ABSTRACT: The stiffened rectangular plate was usually adopted in the blast airtight doors. In order to improve the buckling capacity of stiffened rectangular plate under uniform normal compression, the optimization model of stiffened rectangular plate was set up based on APDL and ANSYS commands, and the sequential linear programming method was executed to optimize the thickness of plate and the sizes of stiffeners. Moreover, we compared the mechanical property of the optimized stiffened rectangular plate with the theoretical value of no-stiffener plate with equal volume, and obtained the reasonable stiffener distribution based on the optimization results of five different longitudinal and transverse stiffener patterns. The results showed that the buckling
capacity of stiffened rectangular plate under uniform normal compression could be improved by approximately 50% on the condition of reasonable stiffeners distribution.

ABSTRACT: In this paper, we study the equilibrium states of a compressible hyperelastic layer under compression after the primary and secondary bifurcations. Starting from the two-dimensional field equations for
a compressible hyperelastic material, we use a methodology of coupled series-asymptotic expansions developed earlier to derive two coupled non-linear ordinary differential equations (ODEs) as the model equations. The critical buckling stresses are determined by a linear bifurcation analysis, which are in agreement with the results in the literature. The method of multiple scales is used to solve the model equations to obtain the second-order asymptotic solutions after the primary bifurcations. An analytical formula for the post-buckling amplitudes is derived. Two kinds of numerical solutions are also obtained, the numerical solutions of the model equations by a difference method and those of the two-dimensional field equations by the finite elements method. Comparisons among the analytical solutions, numerical solutions and solutions obtained by the Lyapunov–Schmidt–Koiter (LSK) method in the literature are made and good agreements for the displacements are found. It is also found that at some places the axial strain is tensile, although the layer is under compression. To consider the secondary bifurcation, we superimpose a small deformation on the state after the primary bifurcation. With the analytical solution of the primary bifurcation, we manage to reduce the problem of the secondary bifurcation to one of the first bifurcations governed by a second order variable-coefficient ODE. And, our analysis identifies an explicit function and from the existence/non-existence of its zero one can immediately judge whether a secondary bifurcation can take place or not. The zero corresponds to a turning point of the governing ODE, which leads to non-trivial solutions. Further, by the WKB method the equation (in a very simple form) for determining the critical stress for the secondary bifurcation is derived. We further use AUTO to compute the secondary bifurcation point numerically, which confirms the validity of our analytical results. The numerical solution in the secondary bifurcation branch is also computed by AUTO. It is found that the secondary bifurcation induces a “wave number doubling” phenomenon and also the shape of the layer has a convexity change along the axial direction.

ABSTRACT: Thermal buckling analysis of multi-layered composite spheroidal spherical shells with clamped boundary condition under uniform distribution thermal load is investigated using the finite element method to produce the theoretical modeling. The results obtained are compared with the know data in the literature for composite shells. The effect of important parameter spherical angle, fiber orientation, number of layers of composite shell and radius to thickness ratio are taken in to consideration on the structure stability.

ABSTRACT: It is desired to calculate the critical buckling pressure in double wall cryogenic storage tank. These storage tanks are usually composed of two separated walls in which the inner wall is responsible to store the cryogenic liquid. The space between two walls should be filled by loose perlite to minimize heat transfer from ambient. So, it is expected to expose an external pressure more than vapor pressure on inner tank wall. The results show that the accuracy of analytical equations is not acceptable and should be revised. So, in this study, new correlations were proposed based on numerical results obtained by Ansys.

ABSTRACT: This paper discusses CAE simulation methods to predict the thermal induced buckling issues when vehicle body panels are subjected to the elevated temperature in e-coat oven. Both linear buckling analysis and implicit quasi-static analysis are discussed and studied using a quarter cylinder shell as an example. The linear buckling analysis could produce quick but non-conservative buckling temperature. With considering nonlinearity, implicit quasi-static analysis could predict a relative conservative critical temperature. In addition, the permanent deformations could be obtained to judge if the panel remains visible dent due to the buckling. Finally these two approaches have been compared to thermal bucking behavior of a panel on a vehicle going through thermal cycle of e-coat oven with the excellent agreement on its initial design and issue fix design. In conclusion, the linear buckling analysis could be used for quick thermal buckling evaluation and comparison on a series of proposals. The implicit quasi static analysis is must to conduct to determine if a body panel will buckle or not and how much permanent deformation may remain in any thermal circumstance.

ABSTRACT: A good understanding of the mechanical behavior of functionally graded material (FGM) cylindrical shells is necessary for designers and researchers. However, the 3D transient response of FGM
cylindrical shells under various boundary conditions has not yet been analyzed. In this paper, the problem is addressed by proposing an approach integrating the state space method, differential quadrature method, and Durbin’s numerical inversion method of Laplace transform. The laminate model is used to obtain the transient solution in the radial direction. At the edges, four kinds of boundary conditions are considered: Clamped-Clamped, Clamped-Simply supported, Clamped-Free, and Simply supported-Simply supported. The results of the proposed method and finite element (FE) method agree with each other excellently. Convergence studies show that the proposed method has a fast convergence rate. The natural frequencies obtained by the proposed method, experiment, and other theoretical methods are in close agreement with each other. The effects of the load frequency and duration, length/outer radius ratio, and the (outer radius-inner radius)/outer radius ratio on the transient response of FGM shells are investigated. Two laws of variation of material properties along the radial direction are considered: the first has material properties varying according to an exponential law along the radial direction, while the second has material properties varying according to a power law. The effect of a functionally graded index on the transient response of FGM shells is investigated in both cases. The results obtained in this paper can serve as benchmark data for further research.

“Scaling instability in buckling of axially compressed cylindrical shells”,

ABSTRACT: In this paper we continue the development of mathematically rigorous hyperelastic theory of “near-flip” buckling of slender bodies of arbitrary geometry. In order to showcase the capabilities of this theory
we apply it to buckling of axially compressed circular cylindrical shells. The theory confirms the classical formula for the buckling load, whereby the perfect structure buckles at the stress that scales as the first power of shell’s thickness. However, in the case of imperfections of load, the theory predicts scaling instability of the buckling stress. Depending on the type of load imperfections, buckling may occur at stresses that scale as thickness to the power 1.5 or 1.25, corresponding to the lower and upper ends, respectively, of the historically accumulated experimental data. Thus, the theory provides the first mechanically rational and mathematically rigorous explanation of experimentally observed scaling laws.

ABSTRACT: The Suspended Latticed Intersected Cylindrical Shell (SLICS) is a new structural system, composed by the single layer Latticed Intersected Cylindrical Shell (LICS) and the prestressed cable-strut system. Mechanical properties of this structure were investigated through nonlinear buckling analysis by the consistent imperfect buckling analysis method, compared with the single layer LICS. Structure parameters including prestress level, member section, length of bar, rise-span ratio, obliquity were analyzed. And the effect of material nonlinearity on the stability was studied. Results show that the ultimate bearing capacity of the SLICS is improved as the introduction of prestress. However the prestress level has a limited impact on the ultimate bearing capacity. And the material nonlinear is very important to the stability of the SLICS.

ABSTRACT: This paper represents discussion about the Buckling mechanism in the cylindrical vessels and plates as buckling is characterized by sudden failure of structural member subjected to high compressive stress, where the actual compressive stress at the point of failure is less than the ultimate compressive stresses that the material is able to withstand. Pressure vessels are the equipments which are used for the storage of gases or liquids at specific temperature and pressure condition. The load carried by these pressure vessels also imparts forces on its shell structure which are likely to be buckle.

ABSTRACT: An experimental study is designed to understand the effect of delamination on critical buckling load and mode of failure for glass/carbon hybrid laminates. Firstly, delaminated specimens are compressed using a universal testing machine and buckling tests performed after the ends of each specimen are hinged to a special fixture designed to permit rotational boundary conditions. Non-linear buckling analysis based on incremental iteration method is conducted using finite element analysis (FEA) package (ANSYS) after conducting tensile tests to find the material properties. Critical buckling loads are found for symmetric [C0/G45/G-45/G90]s and anti-symmetric [C0/G45/G-45/G90//G90/G45/G-45/C0] laminate configurations with four different delamination lengths (a/L= 0.2, 0.3, 0.4 and 0.5) created at two different delamination positions (t/h = 0.5 and 0.25). In this study, the critical buckling load decreased as the delamination length increased. Moreover, the critical buckling load tended to decrease when the delamination approached the surface.

“An engineering analysis method for post-buckling of composite stiffened panels”, 29th Congress of the
ABSTRACT: The paper presents a project simplified theory and a method of calculating post-buckling loading capacity of composite stiffened panels based on the basic mechanics characters of composite materials, combining FEM theory and engineering experience. Composite J-stiffened panels are taken as an example to illustrate thinking and computational formula of post-buckling analysis from the perspective of engineering. The validity and effectiveness of the method are demonstrated with the experiment. It is shown the analysis method of stability loading capability can solve the geometric non-linear problem of composite stiffened panel structure load capability and keep high accuracy in the aero-structure design.

References listed at the end of the paper:

ABSTRACT: Most researches on the static performance of stiffened panel joined by friction stir welding (FSW) mainly focus on the compression stability rather than shear stability. To evaluate the potential of FSW as a replacement for traditional rivet fastening for stiffened panel assembly in aviation application, finite element method (FEM) is applied to compare compression and shear stability performances of FSW stiffened panels with stability performances of riveted stiffened panels. FEMs of 2024-T3 aluminum alloy FSW and riveted stiffened panels are developed and nonlinear static analysis method is applied to obtain buckling pattern, buckling load and load carrying capability of each panel model. The accuracy of each FEM of FSW stiffened panel is evaluated by stability experiment of FSW stiffened panel specimens with identical geometry and boundary condition and the accuracy of each FEM of riveted stiffened panel is evaluated by semi-empirical
calculation formulas. It is found that FEMs without considering weld-induced initial imperfections notably overestimate the static strengths of FSW stiffened panels. FEM results show that, buckling patterns of both FSW and riveted compression stiffened panels represent local buckling of plate between stiffeners. The initial buckling waves of FSW stiffened panel emerge uniformly in each plate between stiffeners while those of riveted panel mainly emerge in the mid-plate. Buckling patterns of both FSW and riveted shear stiffened panels represent local buckling of plate close to the loading corner. FEM results indicate that, shear buckling of FSW stiffened panel is less sensitive to the initial imperfections than compression buckling. Load carrying capability of FSW stiffened panel is less sensitive to the initial imperfections than initial buckling. It can be concluded that buckling loads of FSW panels are a bit lower than those of riveted panels whereas carrying capabilities of FSW panels are almost equivalent to those of riveted panels with identical geometries. Finite element method for simulating static performances of FSW and riveted stiffened panels is proposed and evaluated and some beneficial conclusions are obtained, which offer useful references for analysis and application of FSW to replace rivet fastening in aviation stiffened panel assembly.

DOI: 10.1016/j.tws.2011.02.001
ABSTRACT: The stiffened plate structures in ships and ship-shaped offshore installations often consist of non-uniform plate thicknesses. Nonlinear finite element methods are usually employed to predict structural strength for such panels. However, the introduction of non-uniform plate thicknesses renders such calculations difficult when analytical methods and design equations are used. The authors have suggested an equivalent plate thickness method that is based on the weighted average approach to analyse the strength of stiffened panels with non-uniform plate thicknesses. In the present paper, the validity of the equivalent plate thickness method to the ultimate strength analysis of stiffened panels with non-uniform plate thicknesses is checked through nonlinear finite element method computations. It is concluded that the equivalent plate thickness method is accurate for the panel ultimate strength analysis under combined biaxial compression and lateral pressure loads.

ABSTRACT: In this work, three optimization algorithms—Levenberg–Marquardt, simulated annealing and a newly developed and proposed hybrid differential evolution particle swarm optimization—are considered in the shape optimizations of cross-sections of integrally stiffened panels (ISP) for aeronautical applications, when subjected to buckling deformation modes within the elasto-plastic range. The proposed algorithm is shown to be robust and more effective, in the tested examples, than conventional optimization algorithms, leading to optimum designs of ISP cross-sections for a pre-defined buckling load-carrying capacity, combined with elasto-plastic nonlinear behaviors.

ABSTRACT: An experimental investigation was carried out to determine the ultimate strength of welded stiffened aluminium panels in alloy 6082 T6 subjected to in-plane compressive loads normal to the directions of the stiffeners. This load case is not treated in the European standard for aluminium structures, Eurocode 9. A total of 21 panel specimens with various side aspect ratios and both open and closed stiffener sections were tested in a purpose made test rig. Great care was taken to ensure the rig gave very precise boundary conditions. The panels were manufactured by metal inert gas arc welding and friction stir welding. An extensive measurement program was carried out to determine the distribution of material strength and initial geometric imperfections. Small imperfection amplitudes were found. Tensile tests revealed variation in material properties, but the strength values were on average higher than the values stated in Eurocode 9. The panels
failed by two different deformation modes; global flexural buckling and local buckling of the plate elements between the stiffeners.

DOI: 10.1016/j.actamat.2014.11.041
ABSTRACT: Lattice materials composed of hollow nanocrystalline struts have recently made it possible to access new regions of material property space, by exploiting structural efficiencies along multiple length scales (nanometre to centimetre range). An important design issue for these materials is to understand how the failure mechanisms that act at these scales affect the macroscopic mechanical properties. In this study, we tested hollow nanocrystalline cylinders of two different grain sizes (20 nm and 100 nm) in uniaxial compression to investigate the effect of grain size on dominant failure mechanisms, and the influence of the latter on the compressive strength. The finite element method was used to model the interaction of the three observed failure mechanisms: shell buckling (SB), yielding (Y) and fracture (F). Depending on the grain size and geometry, the failure sequence can be SB–Y–F, Y–SB–F, SB–Y or Y–SB, the order of which has important implications in defining the limits of mechanical performance. One such implication is that when shell buckling occurs in the inelastic regime of the material, the macroscopic strength increase due to grain size refinement can be greater than the inherent yield strength increase of the material. Second, material fracture and shell buckling may not be competing failure mechanisms, which means that the effectiveness of grain size reduction in increasing the structural efficiency of cylindrical strut members can span the entire Hall–Petch range of the material.

Kalurkar (Dept. of Civil Engineering, Jawaharlal Nehru Engineering College, Aurangabad, Maharashtra, India), “Study of buckling behaviour of beam and column subjected to axial loading for various rolled I sections”, International Journal of Innovative Research in Science, Engineering and Technology (IIRSET), Vol. 3, No. 11, November 2014

ABSTRACT: In this paper the buckling behaviour of an I - beam under axial load on column and beam is examined. Buckling loads are critical loads where certain types of structure become unstable. The results of an extensive parametric study are presented in graphical form and summarized by simple design curves and evaluating the effect of critical buckling load for various symmetrical rolled I - sections like Indian Standard Junior Beam (ISJB), Indian Standard Light Weight Beam (ISLB), Indian Standard Medium Weight Beam (ISMB), Indian Standard Wide Flange Beam (ISWB), Indian Standard Heavy Weight Beam (ISHB) for different depth are calculated by using software ANSYS. The results of critical buckling load calculated using ANSYS are compared with the conventional method of Euler Buckling theory analytically.

References listed at the end of the paper:

ABSTRACT: Buckling is a critical state of stress and deformation, at which a slight disturbance causes a gross additional deformation, or perhaps a total structural failure of the part. Structural behavior of the part beyond 'buckling' is not evident from the normal arguments of static. Buckling failures do not depend on the strength of the material, but are a function of the component dimensions & modulus of elasticity. Therefore, materials with a high strength will buckle just as quickly as low strength ones. If a structure is subject to compressive loads, then a buckling analysis may be necessary. The study presented in this paper is intended to help designers of steel braced barrel vaults by identifying the significant differences in determining which configuration(s) would be best in different conditions of use. The study presented is of parametric type and covers several important parameters like rise to span ratio, different boundary conditions, such that barrel vault acts as an arch, as a beam or as a shell, The buckling strength of a three different configuration of a double layer braced barrel vaults are presented in this paper for rise/span ratio varying from 0.2-0.7 and having four different types of boundary conditions. Through consideration of these parameters, the paper presents an assessment of the effect of the vault configuration on the overall buckling strength.

ABSTRACT: This master thesis details the investigation of the effect of geometrical imperfection on thin shell structures using general FEM software packages. The author proposes a finite element based method for the analysis and design of thin shell structures, and describes the implementation of such a procedure on four different FEM packages. The procedure involves the assessment of imperfection sensitivity of a design, and imposing geometrical imperfection in the shape of the first buckling mode prior to a geometrically non-linear analysis. Starting with thin metallic cylinders, by incorporating imperfection to the surface, the author shows that ANSYS is capable of reproducing results similar to Koiter's asymptotic theory and to experimental data. The author further demonstrates the robustness and easy-to-use nature of the imperfection procedure by implementing it on four simple yet realistic structures with both symmetric and asymmetric load cases. For extremely imperfection sensitive structures such as an axially loaded cylinder, the author then introduces four different types of imperfection that may be imposed in place of the first buckling mode, and gauges the effectiveness of each with a modified knock-down factor. By varying the vertical curvature, it is discovered that an axisymmetric imperfection shape governs the ultimate buckling capacity of any near-cylindrical shells. An theory is being developed that explains the effect of the axisymmetric shape. Change in Gaussian curvature is calculated as the end of every load step in the FEM analysis. By plotting the change in Gaussian curvature, the onset of buckling can be readily defined. Finally, physical non-linearities are introduced to the FEM models to gauge the effect of yielding and cracking on a steel cylinder, and a reinforced concrete (RC) cooling tower respectively. It is found that metal buckles within the elastic range, and yielding eliminates post-buckling capacity without altering the ultimate capacity. With RC cracking, it is discovered that instability occurs soon after cracks develop at the buckles of the imperfection shape, therefore reducing the capacity by as much as 8 times from that of the elastic model.

“Buckling Analysis for a Ring-Stiffened FGM Cylindrical Shell under Hydrostatic Pressure and Thermal Loads”, Journal of Mechanics, pp. 1-8, May 2014, DOI: http://dx.doi.org/10.1017/jmech.2014.34

ABSTRACT: This paper studies the buckling analysis for a ring-stiffened cylindrical shell consisted of functionally graded material (FGM) subjected to hydrostatic pressure and thermal loads. Material properties of the ring-stiffened FGM cylindrical shell are assumed to be temperature-dependent, and vary smoothly through the thickness direction of the structure according to a volume exponent. Based on the Donnell assumptions, buckling loads of the ring-stiffened FGM cylindrical shell are presented by utilizing the Galerkin method. Numerical results reveal that thermal loads, volume exponent and geometric parameters have significant effects on the buckling behavior of the ring-stiffened cylindrical shell.

19.1 INTRODUCTION: An efficiency of the membrane stress state, based on the strength conditions only, enables one to employ a very small shell thickness, as discussed in the preceding chapters of Part II. However, a possibility of the shell buckling impedes that, causing us either to increase the shell thickness or to reinforce the shell by stiffeners. It should be noted that the shell buckling is always disastrous, unlike, for example, a column or plate buckling. Therefore, the problem of the stability in designing shell structures is extremely vital. This problem is made worse because of some specific difficulties associated with determining correctly the critical values of loads applied to thin shells. Note that these difficulties are much greater than in the buckling analysis of columns, frames, and flat plates. They are associated with a complicated mathematical description of the deformed state of shells, and with a diversity of situations at which a shell can buckle. General postulations, definitions, and fundamentals of the structural stability theory, introduced in Chapter 8 for the plate buckling problems, can be applied also to the shell buckling analysis. In this chapter, we present a systematic but simplified analysis of shell buckling, and obtain some useful relationships between the critical values of applied loads and shell parameters. We limit ourselves to the consideration of thin shells for which elastic buckling without plastic deformation is possible.
ABSTRACT: It is widely accepted that for many buckling problems of plates and shells in the plastic range the flow theory of plasticity leads to a significant overestimation of the buckling stress while the deformation theory provides much more accurate predictions and is therefore generally recommended for use in practical applications. The present work aims to contribute to further understanding of the seeming differences between these two theories with particular regards to circular cylindrical shells subjected to axial compression. A clearer understanding of the two theories is established using accurate numerical examples and comparisons with some widely cited accurate physical test results. It is found that, contrary to common perception, by using a geometrically nonlinear finite element formulation with carefully determined and validated constitutive laws very good agreement between numerical and test results can be obtained in the case of the physically more sound flow theory of plasticity. The reasons underlying the apparent buckling paradox found in the literature regarding the application of deformation and flow theories and the different conclusions reached in this work are investigated and discussed in detail.

References listed at the end of the paper:

ABSTRACT: It is widely accepted that, for many buckling problems of plates and shells in the plastic range, the flow theory of plasticity either fails to predict buckling or significantly overestimates buckling stresses and strains, while the deformation theory, which fails to capture important aspects of the underlying physics of plastic deformation, provides results that are more in line with experimental findings and is therefore generally recommended for use in practical applications. This thesis aims to contribute further understanding of the reasons behind the seeming differences between the predictions provided by these two theories, and therefore provide some explanation of this so-called ‘plastic buckling paradox’.

The study focuses on circular cylindrical shells subjected to either axial compression or non-proportional loading, the latter consisting of combined axial tensile stress and increasing external pressure. In these two cases, geometrically nonlinear finite-element (FE) analyses for perfect and imperfect cylinders are conducted using both the flow and the deformation theories of plasticity, and the numerical results are compared with data from widely cited physical tests and with analytical results. The plastic buckling pressures for cylinders subjected to non-proportional loading, with various combinations of boundary conditions, tensile stresses, material properties and cylinder’s geometries, are also obtained with the help of the differential quadrature method (DQM). These results are compared with those obtained using the code BOSOR5 and with nonlinear FE results obtained using both the flow and deformation theories of plasticity.

It is found that, contrary to common belief, by using a geometrically nonlinear FE formulation with carefully determined and validated constitutive laws, very good agreement between numerical and test results can be obtained in the case of the physically more sound flow theory of plasticity. The reason for the ‘plastic buckling paradox’ appears to be the over-constrained kinematics assumed in many analytical and numerical treatments, such as BOSOR5 and NAPAS, whereby a harmonic buckling shape in the circumferential direction is prescribed.

ABSTRACT: Incremental launching of steel bridges is a demanding undertaking, on the erection site as well as on the designers desk. Not seldom, the structure itself is during the launching subjected to high concentrated forces on the lower flange when passing over a launching shoe or an intermediate support (e.g. column). These concentrated forces, commonly referred to as patch loads, may be of such magnitude that it governs the thickness of the web in the bridge girder. Though, a small increase in web thickness leads to a substantial gain of steel weight of the bridge. Hence also a higher material cost.

One solution to this problem is to increase the buckling resistance of the web with the use of a longitudinal stiffener of open (a plate) or closed type (closed profile of e.g. V-shape). The improved patch load resistance is in the european design code EN 1993-1-5 nowadays determined with the help of the yield resistance for the web and contributing parts of the loaded flange reduced with a factor dependent of the slenderness of the web and the influence of one or more longitudinal stiffeners. Parts in the expression for the yield resistance and the reduction factor have been somewhat questioned and over the years a substantial amount of tests and FE simulations of longitudinally stiffened webs has been carried out. This research work has produced a large amount of test data which has been used herein to further improve the prediction of the patch load resistance of longitudinally stiffened steel girder webs.

Based on the use of the gathered test data from the literature and previously done research, a calibrated patch load resistance function was developed for both open and closed longitudinal stiffeners. Furthermore, a partial safety factor for the proposal was determined according to the guidelines in EN 1990 (2002). In all, the proposal was shown to clearly improve the accuracy of resistance prediction when compared to other resistance models as well as the EN 1993-1-5.
Another questioned part in the commonly used design codes is the reduction function regarding local buckling under uniform in-plane compression. The nowadays used function (the Winter function) has been developed during the 1930’s and was based on tests on cold formed specimens. This reduction function has been criticized as being too optimistic regarding plates with large welds. A series of tests on welded specimens made of high strength steel with large welds was conducted to investigate the aforementioned concerns. Along with test data found in literature survey, the Winter function was proven to be too optimistic regarding these heavily welded plates. A new reduction function, based on the test data, was proposed and validated through a comparison with the available experimental results.

ABSTRACT: Modern steel constructions such as long span bridges are characterised by slender plated structures with low material consumption and the optimisation of their fabrication, leading to low dead loads and a high utilisation. Since often several internal forces act at the same time on the cross-section, very complex multiaxial stress states may develop. The aim of this work is to analyse the buckling behaviour of multiaxially loaded plates in order to increase the insight and to allow the enhancement of the current design rules of unstiffened and stiffened plates under several load combinations focusing on the reduced stress method according to Chapter 10, EN 1993-1-5 [36] and especially to analyse the influence of tensile stress states. As in EN 1993-1-5 [36] according to the reduced stress method multiaxial stress states are already considered in the determination of the single plate slenderness, this theoretically allows for taking into account the positive effect of tensile stress on the buckling behaviour. However, only few studies have looked on this effect until now and systematic investigations are missing, so that this work clarifies this open issue.

In a first step the elastic buckling of flat plates and the effect of multiaxial stress states are described. The buckling coefficient for unstiffened panels is given as a function of the panel aspect ratio and the stress state resulting in significantly elevated values if tensile stresses are acting. However, the evaluation of the buckling
coefficient shows pronounced peaks for certain cases, where it is questionable if they should be taken into account for the design. Therefore, a formulation is presented for ignoring these peaks. For the assessment of the buckling coefficient in case of stiffened plates several possibilities are explained. The complexity in the determination of the buckling coefficient, which involves a variety of parameters, leads to the conclusion that nowadays numerical techniques are the most appropriate approaches. Furthermore, the current rules according to EN 1993-1-5 [36] are explained in detail with a particular look on multiaxially loaded plates showing the impact of the stress state on the plate slenderness and therefore on the interaction curves. The interaction curves according to EN 1993-1-5 [36] allow a systematic utilisation of the favourable effect of tensile stresses on the buckling behaviour, especially compared to the rules according to DIN 18800-3 [22]. However, studies to justify this beneficial effect are missing. Therefore, experimental and numerical investigations are conducted to give an insight in the buckling behaviour of multiaxially loaded plates.

Thermal buckling analysis of cross-ply laminated rectangular plates under nonuniform temperature distribution: A differential quadrature approach

ABSTRACT: Differential quadrature method (DQM) is implemented for analyzing the thermal buckling behavior of the symmetric cross-ply laminated rectangular thin plates subjected to uniform and/or non-uniform temperature fields. The approach includes two steps: (1) solving the problem of in-plane thermo-elasticity to obtain the in-plane force resultants and (2) solving the buckling problem under the force distribution obtained in the previous step. Solution procedures are numerically performed by discretizing the governing differential equations and boundary conditions using DQM method. Applying the developed DQ formulation, the buckling loads are obtained for several sample plates. The numerical results compared well with those available in the literature as well as those obtained by ABAQUS. Parametric studies are conducted to investigate the influence of some important parameters including the plate aspect ratio, cross-ply ratio, and stiffness ratio on the critical temperature and mode shape of buckling.

ABSTRACT: This paper presents a finite element based numerical study on controlling the postbuckling behavior of thin-walled cylindrical shells under axial compression. With the increasing interest of various disciplines for harnessing elastic instabilities in materials and mechanical systems, the postbuckling behavior of thin-walled cylindrical shells may have a new role to design materials and structures at multiple scales with switchable functionalities, morphogenesis, etc. In the design optimization approach presented herein, the mode shapes and their amplitudes are linearly combined to generate initial geometrical designs with predefined imperfections. A nonlinear postbuckling finite element analysis evaluates the design objective function, i.e., the desired postbuckling force-displacement path. Single and multi-objective optimization problems are formulated with design variables consisting of shape parameters that scale base eigenvalue shapes. A gradient-based algorithm and numerical sensitivity evaluations are used. Results suggest that an optimized shape for a cylindrical shell can achieve a targeted response in the elastic postbuckling regime with multiple mode transitions and energy dissipation characteristics. The optimization process and the obtained geometry can be potentially used for energy harvesting and other sensing and actuation applications.

ABSTRACT: We formulate in situ parameter identification techniques for multistable spring models of compressed CNT bundles, which capture the sequential buckling through the height of the bundle, as well as the overall mechanical response. The proposed techniques are validated against a SEM-assisted compression experiment on a CNT pillar [1]. Using multi-spring models, we propose a ‘microscopic’ identification technique based on the determination of stress–strain curves of vertical segments of the tested structure (featuring few micron height). We show that the in situ identified models can effectively reproduce the experimentally-observed stress–strain response (single-spring models), and strain localization effects (multi-spring model), within a simple 1D framework.

S. Ajori and R. Ansari (Department of Mechanical Engineering, University of Guilan, P.O. Box 3756, Rasht, Iran), “Torsional buckling behavior of boron-nitride nanotubes using molecular dynamics simulations”, Current
ABSTRACT: Based on molecular dynamics simulations, the mechanical properties and buckling behavior of boron-nitride nanotubes under the action of torsional load are investigated. According to the results, the torsional properties of a boron-nitride nanotube are higher than those of its carbon counterpart. The effect of geometrical parameters on these parameters is also investigated. It is observed that by increasing the radius of nanotubes of the same length, unlike the critical shear strain, the critical torque considerably increases. The effect of chirality is also found to be negligible in the cases of critical shear strain and buckling mode, unlike the critical torque.

ABSTRACT: The buckling of cylindrical shells has long been regarded as an undesirable phenomenon, but increasing interests on the development of active and controllable structures open new opportunities to utilize such unstable behavior. In this paper, approaches for modifying and controlling the elastic response of axially compressed laminated composite cylindrical shells in the far postbuckling regime are presented and evaluated. Three methods are explored (1) varying ply orientation and laminate stacking sequence; (2) introducing patterned material stiffness distributions; and (3) providing internal lateral constraints. Experimental data and numerical results show that the static and kinematic response of unstable mode branch switching during postbuckling response can be modified and potentially tailored.

References listed at the end of the paper:

ABSTRACT: Elastic instability, long considered mainly as a failure limit state or a safety guard against ultimate failure is gaining increased interest due to the development of active and controllable structures, and the growth in computational power. Mode jumping, or snap-through, during the postbuckling response leads to sudden and high-rate deformations due to generally smaller changes in the controlling load or displacement input to the system. A paradigm shift is thus emerging in using the unstable response range of slender structures for purposes that are rapidly increasing and diversifying, including applications such as energy harvesting, frequency tuning, sensing and actuation. This paper presents a finite element based numerical study on controlling the postbuckling behavior of fiber reinforced polymer cylindrical shells under axial compression. Considered variables in the numerical analyses include: the ply orientation and laminate stacking sequence; the material distribution on the shell surface (stiffness distribution); and the anisotropic coupling effects. Preliminary results suggest that the static and dynamic response of unstable mode branch switching during postbuckling can be fully characterized, and that their number and occurrence can be potentially tailored. Use of the observed behavior for energy harvesting and other sensing and actuation applications will be presented in future studies.

ABSTRACT: This paper investigates the reversible retraction of a spherical perforated shell that is made from nonlinear soft material. The buckling and post-buckling simulation in Abaqus shows the skeleton ligaments of such a buckliball rotate in the beginning and buckle thereafter, resulting in the shrinkage and encapsulation of the whole structure in the final stage. We used dynamic-explicit method in the simulation and its superiority over others is verified by obtaining correct buckling patterns efficiently and stably.

ABSTRACT: Using GNIA or GMNIA in new, still unmade shells is related with a large scope, heavy and continuous calculations. Main difficulty is modeling of imperfections with correct values. Ordinary designers who are usually hard pressed by time and are not familiar with computing software, enabling full GNIA or GMNIA analysis of shells, require simplified procedures in which imperfections are not included. Such a procedure, called LBA-MNA, is presented here. It allows analysis of real shells, modelled as perfect structures.

Jin-Wu Jiang, “The strain rate effect on the buckling of single-layer MoS2”, Scientific Reports, Vol. 5, Article Number 7814, January 2015, DOI: 10.1038/srep07814

ABSTRACT: The Euler buckling theory states that the buckling critical strain is an inverse quadratic function of the length for a thin plate in the static compression process. However, the suitability of this theory in the dynamical process is unclear, so we perform molecular dynamics simulations to examine the applicability of the Euler buckling theory for the fast compression of the single-layer MoS2. We find that the Euler buckling theory is not applicable in such dynamical process, as the buckling critical strain becomes a length-independent constant in the buckled system with many ripples. However, the Euler buckling theory can be resumed in the dynamical process after restricting the theory to an individual ripple in the buckled structure.

ABSTRACT: In ship construction it is very much essential to keep the hull weight to a minimum in order to achieve higher fuel efficiency. The lighter the structure lesser will be the power requirement for certain speed of operation. This has led to the usage of more and more thinner structural components making them more vulnerable to buckling. The basic structural components of ships are orthogonally stiffened plate panels. The increased use of thin plates in panel fabrication results in significantly increased buckling distortion. Competitiveness in cost and time can be increased by eliminating or mitigating these distortions during the design and fabrication stage rather than allowing them to accumulate and then removing them. In this study an investigation on buckling phenomenon in fabrication of typical stiffened panels as used in shipbuilding was carried out. A method of distortion mitigation by counteracting the compressive forces developed due to welding of stiffeners was developed and investigated in detail. The method developed is named as Thermo-Mechanical Tensioning (TMT). It was found to be very effective yet simple-to-implement method of buckling distortion control. Extensive experimentation was carried out both in laboratory and in full scale in Cochin Shipyards Ltd. It was observed that, this pre-tensioning technique TMT can be very gainfully applied as an active in-process control method to avoid buckling distortion in stiffened panels.

