predictions resulting from this analysis are shown to reproduce past
empirically observed propagation pressures; they also successfully predict the variations in the forms of ring collapse modes resulting from differing strain-hardening properties. Upon suitable non-dimensionalisation this analysis shows how predicted propagation pressures may be represented in terms of just one composite material and geometric ‘propagation parameter’. This eliminates the need for recourse to empirically fitted design curves and allows resolution of certain anomalies experienced in past analyses. It emphasises the need for more complete information regarding material strain-hardening properties if test results are to be properly interpreted. Most importantly, the present analysis offers the potential for future design of pipelines being at once more rationally and parametrically complete, and yet compact and simple to apply.

ABSTRACT: A recently developed procedure for predicting the elastoplastic axisymmetric collapse of cylinders subjected to combinations of axial compression and pressure loading is described. This allows the modelling of radial pressure induced deformations, boundary effects and initial geometric imperfections in terms of an equivalent imperfection in a “column type” bifurcation analysis. Together with the incorporation of a more rational means of specifying initial geometric tolerances, it is used to develop compact design-orientated procedures for predicting safe design loads for this form of elastoplastic collapse of cylinders.

ABSTRACT: This paper deals with buckling of thin-walled cylindrical shells under compression. It is well-known that axially compressed cylindrical shells have buckling behaviour which is very sensitive to initial geometric imperfections. However, current approaches using mathematical algorithms to optimise the linearised classical critical loads with respect to many design variables, generally ignore the potential reductions in elastic load carrying capacities that result from the initial imperfections. They present major problems for incorporation into design processes and often involve excessive computational effort. Adopting 6-ply symmetric, glass-epoxy cylindrical shells, this paper carries out classical buckling analysis for perfect shells and nonlinear analysis for imperfect shells. In addition the present paper applies an alternative lower bound design concept called the reduced stiffness method. By confirming the correspondence between the lower bounds of nonlinear buckling analysis and the reduced stiffness analysis, it suggested that the reduced stiffness method could provide an important basis for design.

ABSTRACT: Thin metallic shells have long been adopted as major structural components in weight-sensitive applications, especially in marine engineering. Imperfection sensitive buckling is a critical design factor when these structures are loaded in compression. Traditional experimental design method depends on deriving lower bounds to the scatter of large sets of test results. This paper aims to present an analytical approach, the so-called reduced stiffness method (RSM) to the lower-bound buckling of thin-metallic shells. The validity of the RSM for the prediction of the safe lower bounds to the buckling of thin shells is verified through carefully controlled finite element analysis and the comparative studies confirm the reliability of the RSM.

ABSTRACT: An elastic, nonlinear, Ritz analysis has been developed to allow investigation of the imperfect behavior of axially compressed orthotropic fiber reinforced polymer cylindrical shells. In a particular mode, buckling loads are shown to be strongly influenced by the constitutive material coefficients and are sensitive to initial geometric imperfections. Just as for the previously analyzed isotropic cylindrical shells, the reduced stiffness criteria are shown to provide close lower bounds to the imperfection sensitive elastic buckling loads. The potential benefits in the use of the reduced stiffness theoretical results to allow specification of the optimal designs are illustrated.

ABSTRACT: In this paper, the strengthening of thin-walled metallic shells with the application of CFRP (carbon fibre reinforced polymer) has been investigated. To lower down the downside of the lower stiffness exhibited by CFRP shells and to diminish the major problem associated with steel shells, a new composite sandwich structure has been introduced in this paper and effect of CFRP reinforcements under axial compression has been studied through three kinds of analytical procedures; the linear Eigen value problem, the modified RS (reduced stiffness) analysis and the fully nonlinear numerical experiment. With these multiple treatments it has been suggested that recently developed modified RS analysis which effectively compute the lower bounds provides the significant information to evaluate the buckling capacity of reinforced shells that display the unstable behaviour and imperfection-sensitivity than the general RS Analysis. This paper also illustrates the application of the methodology to cases of axially loaded shells with varying thickness of veneers of CFRP.

ABSTRACT: The imperfection sensitive buckling loads of fibre reinforced polymeric (FRP) composite cylindrical shells under axial compression can be optimised with respect to many material and geometric parameters. Current approaches, using mathematical algorithms to optimise the linearised classical critical loads with respect to many design variables, generally ignore the potential reductions in elastic load carrying capacities that result from the severe sensitivities of buckling loads to the effects of initial imperfections. This paper applies a lower-bound design philosophy called the reduced stiffness method (RSM) to the optimisation design of FRP shell buckling. A physical optimisation in terms of parametric studies is carried out for simply supported, 6-ply symmetric, glass-epoxy circular cylindrical shells under uniform axial load. It is shown that under the guidance of RSM, safe lower-bound buckling loads can be enhanced greatly by choosing appropriate combinations of design parameters. It is demonstrated how this approach encourages the delineation of those components of the shell’s membrane and bending stiffness that are important and those that are unimportant within each of the prospective buckling modes. On this basis, it is argued that the RSM provides not only a safe but also a more rational strategy for better design decision making.

ABSTRACT: Methods are proposed for the determination of the optional ply angle variation through the thickness of symmetric angle-ply shells of uniform thickness. These methods use continuous piecewise-linear segment approximations or discontinuous piecewise-constant segment approximations to the ply angle function. A mathematical programming (MP) problem is formulated using segment ply angles and thicknesses as design variables. A special MP algorithm, capable of treating multiple objective functions, combined with a critical mode search is used to solve this problem. The procedure is applied to the maximization of the minimum natural frequency or buckling load of a thin, simply supported, circular, cylindrical, angle-ply shell. Results show large performance gains result from the use of optimal variable ply angle configurations, compared to an optimal constant ply angle. The continuously variable ply angle approximation is particularly effective.