ABSTRACT: In this paper, the displacements of a cylindrical shell with varying thickness and subjected to axial and external pressure are calculated analytically using the first-order shear deformation theory. The kinematics of the problem is defined by von Kármán theory, and the constitutive equation obeys Hooke’s law. The governing equations, which are a system of nonlinear differential equations, are extracted by applying the virtual work principle; the matched asymptotic expansion method of the perturbation technique is used to calculate the analytical solution. The effects of different load profiles and thicknesses on the results are investigated. Also, a comparison with the FEM is performed.

ABSTRACT: With the raised performance of advanced aircraft, hypersonic vehicles are subjected to increasingly severe environment. Very severe elevated temperature and high intensity acoustic loads will cause the thin-walled structures of aircraft to respond in a strong nonlinear large deflection vibration, and leading to premature fatigue failure of the structure. According to the Von Karman large deflection theory, the large deflection governing equation of plate under thermo-acoustic loadings is obtained. The Galerkin method is employed to obtain the ordinary differential equation under modal coordinates and the stress expressed by modal displacement for the simply-supported plate and the clamped plate. The critical thermal buckling temperatures and modal frequencies of simply-supported plate and thin-walled cylindrical shell under thermal loads with linear temperature gradient, the dynamic responses of them under thermo-acoustic loads, are obtained using finite element numerical stimulation, The thermal-acoustic responses of simply-supported plate and thin-walled cylindrical shell with different combinations of thermal-acoustic loadings are obtained, including the random vibration in pre-buckled regime, snap-through motion between post-buckled equilibrium positions and nonlinear vibration around one post-buckled position.

ABSTRACT: Nonlinear dynamic behaviors of ceramic-metal graded truncated conical shell subjected to complex loads are investigated. The shell is modeled by first-order shear deformation theory. The nonlinear partial differential governing equation in terms of transverse displacements of the FGM truncated conical shell is derived from the Hamilton's principle. Galerkin's method is then utilized to discretize the partial governing equations to a two-degree-of-freedom nonlinear ordinary differential equation. The temperature-dependent materials properties of the constituents are graded in the radial direction in accordance with a power-law distribution. The aerodynamic pressure can be calculated by using the first-order piston theory. The temperature field is assumed to be a steady-state constant-temperature distribution. Bifurcation diagrams, the maximum Lyapunov exponents, wave forms and phase portraits are obtained by numerical simulation to demonstrate the complex nonlinear dynamics response of the FGM truncated conical shell. The influences of the semi-vertex angle, the material gradient index, in-plane and aerodynamic load on the nonlinear dynamics are studied.

ABSTRACT: The first part reviews numerical procedures developed for stiffened panels subjected to explosive forces. The structural idealization, the theoretical basis, and the merits of these methods are discussed. The second part reviews the probabilistic procedures developed for analysis of deteriorering stiffened panels. The third part reviews recent work developed in several finite element modelling philosophies for analysis of stiffened panels. The influence of various parameters affecting the structural performance, such as geometric and material imperfections, corrosion, residual stresses, etc. is discussed. The fourth part reviews hybrid procedures developed to provide approximate solutions for the designers. Numerical procedure is presented using combination of energy formulations and mathematical programming techniques to model the interaction between the box girder components. Localized damage largely affects the performance of stiffened panels and must be accounted for in the design phase. Little emphasis was given in the published literature to developing simplified analytical models that can be used in practice to compute the residual strength of the stiffened panels under these types of loadings. Furthermore, analytical expressions are required to compute the reduction in the stiffness induced due to the structural or material defects. These expressions must be dependent on the type of damage. It must be noted that some of this damages is localized in nature and must be accounted for by using specialized functions to assess the structural defect accurately. Research work is required in this direction.

ABSTRACT: The paper offers to practitioners economical procedures that can be utilized to optimize the design of built up box sections subject to compression and biaxial bending. Little emphasis appeared in the published literature that addressed this general loading condition. The analysis methodology and structural idealization are first overviewed. Diagrams are presented showing buckling behavior of the section by accounting rotational and lateral restraints. The post-buckling response is also illustrated for various applied stress ratios. A design space concept is then introduced showing interaction of serviceability and strength limit states. These procedures are cost effective and appropriate for industrial implementation to optimize the structural design.

ABSTRACT: In this paper, the dynamic stability and bifurcation phenomenon for a class of isotropic functionally graded plates including power-law, sigmoid and exponential function under lateral stochastic loads are studied and compared. Due to the existence of random loads, both the behavior investigation and response analysis are not conventional deterministic methods. So, the instability region and border curves of bifurcation are evaluated via a probability density function of the response. The latter is computed from a completely exact solution of the Fokker–Planck–Kolmogorov equation. The three-dimensional instability region and the border curves of bifurcation are drawn with respect to material parameter, in-plane forces and the mean value of lateral forces. To generalize the results, all the parameters are transformed to some suitable nondimensional variables, and then, the effects of all mentioned parameters on the dynamic stability are completely discussed and compared. Finally, the analytic results are validated by drawing numeric bifurcation diagrams for the nondimensional deflections of plates.

ABSTRACT: Buckling of soft matter is ubiquitous in nature and has attracted increasing interest recently. This paper studies the retractile behaviors of a spherical shell perforated by sophisticated apertures, attributed to the buckling-induced large deformation. The buckling patterns observed in experiments were reproduced in computational modeling by imposing velocity-controlled loads and eigenmode-affine geometric imperfection. It was found that the buckling behaviors were topologically sensitive with respect to the shape of dimple (aperture). The shell with rounded-square apertures had the maximal volume retraction ratio as well as the lowest energy consumption. An effective experimental procedure was established and the simulation results were validated in this study.

ABSTRACT: The buckling behaviour of pin ended cold-formed steel lipped channel columns affected by local / distortional / global buckling mode interaction under axial loading is simulated by using finite element software ABAQUUS, and the results are compared with the test results available in the literature. The comparisons show that the proper analysis model can simulate the buckling behaviour and ultimate capacity of cold-formed steel columns. Then a parametric analysis is carried out for 15 column geometries of 3 yield stress values of different dimension, thickness and lengths. The cross sectional dimensions and length of the specimen have been chosen such that to have almost equal local, distortional and global critical buckling stresses by using the CUFSM software. The selected sections also satisfied the limitations given for pre-qualified sections in Direct Strength Method (DSM). After comparing the FEM column ultimate loads with the estimates predicted by the current Direct Strength Method (DSM) design curves against local, distortional and global failures, which clearly shows that they lead to inaccurate and often very unsafe ultimate load estimates. At the end, a design recommendation is made for current design practice of evaluating the ultimate strength of the lipped channel columns.

ABSTRACT: The structural performance of two advanced composite tow-steered shells with cutouts, manufactured using an automated fiber placement system, is assessed using both experimental and analytical methods. The shells' fiber orientation angles vary continuously around their circumference from +/−10 degrees on the crown and keel, to +/−45 degrees on the sides. The raised surface features on one shell result from application of all 24 tows during each fiber placement system pass, while the second shell uses the system's tow drop/add capability to achieve a more uniform wall thickness. These unstiffened shells were previously tested in axial compression and buckled elastically. A single cutout, scaled to represent a passenger door on a commercial aircraft, is then machined into one side of each shell. The prebuckling axial stiffnesses and bifurcation buckling loads of the shells with cutouts are also computed using linear finite element structural analyses for initial comparisons with test data. When retested, large deflections were observed around the cutouts, but the shells carried an average of 92 percent of the axial stiffness, and 86 percent of the buckling loads, of the shells without cutouts. These relatively small reductions in performance demonstrate the potential for using tow steering to mitigate the adverse effects of typical design features on the overall structural performance.

“Conflicting Axial Buckling Strains from Two Criteria to Detect Instability in Single-Walled Carbon Nanotubes”, XII International Conference on Nanostructured Materials (NANO 2014), July 13-18, 2014, Moscow, Russia

ABSTRACT: Until today mechanical characterization of single-walled carbon nanotubes remains a challenging issue due to an ambiguity in definition of its wall thickness. This leads to a wide scatter in its Young’s modulus [1]. However, very recently Gupta et al. [2] have derived a mathematical relationship between the wall
thickness and radius of single-walled carbon nanotubes (SWCNTs) using molecular mechanics simulations. They used inextensional modes of vibrations of SWCNTs and continuum mechanics to deduce the aforementioned relationship. Another route to characterize a SWCNT is to study its axial buckling using molecular mechanics/dynamics and employing continuum theories [3,4]. In general, in simulations axial buckling due to compressive strains is determined by a sudden drop in the potential energy [5] or a sudden drop in the load-deflection curve in experiments [6] with increasing compressive strain. Inspired by the fact that at the onset of buckling of beams and shells their fundamental frequency becomes zero we determine the critical buckling strain by computing vanishing eigen values [7] of the Hessian of a SWCNT under compression using molecular mechanics. In the present study several molecular mechanics simulations using MM3 potential [8] have been carried out to identify an appropriate criterion for detecting initiation of buckling of slender (aspect ratio ~ 15), clamped-clamped SWCNTs subjected to axial compressive strains. Armchair and zigzag chiralities of SWNTs have been considered to study the two criteria for detecting onset of instability in SWCNTs. In Fig. 1 we show the eigen value loci of bending modes and potential energy of (7,0) SWCNT for each incremental compressive strain. It is found that the two criteria yield different values of the critical buckling strain. Furthermore, if SWCNTs were modelled as continuum beam or shell, both these criteria will result in the same values of the critical buckling strain.

Summary: We focus on the graphene wrinkling, from its formation to collapse, and its dependence on aspect ratio and temperature using molecule dynamics simulation. Based on our results, the first wrinkle is not formed on the edge but in the interior of graphene. The fluctuations of edge slack warps drive the wrinkling evolution in graphene which is distinguished from the bifurcation in continuum film. There are several obvious stages in wrinkling progress, including incubation, infancy, youth, maturity and gerontism periods which are identified by the atomic displacement difference due to the occurrences of new wrinkles. The wrinkling progress is over when the C–C bonds in highly stretched corners are broken which contributes to the wrinkling collapse. The critical wrinkling strain, the wrinkling pattern and extent depend on the aspect ratio of graphene, the wrinkling level and collapsed strains do not. Only the collapsed strain is sensitive to the temperature, the other wrinkling parameters are independent of the temperature. The results would benefit the understanding of the physics of graphene wrinkling and the design of nanomechanical devices by tuning the wrinkles.

ABSTRACT: This paper describes the collaborative research carried out into various aspects of the behaviour of thin-walled structures at the University of Strathclyde and the Technical University of Lodz over the past 40 years or so. The two Universities have had links over the past 45 years, and collaboration has been carried out in many disciplines. The collaboration between the Department of Mechanical Engineering at Strathclyde and the Department of Strength of Materials at Lodz has been largely concentrated on thin-walled structures, and some aspects of this collaboration are outlined in this paper.

ABSTRACT: Numerical simulations of thin sheets undergoing large deformations are computationally challenging. Depending on the scenario, they may spontaneously buckle, wrinkle, fold, or crumple. Nature’s thin tissues often experience significant anisotropic growth, which can act as the driving force for such instabilities. We use a recently developed finite element model to simulate the rich variety of nonlinear responses of Kirchhoff-Love sheets. The model uses subdivision surface shape functions in order to guarantee convergence of the method, and to allow a finite element description of anisotropically growing sheets in the classical Rayleigh–Ritz formalism. We illustrate the great potential in this approach by simulating the inflation of airbags, the buckling of a stretched cylinder, as well as the formation and scaling of wrinkles at free boundaries of growing sheets. Finally, we compare the folding of spatially confined sheets subject to growth and shrinking confinement to find that the two processes are equivalent.

ABSTRACT: We present the results of an experimental investigation on the crystallography of the dimpled patterns obtained through wrinkling of a curved elastic system. Our macroscopic samples comprise a thin hemispherical shell bound to an equally curved compliant substrate. Under compression, a crystalline pattern of dimples self-organizes on the surface of the shell. Stresses are relaxed by both out-of-surface buckling and the emergence of defects in the quasi-hexagonal pattern. Three-dimensional scanning is used to digitize the topography. Regarding the dimples as point-like packing units produces spherical Voronoi tessellations with cells that are polydisperse and distorted, away from their regular shapes. We analyze the structure of crystalline defects, as a function of system size. Disclinations are observed and, above a threshold value, dislocations proliferate rapidly with system size. Our samples exhibit striking similarities with other curved crystals of charged particles and colloids. Differences are also found and attributed to the far-from-equilibrium nature of our patterns due to the random and initially frozen material imperfections which act as nucleation points, the presence of a physical boundary which represents an additional source of stress, and the inability of dimples to rearrange during crystallization. Even if we do not have access to the exact form of the interdimple interaction, our experiments suggest a broader generality of previous results of curved crystallography and their robustness on the details of the interaction potential. Furthermore, our findings open the door to future studies on curved crystals far from equilibrium.

ABSTRACT: Graphene/hexagonal boron nitride (h-BN) heterostructure has showed great potential to improve the performance of a graphene device. A graphene on an h-BN substrate may buckle due to the thermal expansion mismatch between the graphene and h-BN. We used an energy method to investigate the periodic buckling patterns including one-dimensional, square checkerboard, hexagonal, equilateral triangular and herringbone mode in a graphene/h-BN heterostructure under equi-biaxial compression. The total energy, consisting of cohesive energy, graphene membrane energy and graphene bending energy, for each buckling pattern is obtained analytically. At a compression slightly larger than the critical strain, all buckling patterns have the same total energies, which suggests that any buckling pattern may occur. At a compression much larger than the critical strain, the herringbone mode has the lowest total energy by significantly reducing the membrane energy of graphene at the expense of a slight increase of the bending energy of graphene and cohesive energy. These results may serve as guidelines for strain engineering in graphene/h-BN heterostructures.

ABSTRACT: Corrugated shell structures are widely used in civil, naval, automotive, and aerospace engineering because of their superior properties. In this paper, the nonlinear dynamic deformation of a class of longitudinally corrugated shell with a second-order differentiable wave under a uniform load was investigated. On the basis of their previous research result—that the corrugated shell undergoes large deformation but small strains—the authors proposed an assumption that the dynamic configuration of the corrugated shell is the same as the static configuration with a different load. Then the governing equations of the dynamic deformation of the corrugated shell were derived using Lagrange’s equation, and an efficient numerical method without element discretization to solve those nonlinear differential equations was formulated. The accuracy of the present simplification was proved by comparing it with results obtained from a widely used nonlinear finite-element program, and the assumption on the dynamic configuration was shown to be applicable for most engineering applications. Furthermore, the developed method was adopted to perform parametric studies and it is found that the loading rates, the depth of wave, and the number of wave can greatly change the expansion velocity of the corrugated ring. And most importantly, the authors revealed that different corrugation types with the same ratio of the radius of the median surface to the depth of wave $R_0/L_w$, the number of waves $N$ and the circumference $C_t$ can yield similar dynamic expansion responses, which should be useful for future design of corrugated shell.

ABSTRACT: We theoretically explain the complete sequence of shapes of deflated spherical shells. Decreasing the volume, the shell remains spherical initially, then undergoes the classical buckling instability, where an axisymmetric dimple appears, and, finally, loses its axisymmetry by wrinkles developing in the vicinity of the dimple edge in a secondary buckling transition. We describe the first axisymmetric buckling transition by numerical integration of the complete set of shape equations and an approximate analytic model due to Pogorelov. In the buckled shape, both approaches exhibit a locally compressive hoop stress in a region where experiments and simulations show the development of polygonal wrinkles, along the dimple edge. In a simplified model based on the stability equations of shallow shells, a critical value for the compressive hoop stress is derived, for which the compressed circumferential fibres will buckle out of their circular shape in order to release the compression. By applying this wrinkling criterion to the solutions of the axisymmetric models, we can calculate the critical volume for the secondary buckling transition. Using the Pogorelov approach, we also obtain an analytical expression for the critical volume at the secondary buckling transition: The critical volume difference scales linearly with the bending stiffness, whereas the critical volume reduction at the classical axisymmetric buckling transition scales with the square root of the bending stiffness. These results are confirmed by another stability analysis in the framework of Donnel, Mushtari and Vlasov (DMV) shell theory, and by numerical simulations available in the literature.

ABSTRACT: This thesis presents research results on the deformation of elastic shells, especially concerning buckling and wrinkling instabilities. The theoretical description of such deformations is used to develop methods of shape analysis, which serve to infer material properties from simple experimental observations of deformed shells. When an initially spherical shell is deflated, two successive instabilities can typically be observed. In a first buckling transition, an axisymmetric dimple appears. It grows with proceeding deflation and acquires a polygonal shape in a secondary buckling transition. The onset of the first instability is well known. Here, we draw a complete picture of axisymmetric buckled shapes from the onset to a fully collapsed state, where opposite sides of the shell are in contact. Furthermore, it is shown that the stability of buckled shapes with respect to further spontaneous deflation depends decisively on whether the interior shell volume is prescribed (buckled shapes are stable), the pressure difference is fixed (shapes are unstable and collapse immediately after the onset) or the deflation is controlled by osmosis (intermediate between the former cases).

For the description of axisymmetric buckled shapes, we use two approaches: firstly non-linear shell theory and secondly a simple analytic model proposed originally by Pogorelov. The secondary buckling instability has so far only been observed in simulations and experiments. Here, we provide a theoretical explanation and analyse its onset quantitatively. A compressive circumferential stress in the vicinity of the dimple edge is identified as the driving force of the secondary buckling transition. Using the stability equations for shallow shells, we derive a critical circumferential stress which leads to wrinkles along the dimple edge, similar to the Euler buckling of straight rods. Subsequently, we introduce a model for capsules that are created from liquid drops by an interfacial reaction and hang from a capillary. The interior liquid can be removed by suction through the capillary, which usually leads to wrinkling of the capsule membrane. The theoretical model is applied to completely characterise the elastic moduli of the membrane by an analysis of the capsule contour and wrinkle wavelength detected in experimental images. A test on two different capsule systems, polymerised polysiloxane capsules and bubbles coated with a layer of the protein hydrophobin, proves the concept of the proposed elastometry method. In the analysis of the hydrophobin capsule, we find an interesting non-linear elastic
response which can be attributed to the molecular structure of the proteins consisting of a hard core and a softer shell. This motivates the development of a custom elasticity model based on the microscopic view of a bead-spring model including steric repulsions and can in part explain the experimental results of the hydrophobin capsule.

ABSTRACT: Thin shells are found in nature at scales ranging from viruses to hens’ eggs; the stiffness of such shells is essential for their function. We present the results of numerical simulations and theoretical analyses for the indentation of ellipsoidal and cylindrical elastic shells, considering both pressurized and unpressurized shells. We provide a theoretical foundation for the experimental findings of Lazarus et al. [following paper, Phys. Rev. Lett. 109, 144301 (2012)] and for previous work inferring the turgor pressure of bacteria from measurements of their indentation stiffness; we also identify a new regime at large indentation. We show that the indentation stiffness of convex shells is dominated by either the mean or Gaussian curvature of the shell depending on the pressurization and indentation depth. Our results reveal how geometry rules the rigidity of shells.

ABSTRACT: Smooth wrinkles and sharply crumpled regions are familiar motifs in biological or synthetic sheets, such as rapidly growing plant leaves and crushed foils. Previous studies have addressed both morphological types, but the generic route whereby a featureless sheet develops a complex shape remains elusive. Here we show that this route proceeds through an unusual sequence of distinct symmetry-breaking instabilities. The object of our study is an ultrathin circular sheet stretched over a liquid drop. As the curvature is gradually increased, the surface tension stretching the sheet over the drop causes compression along circles of latitude. The compression is relieved first by a transition into a wrinkle pattern, and then into a crumpled state via a continuous transition. Our data provide conclusive evidence that wrinkle patterns in highly bendable sheets are not described by classical buckling methods, but rather by a theory which assumes that wrinkles completely relax the compressive stress. With this understanding we recognize the observed sequence of transitions as distinct symmetry breakings of the shape and the stress field. The axial symmetry of the shape is broken upon wrinkling but the underlying stress field preserves this symmetry. Thus, the wrinkle-to-crumple transition marks symmetry-breaking of the stress in highly bendable sheets. By contrast, other instabilities of sheets, such as blistering and cracking, break the homogeneity of shape and stress simultaneously. The onset of crumpling occurs when the wrinkle pattern grows to half the sheet’s radius, suggesting a geometric, material-independent origin for this transition.

“Scale effects on buckling analysis of orthotropic nanoplates based on nonlocal two-variable refined plate theory”, Acta Mechanica, Vol. 223, No. 2, pp 395-413, February 2012

ABSTRACT: This article presents the buckling analysis of orthotropic nanoplates such as graphene using the two-variable refined plate theory and nonlocal small-scale effects. The two-variable refined plate theory takes account of transverse shear effects and parabolic distribution of the transverse shear strains through the thickness of the plate, hence it is unnecessary to use shear correction factors. Nonlocal governing equations of motion for the monolayer graphene are derived from the principle of virtual displacements. The closed-form solution for buckling load of a simply supported rectangular orthotropic nanoplate subjected to in-plane loading has been obtained by using the Navier’s method. Numerical results obtained by the present theory are compared with first-order shear deformation theory for various shear correction factors. It has been proven that the nondimensional buckling load of the orthotropic nanoplate is always smaller than that of the isotropic nanoplate. It is also shown that small-scale effects contribute significantly to the mechanical behavior of orthotropic graphene sheets and cannot be neglected. Further, buckling load decreases with the increase of the nonlocal scale parameter value. The effects of the mode number, compression ratio and aspect ratio on the buckling load of the orthotropic nanoplate are also captured and discussed in detail. The results presented in this work may provide useful guidance for design and development of orthotropic graphene based nanodevices that make use of the buckling properties of orthotropic nanoplates.

Partial Introduction: There are various methods for increasing the resistance of a circular plate to buckling. We can apply diverse supports on the boundaries of the structure or at an appropriate inner location where the structure functioning is not disturbed. A possible solution is the simultaneously applied supports at the boundary and in the middle of a solid circular plate or at the inner and outer boundaries of an annular plate. Instead of a support, or in addition to the existing supports we could mount further concentric ring support(s) in order to improve stability of the plate. Additionally, if the applied support restrains rotation of the plate, the stiffening effect can be further increased. We shall derive those nonlinear equation(s) which provide the critical load for a circular plate which is stiffened by a cylindrical shell on its boundary symmetrically to its middle plane or stiffened by a cylindrical shell only on one side of the middle plane.

ABSTRACT: The present paper is concerned with the stability problems of a thin solid circular plate and some annular plates, each stiffened by a cylindrical shell on the external boundary. Assuming an axisymmetric dead load and non-axisymmetric deformations we determine the critical load in order to clarify what effect the stiffening shell has on the critical load. Using Kirchhoff’s theory of thin shells and plates the paper presents the governing equations both for the circular plate and for the cylindrical shell, where the displacement field of the shell is obtained from a Galerkin function. The deflection of the plate and the Galerkin function are expanded into Fourier series and consequently all physical quantities in the structural elements as well. The boundary- and continuity conditions and last but not least numerical results are also presented.

ABSTRACT: We investigate buckling of soft elastic capsules under negative pressure or for reduced capsule volume. Based on nonlinear shell theory and the assumption of a hyperelastic capsule membrane, shape equations for axisymmetric and initially spherical capsules are derived and solved numerically. A rich bifurcation behavior is found, which is presented in terms of bifurcation diagrams. The energetically preferred stable configuration is deduced from a least-energy principle both for prescribed volume and prescribed pressure. We find that buckled shapes are energetically favorable already at smaller negative pressures and larger critical volumes than predicted by the classical buckling instability. By preventing self-intersection for strongly reduced volume, we obtain a complete picture of the buckling process and can follow the shape from the initial undeformed state through the buckling instability into the fully collapsed state. Interestingly, the sequences of bifurcations and stable capsule shapes differ for prescribed volume and prescribed pressure. In the buckled state, we find a relation between curvatures at the indentation rim and the bending modulus, which can be used to determine elastic moduli from experimental shape analysis.

ABSTRACT: We study the buckling of elastic spherical shells under osmotic pressure with the osmolyte concentration of the exterior solution as a control parameter. We compare our results for the bifurcation
behavior with results for buckling under mechanical pressure control, that is, with an empty capsule interior. We find striking differences for the buckling states between osmotic and mechanical buckling. Mechanical pressure control always leads to fully collapsed states with opposite sides in contact, whereas uncollapsed states with a single finite dimple are generic for osmotic pressure control. For sufficiently large interior osmolyte concentrations, osmotic pressure control is qualitatively similar to buckling under volume control with the volume prescribed by the osmolyte concentrations inside and outside the shell. We present a quantitative theory which also captures the influence of shell elasticity on the relationship between osmotic pressure and volume. These findings are relevant for the control of buckled shapes in applications. We show how the osmolyte concentration can be used to control the volume of buckled shells. An accurate analytical formula is derived for the relationship between the osmotic pressure, the elastic moduli and the volume of buckled capsules. This also allows use of elastic capsules as osmotic pressure sensors or deduction of elastic properties and the internal osmolyte concentration from shape changes in response to osmotic pressure changes. We apply our findings to published experimental data on polyelectrolyte capsules.

ABSTRACT: This paper was aimed to investigate the post buckling behaviour of moderately thick-walled filament-wound carbon–epoxy composite cylinders under external hydrostatic pressure through finite element analysis for under water vehicle applications. The winding angles were [±30/90] FW, [±45/90] FW and [±60/90] FW. Finite element software ANSYS 14.0 were used to predicted the buckling pressure of filament-wound composite cylinders. For the finite element modeling of the composite cylinder, an eight-node shell element is used. To verify the finite element results for comparison, three finite element software, MSC/NASTRAN, MSC/MARC and an in-house program ACOS were used. Among these software’s, the finite element software ANSYS predicts the buckling loads within 1.5% deviation.

ABSTRACT: A program to extend the operating depth of Seaglider from 1000 m to 6000 m began in 2002 at the University of Washington. The Deepglider program used carbon fiber composites for the pressure hull because of their ability to achieve weight to displacement ratios of less than 0.5. Advanced fabrication technology, more common in the aerospace industry, allowed the pressure hull to be identical to the shape of the Seaglider AUV so that many of the Seaglider components could be used on Deepglider. In this paper, we describe the development of the carbon fiber/epoxy pressure hull, including material characterization, the design of the interlaminar shear control sleeve, and pressure testing of six pressure vessels. Three of these hulls used a unique tapering diameter, tapering wall thickness construction. A more complete description of the Deepglider program is provided in a companion paper.

ABSTRACT: This presentation introduces a freely available tool for performing automated thin-shell finite element (FE) eigen-buckling modal identification. Commercial finite element software is commonly used to study thin-walled members because it can easily handle complex geometries, perforations, and arbitrary loading and boundary conditions. Each buckling analysis produces many mode shapes that are mixtures of fundamental modes, for example, local buckling, distortional buckling, and global buckling. These fundamental modes are important for use in strength prediction and design code development, however their relative participation can be difficult to quantify in an FE analysis. A modeler may have to sift through hundreds of modes, and even then, the modal identification and participation is subjective. A custom-built Matlab program is presented that performs automated FE eigen-buckling modal identification. Recent research advances have led to software that performs automated eigen-buckling modal identification and participation with the constrained finite strip method (cFSM) and the generalized beam theory (GBT). Our program wraps around this existing code to perform modal decomposition on an FE-generated buckled mode shape. The FE mode shape is input as 3D coordinates from a text file that can be generated by any commercial finite element program. Cross-sectional mode shapes provided by cFSM or GBT are employed to approximate each buckling mode and to determine the modal participation of the fundamental modes. The novelty of the presented method lies in using only the cross-section deformation modes instead of member base shapes. Using the special orthogonality properties of the cross-section deformation modes, the GBT amplitude functions of the fundamental modes are extracted from the FEM displacement field, with great speed and stability.

ABSTRACT: The analysis of slender structures, characterized by complex buckling and postbuckling phenomena and by a strong imperfection sensitivity, is heavily penalized by the lack of adequate computational tools. Standard incremental iterative approaches are computationally expensive and unaffordable, while FEM implementation of the Koiter method is a convenient alternative. The analysis is very fast, its computational burden is of the same order as a linearized buckling load evaluation and the simulation of different imperfections costs only a fraction of that needed to characterize the perfect structure. In this respect it can be considered as a direct method for the evaluation of the critical and post-critical behaviour of geometrically nonlinear elastic structures. The main objective of the present work is to show that finite element
implementations of the Koiter method can be both accurate and reliable and to highlight the aspects that require further investigation.

ABSTRACT: A new quadrilateral four node membrane finite element based on a mixed Hellinger–Reissner variational formulation is proposed. Displacement and stress interpolations are defined by 12 kinematical DOFs (two displacements and one drilling rotation per node) and 9 stress parameters. The displacement interpolation is obtained as a sum of three contributions. The first two correspond to compatible modes that assume a linear and quadratic (Allman-like) shape along the sides. The latter corresponds to a cubic incompatible mode depending on the average nodal rotations of the element. The stress interpolation is obtained from a complete quadratic polynomial by enforcing the internal bulk equilibrium and three further u-sub-lambda Pian equilibrium conditions, so obtaining an equilibrated and non-redundant field. The compliance and compatibility matrices are derived analytically, using an efficient boundary integration scheme. Numerical comparisons show that the proposed element performs better and is less sensitive to mesh distortion than similar elements in the literature. The constant stress states are recovered exactly and a very accurate recovery, for both stress and rotation fields, is also obtained in bending as well as in shear contexts. As shown by some numerical tests in buckling problems, the element is suitable for extension to nonlinear analysis.

ABSTRACT: A mixed, quadrilateral, 3D plate element is proposed for static linear and buckling analysis of folded laminated composite structures. Numerical results show accuracy, comparing to analytical and numerical references, and convergence rate h2 measured using an s-norm. These characteristics are due to the self-equilibrated, isostatic state of stress in the element, and to the element kinematics leading to element compliance and compatibility matrix calculations based solely on the interpolation along the element edges. For folded plates, the drilling rotations do not require penalty functions or non-symmetric formulations, thus avoiding spurious energy modes. Buckling analysis is achieved by a corotational formulation, which is possible thanks to the accuracy of rotation approximations. Benchmarking for laminated composite plates includes convergence of displacements and stress-resultants, global error measures, and comparison with literature
results.

ABSTRACT: Koiter’s asymptotic approach is a powerful alternative to path-following techniques in the analysis of slender structures. Its reliability for the evaluation of post-critical behavior, including strong nonlinear pre-critical and modal interaction, is well known. The most recent finite element implementations of Koiter’s approach are based on corotational formulation, which allows to automatically reuse linear finite elements into a nonlinear context once the geometrically non-linear corotational kinematics are developed. Beam assemblages, folded plates structures are extended here to laminated composite slender structures. By reusing the mixed finite element MISS-4 into a corotational framework, an analysis of folded plate structures
within an FSDT theory is developed. The analysis of a box structure is presented to highlight the accuracy of the Koiter analysis in the recovery of buckling and post-buckling behavior with low computational cost.

ABSTRACT: The wrinkling phenomenon is a commonly-known problem in many fields of engineering applications. Using a general structural analysis framework of the vector-form hybrid particle-element method (VHPEM), this paper presents a newly developed shell-based numerical model for the geometrically nonlinear wrinkling analysis of thin membranes. VHPEM is rooted in vector mechanics and physical perspective. It discretizes the analyzed domain into a group of finite particles linked by canonical elements, and the motions of the free particles are governed by Newton’s second law while the constrained ones follow the prescribed paths. An adaptive convected material frame is adopted for a general kinematical description. Internal forces related to the non-zero bending rigidity of a membrane can be efficiently evaluated by the rotation deformation in a set of deformation coordinates after eliminating rigid body motions simply by a fictitious reverse motion. To overcome the numerical difficulties associated with wrinkles, a pseudo-dynamic scheme using the explicit time integration is introduced into this method. Structural nonlinearity can be easily handled without iterative operations or any other special modification. The wrinkling behavior can be readily obtained by performing a pseudo bifurcation analysis incorporated into the VHPEM. The numerical results reveal that the VHPEM has good reliability and accuracy on solving the membrane wrinkling problem.

"Collapse of Roorda's frame, including the effect of imperfections of arbitrary magnitude", Computational Mechanics 2012 (28th conference with international participation), Spicak, November 12-14, 2012

Text from the paper:
In the present paper we investigate the complete postcritical behavior of an L-shaped frame as well as the complete nonlinear response of imperfect Roorda's frame. We use a dynamical simulation of a frame with 200 mm length, 4 mm width and 0.5 mm depth made of steel. The load vs rotation curve for an imperfection in load eccentricity e = 0.1 is considered. Figure 2 of the paper shows the equilibrium curve of the frame. By controlling the velocity of load we can make a motion picture of the process. As an example, for ten thousands frames we need near 100 MB to calculate and save the motion picture. In conclusion a new post-critical solution of Roorda's frame including the effect of imperfections of arbitrary magnitude was presented in this paper. The presentation include a desk top experiment and a Java applete of Roorda's frame after buckling to right with a 30 mm imperfection of the load eccentricity.

ABSTRACT: Variable angle tow (VAT) laminates have previously shown enhanced buckling performance compared to conventional straight fibre laminates. In this study, an analytical method is developed for the buckling analysis of a novel blade stiffened VAT panel to allow this potential to be more fully exploited. The prebuckling and buckling analysis, performed on a representative section of a blade stiffened VAT panel, are based on a generalised Rayleigh–Ritz procedure. The buckling analysis includes a first order shear deformation
theory by introducing additional shape functions for transverse shear and is therefore applicable to structures with thick skins relative to characteristic length. Modelling of the stiffener is achieved with two approaches; idealisation as a beam attached to the skin’s midplane and as a rigidly attached plate. Comparing results with finite element analysis (Abaqus) for selected case studies, local buckling errors for the beam model and plate model were found to be less than 3% and 2% respectively, whilst the beam model error for global buckling was between 3% and 10%. The analytical model provides an accurate alternative to the computationally expensive finite element analysis and is therefore suitable for future work on the design and optimisation of stiffened VAT panels.

ABSTRACT: The results reported here are analogous to those reported in a previous paper on minimum weight design of elastic axially compressed prismatic complexly corrugated panels and shells in which the corrugations, each of which is a little cylindrical segment, run in the longitudinal direction. Here the corrugations, each of which is a little toroidal segment, run in the circumferential direction. The complexly corrugated shell of revolution is loaded by uniform external lateral normal pressure. There is no axial load component equal to pr/2, and the shell of revolution is free to expand or contract in the axial direction as the external pressure is applied. As before, the GENOPT/BIGBOSOR4 system is used to build the model and to perform the optimization. The minimum weight of the circumferentially corrugated shell is determined in the presence of the following behavioral constraints: 1. The shell shall not buckle locally, 2. The shell shall not buckle in a general mode that is symmetric at the plane of symmetry, 3. The shell shall not buckle in a general mode that is anti-symmetric at the plane of symmetry, 4. The maximum effective stress in the wall of the shell shall be less than a specified value. “Corners” at junctions between adjacent toroidal segments are eliminated by the automatic insertion of small “smoothing” toroidal segments. The circumferentially corrugated shells are optimized with and without the inclusion of nonlinear geometric effects, and it is found that these nonlinear effects are significant. Optimized designs are extremely sensitive to small changes in certain of the decision variables, making it difficult to find “global” optimum designs, especially when nonlinear theory is used. Several optimized designs determined with GENOPT/BIGBOSOR4 are verified by comparison with predictions from the general-purpose computer program STAGS. The agreement between the predictions of GENOPT/BIGBOSOR4 and STAGS is always good when linear theory is used, good for local buckling when either linear or nonlinear theory is used and fair for general buckling when nonlinear theory is used. There is always good agreement between BIGBOSOR4 and STAGS for the prediction of axisymmetric pre-buckling maximum effective stress.

ABSTRACT: Buckling behavior of functionally graded materials cylindrical shell under pure bending is studied in this paper. The stability equations of functionally graded materials cylindrical shell are derived using the classical plate and shell theory with Kirchhoff hypothesis, importing the bending boundary condition to obtain
the critical buckling load. The result shows that the critical moment is linear with the radius, quadratic with the thickness and irrelevant with the length of the cylindrical shell. In addition, the critical moment is decreased by increasing the power law index of the material bulk, trending to a constant finally.

conical shells undergoing external pressure was investigated by numerical analysis. Results are compared with experimental data. It is established that initial imperfections significantly influence the buckling pressure value only for large imperfection amplitude (an order of magnitude more than the shell thickness). The existence is established of the effect of a ‘static resonance’.

ABSTRACT: Ceramics have some of the highest strength- and stiffness-to-weight ratios of any material but are suboptimal for use as structural materials because of their brittleness and sensitivity to flaws. We demonstrate the creation of structural metamaterials composed of nanoscale ceramics that are simultaneously ultralight, strong, and energy-absorbing and can recover their original shape after compressions in excess of 50% strain. Hollow-tube alumina nanolattices were fabricated using two-photon lithography, atomic layer deposition, and oxygen plasma etching. Structures were made with wall thicknesses of 5 to 60 nanometers and densities of 6.3 to 258 kilograms per cubic meter. Compression experiments revealed that optimizing the wall thickness-to-radius ratio of the tubes can suppress brittle fracture in the constituent solid in favor of elastic shell buckling, resulting in ductile-like deformation and recoverability.

M. S. Razzaghi and F. Karimi T. (Qazvin Branch, Islamic Azad University), “Buckling of Stiffened Thin Walled Cylindrical Tanks with Shell Imperfections due to Global Shear and Seismic Loads”, 15 WCEE, Lisboa, Portugal, 2012  
SUMMARY: Thin walled cylindrical shells are important components of industrial structures such as liquid storage tanks, silos, etc. Shell buckling is usually a major failure mode of thin walled shells under extreme loads such as earthquakes. Longitudinal and radial stiffeners are generally used in order to increase buckling capacity of thin walled shells. During an earthquake, cylindrical shells may experience global shear and suffer shear buckling. Buckling of thin walled shells is highly dependent to imperfections. In this study buckling of imperfect cylindrical stiffened tanks due to global shear and seismic loads are studied. To this end nonlinear FE static analyses have been performed in order to estimate buckling capacity of imperfect cylindrical stiffened tanks due to global shear. Herein cylindrical tanks of a constant height and different height to diameter (H/D) ratios were considered. Different arrangements of stiffeners were considered for each tank. Random patterns of imperfection with moderate imperfection amplitude were considered in all tanks. Design relations have been presented based on the results of numerical analyses. Finally, time history analyses were performed in order to evaluate the validity of suggested design relations for buckling of cylindrical stiffened tanks due to seismic loads.

ABSTRACT: Thin-walled cylindrical shells are important components of many industrial complexes. Most of these components have circular cutouts in manholes and pipe-to-shell junctions. Performance of cylindrical shells due to the extreme loading conditions shows that buckling is the major failure mode in such components. This study aims to indicate the effect of circular cutouts on buckling capacity of cylindrical shells due to pure axial compression. To this end, cylindrical shells of different geometric specifications and various arrangements and sizes of cutouts were considered. Numerical nonlinear analyses were conducted using ANSYS software. Result of this study revealed that cutouts can play a noticeable role in creating stress concentration and affect destructively the stability of structures. It is shown that there is a noticeable difference between the effects on cutouts in buckling of thinner shells and thicker ones. Cutouts reduce the local buckling capacity of shell about 10–15 % in the cylindrical shells, with the diameter to thickness ratio of less than 1,000. Meanwhile in shells with diameter to thickness, more than 1,000 such cutouts reduce the shell capacity about 30–35 %.

ABSTRACT: Design of stiffened panels requires evaluating their stability under various loading combinations for all possible scenarios regarding material degradation or initial geometric imperfections that could affect them. Both static and dynamic loading conditions are to be investigated for assessing the buckling strength. In this work, dynamic buckling under in-plane uniform axial compression loading having the form of a transient pulse with finite duration is evaluated through nonlinear finite element modelling. A welding induced defect that consists of an initial geometric imperfection modifying the skin plate curvature in the longitudinal direction was incorporated. The Budiansky buckling criterion was employed to predict instability under this dynamic loading. The obtained results have shown that the pulse period yields a drastic effect on the buckling strength. For the considered boundary conditions, half-sine like pulses having periods that are comparable to two times the period of the first mode of natural vibrations of the stiffened plate were found to reduce hugely the buckling strength, with the dynamic buckling load representing almost only half its static value.

ABSTRACT: Design of stiffened panels requires evaluating their behavior under any loading circumstances by considering initial geometric imperfections and the altering effects resulting from eventual material degradation. Both static and dynamic loading scenarios are to be investigated in order to assess safety for buckling strength of these vital structures. In this work, dynamic buckling under in-plane uniform axial compression loading
having the form of finite duration pulse is analyzed through nonlinear finite element modeling of the structure. Welding induced defects that consist of initial geometric imperfections modifying the skin plate curvature in the longitudinal direction were incorporated. Material degradation in the heat affected zone was also taken into account. The Budiansky and Roth buckling criterion was employed to predict instability under a given dynamic load pattern. Various profiles including rectangular, triangular, double-triangular and half-sine were considered. The obtained results have shown that both the pulse period and the pulse shape have a drastic effect on the buckling strength. For the considered boundary conditions, pulses having periods that are comparable to two times the period of the first natural mode of vibrations were found to reduce the static buckling strength up to 66% in the elastic regime and 33% in the elastic plastic regime.

Hong, Tao, 2000 Dissertation: “Nonlinear, buckling and postbuckling analysis of shells of revolution”, The Hong Kong Polytechnic University, PolyU Institutional Repository, Civil and Environmental Engineering, CEE Theses, http://hdl.handle.net/10397/3062

ABSTRACT: This thesis presents a series of developments leading to an efficient and accurate finite element analysis for nonlinear, buckling and postbuckling behaviour of thin elastic shells of revolution. An accurate isoparametric doubly-curved axisymmetric shell element is employed in these developments, with circumferential variations of loads, deformations and internal forces all represented by Fourier series. The work represents an important step towards the eventual development of a so-called 'advanced analysis' for stability design of steel shell structures in which imperfections, residual stresses and material plasticity are all realistically modelled. A review of the existing literature reveals that while there have been many studies on the finite element analysis of shells of revolution, only a limited number of analyses have been developed for nonlinear shells of revolution under arbitrary loads. A number of deficiencies are identified in existing studies. Among these are the uncertainty concerning the accuracy of existing nonlinear shell theories, the inability to trace the descending part of the load-deflection path of unsymmetrically loaded shells when the pseudo-load concept is used, and the lack of efficient and powerful techniques to predict postbuckling responses with mode
switching. The present developments overcome these existing deficiencies and result in a computer analysis which is both accurate and efficient. A study on suitable nonlinear strain-displacement relations for numerical analysis of complex branched shells is first described. Such relations are a basic building block in any numerical nonlinear, buckling and postbuckling analysis. A number of nonlinear strain-displacement relations have been developed in the past for thin shells. Most of these theories were developed in the pre-computer era for analytical studies when simplicity was emphasized more than accuracy. With the availability of greatly increased computing power in recent years, accuracy rather than simplicity is given more emphasis. A new set of nonlinear strain-displacement relations for thin shells of general form developed directly from the nonlinear elastic theory of three-dimensional solids is thus presented in this thesis. In this new theory, all nonlinear terms, large and small, are retained. This new theory is found to reduce to that of Rotter and Jumikis and others for shells of revolution. This new theory is compared with other nonlinear shell theories both analytically and numerically.

Shells and plates on elastic foundations are found in many practical applications. A large deflection analysis of axisymmetric shells and plates on a nonlinear tensionless elastic foundation is next presented in this thesis. Through the use of discrete data points, any form of nonlinear elastic foundation behaviour can be easily modelled. The analysis is applied to investigate the behaviour of shallow spherical shells subjected to a central concentrated load on tensionless linear elastic foundations. A number of insightful conclusions regarding the behaviour of such structure-foundation systems are drawn. The numerical results for shells are believed to be the first correct results which may be useful in benchmarking results from other sources in the future. A new finite element formulation is then presented for the nonlinear and collapse (limit point buckling) analysis of elastic doubly-curved segmented and branched shells of revolution subject to arbitrary loads. The circumferential variations of all quantities are described by truncated Fourier series with an appropriate number of harmonic terms. Coupling between different harmonics is dealt with directly rather than by the use of pseudo-loads. This coupled harmonics approach allows an easy implementation of the arc-length method. As a result, the postbuckling load-deflection path can be traced efficiently and accurately. The results from the present study are independently verified using ABAQUS, while those from other studies are found to be inaccurate in general. Post-bifurcation buckling analysis of shells of revolution subject to axisymmetric loads is a key to understanding their postbuckling behaviour and imperfection sensitivity. Two efficient and accurate methods are thus developed to trace the postbuckling equilibrium path: the direct method and the load-disturbance method. In the direct method, an automated solution procedure is employed to determine the bifurcation buckling load and the bifurcation buckling mode. Then, a displacement increment parallel to this bifurcation buckling mode is introduced. In the load-disturbance method, small non-symmetric loads in appropriate harmonic modes are added so that the post-bifurcation buckling analysis is converted into a nonlinear non-symmetric analysis. The advantage of the direct method is that the bifurcation load and the postbuckling path in its vicinity can be determined precisely. On the other hand, the load-disturbance method is able to follow mode switching and interaction which cannot be handled by the direct method as presented here. Numerical results obtained here lead to some important conclusions concerning postbuckling analysis and behaviour. Finally, the finite element formulation for perfect shells under arbitrary loading mentioned earlier is extended to shells with non-symmetric imperfections. The initial imperfections are also arbitrary and expanded into truncated Fourier series. As a special case of this analysis, the imperfection-disturbance method is presented for tracing complex postbuckling paths involving mode switching and interaction. In addition, the imperfection sensitivity of a number of problems is examined using the developed analysis.

Xu, Hailan (Ph.D Dissertation, Professor David Hui advisor, Engineering and Applied Science, Dept. of Mechanical Engineering, University of New Orleans), "Buckling, Postbuckling and Imperfection Sensitivity
Analysis of Different Type of Cylindrical Shells by Hui's Postbuckling Method" (2013). University of New Orleans Theses and Dissertations. Paper 1781.

ABSTRACT: Buckling and postbuckling has been critical design parameters for many engineering structures. In recent years, this topic has continued to be of major concern due to (1) the discovery of new materials with amazingly superior properties, (2) increasingly more stringent safety requirements, (3) lighter, and more durable requirements. Such applications can be routinely found in aerospace, naval, civil, and electrical, and nuclear engineering structures and especially in the vehicle industries. Koiter is the first one to show that the imperfection-sensitivity of a structure is determined by its initial postbuckling behavior. In Koiter’s 1945 general postbuckling theory, it defines the initial postbuckling behavior and imperfection sensitivity behavior by the postbuckling b coefficient. Hui and Chen (1986) were the first to show that the well-known Koiter’s General Theory of Elastic Stability of 1945 can be significantly improved by evaluating the postbuckling b coefficient at the actual applied load, rather than at the classical buckling load. The reason for such significant improvement in predicting the imperfection sensitivity is due to the fact that for an imperfection-sensitive structure, the slope of the buckling load versus imperfection amplitude curve approaches negative “infinity” as the imperfection amplitude approaches to zero. Thus for “finite” amplitude of the geometric imperfection, the applied load is significantly lower than the classical buckling load, leading to significant overestimate of imperfection using Koiter’s General theory of 1945. Such improvement method was demonstrated to be (1) very simple to apply with no tedious algebra, (2) significant reduction in imperfection sensitivity and (3) although it is still asymptotically valid, there exists a significant extension of validity involving larger imperfection amplitudes. Strictly speaking, Koiter’s theory of 1945 is valid only for vanishingly small imperfection amplitudes. Hence such improved method is termed Hui’s Postbuckling method. This study deals with the Postbuckling and imperfection sensitivity of different kinds of cylinders by using the Hui’s postbuckling method. For unstiffened cylinder and laminate cylinder, the solution of Hui’s postbuckling method is compared with ABAQUS simulation result. A parameter variation of stringer/ring stiffened cylinder is also evaluated. A positive shift of the postbuckling b coefficient has been observed, which indicates a significant overestimate of the imperfection sensitivity by Koiter's general stability theory. More importantly, the valid region is significantly increased by using Hui's postbuckling method compared with the Koiter's general stability theory.

ABSTRACT: This paper deals with the buckling and initial-postbuckling behavior and imperfection-sensitivity of stringer or ring stiffened cylindrical shells under pure torsion. In particular, the effectiveness of stringer versus ring stiffened shells is examined for various types of stiffener and shell parameters under different boundary condition. The initial-postbuckling single-mode analysis is performed using Koiter’s general theory of elastic stability. By changing the parameters of stringer or ring, we are able to find out how does the stringer or ring affecting the buckling and post-buckling behavior of cylindrical shells.

ABSTRACT: Stability analyses of perfect and imperfect cylindrical shells under axial compression and torsion were presented. Finite element method for the stability analysis of perfect cylindrical shells was put forward through comparing critical loads and the first buckling modes with those obtained through theoretical analysis. Two typical initial defects, non-circularity and uneven thickness distribution, were studied. Critical loads decline with the increase of non-circularity, which exist in imperfect cylindrical shells under both axial...
Compression and torsion. Non-circularity defect has no effect on the first buckling mode when cylindrical shell is under torsion. Unfortunately, it has a completely different buckling mode when cylindrical shell is under axial compression. Critical loads decline with the increase of thickness defect amplitude, which exist in imperfect cylindrical shells under both axial compression and torsion, too. A greater wave number is conducive to the stability of cylindrical shells. The first buckling mode of imperfect cylindrical shells under torsion maintains its original shape, but it changes with wave number when the cylindrical shell is under axial compression.

**ABSTRACT:** Composite stiffened plate structure is widely used in aviation, aerospace and marine areas, in order to ensure the structural reliability, stability analysis is absolutely necessary. The finite element models are established. In this paper, subspace method and arc-length method are applied to analyze the stability of stiffened panel structure, both two methods are effective. Different stringer parameters will have some impact on the stability, including the number and height. Through analyzing the results, some conclusions are drew for increasing the stability. They have a certain value for engineering application.

**ABSTRACT:** Buckling of a thin cylindrical sandwich shell composed of elastic isotropic layers with different elastic properties under normal external pressure is the subject of this investigation. Differential equations based on the assumptions of the generalized kinematic hypothesis for the whole sandwich are used as the governing ones. Two variants of the joint support conditions are considered at the shell edges: a) there are the infinite rigidity diaphragms inhibiting relative shears of layers along the shell edges, b) the diaphragms are absent. Using the asymptotic approach, the critical pressure and buckling modes are constructed in the form of the superposition of functions corresponding to the main stress-strain state and the edges integrals. As an example, a three-layered cylinder with the magnetorheological elastomer (MRE) embedded between elastic layers under different levels of magnetic field is studied. Physical properties of the magnetorheological (MR) layer are assumed to be functions of the magnetic field induction. Dependencies of the buckling pressure on the variant of boundary conditions and the intensity of applied magnetic field are analyzed.

ABSTRACT: Functionally graded materials (FGMs) are microscopically inhomogeneous spatial composite materials typically composed of a ceramic-metal or ceramic-polymer pair of materials. Therefore, it is important to investigate the behaviors of engineering structures such as beams and plates made from FGMs when they are subjected to thermal loads for appropriate design. Therefore, using an improved third order shear deformation theory (TSDT) based on more rigorous kinetics of displacements to predict the behaviors of functionally graded plates is expected to be more suitable than using other theories. In this paper, the improved TSDT is used to investigate thermal buckling of functionally graded plates. Temperature dependent material property solutions are adopted to investigate thermal buckling results of functionally graded plates. To obtain the solutions, the Ritz method using polynomial and trigonometric functions for defining admissible displacements and rotations is applied to solve the governing equations.

ABSTRACT: This paper provides a methodology for the structural reliability analysis of marine vessels based on failure modes of their hull girders, stiffened panels including buckling, fatigue, and fracture and corresponding life predictions at the component and system levels. Factors affecting structural integrity such as operational environment and structural response entail uncertainties requiring the use of probabilistic methods to estimate reliabilities associated with various alternatives being considered for design, maintenance, and repair. Variability of corrosion experienced on marine vessels is a specific example of factors affecting structural integrity requiring probabilistic methods. The Structural Life Assessment of Ship Hulls (SLASH) methodology developed in this paper produces time-dependent reliability functions for hull girders, stiffened panels, fatigue details, and fracture at the component and system levels. The methodology was implemented as a web-enabled, cloud-computing-based tool with a database for managing vessels analyzed with associated stations, components, details, and results, and users. Innovative numerical and simulation methods were developed for reliability predictions with the use of conditional expectation. Examples are provided to illustrate the computations.

Khoeilar AR, Zirakian T, Boyajian D, Maalouf S, Dermendjian N, “Case Study on Retrofit of Steel Plate Shear Walls Using Low Yield Point Steel Infill Plates”, J Steel Struct Constr 2:106. December 2015,
Steel plate shear walls (SPSWs) have been frequently used in seismic design and retrofit of buildings over the past three decades or so. Employment of infill plates made of low yield point (LYP) steel with considerably low yield stress and high elongation capacity is believed to provide the possibility in order to improve the structural and seismic characteristics of such lateral force-resisting systems. Among the various benefits is the early yielding of LYP steel infill plates, which can result in greater energy absorption capacity and limitation of the plastic deformation demand to the surrounding frame structure. On this basis, a case study is performed using numerical simulations and reported in this paper on the seismic retrofit of SPSWs using LYP steel infill plates of double thickness. It is shown that the retrofit of a steel shear wall using a LYP steel infill plate of double thickness can result in desirable plate-frame yielding sequence and interaction. Moreover, this retrofit strategy can improve the initial stiffness, buckling stability, and energy dissipation capacity of the existing SPSW system.

ABSTRACT: The free vibration of curvilinearly stiffened shallow shells is investigated by the Ritz method. Based on the first-order shear deformation shell theory and three-dimensional (3D) curved beam theory, the strain and kinetic energies of the stiffened shells are introduced. The stiffener can be placed anywhere within the shell, without the need for having the stiffener and shell element nodes coincide. Numerical results with different geometrical shells and boundary conditions and different stiffener locations and curvatures are analyzed to verify the feasibility of the presented Ritz method for solving the problems. The results show good agreement with those using other methods, e.g., using a converged set of results obtained by NASTRAN.

ABSTRACT: Pipes for deep-water applications possess a diameter-to-thickness ratio in a region where failure is dominated by both instability and plastic collapse. This implies that prior to failure the compressive yield strength of the material must be exceeded, followed by ovalisation and further local yielding. This paper presents an investigation into the mechanics of this specific problem and develops an analytical approach that accounts for the effects of geometrical and material data on the collapse pressure of inhomogeneous rings under external hydrostatic pressure. The analytical expressions have been correlated to numerical and experimental test data, proving their accuracy.

ABSTRACT: The elastic-plastic collapse of circular beams under uniform lateral pressure with an initial imperfection represented by a combination of different modes and amplitudes and with varying material properties is analysed from a computational viewpoint. The work is stimulated by a number of accurate experimental tests recently performed and it is found that both the initial imperfection and the material inhomogeneity along the beam axis can affect the collapse and produce a sensible variation in the carrying capacity of the structure on account of the changes between the underlying buckling modes. This can give reason for some apparently anomalous observed experimental results.

ABSTRACT: Many authors in the literature agreed that the flow theory of plasticity either fails to predict buckling or overestimates plastic buckling stresses and strains of plates and shells while the deformation theory succeeds in forecasting buckling and provides estimates that are more in line with the experimental results. Following a previous study by the same authors focused on compressed cylinders, the present work aims to investigate the reasons for the discrepancy between the flow and deformation theory predictions in the case of cylinders subjected to combined axial tensile load and increasing external lateral pressure. To this end, geometrically nonlinear finite-element calculations of selected cylindrical shells using both the flow theory and the deformation theory of plasticity have been conducted, and the results are compared with some accurate physical test results and with numerical results obtained by other authors using the code BOSOR5. It is found, contrary to common belief, that very good agreement between numerical and test results can be obtained in the case of the flow theory of plasticity. The reasons underlying the apparent plastic buckling paradox are discussed in detail.

ABSTRACT: This study analyzes the buckling capacity of steel cylindrical shells that exhibit the lower segment of 2MW, 3MW and 5MW wind towers. Four cases of steel cylindrical shells are modeled: shell with neither door opening nor collar stiffener; shell with door opening but without collar stiffener; shell without door opening but with collar stiffener; and shell with both door opening and collar stiffener. Buckling capacity is analyzed numerically using finite element analysis and parametrically using Eurocode 3: Design of Steel Structures and Guideline for the Certification of Offshore Wind Turbines. In finite element analysis, buckling capacity is calculated linearly using eigenvalue analysis and non-linearly using static Riks. Results show that steel cylindrical shell with discontinuity or modification in geometry such as door opening and collar stiffener indicates local buckling. Furthermore, a 35% decline of critical (bifurcation) buckling capacity is observed when linear buckling analysis is compared to nonlinear buckling analysis. Linear buckling analysis provides a
good starting point in solving buckling collapse load, but non-linear analysis delivers a more accurate assessment due to the consideration of influences in material and geometrical nonlinearity.

ABSTRACT: The paper presents problems related to the numerical modeling of profiled steel sheets used as self-supporting arch structures for roof covering. The rules of preparing and full analysis of a set of numerical models of these elements with a different level of complexity are given. The models are evaluated by comparing numerical results with the results of extended experimental tests performed by 3D Digital Image Correlation (DIC) method. For each model the comparison of numerical and experimental results has been made for samples of a single-wave trapezoidal profile with corrugated web and lower flanges subjected to compression and bending. The full-field analysis allows to determine the allowed simplification of numerical models which do not affect in significant way the reliability of the results. The proposed methodology is the first step in the development of full assessment methodology for different types of self-supporting arch structures produced by ABM technology.

ABSTRACT: A new formulation for plates/shells with large deformations and large rotations is derived from the principles of continuum mechanics and calculated using the absolute nodal coordinate formulation (ANCF) techniques. A class of triangular elements is proposed to discretize the plate/shell formulation, which does not suffer from shear locking or membrane locking issue, and full quadrature can be performed to evaluate the integrals of each element. The adaptability of triangular elements enables the current approach to be applied to plates and shells with complicated shapes and variable thicknesses. The discretized mass matrix is constant, and the elastic force and stiffness matrix are polynomials of the generalized coordinates with constant coefficients. All the coefficients can be evaluated accurately beforehand, and numerical quadrature is not required in each time step of the simulation, which makes the current approach superior in numerical efficiency to most other approaches. The accuracy, robustness, and adaptability of the current approach are validated using both finite element benchmarks and multibody system standard tests.

ABSTRACT: In this paper, nonlinear dynamical behavior of a rectangular plate traveled by a moving mass as well as an equivalent concentrated force with non-constant velocity is studied. The nonlinear governing coupled partial differential equations (PDEs) of motion are derived by energy method using Hamilton’s principle based on the large deflection theory in conjunction with the von-Karman strain-displacement relations. Then
Galérkin’s method is used to transform the equations of motion into a set of three coupled nonlinear ordinary differential equations (ODEs) which then is solved in a semi-analytical way to get the dynamical response of the plate. Also, by using the Finite Element Method (FEM) with ANSYS software, the obtained results in nonlinear form are verified by FEM results. Then, a parametric study is conducted by changing the size of moving mass/force and the velocity of the traveling mass/force with a constant acceleration/deceleration, and the outcome nonlinear results are compared to the results from linear solution.

“Effect Of Initial Geometrical Imperfections On The Buckling Load Of Cylindrical Sandwich Shells Under Axial Compression”, DESICOS (www.DESICOS.eu), 2014 or 2015. [3rd Int. Conf. on Buckling and Postbuckling Behaviour of Composite Laminated Shell Structures with DESICOS Workshop (25.-27.03.2015)]

ABSTRACT: The impact of geometrical imperfections on the general instability of laminated cylindrical sandwich shells was assessed by means of a numerical investigation. Five forms of ‘ideal’ initial geometrical imperfection patterns were studied: eigen-mode shaped, axisymmetric dimple, geometric dimple, single perturbation load and single stress-free dimple. Implementation of such imperfections, despite their simplicity, can provide a method for predicting lower-bound buckling loads during the preliminary design phase, when the structural defects of the real hardware are unknown. Numerical prediction of the non-linear instability of the cylinders under axial compression was performed using the finite element method. A typical launcher Inter Stage Skirt (ISS) structure is used as the basis for the chosen geometry and materials. In order to make design and qualification tests more affordable, it is common to use representative sub-scaled hardware. This paper verifies the validity of the chosen sub-scaling method of an ISS cylindrical shell. Buckling mechanisms are described and the different lower-bound methods are discussed.

ABSTRACT: A numerical investigation was carried out to assess the impact of geometrical imperfections on the stability of laminated sandwich cylindrical shells. This paper summarizes the most interesting results of a more extensive investigation in which a number of geometrical imperfection patterns were implemented. Specifically, eigenmode-shaped and single perturbation load imperfections are discussed herein. Such imperfections might provide a method for fast prediction of lower-bound buckling loads during the design phase, when details about the real structural and material defects are unknown. In order to make design and qualification more affordable, it is common practice to use sub-scaled hardware for testing. As part of the DESICOS project, a sandwich cylinder product of the sub-scaling of a typical launcher Inter Skirt Structure (ISS) will be tested. This paper verifies the sub-scaling method, validates the test setup and makes a prediction of the test results. Buckling mechanisms are described and the different lower-bound methods are discussed.

ABSTRACT: A buckling analysis of rectangular laminated composite plates with an edge delamination under in-plane compressive loading is performed using the finite element method. Such plates may be considered as simplified models of stiffener plates of a stiffened panel. The buckling load and buckling mode are obtained by solving an eigenproblem. In an unconstrained analysis physically inadmissible sublaminates may appear because of the overlap between separated sublaminates in the delaminated region. To eliminate overlap, constraints are added iteratively on the entire overlapped area using penalty function method. The validity and superiority of the analysis method in predicting buckling load and buckling mode are shown in comparison with the experimental and analytical results available in the literature. Numerical results show the effect of delamination width and depth and boundary conditions on the buckling load.

ABSTRACT: We consider the form of an elastic loop adhered to a rigid substrate: the ‘Sticky Elastica’. In contrast to previous studies of the shape of delamination ‘blisters’, the theory developed accounts for deflections with large slope (i.e. geometrically nonlinear). Starting from the classical Euler Elastica we provide numerical results for the dimensions of such blisters for a variety of end–end confinements and develop asymptotic expressions that reproduce these results well, even up to the point of self-contact. Interestingly, we find that the width of such blisters does not grow monotonically with increased confinement. Our theoretical predictions are confirmed by simple desktop experiments and suggest a new method for the measurement of the
elastocapillary length for deformations that cannot be considered small. We discuss the implications of our results for applications such as flexible electronics.

ABSTRACT: We study theoretically the deposition of few layer graphene sheets onto a grooved substrate incorporating adhesion between substrate and sheet. We develop a model to understand the equilibrium of the sheet allowing for partial conformal deformation of sheet to substrate. This model gives physical insight into recent observations of “snap-through” from flat to conforming states and emphasizes the crucial role of substrate shape in determining the nature of this transition. Our analytical results are consistent with numerical simulations using a van der Waals-like interaction. Finally, we propose a substrate shape that should exhibit a continuous, rather than “snap-through”, transition.

Dominic Vella, Amin Ajdari, Ashkan Vaziri and Arezki Boudaoud, “The indentation of pressurized elastic shells: from polymeric capsules to yeast cells”, Journal of the Royal Society Interface, August 2011,
DOI: 10.1098/rsif.2011.0352
ABSTRACT: Pressurized elastic capsules arise at scales ranging from the 10 m diameter pressure vessels used to store propane at oil refineries to the microscopic polymeric capsules that may be used in drug delivery. Nature also makes extensive use of pressurized elastic capsules: plant cells, bacteria and fungi have stiff walls, which are subject to an internal turgor pressure. Here, we present theoretical, numerical and experimental investigations of the indentation of a linearly elastic shell subject to a constant internal pressure. We show that, unlike unpressurized shells, the relationship between force and displacement demonstrates two linear regimes. We determine analytical expressions for the effective stiffness in each of these regimes in terms of the material properties of the shell and the pressure difference. As a consequence, a single indentation experiment over a range of displacements may be used as a simple assay to determine both the internal pressure and elastic properties of capsules. Our results are relevant for determining the internal pressure in bacterial, fungal or plant cells. As an illustration of this, we apply our results to recent measurements of the stiffness of baker’s yeast and infer from these experiments that the internal osmotic pressure of yeast cells may be regulated in response to changes in the osmotic pressure of the external medium.

DOI: 10.1016/j.tws.2013.06.012
ABSTRACT: In this study, the buckling of two joined isotropic conical shells under axial compression and simply supported boundary conditions is investigated. The governing equations are obtained using thin-walled shallow shell theory of Donnell-type and theorem of minimum potential energy. The continuity conditions at the joining section of the cones are appropriate expressions among stress resultants and deformations. The equations are solved by assuming trigonometric response in circumferential and series solution in meridional direction. The results are validated in comparison with the available results in the literature. Effects of semi-vertex angles and meridional lengths on the buckling load and typical mode shape and circumferential wave number are investigated. In addition, the application of the results of this study on the load carrying capacity of these structures is presented.

ABSTRACT: Elastic stability of shell structures under certain loading conditions is characterized by a dramatically unstable postbuckling behavior. The presence of simultaneous ‘competing’ buckling modes (corresponding to the same critical buckling load) is understood to be largely responsible for such behavior. In this paper, within the framework of linear bifurcation eigenvalue analysis and Donnell shallow shell theory, the presence of simultaneous buckling modes in axially compressed isotropic cones is determined using the semi-analytical method of Galerkin. The results are presented in the plane of the dimensionless reciprocal meridional and circumferential buckling half wavelengths, and are compared with the locus of simultaneous buckling modes of axially compressed cylinders, described by the so-called Koiter circle. By using an optimizing procedure, it is shown that the cluster of simultaneous buckling modes in cones is well described by the Koiter circle of an equivalent cylinder with appropriate length and radius. Such optimizing values of length and radius allow us to gain some insight into the simplifying treatment of the buckling of cones through the concept of equivalent cylinder.