ABSTRACT: The free vibration characteristics of a submarine hull have an important influence on the noise signature. A submarine hull, or portion of one, can frequently be idealised as a ring stiffened cylinder subjected to external loading from the surrounding water, for the purposes of vibration analysis. The modal behaviour of ring stiffened cylinders is reviewed, including the effect of external pressure loading and added mass effects from surrounding fluid. The existing unclassified literature is inadequate in its coverage of the problem and these shortcomings are discussed, in order to identify the requirements for further work in order to be able to satisfactorily analyse a submarine hull structure.

Anonymous, “Dynamic Buckling of Shells” (an abstract, not a paper)
ABSTRACT: SRI performed experiments and analyses on impulsively loaded thin cylindrical aluminum shells. The cosine distributed external impulsive loads drive the shell inward producing compressive circumferential stresses and pulse buckling on the loaded side of the shell. These buckles produce strain concentrations that govern the eventual fracture of the structure. Thus the buckling response needs to be correctly modeled to predict failure. Predicting the buckling response of thin shells is difficult because most finite element models do not include the physical characteristics of the problem that initiate instabilities. A methodology was developed to accurately predict the buckling response of the thin shell structures by incorporating either the measured imperfections in the structure and loading, or accurate statistical approximations to the imperfections. A cross section of a dynamically pulse buckled thin cylindrical shell and the calculated response are shown in Figure 1. In the calculation, we used the measured imperfections in the cylinder shape to initiate the buckling. The buckling response can clearly seen on the loaded (front) side of the cylinder and is accurately reproduced in the
calculation. These modeling techniques, developed for analysis of pulse buckling of thin aerospace shell structures, have been used in other structural applications. These include analysis of crash energy management structures for vehicles, static axial collapse of cylinders, and dynamic buckling of thick shells. One example application for thick shells is the buckling that occurs in explosively formed penetrators (EFPs) as shown in Figure 2. Understanding and modeling the processes that lead to dynamic plastic buckling in EFP liners allows the designer to control the buckling process to gain enhanced aerostability.

ABSTRACT: Thin cylindrical shells were tested under axial compression beyond the critical buckling load. Both pretest and posttest finite element calculations were performed to calculate the buckling loads and post-buckling deformations. Finite element simulations of the shell included pretest measured imperfections in shell geometry and asymmetry in the axial load. Results show that the axial collapse load is sensitive to imperfections in both the shell geometry and the load distribution. Careful modeling of the imperfections resulted in accurate predictions of the buckling load and postbuckling deformations for the shells.

ABSTRACT: When a cylindrical shell is subjected to dynamic impulsive loading in radial direction and the ratio of radius-to-thickness exceeds a special value, the cylindrical shell will produce elastic dynamic buckling. This paper which is based on the results of some relative experiments, assumes deformation mode and utilizes Lagrange method to analyse the elastic pulse buckling of a thin cylindrical shell with a finite length under a cosine impulse. The dynamic buckling equations are derived and solved by numerical method. The results of calculation are compared with some relative calculation results which were obtained by other authors. ABSTRACT: In the traditional buckling analysis of rectangular plates the classical thin plate theory is generally applied, so neglecting the plating shear deformation. It seems quite clear that this method is not totally appropriate for the analysis of thick plates, so that in the following the two variable refined plate theory proposed by Shimpi (2006), that permits to take into account the transverse shear effects, is applied for the buckling analysis of simply supported isotropic rectangular plates, compressed in one and two orthogonal directions. The relevant results are compared with the classical ones and, for rectangular plates under uniaxial compression, a new direct expression, similar to the classical Bryan’s formula, is proposed for the Euler buckling stress. As the buckling analysis is a widely diffused topic for a variety of structures, such as ship ones, some applications for plates uniformly compressed in one and two orthogonal directions are presented and the relevant theoretical results are compared with those ones obtained by a FEM analysis, carried out by ANSYS, to show the feasibility of the presented method.

V. Piscopo, “Buckling analysis of rectangular plates under the combined action of shear and uniaxial stresses”, World Academy of Science, Engineering and Technology, Vol. 4, 2010-10-4

ABSTRACT: In the classical buckling analysis of rectangular plates subjected to the concurrent action of shear and uniaxial forces, the Euler shear buckling stress is generally evaluated separately, so that no influence on the shear buckling coefficient, due to the in-plane tensile or compressive forces, is taken into account. In this paper the buckling problem of simply supported rectangular plates, under the combined action of shear and uniaxial forces, is discussed from the beginning, in order to obtain new project formulas for the shear buckling coefficient that take into account the presence of uniaxial forces. Furthermore, as the classical expression of the shear buckling coefficient for simply supported rectangular plates is considered only a “rough” approximation, as the exact one is defined by a system of intersecting curves, the convergence and the goodness of the classical
solution are analyzed, too. Finally, as the problem of the Euler shear buckling stress evaluation is a very important topic for a variety of structures, (e.g. ship ones), two numerical applications are carried out, in order to highlight the role of the uniaxial stresses on the plating scantling procedures and the goodness of the proposed formulas.

ABSTRACT: An efficient beam-column approach, using an improved step-by-step numerical method, is developed in the current research for studying the ultimate strength problems of stiffened panels with two load cases: 1) under longitudinal compression, and 2) under transverse compression. Chapter 2 presents an improved step-by-step numerical integration procedure based on (Chen and Liu, 1987) to calculate the ultimate strength of a beam-column under axial compression, end moments, lateral loads, and combined loads. A special procedure for three-span beam-columns is also developed with a special attention to usability for stiffened panels. A software package, ULTBEAM, is developed as an implementation of this method. The comparison of ULTBEAM with the commercial finite element package ABAQUS shows very good agreement.