Rohit Kumar Singh, “Thermal buckling analysis of laminated composite shell panel embedded with shape memory alloy fibre under TD and TID”, Master’s Thesis, Department of Mechanical Engineering, National Institute of Technology Rourkela Odisha, India, June 2014 (Professor S. K. Panda, Advisor)
ABSTRACT: Laminated composite shell panels are increasingly used in aeronautical, marine and mechanical industries as well as in other fields of modern technology because of its advance mechanical properties. It is well known that the composites have high strength to weight ratio and stiffness to weight ratio as compared to any conventional materials like concrete, metal, and wood. As the uses of the composites in different industries have increased which leads to their analysis through mathematical, experimental and/or simulation based model for accurate design and subsequent manufacturing. The structural components of aircraft, launch vehicle and
missiles are subjected to various types of combined loading and exposed to large acoustic, vibration, inertia excitation during their service life. In addition to that the structural components are also exposed to elevated thermal environment due to the aerodynamic heating. This often changes the original geometry of the panel due to excess deformation and the structural performances reduce. In this work, thermal buckling behaviour of laminated composite curved panel embedded with shape memory alloy fibre (SMA) is investigated. The material properties of composite laminate and SMA fibres are taken as temperature dependent. The mathematical model is developed based on higher order shear deformation theory (HSDT) to count the exact flexure of the laminate. The buckling behaviour is evaluated based on the Green-Lagrange strain-displacement equations for in-plane strains to account the large deflections under uniform temperature loading. The nonlinear material behaviour of shape memory alloy is introduced through a marching technique. The responses are obtained using variational principle in conjunction with suitable isoparametric finite element modelling based on the MATLAB code. In addition to that, a simulation model is also being developed in ANSYS environment using ANSYS parametric design language code for laminated composites curved panel and the corresponding responses are compared with those available literatures. The effects of layup sequence, thickness ratio, ply angle, support conditions and temperature dependence material properties on thermal buckling load are obtained and discussed.

ABSTRACT: The nonlinear forced vibration of infinitely long functionally graded cylindrical shells is studied using the Lagrangian theory and multiple scale method. The equivalent properties of functionally graded materials are described as a power-law distribution in the thickness direction. The energy approach is applied to derive the reduced low-dimensional nonlinear ordinary differential equations of motion. Using the multiple scale method, a special case is investigated when there is a 1:2 internal resonance between two modes and the excitation frequency is close to the higher natural frequency. The amplitude–frequency curves and the bifurcation behavior of the system are analyzed using numerical continuation method, and the path leading the system to chaos is revealed. The evolution of symmetry is depicted by both the perturbation method and the numerical Poincaré maps. The effect of power-law exponent on the amplitude response of the system is also discussed.

ABSTRACT: Thin cylindrical shells are commonly employed in civil and structural applications in which the dominant loading condition is global bending. In applications such as wind turbine towers and offshore piles, the design of the structure is commonly limited by buckling. The traditional approach to improving buckling strength pursuant of greater design economy is to use steel ring and/or axial stiffeners. However, the total steel tonnage may be reduced with stiffeners, but the additional fabrication costs can limit the cost advantage. Meanwhile, it has long been observed in the silo industry that granular filled cylinders exhibit strength gains due to the internal pressure and stiffness of the granular bulk solid against the shell wall. For
large diameter fabricated steel tubes in bending, an elastic granular fill may be useful in replacing ring stiffeners, increasing critical buckling moments, and reducing risk by providing more stable postbuckling behaviour. However, the strength gains related to the elastic stiffness of a granular core has received very little attention and has been limited to the axial loading condition. In the project work, the candidate uses theoretical and computational methods to investigate the effects of an elastic granular fill on the buckling strength of cylindrical shells subject to global bending. In particular, cylinders in the elastic-plastic range will be considered in order to represent applications such as wind turbine towers and offshore piles. Effects of an elastic bulk fill on strength gains and imperfection sensitivity are considered with interest in improving design economy.

ABSTRACT: IPN and IPE sections, which are commonly used European I shapes, are widely used in steel structures as cantilever beams to support overhangs. A considerable number of studies exist on calculating lateral torsional buckling load of I sections. However, most of them provide series solutions or complex closed-form equations. In this paper, a simple equation is presented to calculate lateral torsional buckling load of IPN and IPE section cantilever beams. First, differential equation of lateral torsional buckling is solved numerically for various loading cases. Then a parametric study is conducted on results to present an equation for lateral torsional buckling load of European IPN and IPE beams. Finally, results obtained by presented equation are compared to differential equation solutions and finite element model results. ABAQUS software is utilized to generate finite element models of beams. It is seen that the results obtained from presented equation coincide with differential equation solutions and ABAQUS software results. It can be suggested that presented formula can be safely used to calculate critical lateral torsional buckling load of European IPN and IPE section cantilevers.

ABSTRACT: In this paper, mechanical buckling analysis of open circular cylindrical shell reinforced by single-walled carbon nanotubes subject to axial loading is studied. Based on the first order shear deformation theory, the equilibrium and stability equations have been derived using the total potential energy equations and Euler equations. To estimate the material properties, the rule of mixture has been used. The governing equations are solved by considering the boundary conditions of problem and the effects of geometrical parameters and material properties on the critical buckling load have been studied. In order to validate obtained results, comparison study with other available literature has been carried out.

2013

ABSTRACT: Static, vibration and buckling behavior of laminated composite and sandwich skew plates is
studied using an efficient C0 FE model developed based on refined higher order zigzag theory. The C0 FE
model satisfies the interlaminar shear stress continuity at the interfaces and zero transverse shear stress
conditions at plate top and bottom. In this model, the first derivatives of transverse displacement have been
treated as independent variables to overcome the problem of C1 continuity associated with the plate theory. The
C0 continuity of the present element is compensated in the stiffness matrix formulation by adding a suitable
term. In order to avoid stress oscillations observed in the displacement based finite element, the stress field
derived from temperature is made consistent with the total strain field by using field consistent approach.
Numerical results are presented for different static, vibration and buckling problems by applying the FE model
under thermo mechanical loading, where a nine noded C0 continuous isoparametric element is used. It is
observed that there are very few results available in the literature on laminated composite and sandwich skew
plates based on refined theories. As such many new results are also generated for future reference.

ABSTRACT: Nondestructive experimental methods to calculate the buckling load of imperfection sensitive thin-walled structures are one of the most important techniques for the validation of new structures and numerical models of large scale aerospace structures. Vibration correlation technique (VCT) allows determining equivalent boundary conditions and buckling load for several types of structures without reaching the instability point. VCT is already widely used for beam structures, but the technique is still under development for thin-walled plates and shells. This paper intends to explain the capabilities and current limitations of this technique applied to two types of structures under buckling conditions: flat plates and cylindrical shells prone to buckling. Experimental results for a flat plate and a cylindrical shell are presented together with reliable finite element models for both cases. Preliminary results showed that the VCT can be used to determine the realistic boundary conditions of a given test setup, providing valuable data for the estimation of the buckling load by finite element models. Also numerical results herein presented show that VCT can be used as a nondestructive tool to estimate the buckling load of unstiffened cylindrical shells. Experimental tests are currently under development to further validate the approach proposed herein.

ABSTRACT: Nondestructive methods, to calculate the buckling load of imperfection sensitive thin-walled structures, are one of the most important techniques for the validation of new structures and numerical models of large scale aerospace structures. The vibration correlation technique (VCT) allows determining the buckling load for several types of structures without reaching the instability point, but this technique is still under development for thin-walled plates and shells. This paper presents and discusses an experimental and numerical validation of a novel approach, using the vibration correlation technique, for the prediction of realistic buckling loads on unstiffened cylindrical shells loaded in compression. From the experimental point of view, a batch of three composite laminated cylindrical shells are fabricated and loaded in compression up to buckling. An unsymmetric laminate is adopted in order to increase the sensitivity of the test structure to initial geometric imperfections. In order to characterize a relationship with the applied load, the first natural frequency of vibration and mode shape is measured during testing using a 3D laser scanner. The proposed vibration correlation technique allows one to predict the experimental buckling load with a very good approximation, without actually reaching the instability point. Furthermore, a series of numerical models, including non-linear effects such as initial geometric and thickness imperfection, are carried-out in order to characterize the variation of the natural frequencies of vibration with the applied load and compare the results with the experiment
findings. Additional experimental tests are currently under development to further validate the proposed approach for metallic and balanced composite structures.

“The Influence of Geometrical Parameters on the Buckling Behavior of Conical Shell by the Single Perturbation Load Approach”, Applied Composite Materials, Vo. 22, No. 4, pp 405-422, August 2015, DOI: 10.1007/s10443-014-9414-3

ABSTRACT: Since the development of the first theories to predict the buckling induced by axial compression in shells sensitive to imperfections, a significant discrepancy between theoretical and experimental results has been observed. Donnell and Koiter are among the first authors demonstrating, for these structures, the relevant influence of the geometrical imperfections on the reduction of the buckling load. Currently, the preliminary design of imperfections sensitive shell structures used in space applications is carried out according to the NASA SP-8007 guideline. However, several studies have proven that this guideline leads to over-conservative design configurations when considering the geometrical and material imperfections existing in real cones. Since the pioneer work of Arbocz, alternative methods have been investigated to overcome this issue. Among the different approaches, in this paper, the Single Perturbation Load Approach (SPLA), originally developed by Hühne as a deterministic way to calculate the knock-down factor of imperfection sensitive shells, is further studied. Indeed, a numerical investigation about the application of the SPLA to the simulation of the mechanical behavior of imperfection sensitive composite conical structures under axial compression is presented. This study is related to part of the work performed in the frame of the European Union (EU) project DESICOS.

References listed at the end of the paper:

ABSTRACT: The importance of taking into account geometric imperfections for cylindrical and conical thin-walled structures prone to buckling had been already recognized by the first authors dealing with new formulations. Nowadays, the analysts still use empirically based lower-bound methods such as the NASA SP-8007 guideline to calculate the required knock-down factors (KDFs), which does include important mechanical properties of laminated composite materials, such as the stacking sequence. New design approaches that allow taking full advantage of composite materials are required. The single perturbation load approach (SPLA), a new deterministic approach first proposed by Hühne, will be investigated with unstiffened composite conical structures varying the geometry, lamina and layup. The SPLA’s capability for predicting KDF is compared with the NASA approach. The SPLA was applied to the geometrically perfect structures and to the structure with geometric imperfections of two types, mid-surface imperfections and thickness imperfections. The study contributes to the European Union (EU) project DESICOS, whose aim is to develop less conservative design guidelines for imperfection sensitive thin-walled structures.

Junle Cai, Zhanjie Li, Cristopher Moen, Mihai Nedelcu, Benjamin Schafer, “Automated modal identification for thin shell finite element eigen-buckling solutions”,

EMI 2014 Engineering Mechanics Institute Conference August 5-8, 2014

ABSTRACT: This presentation introduces a freely available tool for performing automated thin-shell finite element (FE) eigen-buckling modal identification. Commercial finite element software is commonly used to study thin-walled members because it can easily handle complex geometries, perforations, and arbitrary loading and boundary conditions. Each buckling analysis produces many mode shapes that are mixtures of fundamental modes, for example, local buckling, distortional buckling, and global buckling. These fundamental modes are important for use in strength prediction and design code development, however their relative participation can be difficult to quantify in an FE analysis. A modeler may have to sift through hundreds of modes, and even then, the modal identification and participation is subjective. A custom-built Matlab program is presented that performs automated FE eigen-buckling modal identification. Recent research advances have led to software that performs automated eigen-buckling modal identification and participation with the constrained finite strip method (cFSM)1 and the generalized beam theory (GBT)2. Our program wraps around this existing code to perform modal decomposition on an FE-generated buckled mode shape. The FE mode shape is input as 3D coordinates from a text file that can be generated by any commercial finite element program. Cross-sectional mode shapes provided by cFSM or GBT are employed to approximate each buckling mode and to determine the modal participation of the fundamental modes3. The novelty of the presented method lies in using only the cross-section deformation modes instead of member base shapes. Using the special orthogonality properties of the cross-section deformation modes, the GBT amplitude functions of the fundamental modes are extracted.
from the FEM displacement field, with great speed and stability.

ABSTRACT: Based the nonlinear elastic shell theory, the governing equations of motion for axisymmetrical laminated cylindrical shell with delamination were derived. The governing equation of transverse motion was modified by introducing pseudo spring to calculate the contact force to avoid the penetration between two delaminated layers. The problem was solved by finite difference method. In numerical examples, the effects of various sizes, depths, delamination positions and loads on the nonlinear dynamic response of the axisymmetrical delaminated laminated cylindrical shell were discussed in detail. Numerical results demonstrate the importance of considering the contact effect in the dynamic response analysis of the structures with delamination. It can prevent physically impossible interpenetration from emerging for delaminated structures.

A. Shahbazian and Y.C. Wang (School of Mechanical, Aerospace and Civil Engineering, the University of Manchester, UK), “Calculating the global buckling resistance of thin-walled steel members with uniform and non-uniform elevated temperatures under axial compression”, Thin-Walled Structures, Vol. 49, No. 11, pp 1415-1428, November 2011, DOI: 10.1016/j.tws.2011.07.001
ABSTRACT: This paper develops a method, based on the Direct Strength Method (DSM) global buckling curve, to calculate the global buckling ultimate strength of cold-formed thin-walled (CF-TW) steel members under uniform and non-uniform elevated temperatures. The assessment is carried out by checking the DSM curve-based results with numerical simulation results using the general finite element software ABAQUS. The numerical model has been validated against a series of ambient temperature and fire tests on panels made of two different lipped channel sections tested to their ultimate load carrying capacities at ambient temperature or to their fire resistance at different load levels. The validated numerical model has been used to generate a database of numerical results of load carry capacity of CF-TW members with different uniform and non-uniform temperature distributions in the cross-sections under different boundary and loading conditions and with different dimensions. It is concluded that the DSM global buckling column curve is directly applicable for uniform temperature but a simple modification is required for non-uniform temperature distributions.

ABSTRACT: Based on the nonlinear theory of shallow spherical thick shells and the damage mechanics, a set of nonlinear equations of motion for the laminated shallow spherical thick shells with damage subjected to a normal concentrated load on the top are established. According to Hertz law, the contact force acted upon the shells is determined due to the impact of a mass, and it is related to the mass and initial velocity of the striking object, the geometrical and physical character of the shell. By using the finite difference method and the time increment procedure, the nonlinear equations are resolved. In the numerical examples, the effects of the damage, the initial velocity, and mass of the striking object, the shells’ geometrical parameters on the dynamic responses and dynamic buckling of the laminated shallow spherical thick shells are discussed.

ABSTRACT: Advanced Grid Stiffened (AGS) composite cylindrical shells are widely used in aerospace industry. This study analyzes the buckling loads for various types of grid structures of AGS composite cylindrical shells. The grid structures are classified as Angle-grid, Iso-grid, Kagome-grid, Ortho-grid, Orthotropic-grid and the characteristics had been analyzed for each grid type. In this study, the various types of grid structure were designed that weight of the whole structure keeps a constant. Under the condition of constant-weight, design variables such as grid angle, number of the grid, h/t ratio of the grid were controlled, and buckling loads of the grid structures were analyzed. The results were analyzed for each type of grid and each design variable of the structures. This study was performed through finite element method and the accuracy of the analysis was verified by previous studies. Finally, buckling modes were analyzed with the thickness of the skin. The selection for the most appropriate design variables had been verified for each grid type and the result can be applied to the optimization of grid structure design, and is also very helpful for reducing the computational cost and obtaining optimization values more accurately.

ABSTRACT: Advanced grid stiffened composite cylindrical shell is widely adopted in advanced structures due to its exceptional mechanical properties. Buckling is a main failure mode of advanced grid stiffened structures in engineering, which calls for increasing attention. In this paper, the buckling response of advanced grid stiffened structure is investigated by three different means including equivalent stiffness model, finite element model and a hybrid model (H-model) that combines equivalent stiffness model with finite element model. Buckling experiment is carried out on an advanced grid stiffened structure to validate the efficiency of different modeling methods. Based on the comparison, the characteristics of different methods are independently evaluated. It is arguable that, by considering the defects of material, finite element model is a suitable numerical tool for the buckling analysis of advanced grid stiffened structures.

ABSTRACT: In this study, a two-stage optimization framework is proposed for cylindrical or flat stiffened
panels under uniform or non-uniform axial compression, which are extensively used in the aerospace industry. In the first stage, traditional sizing optimization is performed. Based on the buckling or collapse-like deformed shape evaluated for the optimized design, the panel can be divided in sub-regions each of which shows characteristic deformations along axial and circumferential directions. Layout optimization is then performed using a stiffener spacing distribution function to represent the location of each stiffener. A layout coefficient is assigned to each sub-region and the overall layout of the panel is optimized. Three test problems are solved in order to demonstrate the validity of the proposed optimization framework: remarkably, the load-carrying capacity improves by 17.4 %, 66.2 % and 102.2 % with respect to the initial design.

“Hybrid optimization of hierarchical stiffened shells based on smeared stiffener method and finite element method”, Thin-Walled Structures, Vol. 82, pp 46-54, September 2014, DOI: 10.1016/j.tws.2014.04.004

ABSTRACT: In this study, Smeared Stiffener Method (SSM) of hierarchical stiffened shells is derived to release the prediction burden of buckling loads. Then, a minimum-weight optimization formulation for hierarchical stiffened shells is developed based on SSM, attempting to demonstrate the higher lightweight potential of hierarchical stiffened shells compared to the traditional ones. Further, the main aim of this paper is to present a hybrid optimization framework of hierarchical stiffened shells including imperfection sensitivity, combining the efficiency of SSM with the accuracy of FEM, since there are currently no closed-form solutions to take imperfections into account accurately. The illustrative example demonstrates that the proposed
framework has a higher optimization efficiency and global optimization capability compared to the conventional methods.

ABSTRACT: A two-dimensional variant of connected nonlinear equations of electrodynamics of the current—carrying orthotropic rotation shells, under no stationary loads is presented. A procedure for solution of asymmetrical problems of magneto elasticity of flexible current-carrying orthotropic rotation shells under no stationary actions of mechanical and electromagnetic forces is plotted. A stress-strained state of flexible current-carrying orthotropic rotation shells is geometrically nonlinear statement.

ABSTRACT: According to previous studies, stiffened shells with convex hyperbolic generatrix shape are less sensitive to imperfections. In this study, the effects of generatrix shape on the performances of elastic and plastic buckling in stiffened shells are investigated. Then, a more general description of generatrix shape is proposed, which can simply be expressed as a convex B-spline curve (controlled by four key points). An optimization framework of stiffened shells with a convex B-spline generatrix is established, with optimization objective being measured in terms of nominal collapse load, which can be expressed as a weighted sum of geometrically imperfect shells. The effectiveness of the proposed framework is demonstrated by a detailed comparison of the optimum designs for the B-spline and hyperbolic generatrix shapes. The decrease of imperfection sensitivity allows for a significant weight saving, which is particularly important in the development of future heavy-lift launch vehicles.

ABSTRACT: Aircraft wings are the major lift-load carrying members in the airframe structure. 80% of the lift load will be carried by wing structure in a transport category aircraft. Because of the lift load, wings will bend upward during flight. This action makes the upper skin of the wing to experience compression and the lower skin tension. This will cause the upper skin to buckle. Buckling will reduce the load carrying capability and the component may fail below the design limit load. For a structure to be safe against buckling buckling factor should be greater than one. In this work a standard transport aircraft wing is considered and buckling analysis is carried out. The initial design was found to buckle. So several design modifications were made to make the design safe in buckling. Linear static analysis is also carried out.

ABSTRACT: The transient behaviour of laminated composite spherical shell cap is investigated using the finite element method. An eight node degenerated isoparametric shell element is considered with five degrees of freedom at each node. The governing equations of forced vibration are solved using the Newmark’s direct integration method. Results are presented for dynamic response of deflection and stresses of orthotropic and laminated spherical shell caps subjected to suddenly applied uniform normal pressure.

ABSTRACT: Numerical–experimental correlation study for small scale damaged stiffened panels was
performed. Six small scale models were fabricated. Two of them were employed for the correlation of intact panels and the remaining four for the correlation of dented panels. Ultimate strength analyses were carried out in order to adjust the numerical model for further use in parametric studies. The damage was imposed by a local indentation of the panels. Measurements of geometric imperfection distributions and damage shapes have been performed before and after the damage using a laser tracker equipment. The numerical models were represented by shell elements assuming finite membrane strains and large rotations, considering both geometric and material nonlinearities. Results obtained showed very good agreement between experimental and numerical analyses for both intact and dented panels. Additionally, numerical simulations of damaged stiffened panels were performed. The aim of the parametric study was to evaluate the behavior up to and beyond buckling, to observe the strength loss due to the presence of the damage on the panel. The explicit nonlinear finite element code from ABAQUS program was employed to simulate the dent damage. Therefore, distortions and the residual stresses due to the damage were both considered in subsequent numerical compression analyses.

ABSTRACT: The effects of water filling and electric field on the mechanical property of carbon nanotubes (CNTs) are investigated with molecular dynamics simulations. The simulation results indicate that the water filling and electric field could enhance the elastic modulus but reduce the Poisson’s ratio of the CNTs. As for the buckling behaviors, a significant enhancement could be observed in the yield stress and average post-buckling stress of the CNTs. In particular, the enhancement in the yield stress induced by the water filling and electric field could be even higher than that resulted from the solid filling. Moreover, a transition mechanism from the rod instability to shell buckling is shown to explain the nonmonotonic variation of yield stress, and the critical diameter can be tuned through filling the water molecules and applying the electric field. The present findings provide a valuable route for the optimized design and application of the nanoscale functional devices based on the water-filled CNTs.

ABSTRACT: The problem of buckling of a thin elastic spherical shell inside a spherical cavity of uniformly contracting massive body is considered. This problem arises, for example, when designing pressure vessels made of composite materials with a thin metal cap layer. It is assumed that at the beginning of the compression the shell fits tightly against the wall of the cavity (to the rigid frame). An algorithm for searching the equilibrium state of the shell in the supercritical state is described. As a result of solving the problem, among other things, critical values of compressive strain and shell configuration in the supercritical state were obtained.

ABSTRACT: The synthesis of sound based on physical models of 2-D percussion instruments is problematic and has been approached only infrequently in the literature. Beyond the computational expense inherent to the simulation of 2-D systems, a deeper difficulty is in dealing with the strong nonlinearity exhibited by thin structures when struck—this nonlinearity leads to phenomena which are not captured, even approximately, by a linear model, and nearly all synthesis work is based on the assumption that the distributed resonating component of a musical instrument is linear. Perceptually, the effects of the vibration of a thin structure at high amplitudes can be heard as crashes, pitch glides, and the slow buildup of high-frequency energy characteristic of gongs. A large family of instruments may be described, approximately, as circular thin shells, of approximately spherical geometry, in which case a tractable PDE description, described here, is available. Time-domain finite-difference schemes, in radial coordinates, are a suitable method for synthesis. Stability conditions, numerical boundary conditions both at the edge and center, and implementation details are discussed, and simulation results are presented, highlighting the various perceptual effects mentioned above.

ABSTRACT: Nonlinear vibrations of thin rectangular plates are considered, using the von kármán equations in order to take into account the effect of geometric nonlinearities. Solutions are derived through an expansion over the linear eigenmodes of the system for both the transverse displacement and the Airy stress function, resulting in a series of coupled oscillators with cubic nonlinearities, where the coupling coefficients are functions of the linear eigenmodes. A general strategy for the calculation of these coefficients is outlined, and the particular case of a simply supported plate with movable edges is thoroughly investigated. To this extent, a
A numerical method based on a new series expansion is derived to compute the Airy stress function modes, for which an analytical solution is not available. It is shown that this strategy allows the calculation of the nonlinear coupling coefficients with arbitrary precision, and several numerical examples are provided. Symmetry properties are derived to speed up the calculation process and to allow a substantial reduction in memory requirements. Finally, analysis by continuation allows an investigation of the nonlinear dynamics of the first two modes both in the free and forced regimes. Modal interactions through internal resonances are highlighted, and their activation in the forced case is discussed, allowing to compare the nonlinear normal modes (NNMs) of the undamped system with the observable periodic orbits of the forced and damped structure.

coupling coefficients for reduced-order shell models”, Computational Mechanics, Springer Verlag, 2014, 54, pp 567-580, DOI: 10.1007/s00466-014-1006-4

ABSTRACT: We propose a direct method for computing modal coupling coefficients – due to geometrically nonlinear effects – for thin shells vibrating at large amplitude and discretized by a finite element (FE) procedure. These coupling coefficients arise when considering a discrete expansion of the unknown displacement onto the eigenmodes of the linear operator. The evolution problem is thus projected onto the eigenmodes basis and expressed as an assembly of oscillators with quadratic and cubic nonlinearities. The nonlinear coupling coefficients are directly derived from the finite element formulation, with specificities pertaining to the shell elements considered, namely, here elements of the “Mixed Interpolation of Tensorial Components” family (MITC). Therefore, the computation of coupling coefficients, combined with an adequate selection of the significant eigenmodes, allows the derivation of effective reduced-order models for computing – with a continuation procedure – the stable and unstable vibratory states of any vibrating shell, up to large amplitudes. The procedure is illustrated on a hyperbolic paraboloid panel. Bifurcation diagrams in free and forced vibrations are obtained. Comparisons with direct time simulations of the full FE model are given. Finally, the computed coefficients are used for a maximal reduction based on asymptotic nonlinear normal modes (NNMs), and we find that the most important part of the dynamics can be predicted with a single oscillator equation.

ABSTRACT: This paper deals with the linear and nonlinear vibrations of a truncated conical shell; both internal and external surfaces are covered by functionally graded coatings (FGCs). The theoretical formulation is based on the von Karman–Donnell–type nonlinear kinematics. The material properties of FGCs are assumed to be graded in the thickness direction according to a simple power-law distribution in terms of the volume fractions of the constituents. The fundamental relations, the modified Donnell-type nonlinear motion, and compatibility equations of the truncated conical shell with FGCs are derived. The basic equations are reduced to the ordinary differential equation depending on time with geometric nonlinearity using the Superposition and Galerkin methods. By applying the homotopy perturbation method to the foregoing equation, the relation between nonlinear frequency parameters with the dimensionless amplitude of a truncated conical shell with FGCs is obtained. Parametric studies are performed to illustrate the effect of different values of thickness and material composition of the FGCs on the frequency-amplitude relationships. The validity of the present solution is demonstrated by comparison with solutions available in the literature.

ABSTRACT: An approach is presented to investigate the nonlinear vibration of stiffened plates. A stiffened plate is divided into one plate and some stiffeners, with the plate considered to be geometrically nonlinear, and the stiffeners taken as Euler beams. Lagrange equation and modal superposition method are used to derive the dynamic equilibrium equations of the stiffened plate according to energy of the system. Besides, the effect caused by boundary movement is transformed into equivalent excitations. The first approximation solution of the non-resonance is obtained by means of the method of multiple scales. The primary parametric resonance and primary resonance of the stiffened plate are studied by using the same method. The accuracy of the method is validated by comparing the results with those of finite element analysis via ANSYS. Numerical examples for different stiffened plates are presented to discuss the steady response of the non-resonance and the amplitude-frequency relationship of the primary parametric resonance and primary resonance. In addition, the analysis on how the damping coefficients and the transverse excitations influence amplitude-frequency curves is also carried out. Some nonlinear vibration characteristics of stiffened plates are obtained, which are useful for engineering design.

ABSTRACT: This paper discusses the dynamic analysis of thin-walled composite shells under axial load. Analytical and numerical methods are used to analyze and validate the results with experimental results has been made. In this paper effects of orthotropic of materials, boundary conditions, geometry, geometric imperfections and time course load on the linear and nonlinear analysis of thin-walled composite shells are studied. In the first analyze the sample without to consider geometric imperfections and then the effects of imperfections equal to the actual shell. The critical buckling dynamic is reported in load time that will show the sharp reduction in the buckling load with in increases load time and stiffens of shell is inversely to load time. This effect is more pronounced in the case of layup. With the increase of load time, the dynamic critical load dropped quickly and smaller than the critical buckling load is static. So in general, the choice of the static critical load is wrong as a criterion for dynamic design. In addition to the static buckling load, dynamic buckling load is reduced with increasing geometric imperfections of sample. Sensitivity to geometric imperfections is dependent on the type of the lay up. The geometric imperfections are the same effect on the dynamic critical load and static critical load for unlimited periods.

ABSTRACT: In the field of structural mechanics the word shell refers to a spatial, curved structural member. In shells, the external loads are carried by both membrane and bending response. The effect of such responses needs careful observation. This project fulfills the need on study of behavior of shell structures by both mathematical and numerical methods. In the present development, the Donnell’s relation forms the basis of stability equation for circular cylindrical shells. The effect of stiffeners on cylindrical structures has been studied, by varying the geometry and orientation of stiffeners. The paper aims to analyze the cylindrical section of an underwater pressure hull, using finite element analysis and strengthen it accordingly. The project considers the finite element method for static structural and deflection analysis of underwater cylindrical structure by using ANSYS15 software.

ABSTRACT: This paper proposes an approximate formulation to estimate the bifurcation buckling loads of cylindrical shells with soft elastic cores under the conditions of axial compression. In general, thin-walled, axially compressed cylindrical shells buckle into a diamond pattern in the elastic range. However, buckling symmetrical with respect to the axis of the cylinder may occur when the cylindrical shell is supported by an elastic medium. By considering this characteristic, we introduce the simplified approximate formulation that can give sufficiently accurate results for the bifurcation buckling loads of cylindrical shells. Moreover the results are compared with the exact buckling loads in order to confirm the accuracy of the proposed approximate formulation.

ABSTRACT: This study examined the critical buckling characteristics of hydrostatically pressurized double-walled complete spherical shells. An analytical model based on small deflection thin shell theory is presented; the equations are solved in conjunction with variational principles. Axisymmetric and inextensional assumptions are not initially used in the exact formulation. This approach therefore avoids any discussion about the validity of the solution and allows the model to be extended to cover more generic nonaxisymmetric cases with relative ease. The analytical results are presented using illustrative buckling modes. Based on the developed formulation, only axisymmetric eigenmodes were found to occur despite the inclusion of the effect of interactions between outer and inner shells. Critical modes that are symmetric or antisymmetric about the equator may be determined depending on the combination of the stiffness connecting the outer and inner shells and the radius-to-wall thickness ratios.

ABSTRACT: Rise/span ratio has been mentioned as one of the reasons which contribute to the lower buckling load as compared to the Classical theory buckling load but this ratio has not been quantified in the equation. The purpose of this study was to determine a more realistic buckling load by quantifying the effect of the rise/span ratio because experiments have shown that the Classical theory overestimates the load. The buckling load equation was derived based on the theorem of work done and strain energy. Thereafter, finite element modeling and simulation using ABAQUS was done to determine the variables that determine the constant in the derived equation. The rise/span was found to be the determining factor of the constant in the buckling load equation. The derived buckling load correlates closely to the load obtained from experiments.

ABSTRACT: This paper presents a free-form optimization method for maximizing the elastic buckling load of a shell structure. A shell structure is assumed to be movable in the normal or the tangent direction to the surface for the shape optimization. The 1st buckling load factor is maximized under a volume constraint. The 1st eigenvalue constraint is employed to avoid the repeated eigenvalues problem in this max-min problem. This problem is formulated as a distributed-parameter shape optimization problem, and the shape gradient function for this problem is theoretically derived using the Lagrange multiplier method, the adjoint variable method and the formulae of the material derivative. The shape gradient function derived is applied to the free-form optimization method for shells, a gradient method in the Hilbert space, where the optimal shape variation is calculated as the displacement field of the linear elastic analysis of the fictitious shell model. With this method, the optimal free-form surface or boundary is determined without shape parameterization. The effectiveness of the 1st eigenvalue constraint is also studied. The results show the validity of this method to determine the optimal free-form of shell structures for the elastic buckling design problem.

ABSTRACT: In this research, linear thermal buckling of a composite conical shell made from a polymeric matrix and reinforced with carbon nanotube fibres is investigated. Distribution of reinforcements across the shell thickness is assumed to be uniform or functionally graded. Thermomechanical properties of the constituents are temperature dependent. Under the assumption of first order shear deformation shell theory, Donnell kinematic assumptions and von Kármán type of geometrical nonlinearity, the complete set of equilibrium equations and boundary conditions of the shell are obtained. A linear membrane analysis is carried out to obtain the pre-buckling thermal stresses of the shell. Adjacent equilibrium criterion is implemented to establish the stability equations associated with the buckling state. The resulting equations are discreted by means of trigonometric expansion through the circumferential direction and discrete singular convolution method through the shell length. The established eigenvalue problem is solved iteratively to obtain the critical buckling temperature and critical mode number. Parametric studies are presented to explore the influences of semi-vertex angle, volume fraction of CNTs, distribution pattern of CNTs and boundary conditions. It is shown that, conical shells with intermediate carbon nanotube volume fraction do not have, necessarily, intermediate critical buckling temperature.

ABSTRACT: The low velocity axial impact of thin-walled circular CK45 tubes is taken. The wrinkles develop progressively and the phenomenon is known as dynamic progressive buckling. In the present paper, experimental and theoretical studies on dynamic plastic buckling of circular cylindrical shells under axial impact are carried out by designing and building a device to study the behavior of CK45 under low speed impact (3.8-6.25) m/s. The work consists of experimental and theoretical (Abramowicz model) for the energy absorbers and dynamic load under different velocities. The results show that when the velocity of impact increases, the value of the dynamic crushing stress for CK45 will increase, also for elastoplastic collapse deformation, a tube initially goes through elastic deformation, then plastic deformation occurs, after that the tube goes through plastic collapse. As the force decreases, the displacement still increases. Abramowicz model for dynamic impact shows well coincide with discrepancy 45%. It can be indicated that the increasing in the velocity or kinetic energy leads to increase in the load in the practical part while it seems to be horizontally linear in the theoretical part.

ABSTRACT: Current advances in today’s industries increasingly expand the need for using composite materials in order to achieve desirable characteristics. Regarding the important role these materials play in...
engineering sciences, conducting precise analysis on such composites is admitted to be of great significance. One of the greatest weaknesses of these composites is their Shear Strength; hence, since the shear deformation has been ignored in the Classic Theory, the First Order Shear Theory has been adapted in the present paper. Deformation-related loads are loads in line with the loads resulted from deformation process which are usually being considered constant to facilitate load direction analyses. Shell materials have been set to be layered composites and the calculation method is of semi-analytical type. Displacement functions are defined as the combination of Fourier series in the perimeter dimension of shell and polynomial functions in the length dimension of shell. Results gathered from the proposed software for buckling of cylindrical shells have been compared with results from other references and also with those from ABAQUS finite element software suite. ABSTRACT: The object of this paper is to investigate the effects of geometry and load perturbation to buckling in multilayered pressure vessel heads. The pressure vessel head in concern is thin walled torispherical geometry. Geometric and load perturbation can alter both the critical load for buckling and the buckled shape. Two and three layered torispherical heads are considered. Two layered models include steel–aluminum and titanium–aluminum configurations and three layered models include copper–steel–copper configuration. Internally pressurized three-dimensional torispherical pressure vessel head model that is previously used in literature is constructed. As a first step eigenvalue solutions are obtained for each model. After this instability solutions with large deformation effects are conducted to obtain more realistic instability pressure values nonlinear. The solution is performed by finite element program ANSYS Workbench. In nonlinear analyses, perfectly plastic material model is used. It is concluded that geometric and load perturbations cause the instability pressure to decrease and cause the structure to buckle at a lower pressure value. It is also observed that for steel-aluminum configuration geometric perturbation is more critical than load perturbation whereas for aluminum-titanium the reverse is valid.

ABSTRACT: This paper investigates theoretically the compressive load-carrying behaviour of geometrically imperfect web-core sandwich plates. Slender plates, which first buckle globally, are considered. The study is carried out using two approaches, both solved with the finite element method. The first is the equivalent single-layer theory approach. First-order shear deformation theory is used. The second approach is a three-dimensional shell model of a sandwich plate. Plates are loaded in the web plate direction. Simply supported and clamped boundary conditions are considered with a different level of in-plane restraint on the unloaded edge. The results show that the behaviour of the sandwich plate is qualitatively equal to the isotropic plate of the same bending stiffness for deflections lower than the plate thickness. As the deflections increase, the lower in-plane stiffness of the sandwich plate results in lower post-buckling stiffness. Local buckling of face plates in the post-buckling range of the sandwich plate further reduces the structural stiffness.

ABAQUS, User’s manual, version 6.9.

Det Norske Veritas, Rules for the classification of steel ships. Høvik; 2005.
Furthermore, clamped plates were influenced more than simply supported. The intersection between buckling modes shifted towards higher aspect ratios, in the maximum case by 24%. The results show the importance of considering the deforming weld in buckling analysis.

Jasmin Jelovica (Aalto University, School of Engineering, Dept. of Applied Mechanics, Marine Technology, Helsinki Finland), “Global buckling response of web-core steel sandwich plates influenced by general corrosion”, Doctoral dissertation 140/2014, Aalto University, 

ABSTRACT: A web-core steel sandwich plate is a lightweight, orthotropic structure. The constituent thin plates (2-4 mm) are joined by laser-welding. This thesis investigates the buckling and post-buckling behaviour of slender web-core sandwich plates loaded in the direction of the web plates. The influence of corrosion on the plate buckling is studied via finite element method (FEM). The corrosion scenario used is based on experimental observations from specimens submerged into the sea for 1 and 2 years. The plate strength analyses are performed with two methods: FEM having shell element mesh of the three-dimensional topology and the equivalent single-layer theory (ESL). In the latter, the sandwich plate is represented with constant, homogenised stiffness coefficients, which are related to physical properties of the structure. The first buckling mode of slender web-core sandwich plates is characterised with global deformation between the edge supports. The buckling strength depends on the bending and transverse shear stiffnesses. This thesis revealed that the buckling
strength is very sensitive to the variation in transverse shear stiffness opposite to the web plate direction, especially in sandwich plates with high bending stiffness. Furthermore, the stiffness of the sandwich plate as a whole in the post-buckling is controlled by that of the in-plane stiffness. The web plates impose high, shear-induced, secondary bending stresses on the face plates and these were found to be important for accurate estimation of the onset of yielding. The deformation resulting from the secondary bending of the face plates makes the unloaded edge stiffer. Although membrane stress can be higher there, local buckling during global post-buckling occurs further away where the secondary deformations are smaller, primarily in the centre of the face plate. Furthermore, the corrosion tests revealed that the cross-section is primarily affected by general corrosion. Under this circumstance, the reduction of the thickness of the face and web plates reduces the stiffness coefficients and also the buckling strength linearly. The buckling strength reduces rapidly, especially because of the reduction in the transverse shear stiffness. The reduction of buckling strength doubles if, in addition to the outer faces, corrosion also occurs inside the sandwich plate. Beam bending tests also showed rapid reduction of the ultimate strength but, in addition, that it can be maintained using different protection methods. The results thus indicate that the protection against corrosion should be carefully performed. The future work will involve improving the accuracy of the ESL theory in the presence of local buckling.

ABSTRACT: A homogenization method for geometric nonlinear analysis of structural core sandwich panels is proposed. The method provides high computational performance based on an efficient separation of scales. In the macroscale, the sandwich panel is discretized with an equivalent single layer of shell elements. The macroscale shell stiffness matrix is nonlinear, obtained from the analysis of a representative volume element. Prescribed displacement boundary conditions are applied to the representative unit based on the strain definitions of the first-order shear deformation theory. Changes in local wavelength in the post-buckling are considered in the analyses. Manufacturing-induced imperfections are introduced to local and global scales. The method allows for description of buckling in these two scales and is shown to hold good accuracy with respect to equivalent 3D FEM models. Examples include web-core and corrugated-core sandwich panels. The method can be extended to any periodic structure of complex local topology. It can be easily implemented to commercial FE packages.

Jacek Kruzelecki and Rafal Proszowski (Cracow University of Technology, Poland), “Shape and thickness optimization of thin-walled pressure vessel end closures”, Third International Conference on Engineering Optimization, Rio de Janeiro, Brazil, 1-5 July, 2012
ABSTRACT: In this paper the problem of shape and thickness optimization of thin-walled pressure vessel heads is investigated. The optimal geometry of a closure, which minimizes the design objective containing both depth and capacity or both depth and volume of the material of a closure (two variants) is looked for in the class of the uniform strength structures. Three types of optimization problems are considered: the optimal shape is sought for a prescribe wall thickness, the optimal wall thickness is sought for a prescribed shape of a closure and the case when we look for both shape functions. Domes consisting of both two- and one-arc are considered. The optimal solutions are obtained using the simulated annealing algorithm.

ABSTRACT: In the paper, the influence of support compliances on the stability and the limiting slenderness ratio of compression helical springs was investigated. To analyze the stability of helical springs, the concept of an equivalent column was applied and a general system of supports described by three independent compliances was utilized. In the general case, the solution obtained, which describes the critical force, depends on two rotational compliances and a lateral compliance of a transverse shift of the support. The influence of the individual compliances on the critical load and on the limiting slenderness ratio was studied. Simple approximation formulas were proposed to describe these relationships.

“Cylindrical Shell Buckling Strength according to the "Overall Method" of Eurocode 3 Background and Applicability to the Design of High Strength Steel Slender Circular Hollow Sections.” Proceedings of the Structural Stability Research Council, Toronto, Canada, 2014

ABSTRACT: With the introduction of the Eurocodes, a new design philosophy for the design of cylindrical...
shells against buckling was made available to structural engineers in Europe: the "Overall Method", which makes use of the so-called "Overall Slenderness" of the shell to determine the appropriate (local) buckling reduction factor. There is a certain similarity between this concept and the Direct Strength Method (DSM) used in North America for the design of thin-walled cross-sections: the "Overall Method" also makes use of the results of (numerical) linear buckling analyses (LBA) for the whole shell to determine the slenderness and consequently the buckling reduction factor. In the case of the "Overall Method", the combined load case, which may lead to shear, hoop and axial stresses, is thereby considered in the LBA. The paper discusses the background and application of this method and complications arising in certain cases. In particular, the application of the Eurocode rules to the design of slender ("class 4") cylindrical hollow sections (CHS) will be discussed. While generally suitable for the design of large diameter cylindrical shells (tanks, silos), the application of the rules to the design of locally slender CHS requires a significant amount of interpretation by the code user and is generally not very accurate. Due to the increased use of (very) high strength steel grades for hollow sections in Europe (with yield strengths of fy=770 MPa and beyond), the local buckling design of HS steel CHS is becoming increasingly relevant. First steps by the authors towards the development of DSM-like design rules for high strength steel CHS under combined load cases will be discussed.

ABSTRACT: The purpose of this paper is to investigate on the behaviour of a delaminated stiffened panel; the delamination growth is simulated via fracture elements implemented in B2000++® code based on the Modified Virtual Crack Closure Technique (MVCCT), matrix cracking and fibre failure have been also taken into account. In order to correctly apply the MVCCT on the delamination front a very fine three-dimensional (3D) mesh is required very close to the delaminated area, while a 2D-shell model has been employed for the areas of minor interest. In order to couple the shell domain to the solid one, shell-to-solid coupling elements based on kinematic constraints have been used. Results obtained with the global/local approach are in good correlation with those obtained with experimental results.

ABSTRACT: The most important aspects in the aircraft design are safety and weight of the structure. Fuselage is one of the major components of the aircraft. Depending on the mass distribution of the fuselage structure the inertia forces will vary along the length of the fuselage. The inertia force distribution makes the fuselage to bend downward about wing axis. This bending will create tension in the upper portion of the fuselage; simultaneously the bottom portion of the fuselage will undergo compression. The current investigation addresses the issue of the compression buckling of the panels in the bottom portion of the fuselage. The panels with maximum compression load will be identified as critical panels for buckling analysis. Classical approach will be followed to calculate the critical buckling load on each panel. These calculations will be substantiated by panel buckling analysis through finite element method.

ABSTRACT: A numerical study is carried out using finite element method, to examine the effects of square and rectangular cutout on the buckling behavior of a sixteen ply quasi-isotropic graphite/epoxy symmetrically laminated rectangular composite plate [0 / +45 / -45 / 90]2s subjected to various linearly varying in-plane compressive loads. Further, this paper addresses the effects of size of square/rectangular cutout, orientation of square/rectangular cutout, plate aspect ratio(a/b), plate length/thickness ratio(a/t), boundary conditions on the buckling behaviour of symmetrically laminated rectangular composite plates subjected to various linearly varying in-plane compressive loading. It is observed that the various linearly varying in-plane loads and boundary conditions have a substantial influence on buckling strength of rectangular composite plate with square/rectangular cutout.

ABSTRACT: We use a proof-of-concept experiment and two mathematical models to explore growth-induced tissue buckling, as may occur in colorectal crypt formation. Our experiment reveals how growth of a cultured epithelial monolayer on a thin flexible substrate can cause out-of-plane substrate deflections. We describe this system theoretically using a ‘bilayer’ model in which a growing cell layer adheres to a thin compressible elastic...
beam. We compare this with the ‘supported-monolayer’ model due to Edwards and Chapman (Bull Math Biol 69:1927–1942, 2007) for an incompressible expanding beam (representing crypt epithelium), which incorporates viscoelastic tethering to underlying stroma. We show that the bilayer model can exhibit buckling via parametric growth (in which the system passes through a sequence of equilibrium states, parameterised by the total beam length); in this case, non-uniformities in cell growth and variations in cell–substrate adhesion are predicted to have minimal effect on the shape of resulting buckled states. The supported-monolayer model reveals how competition between lateral supports and stromal adhesion influences the wavelength of buckled states (in parametric growth), and how non-equilibrium relaxation of tethering forces influences post-buckled shapes. This model also predicts that non-uniformities in growth patterns have a much weaker influence on buckled shapes than non-uniformities in material properties. Together, the experiment and models support the concept of patterning by growth-induced buckling and suggest that targeted softening of a growing cell layer provides greater control in shaping tissues than non-uniform growth.

ABSTRACT: We derive the equations for a thin, axisymmetric elastic shell subjected to an internal active stress giving rise to active tension and moments within the shell. We discuss the stability of a cylindrical elastic shell and its response to a localized change in internal active stress. This description is relevant to describe the cellular actomyosin cortex, a thin shell at the cell surface behaving elastically at a short timescale and subjected to active internal forces arising from myosin molecular motor activity. We show that the recent observations of cell deformation following detachment of adherent cells (Maître J-L et al 2012 Science 338 253–6) are well accounted for by this mechanical description. The actin cortex elastic and bending moduli can be obtained from a quantitative analysis of cell shapes observed in these experiments. Our approach thus provides a non-invasive, imaging-based method for the extraction of cellular physical parameters.

ABSTRACT: Biological soft tissues exhibit elastic properties which can be dramatically different from rubber-type materials (elastomers). To gain a better understanding of the role of constitutive relationships in...
determining material responses under loads we compare three different types of instabilities (two in compression, one in extension) in hyperelasticity for various forms of strain energy functions typically used for elastomers and for soft tissues. Surprisingly, we find that the strain-hardening property of soft tissues does not always stabilize the material. In particular we show that the stability analyses for a compressed half-space and for a compressed spherical thick shell can lead to opposite conclusions: a soft tissue material is more stable than an elastomer in the former case and less stable in the latter case.

ABSTRACT: Based on a new improved higher-order sandwich panel theory, the buckling analysis of a truncated conical composite sandwich panel with simply supported and fully clamped boundary conditions was performed for the first time. This panel was subjected to axial compression and external pressures. The governing equations were derived by using the principle of minimum potential energy. The first-order shear deformation theory was used for the composite face sheets, and for the core, a polynomial description of the displacement fields was assumed. Geometry was used for the consideration of different radii curvatures of the face sheets and the core was unique. The effects of types of boundary conditions, conical angles, length to smaller radius of core ratio, core to panel thickness ratio, and smaller radius of core to panel thickness ratio on the buckling response of truncated conical composite sandwich panels were also studied. The results were validated by the results published in the literature and the presented FE results were obtained by ABAQUS software.

ABSTRACT: Composite thin cylindrical shells are most widely used structural forms in aerospace and missile applications. In missile and airframe, the composite cylindrical shell structures are generally provided with cut-outs for accessing internal components during integration. The cut-outs invariably reduce the strength of the composite cylindrical shell and more specifically the buckling load. It has been a design practice to improve strength by addition of stiffener around cut-out. The cut-out not only introduces stress concentration but also significantly reduces buckling load.

ABSTRACT: In this present study the post buckling characteristics of moderately thick-walled filament-wound carbon–epoxy composite cylinders under external hydrostatic pressure were investigated through finite element analysis for under water vehicle applications. The winding angles were [±30/90] FW, [±45/90] FW and [±60/90] FW. Finite element software ANSYS 14.0 were used to predicted the buckling pressure of filament-wound composite cylinders. For the finite element modeling of a composite cylinder, an eight-node shell element is used. To verify the finite element results for comparison, three finite element software, MSC/NASTRAN, MSC/MARC and an in-house program ACOS were used. Among these software’s, the finite element software ANSYS predicts the buckling loads within 1.5% deviation. The analysis and test results...
showed that the cylinders do not recover the initial buckling pressure after buckling and that this leads directly to the collapse. Major failure modes in the analysis were dominated by the helical winding angles. The finite element analysis shows global buckling modes with four waves in the hoop direction.

ABSTRACT: The objective of this research is to develop a layer-wise finite prism method for studying the elastic buckling of steel foam sandwich members. Foamed steel, literally steel with internal voids, enables lightweight and stiff components. Steel foam sandwich panels (steel face sheets and low-density, highly porous foam core) exhibit higher bending rigidity and plate buckling strength in comparison to slender, steel plates with the same weight. Analytical sandwich plate buckling solutions are not applicable to buckling analysis of cold-formed sandwich members with interaction between local and global buckling modes. Finite element analysis (either solid 3D or shell representation) provides the most reliable solution; however, its use is complicated, computationally expensive, and not practical for engineers. The proposed layer-wise finite prism solution is an alternative, easy-to-use tool, which builds upon the shape functions available in the literature, and
is verified against eigenbuckling finite element solutions implemented in LS-DYNA software. Future research is needed to incorporate the elastic buckling solutions in the direct strength design of sandwich panel members. References listed at the end of the paper:

ABSTRACT: Mannobiose-modified polyethylenimines (PEI) are used in gene therapy to generate nanoparticles of DNA that can be targeted to the antigen-presenting cells of the immune system. We report that the sugar modification alters the DNA organization within the nanoparticles from homogenous to shell-like packing. The depth-dependent packing of DNA within the nanoparticles was probed using AFM nano-indentation. Unmodified PEI–DNA nanoparticles display linear elastic properties and depth-independent mechanics, characteristic of homogenous materials. Mannobiose-modified nanoparticles, however, showed distinct force regimes that were dependent on indentation depth, with ‘buckling’-like response that is reproducible and not due to particle failure. By comparison with theoretical studies of spherical shell mechanics, the structure of mannobiosylated particles was deduced to be a thin shell with wall thickness in the order of few nanometers, and a fluid-filled core. The shell–core structure is also consistent with observations of nanoparticle denting in altered solution conditions, with measurements of nanoparticle water content from AFM images, and with images of DNA distribution in Transmission Electron Microscopy.

ABSTRACT: GFRP (Glass Fiber Reinforced plastic) composite materials are find many applications in engineering fields like mechanical and civil engineering applications. It is because of the properties of these materials like light weight when compared to other materials, durability, rust proof and many more. The composite cylindrical shells are being used very widely in underground pipelines, Aerospace industries, submarines and so on. In present study, the buckling of thin walled glass reinforced polymer cylindrical shells with and without cutouts has been investigated by applying axial load on the shells. The results which were obtained in this experiment will show how the imperfections like cutouts will affect the buckling behavior of the shells.

ABSTRACT: The results of an experimental study on the buckling behavior of thin-walled GFRP cylindrical shells are presented. The specimens were fabricated from continuous glass fiber using a specially-designed filament winding machine. The buckling behaviors of unstiffened shells and stiffened shells with lozenge, triangular and hexagonal grids were then studied under quasi-static axial loading at room temperature. Due to the thin skin of the shells, all specimens first experienced a general buckling mode as well as barreling under the applied loading. Following this general buckling damage, local buckling mode was seen on all specimens. Based on the experimental results, the critical buckling load was higher for the shells with hexagonal and triangular grids while the unstiffened shells and stiffened shells with lozenge grids exhibited much lower critical buckling load. On the other hand, in very small skin thicknesses, when the specific buckling loads for all specimens were compared, the unstiffened shells showed the highest specific buckling load.

ABSTRACT: The buckling behavior of single layer space structure is very sensitive. The joint rigidity, moreover, is one of the main factors of stability which may determine the entire failure behavior. Thus, the reasonable stiffness of joint system, which is neither total pin assumption nor perfect fix condition, is very important to apply to the real single layer space one. Therefore, the purpose of this work was to investigate the buckling behavior of single layer space structure, using the development of the upgraded stiffness matrix for the joint rigidity. To derive tangential stiffness matrix, a displacement function was assumed using translational and rotational displacement at the node. The geometrical nonlinear analysis was simulated not only with perfect model but also with imperfect one. As a result, the one and two free nodal numerical models were investigated
using derived stiffness matrix. It was figured out that the buckling load increases in proportion to joint rigidity with rise-span ratio. The stability of numerical model is very sensitive with the initial imperfection, responding of bifurcation in the structure.

ABSTRACT: This summary report is based on the experimental and numerical research of thin-walled cross-section compression resistance and shear strength of their joints carried out in St. Petersburg State Polytechnical University and HAMK University of Applied Sciences, Sheet Metal Centre. Current situation on the Russian market concerning the usage of cold-formed thin-walled cross-sections is aimed to find out a base foundation to start up application of the elements under discussion in the building industry (Kolesov et al. 2007; Peleshko, Urchenko 2009; Zhmarin 2012). Some questions about the compression resistance of such cross-sections were raised at different conferences (Vatin, Sinelnikov 2013; Winter 1952; Yu Wei-Wen et al. 1996) by scientific community and by companies such as Rautaruukki Oyj (Finland). Steel galvanized C- and U-profiles and thermo-profiles are types of thin-walled cross-sections that are normally used in small house construction (Shatov 2011; Smaznov 2011). Thermo-profiles have slots in webs that decrease the thermal flow through the web, but have a negative effect on strength of the profiles (Schafer, Pekoz 1998). These profiles were object of the research. Investigations carried out included tests to prove the compression resistance of the thin-walled cross-sections and shear strength of stud-to-rack joints. Numerical modelling of thin-walled cross-sections (Cheng, Schafer 2007) was done with contemporary analysis software (SCAD Office, Lira) (Kriksunov et al. 2010; Perel'muter et al. 2009) using the finite element method (FEM) (Bayan et al. 2011; Gordeeva, Vatin 2011; Rasmussen 2009).

ABSTRACT: The present paper examines the thermal effect on axially compressed buckling of a multiwalled carbon nanotube based on the gradient elasticity theories. The small-size effect, which plays an essential role in the buckling behavior with large aspect ratios under axial compression coupling with temperature change, is captured by applying different gradient elasticity theories including stress and strain. In this model, each of the nested concentric tubes is regarded as an individual column and the deflection of all the columns is coupled together through the van der Waals interactions between adjacent tubes.

ABSTRACT: Response of buried flexible pipe-soil system is studied, through numerical analysis, with respect to deflection and buckling in a spatially varying soil media. In numerical modeling procedure, soil parameters are modeled as two-dimensional non-Gaussian homogeneous random field using Cholesky decomposition technique. Numerical analysis is performed using random field theory combined with finite difference numerical code FLAC 5.0 (2D). Monte Carlo simulations are performed to obtain the statistics, i.e., mean and variance of deflection and circumferential (buckling) stresses of buried flexible pipe-soil system in a spatially varying soil media. Results are compared and discussed in the light of available analytical solutions as well as conventional numerical procedures in which soil parameters are considered as uniformly constant. The statistical information obtained from Monte Carlo simulations is further utilized for the reliability analysis of buried flexible pipe-soil system with respect to deflection and buckling. The results of the reliability analysis clearly demonstrate the influence of extent of variation and spatial correlation structure of soil parameters on the performance assessment of buried flexible pipe-soil systems, which is not well captured in conventional procedures.

The buckling behavior of steel jacking pipes is analyzed by introducing the Winkler Foundation Model. The steel pipes are subjected to complicated loads so that the buckling phenomenon sometime occurs on the pipes. In this paper, the elastic analysis is carried out, in which the stratum provides constraining effect on the outward deflection; whereas, the non-uniform stratum considerably different from the conventional buckling problems due to the pipe-soil interactive behavior. For instance, the stratum may lead to the reduction in the critical elastic buckling load. The tradeoff between economic benefits and engineering safety renders the wall thickness of such pipes becoming increasingly thinner. Meanwhile, the stratum and surrounding environment become more complex. The buckling of steel jacking pipes is analyzed by introducing the Winkler Foundation Model. The steel pipes are subjected to complicated loads so that the buckling phenomenon sometime occurs on the pipes. In this paper, the elastic buckling behavior of steel jacking pipes is analyzed by introducing the Winkler Foundation Model.
Jacking pipes are modeled as cylindrical shells with two simply supported ends. Buckling eigenvalue analysis is conducted for such a model subjected to the axial force. The friction resistance is neglected due to the application of grouting. The surrounding soil is modeled as a series of closely spaced, mutually independent, and linear elastic spring elements. The influences of various parameters are discussed using the numerical analysis. Results obtained will inform the design of an economic and efficient steel jacking pipe.

ABSTRACT: In this paper, a two-layer partial composite columns model is built based on Reddy’s higher order beam theory, and two novel displacement based finite elements for this and Timoshenko composite beams are respectively formulated by means of the principle of minimum potential energy. Subsequently, the buckling analyses of pinned-pinned and clamped-guided composite columns are performed using the proposed finite elements, and the results are compared with those obtained by plane stress model, Timoshenko and Newmark composite beams model respectively. The superior quality of Reddy composite columns model over Timoshenko composite columns model and the correctness of the proposed Timoshenko composite columns model are demonstrated by the numerical comparison. Finally, the parametric study explores effects of parameters including stiffness of shear connectors, span-to-depth ratios, Young’s modulus ratios and sub-layer’s depth on the buckling load. The discrepancies between the performance of higher order and Timoshenko composite columns have also been numerically investigated.

ABSTRACT: In modern weight sensitive applications, especially in marine and offshore engineering, thin shells have been greatly used as structural components due to their efficient load-carrying capacities. Imperfection-sensitive buckling is a critical design factor for this kind of structures when they are under compression. Traditional design method purely relies on experimentally-derived lower-bounds to the scatter of test results and is suggested to be no longer tenable for the buckling design of thin shells with novel material applications and structural forms due to the multitude of additional material and geometric parameters. It is in this context that an analytical lower-bound design method, the so-called reduced stiffness method (RSM) is proposed. The RSM has been shown to be capable of predicting safe and reliable lower bounds for a range of metallic and stiffened shells. The RSM observes that mode coupling, precipitated by initial geometric imperfections, will in the postbuckling state annihilate the membrane energy which provides important contribution to shell’s initial resistance to buckling. By dismissing these energy terms in a modified classical critical load analysis, an analytical lower bound to the imperfection sensitive buckling can be obtained. This paper intends to systematically present the method and validate it through carefully controlled finite element analysis by comparing with the results from other nonlinear buckling analysis.

ABSTRACT: Fuselage buckling of a stiffened composite cylinder is a very complex phenomenon that involves
complex interactions between the skin and the stiffeners. Considering different configurations of the skin and stiffener, different types of buckling failure modes and failure loads are observed in stiffened cylinders. In this work failure modes and the buckling loads of stiffened composite cylinders under uniaxial loading condition is investigated by using analytical and experimental approaches. Initially, a developed model for buckling problem of an isogrid stiffened composite cylinder. In these models the stiffness contributions of the stiffeners is computed by analyzing the moment and force effect of the stiffener on the unit cell. The equivalent stiffness of the stiffener/shell panel is computed by superimposing the stiffness contribution of the stiffeners and the shell. Once the equivalent stiffness parameter is determined for the whole panel buckling load is calculated using the energy method. A 3-D finite-elements model was also built which takes into consideration the exact geometric configuration and the orthotropic properties of the stiffeners and the shell. Based on finite-elements model, a discussion is made on the different buckling failure modes observed. The results of these three types of analysis methods are compared and comments are made on the reliability of the analytical models developed and finally a parametric study was carried out and general conclusions were drawn regarding the optimum configurations of the different parameters of the grid-stiffened cylinder.

“Improved methods for modeling imperfections for buckling analysis of composite cylindrical shells”, 29th Congress of the International Council of the Aeronautical Sciences, September 7-12, 2014
ABSTRACT: Carbon-fibre reinforced polymer (CFRP) cylindrical shells are used in a variety of aerospace applications. Such shells are extremely imperfection sensitive [1, 2] and feature a large scatter in buckling load levels induced from imperfections introduced in their manufacturing process. This paper aims to improve the stochastic modelling of cylindrical thickness imperfections in order to better replicate the stochastic variation of the actual thickness and material imperfections for FE analysis. These results will reduce the cost of producing and aid in improving the design and reliability of newly designed and untested cylinders by accurately modelling thickness and material imperfections for improved
stochastic analysis and robust design.

ABSTRACT: There is a strong requirement for more robust, lighter and cheaper launch vehicle structures. Unstiffened composite cylindrical shells, which are essential to the fabrication of launch vehicle airframes, are prone to buckling and are highly sensitive to imperfections which arise during the manufacturing process. The buckling load is an important characteristic in design, and may vary drastically from the buckling load of the perfect structure when realistic imperfections are present. [1] The current design guidelines for imperfection
sensitive shells are based on the NASA-SP 8007 [2] which dates from 1965. Typically, the theoretical buckling load of a given cylinder design is predicted by performing a linear bifurcation analysis using closed-form equations of the geometrically perfect structure. This theoretical buckling load is then reduced by applying an empirical knockdown factor to account for the differences between theory and test. From recent literature [3-5], the NASA-SP 8007 knockdown factors used in the design of aerospace-quality shell structures were found to be overly conservative and inappropriate.

ABSTRACT: Helical structures, ubiquitous in nature, have inspired design and manufacturing of helical devices with applications in nanoelectromechanical systems, morphing structures, optoelectronics, micro-robotics and drug delivery devices. Meanwhile, multi-stable structures have attracted increasing attention for their applications in bio-inspired robots and deployable aerospace components. Here we show that mechanical anisotropy and geometric nonlinearity can lead to novel selection principle of shape and multi-stability in helical ribbons, with table-top experiments performed to demonstrate the working principle. Our work will promote understanding of large deformation and instability of thin objects, and serve as a tool in developing functional structures for broad applications.

“Uniform concave polystyrene-carbon core-shell nanospheres by a swelling induced buckling process”, Journal of the American Chemical Society, Vol. 137, No. 31, pp 9772-9775, 2015, DOI: 10.1021/jacs.5b05027
ABSTRACT: We have developed a facile procedure that can create asymmetrical building blocks by uniformly deforming nanospheres into $C_\infty v$ symmetry at low cost and high quality. Concave polystyrene-carbon (PS-C) core–shell nanospheres were produced by a very simple microwave-assisted alcohol thermal treatment of spherical PS-C nanoparticles. The dimensions and ratio of the concave part can be precisely controlled by temperature and solvents. The concavity is created by varying the alcohol-thermal treatment to tune the swelling properties that lead to the mechanical deformation of the PS-C core–shell structure. The driving force is attributed to the significant volume increase that occurs upon polystyrene core swelling with the incorporation of solvent. We propose a mechanism adapted from published models for the depression of soft capsules. An extrapolation from this model predicts that the rigid shell is used to generate a cavity in the unbuckled shell, which is experimentally confirmed. This swelling and deformation route is flexible and should be applicable to other polymeric nanoparticles to produce asymmetrical nanoparticles.

ABSTRACT: In this paper, the stability of cylindrical panels with circular cross section in elastic form is estimated using both analytical and Numerical methods. The Donnell equations for linear buckling of cylindrical shells are assumed and finally the equations are resulted to numerical values with the use of Galerkin method. Boundary condition in this case is such that the two curved edges are simply supported and two straight edges are free. The effects of geometrical parameters such as thickness, radius, length and central angle on buckling of cylindrical shells have been investigated both numerically and analytically. Also, the results of both methods are presented in figures.

ABSTRACT: Helical structures are among the most universal building blocks in nature and engineering. In this work, I performed three-dimensional finite element simulations to study the transitions of shapes and multi-stability in the mechanically self-assembled helical structures driven by anisotropic misfit strains. The shape transition between a purely twisted ribbon, or a helicoid, and a general helical ribbon can be achieved by tuning a few relevant geometric and mechanical parameters, including the misfit strains, the geometric misorientation angle, the dimensions, and the mechanical properties of the composite layers. The results of our work show good agreement with the recent theoretical works and will serve as a powerful tool to facilitate on-demand designs of spontaneously curved structures at both macroscopic and microscopic scales, for a number of engineering applications including nanoelectromechanical systems, drug delivery, sensors, drug delivery, active materials, optoelectronics, and microrobotics.

ABSTRACT: Self-shaping of curved structures, especially those involving flexible thin layers, is attracting increasing attention because of their broad potential applications in, e.g., nanoelectromechanical and microelectromechanical systems, sensors, artificial skins, stretchable electronics, robotics, and drug delivery. Here, we provide an overview of recent experimental, theoretical, and computational studies on the mechanical self-assembly of strain-engineered thin layers, with an emphasis on systems in which the competition between bending and stretching energy gives rise to a variety of deformations, such as wrinkling, rolling, and twisting. We address the principle of mechanical instabilities, which is often manifested in wrinkling or multistability of strain-engineered thin layers. The principles of shape selection and transition in helical ribbons are also systematically examined. We hope that a more comprehensive understanding of the mechanical principles underlying these rich phenomena can foster the development of techniques for manufacturing functional three-dimensional structures on demand for a broad spectrum of engineering applications.