The improved beam-column method is first applied for the ultimate strength analysis of stiffened panel under longitudinal compression. The fine mesh elasto-plastic finite element ultimate strength analyses are carried out with 107 three-bay stiffened panels, covering a wide range of panel length, plate thickness, and stiffener sizes and proportions. The FE results show that the three-bay simply supported model is sufficiently general to apply to any panel with three or more bays. The FE results are then used to obtain a simple formula that corrects the beam-column result and gives good agreement for panel ultimate strength for all of the 107 panels. The formula is extremely simple, involving only one parameter: the product $\lambda \Pi_{\text{orth}}^2$.

Chapter 4 compares the predictions of the new beam-column formula and the orthotropic-based methods with the FE solutions for all 107 panels. It shows that the orthotropic plate theory cannot model the “crossover” panels adequately, whereas the beam-column method can predict the ultimate strength well for all of the 107 panels, including the “crossover” panels. The beam-column method is then applied for the ultimate strength analysis of stiffened panel under transverse compression, with or without pressure. The method is based on a further extension of the nonlinear beam-column theory presented in Chapter 2, and application of it to a continuous plate strip model to calculate the ultimate strength of subpanels. This method is evaluated by comparing the results with those obtained using ABAQUS, for several typical ship panels under various pressures.

ABSTRACT: Three blade-stiffened CFRP panels with co-cured stiffener webs, manufactured by means of an elastomeric mould, have been tested under compressive load. Several Bragg grating sensors have been surface bonded on two of the stiffened panels and have been embedded into the stiffener webs of the third panel. The Bragg grating sensors measured the strain distribution in the stiffener web and in the skin panels. The buckling onset was clearly detected in every case, the post-buckling behaviour can be tracked, but the information is heavily dependent on the right choice of the sensor position and the buckling mode. To calibrate the system, and to evaluate the influence of different curing pressures, and the use of unidirectional or fabric prepreg material, tensile test specimens were made on flat panels. The strain measurements provided by the optical fibre sensors in tensile tests were compared with the strain measurements provided by conventional clamp extensometers.

ABSTRACT: The nonlinear stiffness equations that predict local and post-local buckling of plates and plate assemblies are given. These equations are validated by accurate predictions of independent test results. The elastic local buckling of longitudinally stiffened web plates in combined bending and compression is considered. Graphs which may be used to predict the optimum position of a stiffener are presented. The relationship between the area and second moment of area of a stiffener of finite dimensions that optimizes the local buckling coefficient is given for various eccentricities of end load. The post-local buckling of a longitudinally stiffened plate in uniform compression and pure bending is also considered. It is shown that the provision of a longitudinal stiffener, of proportions to enforce a node at the plate–stiffener junction, enhances significantly the postbuckling response of the plate with regard to the serviceability limit state, particularly for the case of pure bending.

ABSTRACT: The buckling of an elastic plate with arbitrary shape flush-mounted on a rigid wall and deforming under the action of a uniform tangential load due to an overpassing simple shear flow is considered. Working under the auspices of the theory of elastic instability of plates governed by the linear von Kármán equation, an eigenvalue problem is formulated for the buckled state resulting in a fourth-order partial differential equation with position-dependent coefficients parameterized by the Poisson ratio. The governing equation also describes the deformation of a plate clamped around the edges on a vertical wall and buckling under the action of its own weight. Solutions are computed analytically for a circular plate by applying a Fourier series expansion to derive an infinite system of coupled ordinary differential equations and then implementing orthogonal collocation, and numerically for elliptical and rectangular plates by using a finite-element method. The eigenvalues of the resulting generalized algebraic eigenvalue problem are bifurcation points in the solution space, physically representing critical thresholds of the uniform tangential load above which the plate buckles and wrinkles due to the partially compressive developing stresses. The associated eigenfunctions representing possible modes of deformation are illustrated, and the effect of the Poisson ratio and plate shape is discussed.

T. Morimoto and Y. Tanigawa (Dept. of Mechanical Systems Engineering, Osaka Prefecture University, Japan),

SUMMARY: A linear buckling analysis is carried out for orthotropic inhomogeneous rectangular plates under uniform in-plane compression. It is assumed that material inhomogeneities of Young's modulus and shear modulus of elasticity are continuously changed in the thickness direction with the power law of the coordinate variable, while Poisson's ratio is assumed to be constant. The buckling equation can be successfully constructed as the linearized von Kármán plate model by introducing the newly defined position of the reference plane which enables us to easily deal with the problem. The critical buckling loads of the simply supported rectangular plate are presented using the derived fundamental relations. Effects of material inhomogeneity, material orthotropy, aspect ratio, width-to-thickness ratio and load ratio are discussed.

3. Feldman, E., Aboudi, J. 1997 Buckling analysis of functionally graded plates subjected to uniaxial loading Compos. Struct.382936
OVERVIEW: Whereas the classical theory of plates is limited to situations in which deflections of the plate are small compared with the plate thickness, the von Kármán theory considered here has been shown to be valid for problems in which the transverse deflection is of the same order as the plate thickness, although small in comparison with the other plate dimensions. This theory makes use of the nonlinear strain–displacement relations in which quadratic terms in the slopes of the plate middle surface are retained but is otherwise consistent with the basic assumptions of the classical theory. The associated governing equations of motion for homogeneous isotropic plates and heterogeneous anisotropic plates are presented. Both the displacement formulation and the stress-function formulation addressed here entail coupled, nonlinear differential equations, and due to their complexity, it is generally necessary to employ approximations...

ABSTRACT: Thermally-induced large-deflection behaviors of laminates, including flat plates and cylindrical and doubly-curved panels, are investigated. The finite element technique based on the first-order shear deformation theory is employed to predict the shell response. Post-critical equilibrium paths are traced using the arc-length and the Riks methods. Laminate strength is also predicted, based upon the Tsai-Wu criterion.
ABSTRACT: The presence of elevated temperature and absorbed moisture can alter significantly the structural response of fibre-reinforced laminated composites. A hygrothermal environment causes degradation in both strength and constitutive properties, particularly in the case of fibre-reinforced polymeric composites. Furthermore, associated hygrothermal expansion, either alone or in combination with mechanically induced deformation, can result in buckling, large deflections, and excessively high stress levels. Consequently, it is often imperative to consider environmental effects in the analysis and design of laminated systems.

ABSTRACT: Based on both moderate and finite rotation bending theories of thin elastic shells including shear deformation, adaptive non-linear static finite element analysis is treated within a displacement approach and h-adaptivity. The a posteriori error indicator given by Rheinboldt, gained by linearization, is investigated in order to decide whether the deformations influence the indicator explicitly and how parameter dependent problems (like the Reissner-Mindlin model) behave in the process of adaptation. In order to achieve overall consistency, dimensional adaptivity (to 3-D elasticity) is implemented within disturbed subdomains, especially at supports. Results are that Rheinboldt’s error indicator is valid under certain restrictions but not directly at bifurcation points and that robustness is not improved by adaptation. Nested quadrilateral finite elements are used for studying pre- and post-buckling states of plates and shells.

ABSTRACT: Power generation is one of the thrust areas for priority investment in developing countries. Cooling towers have become essential structures in many of the super thermal and nuclear power plants. Much technology transfer is taking place at an international level in the areas of thermal and structural design of natural draught cooling towers in concrete. One of the more controversial topics in such technology transfer is buckling safety of the hyperboloidal cooling tower shell. This paper presents a comparative evaluation of the recommendations, in this area, of some of the important national and international codes of practice, by way of case studies on five different cooling towers.

ABSTRACT: Analyses to predict inelastic buckling of axially loaded thin cylindrical shells are carried out.
using the finite element technique. The analyses use a bilinear elastic-perfectly plastic material response based upon the associated flow rule of plasticity. Nonlinear geometric effects, combined with initial imperfections, produce load-deflection curves with descending branches for which the limit points are imperfection sensitive. Results from these analyses are compared with two tests of axially loaded cylinders fabricated from 10-gauge (3.4-mm) and 5-mm plate and approximately 1525 mm in diameter. These tests were carried out in the Structural Engineering Laboratory at the University of Alberta. A rational technique for using measured imperfections to obtain effective initial imperfections for use in the analyses is investigated, and is shown to result in accurate predictions of ultimate load.

ABSTRACT: Solution procedures based on arc-length control have been among the most successful to be applied in nonlinear structural analysis. However, in the course of applying this type of procedure to postbuckling analysis of pipe segments, the writers experienced difficulties with the occurrence of complex roots arising from the arc-length constraint equation and with determining the direction of the load increment. In this paper, modified formulations of the arc-length control criterion and the loading criterion are proposed to address these problems. Applications of the procedures are shown to be successful for postbuckling analysis of pipe segments. Their effectiveness in following and advancing on the equilibrium path for both snap-through and snap-back behavior is illustrated.

ABSTRACT: A method is presented to incorporate the local buckling behavior of line pipe, determined from three-dimensional large deformational elastic-plastic shell analysis, into an interactive soil-structure beam model of a pipeline. The finite element model for the analysis of the pipe as a shell is described and the influence on the results of the buckling analysis of various load combinations are examined from the point of view of buckling configurations, moment-curvature curves and cross-sectional deformations. A method of extracting the stiffness properties of the pipe from these analyses is then described and a technique for determining stiffness coefficients from these properties is developed.

-----ABAQUS Underground pipe buckling
Journal of the Brazilian Society of Mechanical Sciences and Engineering
ABSTRACT: A quasi-bifurcation theory of dynamic buckling and a simple flow theory of plasticity are employed to analyze the axisymmetric, elastic-plastic buckling behavior of buried pipelines subject to seismic excitations. Using the seismic records of the 1971 San Fernando earthquake, a series of numerical results have been obtained, which show that, at strain rates prevalent in earthquakes, the dynamic buckling axial stress or strain of a buried pipe is only slightly higher than that of static buckling.

ABSTRACT: The paper proposes a new approach of predicting the bifurcation points of elastic-plastic buckling of plates and shells, which is obtained from the natural combination of the Lyapunov’s dynamic criterion on stability and the modified adaptive Dynamic Relaxation (maDR) method developed recently by the authors. This new method can overcome the difficulties in the applications of the dynamic criterion. Numerical results show that the theoretically predicted bifurcation points are in very good agreement with the corresponding experimental ones. The paper also provides a new means for further research on the plastic buckling paradox of plates and shells.

ABSTRACT: Initial imperfections have long been acknowledged as having an effect on the behavior of shell structures, affecting both the global and local behavior. Yet, despite their significance, initial imperfections are rarely included in analytical models for pipelines. This is usually because of the complicated nature of initial imperfections, the difficulty in measuring them, and the small amount of available literature that describes their geometry. Some recent investigations at the University of Alberta in Edmonton have focused on the effect of initial imperfections on the behavior of segments of line pipe. Imperfections measured across the inside surface of pipe test specimens were incorporated into a finite element model that was developed to predict the experimental behavior of the specimens tested under combined loads of internal pressure, axial load and
bending moment. Test-to-predicted ratios for the load carrying capacity of the test specimens had a mean value of 1.035 with a coefficient of variation of 0.047. The improvements in the accuracy of the finite element analysis models that include the initial imperfection pattern indicate their importance in modeling the experimental behavior. Once the importance of initial imperfections was established, idealized patterns were developed to simplify numerical modeling. This paper presents the results of different patterns investigated for both plain and girth-welded segments of line pipe and provides recommended simplified assumed initial imperfection patterns.