ABSTRACT: The important role of imperfections on decreasing the buckling load of structural cylinders has been investigated by scientists and engineers for the past century, yet there is currently no method that is able to stochastically replicate the full range of realistic imperfections for a full account of possible buckling loads. This drawback impairs optimised design as designers are restrained to using an outdated and conservative design philosophy which dates from 1968. Modern manufacturing methods and materials such as composites require new, optimised design measures to take full advantage of their efficiencies. Stochastic analyses can optimise and improve the reliability of such cylinders through accurate prediction of the range of conceivable buckling loads by realistic simulation and sensitivity analyses. A stochastic procedure which realistically models imperfection sensitive composite shells is investigated in this paper. Monte-Carlo simulations of axially compressed cylinders with the full range of imperfection types are performed to show that the stochastic methods described here are able to accurately capture the scatter in the buckling load introduced from the imperfections. The results from a sensitivity analysis indicate that loading imperfections play the largest role in reducing the buckling load knockdown factors of the shell.

ABSTRACT: An experimental investigation was performed on stainless steel hemispherical shells under axial compression. Eight kinds of shells with radius-to-thickness ratios that range from 57.1 to 125 were designed and manufactured for this study. The shells were compressed to more than 50% of their radii by a solid flat plate. To avoid contact between the base plate and the deformed central part of the shells, most of the shells were placed on a plate with a hole in the center. Nonetheless, one type of shell was placed on a solid base plate without a hole to analyze the effect of the base plate. As per an observation of collapse modes and load-deformation shell relations, the deformation process of a hemispherical shell that is compressed by a flat plate can be divided into four stages: local flattening (Stage I), axisymmetric inward dimpling (Stage II), non-symmetric multiple lobes (Stage III), and peripheral deformation and buckling stage (Stage IV). The present study mainly studies Stage IV, which can be categorized into peripheral compression (Stage A), peripheral buckling (Stage B), buckling expanding (Stage C), and overall collapse (Stage D).

ABSTRACT: Experiments have been conducted to investigate the buckling and postbuckling behavior of aluminum alloy 7050-T7651 integrally stiffened panel under a combined compression–shear load. A new combined-load test fixture was designed and used in these experiments. There were a total of six large rectangular stiffened panels in the size of 960 by 850 mm, which were classified in two groups according to the cross section and layout of their stiffeners. Three panels, named J panels, were designed in four parallel J-shaped stiffeners. Another three panels, named X panels, were designed in eight orthogonal blade-shaped stiffeners. Strain rosettes bonded back-to-back on the skin were used to measure the strains of skin at their locations in three directions (0, 45, and 90 deg), whereas the strain gauges installed on the stiffeners were used to measure the strains of stiffeners in a single direction. The integrally stiffened panels were loaded up to a sudden drop of the applied load and an accompanying harsh noise caused by the stringers splitting from skins. All the test panels failed in the same modes of global flexural buckling and the spitting of the stiffeners from skins. The mean value of the first buckling loads of X panels is 11.6% higher than that of the J panels. The mean value of the failure loads of X panels is 1.5% less than that of the J panels. All experimental results will be employed for the validation of finite element models and optimization method on the buckling and postbuckling analyses of integrally stiffened aluminum panel in further studies.

ABSTRACT: Postbuckling response, long considered mainly as a failure limit state is gaining increased interest for smart applications, such as energy harvesting, frequency tuning, sensing, actuation, etc. This letter explores the potential of cylindrical shells under axial compression, for which localized buckling events along with high-rate local deformations can be attained in their elastic postbuckling regime under smaller axial system
deformation input, as a prototype for harnessing elastic instabilities. Three avenues are presented to tailor and control the elastic postbuckling response of axially-compressed shells: (1) by introducing seeded geometric imperfections (SGI); (2) by introducing non-uniform stiffness distributions (NSD); and (3) by providing lateral constraints and interactions (LCI). Prototyped cylindrical shells were fabricated through 3D printing and tested under loading–unloading cycles. Experimental results show that, with appropriate selection of geometry, material, and stiffness distribution, these three concepts offer significant advantages over uniform cylindrical shells for use of their notoriously unreliable elastic postbuckling response. This work provides new knowledge on the possibilities and means to design the cylindrical shells with controlled elastic postbuckling behavior and opens new avenues for using this structural form for applications in smart materials and structures.

Rigoberto Burgueño, Nan Hu, Annelise Heeringa and Nizar Lajnef (Department of Civil and Environmental Engineering, Michigan State University, East Lansing, MI 48824, USA), “Tailoring the Elastic Postbuckling Response of Thin-walled Cylindrical Shell under Axial Compression”, Thin-Walled Structures, Vol 84, pp 14-25, November 2014, DOI: 10.1016/j.tws.2014.05.009

ABSTRACT: The buckling of cylindrical shells has long been regarded as an undesirable phenomenon, but increasing interests on the development of active and controllable structures open new opportunities to utilize such unstable behavior. In this paper, approaches for modifying and controlling the elastic response of axially compressed laminated composite cylindrical shells in the far postbuckling regime are presented and evaluated. Three methods are explored (1) varying ply orientation and laminate stacking sequence; (2) introducing patterned material stiffness distributions; and (3) providing internal lateral constraints. Experimental data and numerical results show that the static and kinematic response of unstable mode branch switching during postbuckling response can be modified and potentially tailored.

James Bernasconi (Consulting Engineer, Brisbane, Australia), “Buckling studies into large scale hyperbolic paraboloid shell and lattice structures”, ASEC Conference, 2014

ABSTRACT: This paper covers some aspects of the bifurcation and elastic geometric non-linear buckling behaviour of hyperbolic paraboloid lattice and concrete shells up to 100 metres in plan size. The paper summaries the important design parameters discovered by earlier research and used variations in the rise to span ratio and edge beam flexural stiffness to undertake a parametric study. The bifurcation buckling of lattices was found to be similar to that of shells. The elastic geometric non-linear analysis was always found to be unstable for shells and stable for rectangular lattices. However, diagonal lattices behaved in a similar fashion to the unstable shells.

Mechanics, November 2014, DOI: 10.1007/s00419-014-0944-9

ABSTRACT: The meshless analog equation method, a purely mesh-free method, is applied to the buckling analysis of cylindrical shell panels. The method is based on the principle of the analog equation, which converts the three governing partial differential equations in terms of displacements into three uncoupled substitute equations, two Poisson’s equations and one plate equation, under fictitious sources. The fictitious sources are represented by series of radial basis functions (RBFs) of multiquadric type, and the substitute equations are integrated. This integration allows the representation of the sought solution by new RBFs, which approximate accurately not only the displacements but also their derivatives involved in the governing equations. Then, by inserting the approximate solution in the original differential equations and the associated boundary conditions and collocating at a predefined set of mesh-free nodal points, a linear algebraic eigenvalue problem results, the solution of which gives the buckling loads and modes. The optimal value of the shape parameter of the RBFs is obtained as that minimizing eigenvalues. The method is illustrated by analyzing several shell panels. The studied examples demonstrate the efficiency and the accuracy of the presented method.

DOI: 10.1016/j.compscitech.2013.02.003

ABSTRACT: Carbon nanotube reinforced copper matrix (CNT/Cu) composites with high strength and good damping have been developed using acid treatment, sintering processes and consolidation techniques. Strengthening of the composites as a result of nanotube buckling has been demonstrated by experimental nanoindentation tests and molecular dynamics (MD) simulations. The experimental results show that the buckling behavior of additional CNTs in the CNT/Cu composites varies with the slenderness ratio of CNTs. Specifically, this study shows that the significant buckling behavior of CNTs in the CNT/Cu composites where the shorter CNTs (with a smaller slenderness ratio) give rise to a global buckling and the slender CNTs (with a larger slenderness ratio) induce local buckling. The MD simulation results reveal that the buckling behavior of the CNTs plays a key role in increasing the mechanical strength of CNT/Cu composites by acting as a “buffer” in releasing excess strain in the Cu matrix.

ABSTRACT: The subject of the paper is a metal foam circular cylindrical shell subjected to combined loads. Combinations of the external pressure and axial load are taken into account. The shell is simply supported on all outer edges. The mechanical properties of the metal foam vary continuously in the thickness direction. A non-linear hypothesis of deformation of a plane cross section of the shell is formulated. The field of displacements of any cross section and non-linear geometric relationships are assumed. The system of partial differential equations for the shell is derived on the basis of the
principle of stationarity of the total potential energy. This system is approximately solved by the Bubnov-Galerkin method. The critical loads for shells are numerically determined. Results of the calculation are shown in figures.

ABSTRACT: The aim of this paper is investigation of some important parameters in shell buckling of fused interlining worsted fabric with different weight and considering five different relative orientation angles (0°, 22.5°, 45°, 67.5°, 90°) according to the machine direction of non-woven fusible interlining and a face fabric. The formability of the prepared fused fabric composite based on shell buckling curves and Lindberg's hypothesis is also reported. The shell buckling compression behavior of fused fabric composite is investigated using a special corrugated clamp based to Dahlberg's test method. The result show that with increasing the interlining relative orientation angle, buckling loads and buckling energy parameters decrease, whereas, hysteresis and compression remaining increase. The fused fabric composites exhibit the highest formability at 67.5° relative orientation angle. The results show that at 0° relative orientation angle, the lowest buckling hysteresis, compressibility and compression remaining are obtained.

“Silo Collapse: An experimental study”, (publisher and date not given in the pdf file; most recent citation is 2003.)

ABSTRACT: The purpose of this experimental work is to develop some basic insight into the pre-buckling behavior and the buckling transition toward plastic collapse of a granular silo by studying different patterns of deformation generated on thin paper cylindrical shells during granular discharge. We study the collapse threshold considering the influence of the bed heights, flow rates and grain sizes. We compare the patterns that appear during the discharge of spherical beads, with those obtained in the axially compressed cylindrical shells.
When the height of the granular column is close to the collapse threshold, we observe a ladder like pattern that rises around the cylinder surface in a spiral path of diamond shaped localizations, and develops into a plastic collapsing fold that grows around the collapsing silo.

ABSTRACT: We investigate, at a laboratory scale, the collapse of cylindrical shells of radius R and thickness t induced by a granular discharge. We measure the critical filling height for which the structure fails upon discharge. We observe that the silos sustain filling heights significantly above an estimation obtained by coupling standard shell-buckling and granular stress distribution theories. Two effects contribute to stabilize the structure: (i) below the critical filling height, a dynamical stabilization due to granular wall friction prevents the localized shell-buckling modes to grow irreversibly; (ii) above the critical filling height, collapse occurs before the downward sliding motion of the whole granular column sets in, such that only a partial friction mobilization is at play. However, we notice also that the critical filling height is reduced as the grain size d increases. The importance of grain size contribution is controlled by the ratio d/sqrt(Rt). We rationalize these antagonist effects with a novel fluid-structure theory both accounting for the actual status of granular friction at the wall and the inherent shell imperfections mediated by the grains. This theory yields new scaling predictions which are compared with the experimental results.

ABSTRACT: This paper presents results of a numerical study on the nonlinear behavior of shells undergoing snap-through instability. This research investigates the problem of snap-through buckling of spherical shells applying nonlinear finite element analysis utilizing ANSYS Program. The shell structure was modeled by axisymmetric thin shell of finite elements. Shells undergoing snap-through buckling meet with significant geometric change of their physical configuration, i.e. enduring large deflections during their deformation process. Therefore snap-through buckling of shells basically is a nonlinear problem. Nonlinear numerical operations need to be applied in their analysis. The problem was solved by a scheme of incremental iterative procedures applying Newton-Raphson method in combination with the known line search as well as the arc-length methods. The effects of thickness and depth variation of the shell is taken care of by considering their geometrical parameter l. The results of this study reveal that spherical shell structures subjected to pressure loading experience snap-through instability for values of l≥2.15. A form of ‘turn-back’ of the load-displacement curve took place at load levels prior to the achievement of the critical point. This phenomenon was observed for values of l=5.0 to l=7.0.

Computational Buckling Analysis Of Thin-Walled Structures, First Pan American Congress on Computational Mechanics PANACM 2015 April 27-29, 2015, Buenos Aires, Argentina

ABSTRACT: Thin walled structures, including plates and shells, are widely used in aeronautical, aerospace, civil, mechanical, industrial and automotive engineering. Typical applications in industrial processes include containment structures for the chemical industries, tanks and silos for storage of granular and fluid products, shell structures employed as architectural roof systems, metal sheets employed in the construction of industrial buildings, parts of car bodies, shells in aerospace and aeronautical vehicles, and many others. More recently, thin walled structures have become of great interest in applications at the nanoscale (nanotubes) and in bioengineering.

Engineers design structures with a well-defined shape thoughtfully chosen to fulfill some purpose. But under certain critical conditions the structure cannot withstand further load with the same shape and changes its shape in a slow or sometimes in a violent way. Because those are structures designed to resist loads with a very thin wall, then they are prone to failure by buckling under various load systems. Buckling belongs to a class of problems in mechanics for which some form of singularity occurs in an equilibrium situation.

There are several levels of theories involved in the computational buckling analysis of thin-walled structures: First, there are predictive theories at the level of computations, in which results are obtained; Second, explanatory theories, in which results make sense; and third, classification theories, in which possible solutions are classified. Computational mechanics tends to be associated only to predictive theories, but explanations and classifications are also essential components in any adequate analysis.

This Mini Symposium attempts to embrace all problems involved in the computational buckling analysis of thin-walled structures, including the development of elements with nonlinear capabilities as to address buckling problems, algorithms for tracing nonlinear equilibrium paths, understanding of buckling and post-buckling behavior with the support of computational mechanics, and the application of existing software to the solution of industrial needs. Static as well as dynamic buckling studies are welcomed.
Organizer: DLR (German Aerospace Center), Institute of Composite Structures and Adaptive Systems, Braunschweig, Germany.
Conference Place: Technical University of Braunschweig, Pockelsstrasse 4, Braunschweig, Germany

The conference aims at presenting scientific achievements from the running EU project DESICOS which stands for New Robust DESIgn Guideline for Imperfection Sensitive COMposite Launcher Structures (www.desicos.eu). In addition, papers with related topics outside the project on buckling, postbuckling and collapse behaviour of composite laminated shell structures are presented.

Within the workshop 10 partners demonstrate different improved simulation software and test hardware related to composite structures.

Chairman of the Conference
Prof. Richard Degenhardt, DLR, Braunschweig, D and PFH Göttingen, D

Mr. Avi Wieder, GRIPHUS, Haifa, IL

Publications
Conference handout: Will contain all short abstracts giving an overview
Conference CD: Will contain all extended abstracts
Special issue: Selected presentations of high quality will be published in a special issue of the Int. Journal of Structural Stability and Dynamics.

Please note that the PhD session on 25 March (3.10 pm – 5.50 pm Brussels/Paris/Berlin time) on Buckling of aerospace composite structures is online accessible for free for everybody. For details see below.

Register for free at http://goo.gl/6cWRwR

The conference contains 85 presentations including the following keynote speakers and topics:

1) Prof. Hansjörg Dittus (DLR, Member of executive board, responsible for space) Reusability – DLR’s new R&D-programme for launch technologies
2) Prof. JN Reddy (Texas AM University) Refined theories and finite element models for the analysis of laminated composite structures: An overview
3) Dr. Mark Hilburger (NASA, Senior researcher) Recent Developments in the Analysis and Testing of Large-Scale Buckling-Critical Cylinders
4) Dr. Jochen Albus (Airbus, Senior expert) Parametric Instability of Pressurized Propellant Tanks
5) Dr. Peter Linde (Airbus) Structural Modelling and Simulation of Aircraft Composite Structures; State of the Industry
6) Prof. Andreas Rittweger (DLR, Head of the Institute of Space Systems) Pre-Dimensioning of Launch Vehicles due to Booster Load Introduction based on Semi-Analytical Methods
7) Prof. Jan Blachut (University of Liverpool) Composite spheroidal shells under external pressure
8) Prof. Brian Falzon (Royal Academy of Engineering - Bombardier Chair in Aerospace Composites, Queen’s University Belfast) Modelling damage in thin-walled composite structures
9) Prof. Christian Hühne (DLR, Institute of Composite Structures and Adaptive Systems, Head of department Composite Design) Single perturbation load approach – From the initial idea until today
10) Dr. habil. Christian Mittelstedt (SOGETI High Tech GmbH, Hamburg) Recent developments in the rapid and efficient closed-form analytical modeling of buckling problems in composite lightweight engineering
11) Dr. Tobias Wille (DLR, Institute of Composite Structures and Adaptive Systems, Head of department Structural Mechanics) Challenges in Structural Mechanics of Composite Structures
12) Prof. Ralf Cuntze (retired) Reliable strength design verification - Fundamentals, requirements and some hints
13) Dr. John Hart-Smith (retired) The use of simple strain-energy concepts to debunk the classical thin-shell buckling analyses for once and for all

A1 Keynote lectures
Hansjörg Dittus (DLR, Member of executive board, responsible for space) Reusability DLR’s new R&D-programme for launch technologies
Mark Hillburger (NASA, Senior researcher) Recent Developments in the Analysis and Testing of Large-Scale Buckling-Critical Cylinders
Jochen Albus (Airbus, Senior expert) Launcher Structural Design and Margins
Peter Linde (Airbus) Structural Modelling and Simulation of Aircraft Composite Structures; State of the
A2 DESICOS - Workpackage summaries

Richard Degenhardt (DLR) New Robust Design Guideline for Imperfection Sensitive Composite Launcher Structures - The DESICOS project
K. Kalnins (Riga Technical University) WP 1 Benchmarking
C. Bisagni (Politecnico di Milano) WP 2 Design of test structures
M. Ruess (TU-Delft) WP 3 Development of new design methods
H. Abramovich (Technion) WP 4 Manufacturing and buckling tests
P. Blanchard (Airbus) WP 5 Contribution to improved design guidelines

A3 DESICOS - Achievements of the PhD students Design concepts, tests)

K. Liang, M. Ruess (TU-Delft) New robust knock-down factors for the stiffened cylinder
A. Meurer, M. Dannert, R. Rolfes (Leibniz University Hannover) New Design Approach for Axially Compressed Composite Cylindrical Shells combining the Single Perturbation Load Approach and Probabilistic Analyses
M. Alfano, C. Bisagni (Politecnico di Milano) Reliability assessment of buckling response of an axially compressed sandwich composite shell with and without cut-outs
L. Friedrich, H. Reimerdes, K. Schröder (RWTH Aachen) Advanced sizing strategies for preliminary design of orthotropic grid stiffened shell structures
R. Khakimova, R. Degenhardt (DLR) Assessment of the Single Perturbation Load Approach on composite conical shells
J. Kepple, M. Herath, G. Pearce, G. Prusty, R. Thomson (CRC-ACS) Stochastic analysis of imperfection sensitive composite cylinders using realistic imperfection models (CRC-ACS, University of New South Wales, Advanced Composite Structures Australia)

B1 Keynote lectures

Andreas Rittweger (DLR, Head of Institute of Space Systems) Pre-Dimensioning of Launch Vehicles due to Booster Load Introduction based on Semi-Analytical Methods
JN Reddy (Texas AM University, USA) Refined theories and finite element models for the analysis of laminated composite structures: An overview
John Hart-Smith The use of simple strain-energy concepts to debunk the classical thin-shell buckling analyses for once and for all

B2a Semi-analytical concepts

V. K. Mantzaroudis, D.G. Stamatelos (Hellenic Air Force Academy) Closed-form local skin buckling solution for orthotropic and anisotropic stiffened panels braced with omega stringers
E. Carrera, E. Zappino, T. Cavallo (Politecnico di Torino) Buckling analysis of thin-walled composite Structures using refined one-dimensional models
M. A. Castillo-Acero, C. Cuerno-Rejado, M. A. Gómez-Tierno (Aernnova, UPM) Zero Poisson panels buckling sizing procedure based on Farrar theory
H. Assaee (Shiraz University of Technology) Application of different versions of finite strip Method as fast tools for buckling analysis of Composite stiffened shells
T. A. Schmid Fuertes, H.-G. Reimerdes (Airbus, RWTH Aachen) Buckling and post-buckling analyses of circular composite cylinders under axial compression using a semi-analytical approach

B2b  Damaged structures / Buckling with piezos
A. Köllner, C. Völlmecke (TU-Berlin) Buckling and post-buckling behaviour of delaminated composite struts
K.C. Gopalakrishnan and R. Ramesh Kumar (Government Engineering College, Delamination of secondary bonding around cuts in a compressively loaded CFRP skinned sandwich structure
J.P. Delsemme, M. Bruyneel, Ph. Jetteur, B. Magneville, T. Naito, Y. Urushiyama (SAMTECH) Progressive damage modeling in composite: from aerospace to automotive industry
A. Muc, P. Kedziora (Cracow University of Technology) Buckling enhancement of laminated structures with piezoelectric actuators
L. Czechowski (Lodz University of Technology) Analysis of dynamic buckling of FGM plate under pulse of heat flux and compression force

B2c Design and Analysis
H. Haller (INTALES) Industrial Branching analysis and assessment of the structural load carrying behaviour of composites in the post buckling regime
H. Starmans Industrial Branching analysis and assessment of the structural load carrying behaviour of composites in the post buckling regime
T. Kubiak (Lodz University of Technology) Numerical model of postbuckling behaviour of GFRP beams subjected to pure bending
B. Brank, A. Stanic, B. Hudobivnik (University of Ljubljana) Simulations of surface wrinkling of bi-layer composite
A. Watson, B. Wang, S. Wang, C. Harvey (Loughborough University) Couple Instabilities of Stiffened Panels with Multiple Stiffener Sizes

B2  Keynote lectures
Ralf Cuntze Reliable strength design verification - Fundamentals, requirements and some hints
Christian Mittelstedt (Sogeti) Recent developments in the rapid and efficient closed-form analytical modeling of buckling problems in composite lightweight engineering
Christian Hühne (DLR, Head of department Composite Design) Single perturbation load approach – From the initial idea until today

B3a  Improved theories / concepts
E.L. Jansen, T. Rahman, R. Rolifes (Uni. Hannover, TNO DIANA BV) Towards mode selection criteria for multi-mode initial postbuckling analysis of composite cylindrical shells
S. G. P. Castro, M. A. Arbelo, R. Degenhardt, G. Ziegmann (PFH, DLR, TU Single perturbation load approach: new definition for PI and explaining the constancy of the buckling load (PFH, DLR, TU Clausthal)
V.M.Trach, N.P.Semenyuk, A.V.Podvornyi, N.B.Zhukova (National University of Water Management and
Nature Resources Use, Timoshenko Institute) On the method of calculation of buckling and postbuckling behavior of laminated shells with small arbitrary imperfections  
F. da Cunha, T. Wille, R. Degenhardt, M. Sinapius (DLR) Structural Robustness Assessment of Thin-Walled Composite Structures in the Postbuckling Regime  
E. Jansen, H. Abramovich, R. Rolfes (Leibniz University Hannover, TECHNION)  
Improving the vibration correlation technique for shells using analysis tools  
John-Hart Smith A necessary correction of the classical analyses for buckling of circular arches, rings, and tubes

B3b Experiments  
M. Brojan, D. Terwagne, R. Lagrange, P. Reis (Uni. of Ljubljana, ULB, MIT) Wrinkling of thin spherical shells on elastic substrates  
M. Schultz, L. Oremont, M. Hilburger (NASA) Experimental and analytical characterization of fluted-core sandwich composite structures  
H. Abramovich, D. Govich and A. Grunwald (TECHNION) Curved panels buckling prediction using the Vibration Correlation Technique  
A. Al-Azzawi, J. McCrory, L.F. Kawashita, C.A. Featherston, R. Pullin and K. M. Holford (Cardiff University) Buckling and postbuckling behaviour of glare laminates containing splices and doublers: experimental and numerical investigations  
K. Kalnins, E. Skukis, O. Ozolins, M. A. Arbelo (RTU, PFH) Experimental determination of the buckling load of composite cylindrical shells using Vibration Correlation Technique  
L. Friedrich, A. Dafnis, H. Reimerdes, K. Schröder (RWTH Aachen) Influence of load application on the collapse load of imperfection sensitive shell structures  
Aditi Sharma (Rajalakshmi Engineering College) Design, fabrication and testing of hybrid nano composite structures

B3c Design and Analysis  
S. Freund, A. Sauerbrei, R. Zimmermann (DLR) Multilevel Skin Buckling Analysis using Hierarchical Metamodels  
F. Odermann, M. Geier (DLR) Buckling tests of unstiffened cylindrical composite shells under dynamic axial pulse loading  
R. J. Mania (Lodz University of Technology) Buckling and post-buckling of FML compressed open cross section profiles  
T. Ungwattanapanit, H. Baier (TU Munich) Weight optimization using equivalent static loads of postbuckled, stiffened panels made by steered-fiber laminates  
P. Le Grognec, K. Sad Saoud (Mines Douai) Analytical and numerical analysis of the elastic/plastic local/global buckling and postbuckling of composite structures  
A. Gliszczynski, T. Kubiak (Lodz University of Technology) Load-carrying capacity of thin-walled composite beams subjected to pure bending  
P. Weaver (University of Bristol) Imperfection-insensitive shells using variable stiffness composites

C2a Experiments  
C. Wolff, D. Wilckens (DLR) Testing and Modelling of impact damaged orthotropic stiffened CFRP-Panels  
D. Wilckens, F. Odermann (DLR) Buckling and Post Buckling of Stiffened CFRP Panels under Compression and Shear  
R. Khakimova, S. Castro, R. Degenhardt, D. Wilckens, M. Kepke, B. Hildebrandt, F. Odermann (DLR, PFH) Buckling experiments on imperfection sensitive thin-walled structures using additional perturbation loads
A. Muc, P.D. Pastuszak (Cracow University of Technology) Remarks on buckling analysis of composite plates and shells

C. Bisagni (Politecnico di Milano) Buckling tests of laminated sandwich cylindrical shells

C2b Design and Analysis
R. Wagner, C. Hühne (DLR) Numerical investigation on experimental buckling loads of unstiffened cylindrical composite shells with varying ratio of radius/wall thickness
M. Arbelo, K. Kalnins, O. Ozolinš, S. Castro, R. Degenhardt (ITA, RTU, DLR) Buckling of imperfection sensitive shell structures: experimental characterization of the knock-down factor using the Multiple Perturbation Load Approach
S. Castro, R. Khakimova, G. Ziegmann, D. Degenhardt, R. Degenhardt, Mark Hilburger (PFH, DLR, TU Clausthal, Sogeti, NASA) Simulation of geometric imperfections and uneven edges in thin-walled cylinders
S. G. P. Castro, C. Mittelstedt, M. A. Arbelo, R. Degenhardt, R. Khakimova, M. W. Hilburger, G. Ziegmann (PFH, Non-linear buckling response of unstiffened laminated composite cylinders using different geometric imperfections

Virtual conference on PhD RESEARCH in Buckling of aerospace composite structure held in connection with the 3rd International Conference on Buckling and Postbuckling Behavior of Composite Laminated Shell Structures
Date: Wednesday 25 March 2015
Time: 3.10 pm – 5.50 pm Brussels/Paris/Berlin time
Location: Virtual (Online) Conference
Contacts: DLR: Richard Degenhardt
NASA: Rebecca Vieyra

IFAR – Young Researchers Networking Virtual Conference “PhD RESEARCH in Buckling of aerospace composite structures” Organized by IFAR and DLR in collaboration with NASA Free registration at http://goo.gl/6cWRwR This virtual conference takes place as a self-standing internet conference as part of the 3rd Int. Conf. on Buckling and Postbuckling Behavior of Composite Laminated Shell Structures held from 25 - 27 March 2015 organized by DLR in Braunschweig, Germany.

Topic:
Seven PhD students present their final results in the development of new design guidelines for imperfection sensitive composite light weight structures as used in aerospace applications. The current guideline NASA SP 8007 is from 1968 and was developed for metallic structures. The use of composite materials allows lighter structures but new design guidelines need to be developed. This was the aim for all students. Their work differs in the kind of structure considered (monolithic or sandwich, cylinder or cone) and type of new approach.

Aim of the virtual conference:
· Stimulate technical and scientific interaction between young researchers.
· It will be interactive and participation is free.
· The question-answer session will be accessible from participating IFAR organizations and partner universities.

Who can participate?
The main focus is for young researchers from IFAR organizations and partner universities, but the event is fully open to all researchers from other organizations.

Registration: – Register for free at http://goo.gl/6cWRwR

Pre-Discussion with the Presenters (for IFAR members only):
· Log into IFARlink (www.ifarlink.aero) or register as a new user.
Click on “Discussion Groups” and select the DLR Virtual Conference – click on the discussion group to interact with the presenter(s) of interest to you.

The following virtual conference takes place as a self-standing internet conference as part of the 3rd Int. Conf. on Buckling and Postbuckling Behavior of Composite Laminated Shell Structures held from 25 - 27 March 2015 organized by DLR in Braunschweig, Germany.

Chair of the Virtual Conference: Chiara Bisagni (TU-Delft)
Date: 25 March, 2015 (The times given below are Brussels, Paris, Berlin times.)
3.10 pm Richard Degenhardt (DLR+PFH) Introduction
3.20 pm K. Liang, M. Ruess (TU-Delft) New robust knock-down factors for the stiffened cylinder
3.40 pm A. Meurer, M. Dannert, R. Rolfes (Leibniz University Hannover) New Design Approach for Axially Compressed Composite Cylindrical Shells combining the Single Perturbation Load Approach and Probabilistic Analyses
4.00 pm S. G. P. Castro, C. Mittelstedt, F. A. C. Monteiro, M. A. Arbelo, R. Degenhardt, G. Ziegmann (PFH, DLR, TU Clausthal. Sogeti) A semi-analytical approach for linear and non-linear analysis of unstiffened laminated composite cylinders and cones under axial, torsion and pressure loads
4.20 pm M. Alfano, C. Bisagni (Politecnico di Milano) Reliability assessment of buckling response of an axially compressed sandwich composite shell with and without cut-outs
4.40 pm L. Friedrich, H. Reimerdes, K. Schröder (RWTH Aachen) Advanced sizing strategies for preliminary design of orthotropic grid stiffened shell structures
5.00 pm R. Khakimova, R. Degenhardt (DLR) Assessment of the Single Perturbation Load Approach on composite conical shells
5.20 pm J. Keppe, M. Herath, G. Pearce, G. Prusty, R. Thomson (CRC-ACS, University of New South Wales, Advanced Composite Structures Australia) Stochastic analysis of imperfection sensitive composite cylinders using realistic imperfection models
5.40 pm Discussion
5.50 pm End of Virtual Conference

End of 3rd International Conference on Shell Buckling and Postbuckling

----------------------------------------------------------------------------------------------------------------------

Tsuboi Award Recipients [awarded by The International Association for Shell and Spatial Structures (IASS)]

The Tsuboi Award was established in 1991 with the help of a donation from the late Mrs. Kazuko Tsuboi. This award honors the memory of Professor Yoshikatsu Tsuboi (Japan, 1907-1990), former President and Honorary Member of the IASS, and his outstanding contributions to structural and architectural design.

Tsuboi Awards are awarded annually by the Tsuboi Awards Committee in two categories:
(A) For the most meritorious paper published in the Journal of the IASS in the preceding calendar year.
(B) For the most outstanding paper presented and published in the Proceedings of the previous year's annual IASS Symposium.
Each award consists of a Japanese lacquerware sculpture with an appropriate engraved plaque attached to its base. The sculpture was designed by Hiroko Hatekenaka and Ryohei Miyata, and the awards are handcrafted by Takju Ogimura, with important contributions to the design and fabrication efforts by Yoshiaki Tsuboi, the son of Professor Tsuboi.

The first Tsuboi Award for the best paper published in the Journal of the IASS was conferred to the German Architect, Michael Balz and for the proceedings paper to the German engineer, Prof. Ekkehard Ramm in 1991. So far in the last 18 years, 17 awards were conferred in the Journal category and 19 awards in the Proceedings category.