Yaw-Jeng Chiou and Shue-Yeong Chi, “Beam and Shell Modes of Buckling of Buried Pipes Induced by Compressive Ground Failure”, ASCE Lifeline Earthquake Engineering (1995), pp. 176-183

ABSTRACT: The buckling of buried pipeline induced by compressive ground failure was investigated. Both the beam mode of buckling and local shell mode of buckling, and their interactions were studied. The pipeline response was analyzed numerically. The results agree qualitatively with past researches and possess satisfactory comparisons with actual case histories. The relations of critical buried depth versus ratio of pipe diameter to thickness for buried pipe with different imperfections and various soil foundations were established.

ABSTRACT: A shell model which takes into account the dynamic interaction terms for the earthquake behaviour of buried pipes is presented. A more realistic ground motion input for seismic waves is chosen in the analysis. Then a parametric study is conducted to investigate the effects of pipe radius, slenderness of the pipe, soil stiffness and wave propagation velocity on the modal amplitudes.

ABSTRACT: The Donnell and Flügge forms of the stability equations of cylindrical shells are employed to analyze the axisymmetric, elastic quasi-static buckling of buried pipelines subject to seismic excitations. Using shell dimensions and the stiffness of the soil medium surrounding the pipe as parameters, a series of numerical results are obtained, which shows that no significant half sine wave occurring in the circumferential direction for relatively long pipes when axial buckling load reaches its minimum. It also is shown that for a given pipeline an increase in soil stiffness causes a decrease in wavelength of the critical-load instability mode and, consequently, causes an increase in axial critical load.

ABSTRACT: This paper deals with the tensile failure of buried pipelines subject to abrupt fault movements. The pipe is modeled as a thin cylindrical shell which is essentially semi-infinite. The Sanders nonlinear shell theory is used with the inclusion of soil effects, and a simple flow theory of plasticity. A number of parametric studies are carried out and discussed to identify some design parameters of buried pipelines.

ABSTRACT: An analysis method for the buckling process of a pipe section with a random pipelay imperfection is proposed. Four basic lateral modes, acquired by finite-element (FE) eigenvalue buckling analysis, are combined to provide the needed grid configurations for describing a real pipelay imperfection and an arc-length algorithm is used to analyze the snap-through process of the shell-element-grid model under nonlinear frictional boundary conditions. This paper also presents evaluation methods for the lateral buckling of two types of pipe-in-pipe systems that are used in the offshore oil and gas industry. For evaluating the buckling and postbuckling of compliant pipe-in-pipe systems FE analyses were carried out to judge the occurrence of the system buckling and furthermore to check postbuckling stresses induced in the buckles. The calculated results of the modified Riks algorithm indicate that only when high temperature would not trigger an abrupt short-wavelength buckle and when no yielding has been induced in the unavoidable long-wavelength buckles, the thermal stability and safety of compliant pipe-in-pipe systems can be proved. In the non-compliant pipe-in-pipe systems, firstly
small-amplitude buckles of the carrier pipe may occur in the annulus between carrier pipe and casing pipe and the contact forces between the spacers and the casing pipe may drive the buckle of the pipe-in-pipe systems on the seabed. Based on the classical analytical solution of pipe buckling, four potential buckling modes corresponding to finite-element models are developed to evaluate the stability and the postbuckling strength of such pipe-in-pipe systems.

ABSTRACT: The currently valid worldwide standards allow for taking into consideration plastic deformations in order to achieve a higher degree of utilization. The maximum plastic strains, which can be allowed for steel pipes subjected to internal pressure and additional loads, are particularly interesting. In this paper results of investigations on the elasto-plastic bearing behavior of steel pipelines subjected to internal pressure and bending are presented. Four-point bending tests on eight steel pipes were carried out in order to make the buckling analysis in the elasto-plastic range possible. Finite-element-models were checked by test results for the application on buried pipelines. Taking into account bedding conditions of the pipeline in the soil was made possible. Furthermore, an analytical method based on the differential equation for beams with longitudinal tensile force and variable bending stiffness was developed. It is suitable to determine the elasto-plastic bearing capacity for internal pressure and bending. The collapse due to plastic shell buckling is considered by a limit criterion based on critical strains.

ABSTRACT: A new kind of tower construction, calling hybrid tower, is developed for offshore wind energy converters. The tower sections consist of two steel shells which are bonded together with a core material. The core between the inner an outer steel face increases the stability of the shells. In comparison with linear buckling analyses the validity of a laminate composite shell theory was proven. With model scale tests the stability of sandwich shells was analyzed against shell buckling due to axial compression and compared to tests with steel shells. Optical measurements were used to record the geometrical imperfections and to import the imperfect geometry of such shells in FE-models. Furthermore, a comparison of critical buckling loads was carried out with numerical solutions. The test series show a significant increase in bearing capacity for sandwich cylinders, which depends on the compressive strength of the core materials. The sandwich shells with a grout as core material show a catastrophic post buckling like steel shells. In contrast to this the elastomer core supports a ductile post buckling. The failure criteria for all variants of tested sandwich shells is more a local failure due to the steel faces called face wrinkling and not a global shell buckling.

ABSTRACT: The cylindrical shell with rectangle stiffeners was usually utilized in coal mine refuge chambers. Aiming at the buckling deformation of thin cylindrical shell under uniform axial compression, finite element analysis software ANSYS was employed to set up the optimization model of stiffened cylindrical shell, and the sequential linear programming method was executed to optimize the thickness of shell and the sizes of stiffener. The mechanical property after optimization was compared with the theoretical value of no-stiffener shell with equal volume, and reasonable stiffener distribution was obtained while the optimization results of five different longitudinal and circumferential stiffener patterns were gained. The results showed that the shell’s mechanical capacity of axial compression was basically not improved when the stiffeners were too sparse or overcrowded. Nevertheless, in the condition of reasonable stiffeners distribution, it could be improved by approximately 50%. The stiffener pattern and optimal results obtained in this paper are useful for refuge chamber’s shell design.

ABSTRACT: Lightweight yet stiff and strong lattice structures are attractive for various engineering applications, such as cores of sandwich shells and components designed for impact mitigation. Recent breakthroughs in manufacturing enable efficient fabrication of hierarchically architected microlattices, with dimensional control spanning seven orders of magnitude in length scale. These materials have the potential to exploit desirable nanoscale-size effects in a macroscopic structure, as long as their mechanical behavior at each appropriate scale – nano, micro, and macro levels – is properly understood. In this letter, we report the nanomechanical response of individual microlattice members. We show that hollow nanocrystalline Ni cylinders differing only in wall thicknesses, 500 and 150 nm, exhibit strikingly different collapse modes: the 500 nm sample collapses in a brittle manner, via a single strain burst, while the 150 nm sample shows a gradual collapse, via a series of small and discrete strain bursts. Further, compressive strength in 150 nm sample is 99.2% lower than predicted by shell buckling theory, likely due to localized buckling and fracture events observed during in situ compression experiments. We attribute this difference to the size-induced transition in deformation behavior, unique to nanoscale, and discuss it in the framework of “size effects” in crystalline strength.

ABSTRACT: The John equations are used to model the buckling of a simply-supported elastic spherical cap that is subjected to a constant uniform external load $\lambda$. The Liapunov-Schmidt method is used to solve these equations. We show that solutions possessing circular, pear-shaped, elliptical, triangular, square-shaped, pentagonal and a variety of other symmetries branch from the unbuckled state of the shell. The stability of these solutions is discussed. Some numerics that complement the analytical results are also included.

ABSTRACT: Pumpkin balloon designs such as the constant-bulge-angle design, the constant-bulge-radius design, and hybrids of these design schemes have been used in an attempt to achieve a cyclically symmetric pumpkin-like shape when fully inflated. A number of flight balloons that were built based on these three design concepts encountered deployment problems. . . . Currently, NASA’s approach to superpressure balloon design uses a constant-stress model developed at NASA Goddard Space Flight Center. To fully understand the mechanism behind cleft formation in pumpkin balloons and to explore the constant-stress design space, NASA’s Balloon Program Office carried out a series of inflation tests in 2007 involving four 27-meter-diameter 200-gore pumpkin balloons. . . . In an effort to gauge constant-stress design susceptibility to deployment problems, we carry out a number of parametric studies and assess the stability landscape of the constant-stress design space. In our studies, we examine two types of top end-fitting boundary conditions, one restrictive and one less restrictive, that help to define a cleft-free design envelope. . . . To study scaling effects, we consider a
14-million-cubic-foot design. Our analysis suggest that as one scales up the balloon, the size of the cleft-free envelope shrinks.

SUMMARY: The post-buckling behavior of an elastic spherical shell is studied for large axisymmetric deformations. The complete post-buckling path is given for the experimentally confirmed single dimple solution in a load-deformation diagram, making use of the methods of local bifurcation theory, singular perturbation analysis and numerical analysis. From the specific form of the post-buckling path with its predominating unstable part follows the strong imperfection sensitivity of the shell structure.

ABSTRACT: For the axisymmetric buckling problem of a complete spherical shell we are able to give a complete imperfection sensitivity analysis for the most complicated case to occur, namely that of a double eigenvalue, if we restrict our analysis to nonlinear terms of quadratic order, which is correct mathematically as the bifurcation system turns out to be two determinate. As we make a classical bifurcation analysis our results are strictly local and therefore are of restricted practical importance in two respects. Firstly we do not take care of the fact that we have closely spaced eigenvalues. We comment on this in chapter 7. Secondly we are not able to show that the experimentally observed single dimple solution (Fig. 8) is one of the stable solutions found from our bifurcation equations up to terms of third order.

ABSTRACT: A constructive method is developed to establish the existence of buckled states of a thin, flat elastic plate that is rectangular in shape, simply supported along its edges, and subjected to a constant compressive thrust applied normal to its two short edges. Under the assumption that the stress function and the deformation of the plate are described by the nonlinear von Kármán equations, the approach used yields information regarding not only the number of buckled states near an eigenvalue of the linearized problem, but also the continuous dependence of such states on the load parameter and the possible selection of that buckled state “preferred” by the plate. In particular, the methods used provide a rigorous approach to studying the existence of buckled states near the first eigenvalue of the linearized problem (that is, near the “buckling load”) even when the first eigenvalue is not simple.

References listed at the end of the paper:

ABSTRACT: A method is outlined to obtain the “preferred” buckled states of a (complete) spherical shell under uniform external pressure. The shell model investigated is that of the John equations, a system of six nonlinear partial differential equations. Methods in bifurcation theory and group representations are used to reduce the problem to a finite-dimensional problem whose solutions generate buckled states that are “preferred” in a certain least-energy sense. Asymptotic methods and Newton's method are used in some special cases to relate the “preferred” buckled states obtained by the above approach to actual buckled states observed in experimental studies.

References listed at the end of the paper:

SUMMARY: A finite element method of mixed type is proposed to solve the Dirichlet problem of the von Kármán equations. Existence and convergence of the approximate solution are proved.

References listed at the end of the paper:

SUMMARY: The purpose of this paper is to study the approximation of the Von Karman equations by the mixed finite element scheme of Miyoshi and to follow the solutions arcs at a neighbourhood of the first eigenvalue of the linearized problem. This last problem is solved by a continuation method.