**Recipients for the best papers published in the Journal of the IASS:**

1991 M. Balz (Germany): "Architectural Aspects of Organic Forms and Design of Concrete Shells"
1993 H. Isler (Switzerland): "Generating Shell Shapes by Experiments"
1994 M. Levy (USA): "The Innovation of Lightness"
1995 M.E. Giuliani (Italy): Innovative Composite Spatial Structures for the New Milano Fair Exhibition Facilities"
1997 B. Maurin, R. Motro (France): "Investigation of Minimal Forms with Density Methods"
1999 P. Huybers (The Netherlands): "The Chiral Polyhedra"
2000 C. Otero, V. Gil and J. I. Alvaro (Spain): "CR-Tangent Meshes"
2002 T. Kokawa (Japan): "Field Study of a 30-M Span Ice Dome"
2003 C. Cui, H. Ohmori and M. Sasaki (Japan): "Computational Morphogenesis of 3D Structures by Extended ESO Method"
2006 C. Douthe, O. Baverel and J.F. Caron (France): "Form-Finding of a Grid Shell in Composite Materials"
2007 Y.B Yang, L.J. Chen and C.W. Lin (Taiwan): "Cable Vibrations Caused by Moving Loads in Cable-Stayed Bridges"
2010 P. Casinello and J.A. Torroja (Spain): "Félix Candela: His Vocational Training at the University and his Subsequent Relationship with the Institute Founded by Eduardo Torroja"
2011 F. Escrig (Spain): "Geometry and Structures: Historical Impressions about Architecture"
2012 T. Tachi and K. Miura (Japan): "Rigid-Foldable Cylinders and Cells"
2013 D.S. Hensel and G.B. Bover (Norway): "Nested Catenaries"

**Recipients for the best papers published in Proceedings of IASS Annual Symposia:**

1991 E. Ramm (Germany): "Shape Finding Methods in Shells"
1993 G. Groci and A. Visicovic (Italy): "Causes of the Failure of Coliseums over the Centuries, and Evaluation of Safety Levels"
1994 J. Schlaich and H. Schober (Germany): "Glass-Covered Lightweight Spatial Structures"
1995 F. Escrig, J.P. Valcarcel and J. Sanchez (Spain): "Deployable Structures Squared in Plan: Design and Construction"
1996 M. Saitoh and A. Okada (Japan): (a) Space and Structure-Learning of Conceptual Design in Education: What Can One Learn form Building Structures; (b) From Image to Technology: The Role of String in Hybrid String Structures
1998 Y. Hangai (Japan): "Buckling Analysis of Stress Unilateral Structural Systems"
1999 N. Imagawa (Japan): "Shells and Spatial Structures: From Recent Past to the Millennium"
2000 G. Croci (Italy): "The Restoration of the Basilica of Francis of Assisi"
2001 T. Tarnai (Hungary): "Origami in Structural Engineering"
2001 M. Uchikoshi, S. Kato, S. Nakazawa and Y. Mukaiyama (Japan): "How Do We Realize a Super Large Dome Under Severest Earthquake?: A Dome with Seismic Isolation System"
2002 M. Bechtholt (USA): "Wood-foam Sandwich Shells: Computer-Aided Manufacturing of Complex Shapes"
2004 F. V. Jensen and S. Pellegrino (United Kingdom): "Expandable Blob Structures"
2006 A. Smaili and R. Motro (France): "Folding and Unfolding of Curved Tensegrity Systems by Finite Mechanism Activation"
2007 P. Winslow, S. Pellegrino and S.B. Sharma (UK): "Mapping Two-Way Grids on to Free-Form Surface"
2008 L. De Laet, R. Luchsinger, R. Crettol, M. Mollaert and N. De Temmerman (Belgium): "Deployable Tensairity Structures"
2010 T. Van Mele and P. Block (Switzerland): "A Novel Form Finding Method for Fabric Formwork for Concrete Shells"
2011 F. Dieringer, R. Wüchner, and K.U. Bletzinger (Germany): "Practical advances in numerical form finding and cutting pattern generation for membrane structures"
2012 S. Neuhäuser, M. Weickgenannt, C. Witte, W. Haase, O. Sawodny and W. Sobek (Germany): "Stuttgart Smart Shell - A Full Scale Prototype of an Adaptive Shell Structure"
2013 P. Eisenbach, R. Vasudevan, M. Grohmann, K. Bollinger and S. Hauser (Germany): "Parapluie - Ultra Thin Concrete Shell Made of UHPC Activating Membrane Effects"

-----------------------------------------------
International Conference on Shells, Plates and Beams (SPB2015), Bologna, ITALY, 9-11 September 2015
Conference Website: http://www.spb2015.dicam.unibo.it/
Welcome to the web site of 1st International Conference on Shells, Plates and Beams (SPB2015).
This conference intends to bring forward the best research and applications on shells, plates and beams.
The conference has the support of COMPOSITE STRUCTURES, an International Journal of Elsevier and CURVED AND LAYERED STRUCTURES, an International Journal of De Gruyter Open. Selected papers from this Conference will be published in COMPOSITE STRUCTURES and CURVED AND LAYERED STRUCTURES.

Conference Venue: School of Engineering and Architecture at University of Bologna.

Aims and Scope of the Conference: Thin-walled structures are crucial in modern engineering applications. The computational and experimental methods for shells, plates, beams and arches are the general topics of this conference. We seek papers on buckling, vibrations, repair, reinforcements, concrete, composites, wood, metals, and more recent metamaterials, and advanced materials, nonlinearities, masonry, finite elements, bridges, nano-plates and nano-beams, piezoelectric plates and shells, as prospective topics.

Conference Chairs:
Antonio J. M. Ferreira, University of Porto, Porto, Portugal
Erasmo Viola, University of Bologna, Italy
Francesco Tornabene, University of Bologna, Italy

Local Organizing Committee:
Nicholas Fantuzzi, University of Bologna, Italy

Scientific Committee:
Ahmed Elmarakbi, Univ. Sunderland, UK
Akbar Alibeigloo, Modares Univ., Iran
Alessandro Reali, Univ. of Pavia, Italy
Alexander L. Kalamkarov, Dalhousie Univ., Canada
Alexander Tessler, NASA, USA
Alfred G. Striz, Univ. Oklahoma, USA
Ana Neves, Oxford Brookes Univ., UK
Angelo Di Tommaso, Univ. Bologna, Italy
Antonio Ferreira, FEUP, Portugal
Antonio Miravete, MIT, USA
Aurelio Araujo, Instituto Superior TÊcnico, Portugal
Bachir Kerboua, University of Tlemcen, Faculty of Technology, Algeria
Bhavani Sankar, Univ. Florida, USA
Cristovo Mota Soares, Instituto Superior TÊcnico, Portugal
Damiano Pasini, McGill University, Canada
Erasmo Carrera, Politecnico di Torino, Italy
Erasmo Viola, Univ. Bologna, Italy
Evgeny Morozov, Univ. New South Wales, Australia
Ferdinando Auricchio, Univ. Pavia, Italy
Francesco Tornabene, Univ. Bologna, Italy
Francesco Ubertini, Univ. Bologna, Italy
Fu-Pen Chiang, Stony Brook University, USA
Gaetano Giunta, Centre de Recherche Public Henri Tudor, Luxembourg
Gennady M. Kulikov, Tambov State Technical University, Russia
J. N. Reddy, Texas A&M Univ., USA
Jeng-Tzong Chen, National Taiwan Ocean Univ., Taiwan
K. M. Liew, City Univ. of Hong Kong, China
Lorenzo Dozio, Politecnico di Milano, Italy
Luciano Feo, University of Salerno, Italy
Marco Amabili, McGill University, Canada
Marco Petrolo, RMIT University, Italy
Maria Cinefra, Politecnico di Torino, Italy
Massimo Ruzzene, Georgia Tech., USA
Mohamad Qatu, Univ. Central Michigan, USA
Nuno Silvestre, Instituto Superior TÉcnico, Portugal
Olivier Polit, Univ. Paris X, France
Omer Civalek, Akdeniz Univ., Turkey
Parviz Malekzadeh, Persian Gulf Univ., Iran (The one D. Bushnell found was at Semnan University, Iran)
Patrick Selvadurai, McGill University, Canada
Raj Das, Univ. Auckland, New Zealand
Rakesh Kapania, Virginia Tech., USA
Ramesh Talreja, Texas A&M Univ., USA
Roberta Sburlati, Univ. Genova, Italy
Roberto Capozucca, Univ. Politecnica delle Marche, Italy
Roberto Nascimbene, EUCENTRE, Italy
Romesh Batra, Virginia Tech, USA
Senthil Vel, Univ. Maine, USA
Sun Bohua, Cape Peninsula Univ. of Tech., South Africa
Tsu-Wei Chou, Univ. Delaware, USA
Victor Birman, Missouri University of Science and Technology, USA
Vijay Srivastava, Indian Institute of Technology, India
Van Suong Hoa, Concordia Univ., Canada
Vimu Unnikrishnan, The University of Alabama, USA
Werner Wagner, Univ. Karlsruhe, Germany
WiesBaw M. Ostachowicz, Polish Academy of Sciences, Poland
Wilfried Becker, Univ. Darmstadt, Germany
Yoshihiro Narita, Hokkaido University, Japan
Young Kwon, Naval Postgraduate School, USA
Zdenek P. Bazant, Northwestern Univ., USA
Zengtao Chen, Univ. New Brunswick, Canada

Early Registration: 1st June 2015
Deadline for registration: 1st August 2015

Plenary Lectures and Sessions:
Workshops (to be updated):
Abstract of the workshop: The synergistic integration of smart materials, structures, machines, sensors, actuators, and control electronics can transform conventional passive structures and machines to active, adaptive, and smart _ structronic (structure + electronic) or mechatronic systems with inherent self-sensing, diagnosis, and control capabilities. Research and development of the emerging technology of smart structures and structronic systems have been evolving for nearly three decades. Sophisticated multi-field/control coupling theories have been developed and numerous practical applications have also been proposed. This report focuses on histories, smart materials (e.g., piezoelectrics, electro-/magneto-/photo-strictive materials, shape memory materials, electro- and magneto-rheological fluids, polyelectrolyte gels, pyroelectric materials, magneto-optical materials, superconductors, etc.), precision devices (sensors and actuators), micro-/nano-actuations, smart structures, mechatronic and structronic systems, and photo-thermo-electro-magneto-mechanical systems encompassing elastic, temperature, electric, magnetic, light, and control interactions. Modern research issues are also discussed.

Tutorial Outline of the workshop:
1. Introduction and overview.
3. Design principles, micro-/nano-actuations, precision devices and control.
4. Case studies.
5. Design clinic: Special and customized applications.

Plenary Talks (to be updated):
Smart Shells: Sensing, Actuation and Control. Horn-Sen (H.S.) Tzou, ZheJiang Univ., China.
Virtual element methods for plates and shells. Claudia Chinosi, Univ. of Pavia, Italy.
(being defined). Francesco Ubertini, Univ. of Bologna, Italy.
Precasting of large span shells and plates. Gian Carlo Giuliani, Redesco (Research-Design-Consulting), Italy.

Sessions (to be updated):
RC Beams with NSM FRP rods. Roberto Capozucca, Univ. Politecnica delle Marche, Italy.
Shell theory. Gennady Kulikov, Tambov Univ., Russia

ABSTRACT: The results of buckling tests performed during the project DESICOS funded by the European Commission in the FP7 Programme are here presented. The tested structures are sandwich cylindrical shells that consist of reduced models of a component of the Ariane 5 launcher: the Dual Launch System. In particular, the scaled component is studied with and without the presence of cut-outs. Before performing the tests, the geometric imperfections as well as the thickness variations were measured. The tests were performed using the
buckling testing equipment of Politecnico di Milano. The results of the tests contributed to understand the complex phenomenon of buckling of sandwich cylindrical shells, and to study the effect of initial geometric imperfections. They were also used to validate finite element models useful for the design of future launcher structures, and to set-up a probabilistic approach for the buckling analysis of cylindrical shells.

“Lower Bound Buckling Loads for Design of Laminate Composite Cylinders”, 3rd International Conference on
ABSTRACT: Over a period of more than 45 years, an extensive research programme has allowed a series of very simple propositions, relating to the safe design of shells experiencing imperfection sensitive buckling, to be recast in the form of a series of lemmas. These are briefly summarised and their practical use illustrated in relation to the prediction of safe lower bounds to the imperfection sensitive buckling of axially loaded, fibre reinforced polymeric, laminated cylinders. With a fundamental aspect of the approach, sometimes referred to as the reduced stiffness method, being the delineation of the various shell membrane and bending stiffness (or perhaps more appropriately energy) components contributing to the buckling resistance, the method will be shown to also provide a powerful way of making rational design decisions to optimise the use of fibre reinforcement.

ABSTRACT: This paper presents the nonlinear large deflection of the thin film and the effect of substrate deformation on the thin film deflection through the shaft-loaded blister test. The blister of thin film can be divided into two parts, namely, the annular contact brim and the central noncontact bulge. A two-coupled line spring model is developed to describe the deformation of the contact part, and Föppl–Hencky equations are employed to study the constitutive relation between the applied load and the central deflection. The analytical and numerical solutions for the constitutive relation between the applied load and the deflection of thin film with considering the deformation of substrate are derived.

ABSTRACT: It is widely reported that no efficient guidelines for modelling imperfections in composite structures are available. In response, this work evaluates the imperfection factors of axially compressed Carbon Fibre Reinforced Polymer (CFRP) cylinder with different ply angles through finite element (FE) analysis. The sensitivity of imperfection factors were analysed using design of experiment: factorial design approach. From the analysis it identified three critical factors that sensitively reacted towards buckling load. Furthermore empirical equation is proposed according to each type of cylinder. Eventually, critical buckling loads estimated by empirical equation showed good agreements with FE analysis. The design of experiment methodology is useful in identifying parameters that lead to structures imperfection tolerance.

ABSTRACT: Thin-walled cylindrical shells are susceptible to buckling failures caused by the axial compressive loading. During the design process or the buckling failure evaluation of axially-compressed cylindrical shells, initial geometric and loading imperfections are of important parameters for the analyses. Therefore, the engineers/designers are expected to well understand the physical behaviours of shell buckling to prevent unexpected serious failure in structures. In particular, it is widely reported that no efficient guidelines for modelling imperfections in composite structures are available. Knowledge obtained from the relevant works is open for updates and highly sought. In this work, we study the influence of imperfections on the critical buckling of axially compressed cylindrical shells for different geometries and composite materials (Glass Fibre Reinforced Polymer (GFRP), Carbon Fibre Reinforced Polymer (CFRP)) and aluminium using the finite
element (FE) analysis. Two different imperfection techniques called eigenmode-affine method and single perturbation load approach (SPLA) were adopted. Validations of the present results with the published experimental data were presented. The use of the SPLA for introducing an imperfection in axially compressed composite cylindrical shells seemed to be desirable in a preliminary design process and an investigation of a buckling failure. The knockdown factors produced by the SPLA were becoming attractive to account for uncertainties in the structure.

ABSTRACT: Complex three-dimensional (3D) structures in biology (e.g., cytoskeletal webs, neural circuits, and vasculature networks) form naturally to provide essential functions in even the most basic forms of life. Compelling opportunities exist for analogous 3D architectures in human-made devices, but design options are constrained by existing capabilities in materials growth and assembly. We report routes to previously inaccessible classes of 3D constructs in advanced materials, including device-grade silicon. The schemes involve geometric transformation of 2D micro/nanostructures into extended 3D layouts by compressive buckling. Demonstrations include experimental and theoretical studies of more than 40 representative geometries, from single and multiple helices, toroids, and conical spirals to structures that resemble spherical baskets, cuboid cages, starbursts, flowers, scaffolds, fences, and frameworks, each with single- and/or multiple-level configurations.

ABSTRACT: Fractal-inspired designs for interconnects that join rigid, functional devices can ensure mechanical integrity in stretchable electronic systems under extreme deformations. The bonding configuration of such interconnects with the elastomer substrate is crucial to the resulting deformation modes, and therefore the stretchability of the entire system. In this study, both theoretical and experimental analyses are performed for postbuckling of fractal serpentine interconnects partially bonded to the substrate. The deformation behaviors and the elastic stretchability of such systems are systematically explored, and compared to counterparts that are not bonded at all to the substrate.

ABSTRACT: The aim of this work is to investigate the final failure response of damaged composite stiffened panels in post buckling regime under compressive load, by using progressive failure analysis (PFA) methodology. The selected panel is characterized by T shaped stringers and it is representative of the upper skin panel, toward the wing tip, of the wing box of a typical regional aircraft. PFA methodology has been applied in order to predict in addition to the initiation of the local failure also its propagation up to the final collapse of the panel, in presence of local damage (barely visible impact damage, BVID) and in post-buckling regime. For this purpose, discrete damages have been considered in the skin of the panel. According to the indications contained in many guidelines finalized to the preliminary design of composite structures, a simplified design model of BVID has been considered in this work, in particular a hole 1/4 inch in diameter has been used to simulate this damage. The collapse load of the panel has been evaluated considering different locations of a single damage and also considering multi-damage maps (the latter are more representative of a real damage scenario). The results of PFA presented in this work illustrate the combined effect of the reduction of the panel stiffness and of
the damage propagation, and the sensitivity of the buckling onset and of the residual strength of the panel with respect to different damage locations and damage density.

ABSTRACT: This work presents the robustness assessment of stiffened thin-walled composite structures in post-buckling, which is based on a new design strategy that satisfies weight, load-based performance and energy-based robustness requirements. In this approach, robustness is understood as collapse insensitivity due to a local failure, where global buckling for instance is assumed as a local failure, once the stiffness reduction after this event can lead to a sharp collapse. Following this concept, robustness measures are derived from the structural energy, the area under the load-shortening curve obtained from geometrical nonlinear finite element analysis with material progressive failure. Since inherent uncertainties in geometry, material properties, ply orientation and thickness affect the structural performance and robustness, those variations are accounted for.

As a result, a new argument is given to shift collapse closer to ultimate load, so that lighter structures are achievable with both performance and robustness requirements satisfied. This trade-off is valuable to aerospace applications, where light weight and safety are mandatory. Finally, this innovative strategy is demonstrated for stiffened thin-walled composite structures in post-buckling, and its results compared to others obtained from current practice.

ABSTRACT: Up to today there are no design guidelines which allow designing imperfection sensitive CFRP structures in an efficient way. The upcoming EU project DESICOS (New Robust DESIgn Guideline for Imperfection Sensitive COMposite Launcher Structures) contributes to this aim by a new design procedure exploiting the worst imperfection approach efficiently by implementation of the Single Perturbation Load Approach. Preliminary studies already demonstrated high potential. This paper deals with the objectives of the DESICOS project, describes the line of actions of the new approach, and specifies the theoretical and experimental work to be carried out in order to meet the objectives.

ABSTRACT: It happens many times that the structure is safe in normal stress and deflection but fails in buckling. Buckling analysis is one of the methods to go for such type of analysis. It predicts various modes of buckling. Plates are used in many applications such as structures, aerospace, automobile etc. Such structures are subjected to heavy uniformly distributed load and concentrated load many times over its life span. Strength of these structures are increased by adding stiffeners to its plate. This paper deals with the analysis of rectangular stiffened plates which forms the basis of structures. A comparison of stiffened plate and unstiffened plate is done for the same dimensions. In order to continue this analysis various research papers were studied to understand the previous tasks done for stiffened plate. Hyper mesh and Nastran is used to do the analysis. Buckling analysis is done with aspect ratio of 2. Rectangular flat bar is used as stiffener.

ABSTRACT: One of the most important static analyses for thin plates, is buckling analysis. The most common method to study the Critical Buckling Load of thin plates, is equilibrium method. This method is based on solving a fourth order partial differential equation. This paper presents a finite element model for a simply supported and simply supported-fixed-free rectangular plate. The study uses ABAQUS (v.6.7) software to derive the finite element model of the rectangular plate. Finally, the obtained results through FEM would be compared with an exact solution for both boundary conditions.

ABSTRACT: One of the main failure modes of an aircraft is buckling. Stringers are often bonded to composite panel skins to help increase the panel’s buckling strength; however, if there is a defect in the bond between the stringer and the panel, the structure may be weakened. Developing analysis tools that can accurately simulate the behavior of composite materials is critical to the successful design and use of composite structures. The pre-design of aircraft wing structures relies on finite element models of significantly reduced complexity in which only spar and rib components are explicitly modeled, whereas the wing skin-stringers stiffened panels are implicitly represented by stiffness-equivalent elements. This conventional procedure enables a fast solution technique for large problems.

ABSTRACT: Thin walled integrally stiffened shell structures are frequently used in primary structures of space launcher vehicles. These structures are prone to buckle and thus fail due to a loss of structural stability. It has to be distinguished between two major modes of instability, namely a global buckling of the entire structure and a local buckling of skin sections, longitudinal as well as circumferential stiffeners. Due to the large number of design variables when designing an integrally stiffened shell structure, the preliminary design of these structures is a demanding problem. To allow an efficient preliminary design, advanced sizing strategies have to be developed. For this purpose, analytical methods to allow assessing the local as well as global instability of the integrally stiffened shell structure are employed. Within this contribution, sizing strategies basing on closed form efficient analytical methods are introduced and applied to identify proper designs of integrally orthotropic stiffened shell structures.

ABSTRACT: We present the pre and post buckling analysis of stiffened composite panels based on the finite element models. Individual buckling studies are conducted on the stiffened composite panel made up of woven fabric CFC/epoxy, E-glass/epoxy and the Kevlar/epoxy composites. Straight, T shaped and I shaped stiffeners are considered to stiffen the panel. The panel is fabricated with 8 layers and the stiffeners are made up of 16 layers, of equal thickness arranged in different orientations. The panel is subjected to a uniform axial compression load of 10 kN. The distribution of the buckling stresses and the buckling loads with different panel and stiffener combinations are estimated for three different layup sequences. The variation of the buckling stresses and the buckling loads from the numerical model are compared with the experiment. The results are in excellent agreement.

ABSTRACT: Values of characteristic parameters such as thickness have big influence on the impact behavior of a laminated armor. Determination of those values for an optimum laminated armor usually requires evaluation of many computationally costly impact analyses. In this paper, automated, efficient and effective determination of design parameters in a laminated armor for best impact performance is investigated using an approximate optimization method. The approximate optimization method is generated by coupling a parametric preprocessor, finite element analysis software, response surface approximations and a numerical optimization algorithm. The whole coupling is achieved through a commercial code, ANSYS Design Optimization Module. The laminated armor of interest consists of three layers. The frontal layer is alumina ceramic, and it is supported by a 4340 steel mid-layer and a 2024-T3 aluminum rear layer. The armor is impacted by a projectile with velocities of 1000 and 2000 m/s. The surface normal to the armor has an oblique angle with the projectile’s moving direction. The 3-D impact analysis of the armor is conducted using non-linear explicit dynamic finite element code ANSYS/LS-DYNA. Optimization of the armor is performed to find the best thickness values of layers and oblique (orientation) angle towards the least penetration of the projectile.

-----BOOK
ABSTRACT: Optimization methods are increasingly used to design structures. Structural optimization with linear static analysis is pretty much mature in methodology and therefore several codes now have optimization capability for linear analysis. This is in contrast to optimization with crash and impact responses encountered in automotive, defense, transportation safety and other fields. Impact responses do not present simplicities as with linear static responses. They are highly nonlinear and noisy (i.e. non smooth) preventing the use of conventional optimization methods based on gradients or sensitivities. Also, impact analyses are usually computationally costly. Such difficulties motivated the development of effective and efficient methods for impact optimization. This book elaborates structural optimization procedure under crash and impact loading. For this purpose, analysis and optimization methods are discussed in detail. Impact optimization problems are solved from
several areas.

ABSTRACT: In this article, shape effect on free vibration behavior of functionally graded plates is investigated. Square, rectangular, skew, circular, elliptical, annular and equilateral triangular plates with the same surface area and thickness are considered. Frequency values of these plates are compared for simply supported and clamped boundary conditions. Finite element method (FEM) is used in calculating frequency values and mode shapes. Since commercial codes do not allow inputting functionally graded material properties directly, MATLAB code was developed for FEM solution. Findings of this study can be useful for designers that have freedom to choose the plate shape in engineering applications.

Jazar, pp 219-233, Springer, 2015

ABSTRACT: This study investigates the crush behaviour of a relatively large diameter, thin walled tube through both experimental and finite element methods. The experiments were conducted using test specimens of cylindrical tube which were placed into a load press, and crushed by a distance of 150 mm. The thin walled tubes were found to collapse through localised buckling, with a folding layered mode of failure. Numerical analysis of the cylindrical tube was conducted using finite element (FE) methods through an explicit analysis (utilising a three dimensional shell model). Through the use of both ductile damage criteria and the Müschenborn–Sonne forming limit diagram (MSFLD), the model was able to initiate buckling failure without creating imperfections. The numerical model exhibited a similar layered, ring-folding mode of failure as observed in the experiment. Shear failure was also analysed, however caused a large amount of element distortion. The model showed a large degree of sensitivity to the coefficient of friction used in contact between the tube and the press. With the careful selection of mesh density, friction coefficient, and material properties, the FE model demonstrated very good correlation with the experiment in terms of critical buckling force and post-buckling response.

ABSTRACT: The stretch-induced wrinkling of thin films is solved through the modified von Kármán large deflection equations by first selecting the suitable deformation expressions that satisfy boundary conditions. Then, adopting the principle of minimum potential energy we obtain the deformation equations analytically and experimentally. The methodology also indicates the limit load impending of simply supported rectangular thin films. The obtained significant deflections are nonlinearly elastic and of the lowest order of infinite solutions. The parameters of aspect ratio, the thickness and material of thin films are studied analytically and numerically. The highlighted results of wrinkle amplitude and load are in good agreement with experiments. The methodology also indicates the limit load impending plasticity and predicts the applied load precisely for each wrinkle. Further, it can be extended to the variety of multifunctional orthotropic and multilayered thin films.

DOI: 10.5120/19704-1523

ABSTRACT: Buckling analysis of laminated composite simply supported cylindrical shell under cryogenic environment is solved by using exact approach. The theoretical formulation is based upon the third-order shear deformation theory, then equation of motion are derived and solved using Fourier series to obtain critical buckling load by solving eigenvalue problem for different cryogenic gradients. Many design parameters are changed such as using different material, number of laminate, aspect ratio (L/R) and thickness ratio (R/h).

Results show that changing cryogenic temperature improve buckling load for all material of cylindrical shell, the results show good agreement with those published by other researchers.

ABSTRACT: The present paper deals with the nonlinear thermal instability of geometrically imperfect sandwich cylindrical shells under uniform heating. The sandwich shells are made of a shape memory alloy (SMA)-fiber-reinforced composite and functionally graded (FG) face sheets (FG/SMA/FG). The Brinson phenomenological model is used to express the constitutive characteristics of SMA fibers. The governing equations are established within the framework of the third-order shear deformation shell theory by taking into account the von Karman geometrical nonlinearity and initial imperfection. The material properties of constituents are assumed to be temperature dependent. The Galerkin technique is utilized to derive expressions of the bifurcation points and bifurcation paths of the sandwich cylindrical shells. Using the developed closed-form solutions, extensive numerical results are presented to provide an insight into the influence of the SMA fiber volume fraction, SMA pre-strain, core thickness, non-homogeneity index, geometrical imperfection, geometry parameters of sandwich shells and temperature dependency of materials on the stability of shells. The results reveal that proper application of SMA fibers postpones the thermal bifurcation point and dramatically decreases thermal post-buckling deflection. Moreover, the induced tensile recovery stress of SMA fibers could also stabilize the geometrically imperfect shells during the inverse martensite phase transformation.

“Multiscale computational homogenization of heterogeneous shells at small strains with extensions to finite displacements and buckling”, International Journal for Numerical Methods in Engineering, article published online: 20 May 2015, DOI: 10.1002/nme.4927

ABSTRACT: In this paper, a framework for computational homogenization of shell structures is proposed in the context of small-strain elastostatics, with extensions to large displacements and large rotations. At the macroscopic scale, heterogeneous thin structures are modeled using a homogenized shell model, based on a versatile three-dimensional seven-parameter shell formulation, incorporating a through-thickness and pre-integrated constitutive relationship. In the context of small strains, we show that the local solution on the elementary cell can be decomposed into six strains and six-strain gradient modes, associated with corresponding boundary conditions. The heterogeneities can have arbitrary morphology but are assumed to be periodically distributed in the tangential direction of the shell. We then propose an extension of the small-strain framework to geometrical nonlinearities. The procedure is purely sequential and does not involve coupling between scales. The homogenization method is validated and illustrated through examples involving large displacements and buckling of heterogeneous plates and shells.

ABSTRACT: The stability analysis of slender web loaded in compression was presented. To solve this problem, a specialized computer program based on FEM was created. The nonlinear finite element method equations were derived from the variational principle of minimum of potential energy. To obtain the nonlinear equilibrium paths, the Newton-Raphson iteration algorithm was used. Corresponding levels of the total potential energy were defined. The peculiarities of the effects of the initial imperfections were investigated. Special attention was focused on the influence of imperfections on the post-critical buckling mode. The stable and unstable paths of the nonlinear solution were separated. Obtained results were compared with those gained using ANSYS system.

ABSTRACT: Self-assembly of nano sized particles during natural drying causes agglomeration and shell formation at the surface of micron sized droplets. The shell undergoes sol-gel transition leading to buckling at the weakest point on the surface and produces different types of structures. Manipulation of the buckling rate with inclusion of surfactant (sodium dodecyl sulphate, SDS) and salt (anilinium hydrochloride, AHC) to the nano-sized particle dispersion (nanosilica) is reported here in an acoustically levitated single droplet. Buckling in levitated droplets is a cumulative, complicated function of acoustic streaming, chemistry, agglomeration rate,
porosity, radius of curvature, and elastic energy of shell. We put forward our hypothesis on how buckling occurs and can be suppressed during natural drying of the droplets. Global precipitation of aggregates due to slow drying of surfactant-added droplets (no added salts) enhances the rigidity of the shell formed and hence reduces the buckling probability of the shell. On the contrary, adsorption of SDS aggregates on salt ions facilitates the buckling phenomenon with an addition of minute concentration of the aniline salt to the dispersion. Variation in the concentration of the added particles (SDS/AHC) also leads to starkly different morphologies and transient behaviour of buckling (buckling modes like paraboloid, ellipsoid, and buckling rates). Tuning of the buckling rate causes a transition in the final morphology from ring and bowl shapes to cocoon type of structure.

structures along with interlaminar through-the-thickness cracks have been carried out. The developed FEM based modelling and simulation technique has been yielding results in close agreement with literature. Interlaminar cracks of similar sizes have been considered at edge and internal locations in order to study their effect on natural frequency of vibration of the cantilevered cylindrical composite shell structure. Cracks have been simulated in different locations from the clamped towards the free edge in order to study their effect on free vibration of the laminated shell structure. Interlaminar cracks have been observed to be reducing the natural frequency of vibration of the shell structures to a great extent, hence affecting the stiffness of the structure. However, for similar damage size and locations, internally-cracked composite cylindrical shells are comparatively stiffer than the edge-cracked cylindrical shell structures. Both the edge and internal cracks have been seen to be affecting the stiffness of the shell structure to a great extent through reducing the frequency of vibration, as they are close to the clamped edge. Composite shell structures with cracks towards the free edge have been comparatively safe as they marginally affect the frequency of vibration.

Muna H. Jaber (Civil Engineering, Babylon University), “Strength of tubular hollow steel sections externally reinforced by carbon FRP sheets”, (publisher & date not given in the pdf file; most recent reference is 2008).

ABSTRACT: The experimental research reported is aimed using small quantities of CFRP strips to provide tubular section against local buckling for (five) specimens of steel beams. The tubular hollow steel beams sections are made from welding thin plates at their edges. The use of high-strength advanced composite materials tends to accompany the minimum of structural weight, and is hence presently being assessed for effectiveness as supplementary external reinforcing materials. Composite beams of fiber-reinforced polymers (FRP) and steel formed as tubular steel sections externally reinforced by thin-bonded carbon FRP (CFRP) sheets, exhibit many phenomena not found in conventional structural steel components, and these can have a marked bearing both on the behavior of members composed of these materials and, by connotation, on the way in which such members are designed. The type of strengthen carbon fiber is a unidirectional woven fiber mat of mid strength which is a product of Sika coded as SikaWrap-230C. The CFRP is fixed using a resin Sikadure-330. The study is focusing on the local stability of such members. Also formulation of the finite element method used for analyzing the tested beams. The finite element model will be using the experimental load-deflection results of the steel beams. The use of ANSYS-9 to create the finite element model is adopted, the maximum different between experimental results and ANSYS-9 results is 8.7%.

ABSTRACT: This paper evaluates the vibration characteristics of thin/thick rotating cylindrical shells made of metallic and composite materials. A previous theory of the authors is extended here to include the effects of
geometrical stiffness due to rotation. To this end, variable kinematic one-dimensional (1D) models obtained by applying the Carrera Unified Formulation (CUF) were used. The components of the displacement fields are $x$, $z$ polynomials of arbitrary order $N$, making it possible to go beyond the rigid cross section assumptions of the classical beam theories. A significant contribution of this formulation consists in the possibility to include the in-plane cross-sectional deformations allowing the introduction of the in-plane initial stress effects, e.g., the effect of the geometrical stiffness. Equations of motions, including both Coriolis and in-plane initial stress contributions, were solved through the finite element method. Several analyses were carried out on both thin and thick cylinders made of either metallic or composite materials with different boundary conditions. The results are compared with analytical and numerical shell formulations and three-dimensional solutions available in the literature. Various laminate lay-up have been considered in the case of composites shells. Numerical evaluations of the effect of geometric stiffness are provided, demonstrating its importance in the analyses presented. The 1D models appear very effective to investigate the dynamics of spinning shells and, contrary to shell theories, they do not require any amendments with thick shell geometry. From the computational point of view, the present refined beam models are less expensive than the shell and solid counterparts.

ABSTRACT: The use of thin-walled composite beams in Engineering has attracted great interest in recent years. Composite beams and other structural elements tend to have thin walls due to the high strength of the material. Other important aspect is that, even without reaching large strains and without overcoming the elastic limit of the material, such as beams present geometric nonlinear behavior due to their high slenderness, leading to large displacements and rotations. In this paper, a three-dimensional frame finite element for geometric nonlinear analysis of thin-walled laminated composite beams is presented. The finite element uses the Total Lagrangian formulation in order to allow the treatment of large displacements, but with moderated rotations. The constitutive matrix of the laminated beams is evaluated through a suitable thin-walled beam theory. In this theory, the effects of the couplings for several layups are considered, but the effects of the warping and transverse shear are neglected. Comparisons with numerical experiments demonstrate the very good accuracy of the proposed finite element.