ABSTRACT: In preparing a Swedish handbook on stability of shell structures it was contended that present design codes and recommendations, with few exceptions, employ rather crude rules and also severe tolerance limits especially concerning spherical domes manufactured on site. A re-evaluation of test results available for metal domes subjected to external pressure was made with the aim of establishing a more refined procedure to determine a safe knock-down function to be applied to classical linear buckling strength. In the treatment of the test results a computer program was used allowing a statistical analysis.

“Stability analysis of plates and doubly curved shallow shell structures using finite element methods and applications of MSC/NASTRAN”, (publisher and date not given in the pdf file. Most recent citation is dated 1995.)

ABSTRACT: A variational formulation of doubly curved shallow shells is presented. The analysis used Reissner’s two-field variable variational principle with the transverse displacement w and Airy stress function $F$ as field variable. Euler-Lagrange equations and boundary conditions are obtained. A finite element based on this variational principle preserving $C^1$ continuity is formulated, and your eigenvalues for free vibrations and buckling analyses are obtained. Applications for free vibrations and buckling analysis in MSC/NASTRAN model are given as well as their respective geometry shape. Several numerical calculations are presented. The results obtained are discussed and are compared with previous analytical solutions and numerical calculations.

ABSTRACT: A method is presented for formulating stiffness terms and thermal coefficients of stiffened, fiber-reinforced composite panels. The method is robust enough to handle panels with general cross sectional shapes, including those which are unsymmetric and/or unbalanced. Nonlinear, temperature and load dependent constitutive material data of each laminate are used to ‘build-up’ the stiffened panel membrane, bending, and membrane-bending coupling stiffness terms and thermal coefficients. New thermal coefficients are introduced to quantify panel response from through-the-thickness temperature gradients. A technique of implementing this capability with a single plane of shell finite elements using the MSC/NASTRAN analysis program (FEA) is revealed that provides accurate solutions of entire airframes or engines with coarsely meshed models. An example of a composite, hat-stiffened panel is included to demonstrate errors that occur when an unsymmetric panel is symmetrically formulated as traditionally done. The erroneous results and the correct ones produced from this method are compared to analysis from discretely meshed three-dimensional FEA.

ABSTRACT: The benefits of a software package which couples with the MSC/NASTRAN FEA program is presented. The software, called HyperSizer, performs panel and beam structural sizing optimization with metallic and composite materials. Applications in the aerospace and transportation industries are presented. The aerospace application, an X-34x experimental vehicle, emphasizes capabilities and accuracy required for a high speed flight, thermomechanical environment. The transportation application emphasizes practical and inexpensive capabilities suitable for a cost driven, manufacturing oriented environment.

Abstract Thin cylindrical shells are widely used in modern structures. When the structures are under axial compression, inflectional destruction happens early. In order to design reasonable and reliable shell structures, stiffened cylindrical shells are applied in the dissertation, ANSYS, an valid finite element analysis software, is employed to redevelop and set up parameter calculation model, subjected to volume and variables value range restriction, the structure’s critical buckling load is the objective, and the serial linear programming optimization procedure is executed as well as the optimized thickness of shell and the size of stiffeners are gained accordingly. The critical buckling load of the structure is obviously increased after optimization, and the feasibility of this method is validated due to the comparison with the numerical and theoretical result.

University of Lubxxxx Buckling lecture ESDEP WG 1B: Lecture 1B.8: Learning from Failures

ABSTRACT: Research results concerning the simulation of the crushing behaviour of composite systems with energy absorption characteristics are presented in the present work. The study is focused on the ‘tensor skin’ concept, an energy absorbing composite system that was originally developed to improve the crashworthiness of helicopters under water impact and which is promising for utilization in the construction of the lower part of
composite fuselage aircraft. The ‘tensor skin’ concept comprises a folded or corrugated composite construction, which upon loading unfolds by forming ‘plastic hinges’, leading to an increase in the load bearing capability of the structure. The numerical modelling issues and the critical aspects of the simulation are discussed. Verification of the numerical simulation procedure is performed by experimental work. The experimental results utilized to assess and validate the numerical procedure were derived within the European Research Project ‘Design for Crash Survivability – CRASURV’ (BRITe – Aeronautics Area). The results of the simulations are generally in good agreement with experimental data.

----

ABSTRACT: The purpose of this paper is to present an efficient engineering methodology for solving the problem of non-linear (NL) damage and post-buckling of large-scale structures, which is of high importance mainly for the aircraft industry. The methodology takes advantage of the capabilities of finite element substructuring technique in the simulation of large/complex structures and exploits the advantages of local-global analysis logic. The main innovation deals with the appropriate modification of superelement method, such that it can deal with NL behaviour and efficiently model the entire large-scale structure. In this study, the proposed methodology is demonstrated in the treatment of geometrical non-linearity and its efficiency is assessed in the case of a large-scale fuselage section.

ABSTRACT: A methodology for the analytical assessment of local buckling and post-buckling behavior of isotropic and orthotropic stiffened plates is presented. The approach considers the stiffened panel segment located between two stiffeners, while the remaining panel is replaced by equivalent transverse and rotational springs of varying stiffness, which act as elastic edge supports. A two-dimensional Ritz displacement function (pb-2 Ritz) is utilized in the solution of the local buckling problem of isotropic and laminated symmetric composite panels with arbitrary edge boundary conditions. The buckling analysis of the segment provides an accurate and conservative prediction of the panel local buckling behavior. Consequently, the developed methodology is extended in the prediction of the post-buckling response of stiffened panels of which the skin has undergone local buckling. Of high importance for the calculation of the post-buckling behavior is the selection of appropriate boundary conditions for the structural members analyzed. A comparison of the present methodology results to respective finite element (FE) results has shown a satisfactory agreement.

ABSTRACT: In this paper an outline is given of a theoretical approach which is able to predict the equilibrium behaviour of thin-walled, pin-ended, I-section columns after local buckling. The extreme changes in cross-sectional shape that occur during overall bending of the locally buckled column are accounted for quite easily in the analysis by the inclusion of several local deflection shape functions. The changes in cross-sectional shape that occur during the pure compression phase of behaviour, prior to overall bifurcation, are also accounted for in the analysis. The Rayleigh-Ritz method is used to obtain local buckling loads and a semi-energy method is employed to describe post-buckling interaction behaviour. It is shown that, although all columns exhibit stable equilibrium behaviour after local buckling, the quality of the equilibrium at failure due to overall bifurcation, can be unstable to varying degrees depending on geometry. It is also shown that the theoretical predictions of equilibrium behaviour and ultimate loads are significantly influenced by the number of local deflection shape functions incorporated in the post-buckling analysis. If insufficient functions are employed in the solution, a considerable overestimate of stiffness and hence ultimate load can result. The analysis is able to accommodate eccentricity of applied loading and column axis imperfection in which case, overall bending would occur from the onset of loading. A study is made of the effect of column axis imperfection on the ultimate carrying capability of thin-walled I-section columns and it is shown that, I-sections are appreciably sensitive to this mode of imperfection over a wide design range. Results are presented in the paper in the form of load-deflection equilibrium curves and ultimate load-slenderness plots. A comparison of the theory with independent experimental work is also included and agreement is seen to be good.

ABSTRACT: In the present contribution a novel fast design tool is developed to enable the calculation of critical buckling loads of large structural components comprising stiffened composite panels. In more detail the development of analytical closed form solution for the local buckling problem of a stiffened plate is treated as the buckling of the skin segment enclosed by two consecutive stringers. In this case the effect of the stringers to the skin is modeled by applying appropriate elastic restraints as boundary conditions. The elastic restraints are derived and determined considering the bending and torsional stiffness of the stringers. The solution of the skin local buckling problem is obtained utilizing the Rayleigh-Ritz method. Additionally, the developed closed form solution is extended to the interesting case of anisotropic stiffened panels. Finally, the validation of the analytical results is obtained comparing them with the respective numerical, and a satisfactory correlation is achieved.

ABSTRACT: A stiffened panel demonstrator component typical of that used in the shipbuilding industry was conceived to demonstrate the advantages of three dimensional laser processing using robot manipulated 4kW Nd:YAG lasers. BS EN 10025:1991 Grade S275JR (formally BS 4360: Grade 43D) material in the 6-8mm-thickness range was used. Initial parameter development preceded the fabrication of a 1mx1m test panel and the eventual production of a 4.8mx1.9m full size panel section for destructive testing. Equipment set-up, joint design, effect of fit-up, processing techniques and distortion are described. The completed panel was used to compare the level of distortion induced between laser and conventional arc welding processes, before being used to conduct a similar buckling test comparison.

ABSTRACT: The design wall thickness of many corrugated silos and tanks is governed by the vertical compressive strength of the wall. This paper presents a precise theoretical study of the collapse strengths of cylindrical corrugated shells under axial compression and axial compression combined with internal pressure. Two simple models to describe the collapse strength are proposed, and each is shown to be approximately valid for a certain range of geometries. The true collapse strength is determined using a large displacement elastic-plastic finite element analysis for doubly curved shells of revolution. The form of the corrugation profile is accurately modelled and the collapse strength is found precisely by following the complete loading and unloading paths of the load-deflection curve. Simple design recommendations are given.

ABSTRACT: A very large literature exists on the static analysis of thin shell structures, covering elastic stress states, elastic buckling, plastic collapse and elastic-plastic failures. Modern approaches to these problems usually involve the use of computer programs to perform a variety of different alternative types of calculation. However, the way in which different analyses should be used in the design process has received much less attention until recently. The new European Standard for the Strength and Stability of Shells sets out a philosophical framework that accommodates the results of both algebraic analysis and different levels of sophistication in computer analyses. This paper describes the philosophy on which the new standard is based, and outlines the way in which the various analyses should be used, when applied in design practice. It also identifies some of the remaining difficulties which pose challenges of definition and interpretation, and which need debate in the scientific community.

ABSTRACT: Metal silos and tanks are subject to axial compressive stresses in their cylindrical shell walls. The buckling strength is very sensitive to geometric imperfections in the wall. The most regular and well-defined imperfection is the local depression adjacent to a circumferential weld, caused by the plate rolling process and shrinkage of the weld. This paper examines the elastic buckling strengths of thin cylindrical shells under axial compression, with imperfections arising at circumferential welded joints. The effects of the welded joint depression amplitude, the shell radius-to-thickness ratio, a change of shell plate thickness at the weld, and internal pressurization are all examined. The study is confined to cylinders with a radius-to-thickness ratio in excess of 100, as thicker shells are rare for these structures. It is shown that a welded joint depression is one of the most deleterious practical imperfection forms currently known.

ABSTRACT: Conical shells are often joined to cylindrical shells as end closures, reducers or roofs. Under a variety of loading conditions, the intersection between the large end of a cone and a cylinder is subject to a large circumferential compressive force which can lead to its failure by buckling. The problem may be idealized as a cone-cylinder intersection under a radial inward ring load. This paper first investigates the elastic buckling strength of thin cone-cylinder intersections under a radial inward ring load and develops simple and accurate equations for the prediction of buckling mode and strength. The ability of ring-loaded intersections to conservatively represent intersections under a variety of other loading conditions for their buckling behaviour is then explored. The ring load idealization is shown to be generally conservative, but may become rather conservative for some loading conditions such as uniform internal pressure. The strength of cone-cylinder intersections under uniform internal pressure is examined in detail in the final part of the paper and approximate strength equations are also developed, as this loading condition is important for pressure vessel and piping applications.