ABSTRACT: There is a renewed interest in grid-stiffened composite structures; they are not only competitive with conventional stiffened constructions and sandwich shells in terms of weight but also enjoy superior damage tolerance properties. In this paper, both global and local buckling is investigated for orthogrid- and isogrid-stiffened composite panels. Homogenized properties corresponding to classical lamination theory are obtained by matching the strain energy of stiffened and equivalent unstiffened cells, and then used in global buckling analysis. Bloch wave theory is adopted to calculate the local buckling load, where the interaction of adjacent cells is fully taken into account. Instead of considering skin buckling and stiffener crippling separately, the skin and stiffeners are assembled together at the level of a characteristic cell. The critical instabilities can be captured whether they are related to the skin, stiffener or their interaction. The proposed combination of global/local models can also be used to predict the material failure. Numerical examples of isotropic panels show that the local buckling loads predicted by the proposed method match detailed finite element calculations well for eccentric or symmetrically located stiffeners with different torsional stiffness. The proposed method is further validated using typical composite configurations of flat panels and circular cylinders.

ABSTRACT: This investigation examines the dynamic stability of a damped imperfect spherical shell within the precinct of a random dynamic load applied just after the initial time. The statistical characterizations of the random load, such as the mean and the autocorrelation, are assumed given and non-vanishing. In particular, the autocorrelation of the random dynamic load is a stationary noise that is correlated as an exponentially decaying harmonic function of time. Such stochastic and random characterizations of the dynamic load function confer some element of randomness on the normal displacement whose statistical mean we shall first seek for the determination of the dynamic buckling load. Lastly, the dynamic buckling load is determined via a suitable maximization and certain useful deductions are made. Assuming that the variance of the random load is and using the mean normal displacement as a relevant statistical characterization of the response, it is observed that the dynamic buckling load is of order $R_0^{-1}$, that is $O(1/R_0)$, of the load variance $R_0$

ABSTRACT: This paper is concerned with asymptotic solution, using multi-timing technique, of a nonlinear coupled elastic system in a dynamical setting where the structure investigated is a discretized imperfect spherical shell .The normal displacement at a point on the shell surface is assumed to be partly in the form of a symmetric pre-buckling mode, and partly in the form of buckling modes that have both axisymmetric and non-axisymmetric components. The geometric imperfection is assumed to be in the shape of the buckling modes. The explicitly time-dependent load function is assumed harmonic (or periodic) and the dynamic buckling load is obtained nontrivially with specializations of the results made. The results show, among other things, that (i) the only condition under which the effects of any coupling is felt is if none of the imperfections in the shapes of the modes coupling is neglected and (ii) neglecting an imperfection automatically nullifies the effects of the nonlinearity that is in the shape of the neglected imperfection.

ABSTRACT: Retaining walls are structures used to provide stability for earth or other material where conditions disallow the mass to assume its natural slope and are commonly used to hold back or support soil banks coal or ore piles, and water. Retaining walls must be of adequate proportions to resist overturning (or excessive tilting) and sliding as well as being structurally adequate. Recognition of retaining walls behavior, selection of the best and the most economical design, and the most logical form and their required specifications are the most important issues and worries of designing engineers during designing period. So recognition of the main effective elements on wall construction expenses, and the effect of limitations on acquiring the most economical wall can be a proper help and deserves being completely studied from all points of view in order to acquire the most economical and from the point of technical aspect the most suitable one. According to the elements of design resulting from the theoretical researches on former retaining walls, and for lightening them; in this article a new constructing design of lightened retaining walls is suggested. Meanwhile common proportions and stability of multi cylindrical shell retaining wall have been discussed in this paper.

ABSTRACT: The article is devoted to the influence of carrying capacity on the stability of laterally loaded cylindrical shells. The influence of initial imperfections on the stability of the laterally loaded shell is also taken into consideration. The investigated structure is a simplified variant of the case of cylindrical shell (road tank – for example Paščenko, 2009; Paščenko, Stejskal, 2008) located on two saddle supports. The initial shape imperfections are created by pushing the saddle support into the shell. The new deformed shape is used as an imperfect shell in the following nonlinear analysis of stability. The main objective of the analysis is to find the reduction factor $\alpha$ depending on the change of geometric parameters of the numerical model (embracing angle $2\theta$, wall thickness $t$). The shell deformation around the saddle support is also monitored. Numerical analysis is carried out by means of a computer program COSMOS/M based on the finite element method (FEM).

ABSTRACT: The effect of length and thickness on dynamic stability analysis of cantilever cylindrical shells under follower forces is addressed. Beck’s, Leipholz’s, and Hauger's problems were solved for cylindrical shells with different length-to-radius and thicknesses-to-radius ratios using the Galerkin method. First-order shear theory was used, and rotary inertias were considered in deriving the differential equations. Critical circumferential and longitudinal mode numbers and loads were evaluated for each case. Diagrams containing nondimensional load parameters vs. length and thickness parameters were plotted for each problem. For some shells with small length-to-radius ratios, flutter occurred in high longitudinal mode numbers where the first-order shear theory may not suffice to accurately evaluate the deformations. However, for long and moderately thick shells, there are ranges in which the shell can be analyzed using the simplified equivalent beam model.

ABSTRACT: The stability and sensitivity analysis of anisotropic polymeric material circular cylindrical shells used in underground applications is considered in this work. The presence of helicoidal ribs produces a shell with anisotropic characteristics. The conditions of the surrounding soil have an important effect on the buckling load and the load carrying capacity of the structure. The analysis begins by considering the equations corresponding to the isotropic case and specializing them for the anisotropic case. The anisotropic behavior is due to the effect of the presence of the reinforcement, which is nearly circumferential. The soil-structure interaction has a significant influence in the structural response of the shell, including its buckling load. This is due to the fact that the shell can be considered as a large and flexible one. Several effects on the buckling load are taken into account, those caused by changes in the rheological properties of the soil due to its level of saturation or water content, how compacted it is, empty zones around the shell, asymmetry of the loads and the proximity of other pipelines. Computational tools based on the Finite Element Method are used to solve the shell stability equations under the several conditions mentioned above. A parametric study is carried out where different geometrical configurations are considered. Variations in the thickness/diameter ratio, length/diameter ratio and offset reinforcement angle are included in the analysis. In this way new design structural criteria are obtained and with these criteria, structural designs with higher reliability are expected.

ABSTRACT: Dynamic stability of a sandwich cylindrical shell, supported by both the annular ribs and the cylinder, loaded with external pressure, changed harmonically, is investigated. The normal and tangential components of contact interaction between the shell and ribs are accounted. The cylinder is represented as elastic foundation with coefficient of soil reaction that defined from equations tridimensional theory of elasticity. Solution of differential equations is found in the shape of trigonometric sequence. As a result, the problem reduces to the system of algebraic equation in reference to components of shell’s displacement in the ribs installation places. The number of equation is three for ribs are installed regularly. In the numerical example shows the effect of the ribs and cylinder to the shell’s instability domain.

ABSTRACT: Flutter of cantilevered, functionally graded cylindrical shells under an end axial follower force is addressed. The material properties are assumed to be graded along the thickness direction according to a simple power law. Using the Hamilton principle, the governing equations of motion are derived based on the first-order shear deformation theory. The stability analysis is carried out using the extended Galerkin method and minimum flutter loads and corresponding circumferential mode numbers are obtained for different volume fractions, length-to-radius, and thickness-to-radius ratios. Two different configurations are considered for the FGM: one in which the metal phase is the outer layer and the ceramic phase is the inner one, and the other vice versa. Results indicate the ranges of major influence due to the volume fraction, and the combined effect of thickness and volume fraction on the flutter load. Also, the optimum and critical power parameters between zero and infinity for which the flutter loads are maximum and minimum are determined.

ABSTRACT: In this work we consider the buckling problem for a filled thin-walled transversally isotropic spherical shell under the external pressure and homogeneous heating in the framework of Timoshenko's model. The Winkler's model with the constant coefficient is used to describe the interaction between the shell and the filler. The heating of the filler is neglected and the assumptions of the local buckling theory are accepted. The various cases of the dependence of the critical loading parameter on the parameters of shear, heating and rigidity of the filler are studied. The results are presented in analytical and graphical forms. It is found, that during uniform compression of spherical shell the critical loading decreases with the increase of the temperature and shift. For the filler with the small stiffness the shift exerts main influence, for the higher stiffness the heating of the shell plays the main role. Wherein the increase of the stiffness of the filler the value of critical load may either increase or decrease depending on the interrelations of the parameters of shift and temperature.

ABSTRACT: Studies on the deformation behaviours of cellular entities, such as coated microbubbles and liposomes subject to a cavitation flow, become increasingly important for the advancement of ultrasonic imaging and drug delivery. Numerical simulations for bubble dynamics of ultrasound contrast agents based on the boundary integral method are presented in this work. The effects of the encapsulating shell are estimated by adapting Hoff’s model used for thin-shell contrast agents. The viscosity effects are estimated by including the normal viscous stress in the boundary condition. In parallel, mechanical models of cell membranes and liposomes as well as state-of-the-art techniques for quantitative measurement of viscoelasticity for a single cell or coated microbubbles are reviewed. The future developments regarding modelling and measurement of the material properties of the cellular entities for cutting-edge biomedical applications are also discussed.

ABSTRACT: In this paper the free vibrations and buckling analysis of laminated plates is performed using a global meshless method. A refined version of Kant’s theorie which accounts for transverse normal stress and through-the-thickness deformation is used. The innovation is the use of oscillatory radial basis functions. Numerical examples are performed and results are presented and compared to available references. Such functions proved to be an alternative to the tradicional nonoscillatory radial basis functions.

Vu Thi Thuy Anh, Dao Huy Bich and Nguyen Dinh Duc, “Nonlinear stability of thin FGM annular spherical

ABSTRACT: To increase the thermal resistance of various structural components in high-temperature environments, the present research deals with nonlinear stability analysis of thin annular spherical shells made of functionally graded materials (FGM) on elastic foundations under external pressure and temperature. Material properties are graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of constituents. Classical thin shell theory in terms of the shell deflection and the stress function is used to determine the buckling loads and nonlinear response of the FGM annular spherical shells. Galerkin method is applied to obtain closed – form of load – deflection paths. An analysis is carried out to show the effects of material, geometrical properties, elastic foundations and combination of external pressure and temperature on the nonlinear stability of the annular spherical shells.

ABSTRACT: The nonlinear stability of eccentrically stiffened functionally graded (FGM) annular spherical segment resting on elastic foundations under external pressure is studied analytically. The FGM annular spherical segment are reinforced by eccentrically longitudinal and transversal stiffeners made of full metal or ceramic depending on situation of stiffeners at metal-rich or ceramic-rich side of the shell respectively. Based on the classical thin shell theory, the governing equations of FGM annular spherical segments are derived. Approximate solutions are assumed to satisfy the simply supported boundary condition of segments and Galerkin method is applied to study the stability. The effects of material, geometrical properties, elastic foundations, combination of external pressure and stiffener arrangement, number of stiffeners on the nonlinear stability of eccentrically stiffened FGM annular spherical segment are analyzed and discussed. The obtained results are verified with the known results in the literature.

ABSTRACT: The paper investigates the elastoplastic buckling of thin circular shells subjected to nonproportional loading consisting of axial tensile stress and external pressure. The governing equations of buckling for cylindrical shells derived by Flugge serve as the basis of analysis. To capture the elastic/plastic behavior, two plasticity theories are considered; the flow theory and the deformation theory of plasticity. Plastic buckling pressures for cylinders with various combinations of boundary conditions are presented for which no analytical solutions are available. The results obtained from the flow and deformation theories confirm that, under over-constrained kinematic assumptions, the deformation theory tends to provide lower values of buckling pressure and the discrepancies in the results from the two plasticity theories increase with increasing thickness-to-radius ratios, tensile stresses, boundary clamping and E/σy ratios. The plastic buckling results obtained by means of the differential quadrature method are compared with carefully conducted FEA results for both the flow and the deformation theory of plasticity. The reasons underlying the apparent plastic buckling paradox are thus investigated for a vast class of boundary conditions and loads.
SUMMARY: The spherical shell is a typical form of revolution shells, which is widely used in pressure vessel and piping industry, nuclear power industry and ocean engineering for its specific structural shape to obtain kinds of performance. However compared to the cylindrical or conical shell, the spherical shell is mainly used as main structure or pressure hull in underwater engineering because of the superiority of theoretical solution and its manufacture. For the significance of the spherical shell, many researchers in the region of engineering and mechanics have spent great efforts to solve it and do lots of experiments in order to obtain its accurate theoretical analysis and design method as the engineering rule. To show the characteristics of a spherical shell with some initial imperfections, both material nonlinear and geometric nonlinear Finite Element Analysis (FEA) has been presented in this paper. In this presented Finite Element Method (FEM), the elastic-plasticity stress-strain relations have been adopted, and the initial deflection of spherical shell created by manufacture was also taken into account. It is shown that the nonlinear structural characteristics of the spherical shell vary from its different dimension parameters for initial imperfection through nonlinear FEM. Compared with the different rule’s methods, nonlinear FEM could exactly show sphere’s stability varying by initial imperfections. Then two experiments of spherical model, made by some high strength steel and with same sizes but different initial deflection, have been presented in presentation. The experiment results eventually indicate that the stability of a spherical shell varies by its initial imperfection and such sphere stability could not be accounted by currently rules except nonlinear FEM. It is essential to obtain the design method for spherical shell made by high strength steel used in deep sea vehicle and ocean engineering.

ABSTRACT: By means of the modified iteration method, the nonlinear stability problem of a double-deck reticulated truncated circular shallow spherical shell under uniform pressure was investigated. According to the fundamental equations of double-deck reticulated circular shallow spherical shells, the critical buckling load for the shell with two types of boundary conditions was obtained and the effect of geometric parameters of the shell on the critical buckling load was discussed.

ABSTRACT: In all aircrafts developed by Saab, the structure has to be designed in a way that minimizes weight. This often implies that thin structures are used, for example as machined frames. But, when using thin structures, there is always a risk of buckling. To prevent failure due to buckling, either a post-buckling analysis has to be performed or a non-buckling design has to be used. In order to have a quick and robust tool for a large number of linear buckling calculations, a buckling method for an in-house program has been developed in this thesis. The program handles arbitrary quadrilateral plates with different loads and boundary conditions. In the thesis, a new calculation method called BucklingMesh2D has been created in the existing Saab dimension program DIM that handles linear buckling problems with the Finite Element Method. The module includes a
graphical interface where the user can generate the desired geometry and connect it to a material as well as choosing boundary conditions and defining the element mesh. The loads can be defined using three different load groups with different complexity. The chosen elements are two shell elements, four-noded and eight-noded, called Quad4 and Quad8. Calculations with the Quad8 element generate results that are consistent with results from the FE program Nastran and the other buckling calculation method in DIM, which is not based on FEM. However, the Quad4 element implemented is not recommended to be used since it does not converge fast enough during refinement of the mesh. Investigations have been made to speed up the program code. As a result, superposition of the stress stiffness matrix and reducing sparse matrices are used. Even reduced integration of the stiffness matrix and the stress stiffness matrix has been analysed which produces trustworthy result and speeds up the calculations, compared to fully integration.

ABSTRACT: When a spherical elastic capsule is deflated, it first buckles axisymmetrically and subsequently loses its axisymmetry in a secondary instability, where the dimple acquires a polygonal shape. We explain this secondary polygonal buckling in terms of wrinkles developing at the inner side of the dimple edge in response to compressive hoop stress. Analyzing the axisymmetric buckled shape, we find a compressive hoop stress with parabolic stress profile at the dimple edge. We further show that there exists a critical value for this hoop stress, where it becomes favorable for the membrane to buckle out of its axisymmetric shape, thus releasing the compression. The instability mechanism is analogous to the formation of wrinkles under compressive stress. A simplified stability analysis allows us to quantify the critical stress for secondary buckling. Applying this secondary buckling criterion to the axisymmetric shapes, we can determine the critical volume for secondary buckling. Our analytical result is in close agreement with existing numerical data.

ABSTRACT: This paper presents effects of boundary conditions and axial loading on frequency characteristics of rotating laminated conical shells with meridional and circumferential stiffeners, i.e., stringers and rings, using Generalized Differential Quadrature Method (GDQM). Hamilton's principle is applied when the stiffeners are treated as discrete elements. The conical shells are stiffened at uniform intervals and it is assumed that the stiffeners have similar material and geometric properties. Equations of motion as well as equations of the boundary condition are transformed into a set of algebraic equations by applying the GDQM. Obtained results discuss the effects of parameters such as rotating velocities, depth to width ratios of the stiffeners, number of stiffeners, cone angles, and boundary conditions on natural frequency of the shell. The results will then be compared with those of other published works particularly with a non-stiffened conical shell and a special case where angle of the stiffened conical shell approaches zero, i.e. a stiffened cylindrical shell. In addition, another comparison is made with present FE method for a non-rotating stiffened conical shell. These comparisons confirm reliability of the present work as a measure to approximate solutions to the problem of rotating stiffened conical shells.

References listed at the end of the paper:
This paper focuses on an analysis of free vibration of thick rotating stiffened composite cylindrical shells with different boundary conditions. The analysis is performed on the basis of a three-dimensional theory by using the layerwise-differential quadrature (LW-DQM) method. The equations of motion are derived employing Hamilton’s principle. In order to accurately allow for the thickness effects, a layerwise theory is used to discretize the equations of motion and related boundary conditions through the thickness of the shells. Then, the equations of motion and the boundary conditions are transformed into a set of algebraic equations by using the DQM in the longitudinal direction. This study demonstrates the applicability, accuracy, stability, and fast rate of convergence of the present method in free vibration analyses of rotating stiffened cylindrical shells. The presented results are compared with those of other shell theories obtained by conventional methods and with a special case where the number of stiffeners approaches zero, i.e., an nonstiffened cylindrical shell, and excellent agreements are achieved. Finally, some new results are presented, which can be used as benchmark solutions for future investigations.

ABSTRACT: An approximate solution is presented to investigate the effects of thermal load on the frequency of ring-stiffened rotating FG conical shell. Material properties and the temperature field are assumed to be graded and varied in the thickness direction. The shell is reinforced by equal interval rings. The equations of motion are derived by the Hamilton's principle. Approximate analytical solutions are assumed to satisfy clamped boundary conditions and then Fourier decomposition and Galerkin method are applied to achieve relations of frequencies. To validate, the comparisons are made with a number of particular cases in literature and with the FEM solutions.

ABSTRACT: This paper provides a review of recent research advances and trends in the area of thin shell buckling. The application of thin-walled cylindrical shells, as the essential structural members, has been known for engineers and functional duty of them is basic necessaries of modern industries. These structures are mostly failing by buckling under external pressure. The Buckling load is usually the most used criteria in designing of a long thin shell. Although the buckling capacity of the shells is mainly depends on two geometric conditions i) ratios of "length to radius" (L/R) and ii) ratios "radius to thickness" (R/t), but the effect of thickness variation on the behavior of the shells is complicated to be studied. The effect of thickness variation and Conix angle on the buckling behavior of conical support of pressure vessel is investigated in this paper. Top end of the specimens has conical shape and the bottom end has simply supported conditions. The measured data and obtained results are reported for the specimens under the effect of axial compression. Each specimen has different variation in thickness. The study is carried out using finite element analysis. The widely implemented software ANSYS Workbench is used to perform the analysis.

ABSTRACT: We consider three variants of algorithms for studying the stability of thin-shell: An algorithm based on the Ritz method and iterative processes, an algorithm based on the method of steepest descent, the algorithm based on a method of extending the solution to the parameter. Analyzes the results of the study of shells produced using these algorithms.

DOI: 10.5829/idosi.wasj.2014.30.12.13981

ABSTRACT: The work investigates thin walled orthotropic shells. Their deformation model is built taking into account the geometrical non-linearity and transverse shifts. The investigation algorithm of this model is based on the Ritz method and the method of continuing solution employing the best parameter. This enables the study of strength and stability of the shells under consideration. For analysis of special points (upper and lower critical loads, bifurcation points) the Jacobian matrix of linear equation systems is used. Based on the developed algorithm, a software product is made. A study was carried out on the strength and stability of some versions of sloping shells from different types of carbon fiber-reinforced plastic. It has been shown that the loss of stability of thin-walled shells under consideration occurs before the strength is lost. The loss of strength in different shells takes place in different components of maximum tension. It was established that in case of a geometrically non-linear approach, the critical loads in the event of strength reduction are essentially lower than in case of the linear computing method.

Braun (Georgia Institute of Technology, Atlanta, Georgia, 30332-0150), “Multiobjective Hypersonic Entry Aeroshell Shape Optimization”, (publisher and date not given in the pdf file. Probably an AIAA paper presented at one of the Structures, Structural Dynamics and Materials Meetings. The most recent reference is January 2007.)

ABSTRACT: A capability has been developed that utilizes multiobjective optimization to identify hypersonic entry aeroshell shapes that will increase landed mass capability. Aeroshell shapes are parameterized using non-uniform rational B-splines to generate complete aeroshell surfaces. Hypersonic aerodynamic objectives and constraints are computed by numerically integrating pressure coefficient distributions obtained using Newtonian flow theory. An integrated optimization environment is created using iSIGHT with single- and multiobjective evolutionary algorithms. Results are presented based on optimization using constraints derived from the aeroshell for the Mars Science Laboratory mission. Resulting solutions clearly demonstrate the trade-offs between drag-area, static stability, and volumetric efficiency for this particular mission.

Daniel Burmeister (Dept. of Mechanics, University of Miskolc, 3515 Miskolc-Egyetemvaros, Hungary), “Stability of a circular plate stiffened by a cylindrical shell”, PhD dissertation (date not given), University of Miskolc, Hungary

INTRODUCTION: In the engineering practice stability problems of plates loaded in their own plane are especially interesting ones. To the author’s knowledge paper [1, 1981] by Brian was the first one which dealt with the stability problem of a circular plate. Since then a number of papers have been devoted to this issue. Here we have cited only a few [2, 1933], [3, 1984] and remark that further references can be found in the papers cited.

A circular plate can be stiffened in various ways. For example we can apply a corrugation to it, or it can be stiffened by a cylindrical shell attached to the plate on its boundary. The present paper investigates the stability of a circular plate provided that the plate is stiffened by a cylindrical shell. This problem was partly solved by Szilassy [4, 1971], [5, 1976] who set up a differential equation for the rotation field and solved the corresponding eigenvalue problem under the assumption that the shell is subjected to a constant radial load in the middle plane of the plate. First we shall consider the governing equations of the stability problem if there is no stiffening. Then we shall clarify what conditions are to be satisfied on the circle where the middle surfaces of
the plate and shell meet. By solving the differential equations set up both for the shell and for the plate in terms of the displacements we derive a non-linear equation from the eigenvalue problem to be solved. We shall also present the results of our computations.

ABSTRACT: The present paper is concerned with the stability problems of a solid circular plate and some annular plates each stiffened by a cylindrical shell on the external boundary. Assuming an axisymmetric dead load and axisymmetric deformations we determine the critical load in order to clarify what effect the stiffening shell has on the critical load.

ABSTRACT: In this paper, the dynamical stability analysis of anisotropic cylindrical shells under uniformly distributed periodic extensional axial force is presented, while the winding angle varies. Fiberglass reinforced plastic is considered as a homogeneous solid anisotropic material. The shell’s elastic properties depend on the winding angle of fiberglass. The effect of the winding angle on the critical axial force is investigated. The intervals of winding angles at which the parametrically unstable vibration happen are determined.

Some University of Cambridge, School of Engineering, Structures Research Group (CUSRBG) Ph.D. Dissertations Relating to Buckling of Beams, Plates and Shells (http://www-structures.eng.cam.ac.uk/pubs/phd):

Mark Shenk, “Folded shell structures”, Ph.D. dissertation University of Cambridge, August 2011

ABSTRACT: A novel type of shell structure was analysed, folded shell structures. These shell structures have a distinct structural hierarchy: globally they can be regarded as thin-walled shells, but at a meso scale they consist of tessellated unit cells, which in turn are composed of thin-walled shells joined at distinct fold lines. It is this structural hierarchy that imbues the folded shell structures with their interesting mechanical properties. The global sheet deformations are a combination of bending along the folds, and deformation of the interlying material. The former is primarily a kinematic problem, with a parallel in the flexibility of hinged plate structures. A review of the mathematics of rigid origami provides the necessary background to develop non-trivial geometries of these folded shells that still exhibit a soft deformation mode. Two example folded shell structures are introduced, the Miura and Eggbox sheet. Both consist of a tessellation of parallelogram facets; the first is developable, while the other has points of positive and negative Gaussian curvature. The first property of interest is their increased in-plane flexibility, by virtue of the opening and closing of folds. The Miura and Eggbox sheet respectively have an effective negative and positive in-plane Poisson’s ratio. Secondly, both sheets can modify their global Gaussian curvature, with no stretching at the material level. Thirdly, both sheets exhibit an oppositely signed Poisson’s ratio for in-plane and out-of-plane deformations; e.g. when bending the Miura sheet it exhibits a negative Poisson’s ratio behaviour and deforms anticlastically. The salient global deformations of the sheets were analysed in terms of the kinematics of the constituent unit cells. The characteristic in-plane and out-of-plane properties of the sheets followed directly from developable deformations of the tessellated unit cells. A more holistic top-down numerical approach modelled the sheets as an array of unit cells. The sheets were represented by a pin-jointed bar framework, and additional planarity constraints between facets enabled the inclusion of a bending stiffness for the facets and fold lines. A modal analysis of the sheet’s stiffness matrix showed that the characteristic deformation modes are among the dominant eigenmodes of the sheets for a wide range of geometries and material properties. Many folded shell structures can be folded from flat sheet material, with only minimal material deformations. The manufacturing processes must overcome the intrinsic kinematics of the sheets, whereby the sheet contracts in two directions simultaneously. Existing methods were reviewed, and classified into synchronous folding, gradual folding and pre-gathering techniques. A novel cold gas pressure manufacturing method was introduced, and it was shown that a simple plastic hinge model cannot yet fully account for the total required forming energy.

V. R. Seereeram, “Compliant shell mechanisms and inextensional theory”, Ph.D. dissertation University of Cambridge, November 2012
ABSTRACT: Compliant shell mechanisms are a new class of lightweight structures, comprising discrete shell elements interconnected along hinge-lines. They undergo large changes in overall shape by deforming between, and by articulating about, these hinge-lines, and promise to offer novel solutions for reconfigurable structures such as morphing shells and deployable membranes. This seminar will focus on characterising the behaviour of one type known as a curved corrugated shell. Despite its simplicity, it displays a remarkable range of deformation in the global sense, including coupling between extension and bending as well as changes in Gaussian curvature. Locally, it may be assumed that the shell deforms inextensibly, in order to permit a tractable framework for capturing the overall kinematics and for modelling the load-displacement response. This will be demonstrated for a variety of deformed shapes and will be validated by finite-element analysis and experimental methods.

(http://www-structures.eng.cam.ac.uk/phdabs/wrinkling-in-polygonal-membranes-1)
ABSTRACT: Larger telescopes are required by astronomers to see further into the depths of our Universe, in order to understand its origins and the origins of life. A solution is to replace conventional primary mirrors in space-telescopes by membrane reflectors that can be folded and fitted into a spacecraft before launch. Once deployed, the membrane would provide a large reflective surface necessary to obtain images of faraway celestial objects. Whilst the primary mirror of a space-telescope needs to have a very precise shape, membranes can have an uncertain shape for they are prone to wrinkling. For this reason, there is hesitation in using these structures for telescopes, as the technology needs to mature. In this thesis, regular polygonal membranes tensioned at their vertices are proposed as reflectors; their discrete nature necessitates a lighter support structure compared to circular membranes. Analysis has been made to assess the effect of the wrinkling in these polygonal membranes, where the primary focus has been on nominally flat membranes, alongside parabolic membranes. The area of reflectance of the membrane must be maximal and it is vital to mitigate wrinkles. In this thesis, the origins of the wrinkles are investigated and two novel stress analysis methods for polygonal membranes are developed initially. The first uses Airy stress functions: by superposing a number of these functions, and deriving from it a solution for a free body disk, the stress field of a polygon is approximated with a high degree of accuracy both in terms of distribution and magnitude. The second method uses the analogy of the governing equations of in-plane stresses and of curvatures in the shallow bending of plates. The solution produces the shape of stress fields accurately. The results from these two distinct methods have been validated using Finite Element Analysis (FEA) and, together, they conclude that compressive regions are located close to the corners of all regular polygons, no matter the number of sides. This information is used to develop a method to prevent compressive stresses in membranes; furthermore, the analogy is adapted to show that with a given amount of edge trimming, the tensioned membrane does not produce any compressive stresses and this is confirmed in practise. The minimum amount of trimming required is derived for any regular polygon.

Long, Q, 2010, “Subdivision finite elements for geometrically complex thin and thick shells”
(http://www-structures.eng.cam.ac.uk/phdabs/q-long)
ABSTRACT: The thesis deals with non-smooth and non-manifold subdivision finite elements for general shells and corresponding applications. In the presented approach subdivision surfaces are used for geometric modeling as well as mechanical analysis of shells. The key motivation for performing finite element analysis of the “exact
geometry” provided by subdivision models is the promise of side-stepping the error prone and often user guided generation of finite element meshes. The use of the same shape functions also enables rapid data exchange between design and analysis models, which is, for instance, crucial to design optimisation. The subdivision approach is powerful technique for generating smooth surfaces on arbitrary connectivity meshes. An important feature of the subdivision shape functions is that each shape function reaches beyond the element boundaries with which it is associated. As a result, the enforcement of boundary conditions and the treatment of non-manifold shell geometries are more difficult that the conventional Lagrangian or Hermit-type finite element shape functions. This thesis systematically develops methods for subdivision shells with non-smooth and non-manifold geometries. The introduced methods generalise the original subdivision shells and enable their application to industrial strength geometries. The developed techniques include a new strategy to extract shape functions from highly irregular mesh topologies, control of surface normal at the domain boundaries and corresponding data structures in object oriented C++. As a result, it is possible to exactly discretise shell geometries with intersections and non-smooth features. The developed non-smooth subdivision shells are applied to thin-shell fracture and fragmentation. The original approach of embedding cracks in a shell discretised with subdivision shape functions relied on the introduction of cracks between all element edges with the attendant duplication of mesh entities and high memory usage. The new strategy adaptively introduces cracks along the physical crack path and hence considerably reduces the number of the degrees of freedom.

Schioler, T., 2005, “Multi-stable structural elements”
http://www-civ.eng.cam.ac.uk/abstract/schiolerabs.html
ABSTRACT: This dissertation considers a number of concepts for discretely stable structural elements. All of the concepts can be manufactured entirely out of non metallic components and have no sliding parts. A review
of current manipulator designs, possible actuation technologies and the expected requirements of discretely stable structural elements is made. Discretely stable structural elements are found to have possible applications in serpentine manipulators and variable geometry trusses. Two concepts for discrete rotation elements suitable for serpentine manipulators are presented. One is based on hoops of five non-linear springs, whilst the other is based on a modification of an existing rolling hinge design. An analysis predicting the maximum stresses developed in this modified hinge is presented. Four concepts for linear bistable elements are also presented, along with analytical and experimental results for the behaviour of each. Three of these are based on non-linear springs, whilst the fourth is based on inverting pairs of shallow arches. Out of the four, the most promising were found to be a design based on a four bar linkage with tape springs connecting opposing corners, and a design based on shallow arches. Prototypes of the latter concept were developed, with research presented on possible variations in design and manufacturing technologies, as well as the material behaviour of nylon 6/66. Analytical tools partly based on an extension of the classical elastica analysis are developed to predict the behaviour of the design. Results obtained using these tools agreed relatively well with results obtained from finite element analyses and experimental data. A variable geometry truss incorporating thirty variable length elements was designed and built after research into the most suitable truss architectures had been completed. This truss is shown to behave much as predicted by analytical tools, and serves to demonstrate the possibilities offered by the use of discretely stable structural elements.

Farmer, S.M., 2004, “Large-displacement buckling of centrally loaded simply supported circular plates”
http://www-civ.eng.cam.ac.uk/abstract/farmerabs.html

ABSTRACT: The surface of a thin sheet (of paper or any other material) which has been crumpled can be seen to be covered by a series of high-curvature ridges that meet at sharp points. Indeed, the Föppel-von Kármán (FvK) equations for the large-displacement of a thin elastic sheet predict just such a geometry; and they also show that the point-like regions have the geometry of a so-called ‘developable cone’. ‘Developable Cones’ can be isolated and studied in detail by the application of a central point load to a flat circular plate resting on a circular support. The plate is seen to buckle, with the post-buckled plate containing two distinct regions. First, due to the fact that bending a thin plate is ‘easier’ than stretching it, a region of the plate lifts off the support to form a large buckle. Second, the remainder of the plate forms a shallow conical region. The post-buckled geometry is developable everywhere except in a small crescent-shaped region at the centre of the plate, where a combination of bending and stretching occur. We have studied experimentally the geometry of ‘developable cones’ in both the elastic and elastic-plastic regimes. Subsequently, a finite-element analysis has been conducted for similar plates to the experiments, and shown to give corresponding results. It has then been used to extend both the range of the geometry and the material properties of the plates considered. Hence, empirical relationships have been derived between measurable plate parameters to describe the geometry of ‘developable cones’. In particular, the crease which separates the buckled and conical regions of a deformed plate which is best described as a curve on the plate in its initial, flat configuration – here called the Flattened Curve - has been shown to be approximately stationary on the surface of the plate, apart from in the region of its apex where its geometry changes a little as the deformation proceeds. Also, the regions of highest energy density and stress have been found to be concentrated along the ‘flattened curve’ and along the ridge that runs from the centre of the plate to its edge along the centre of the buckle. Furthermore, analytical models have shown that the stretching and bending behaviour of the crease in the apex region is analogous to the ‘knuckle’ found in an inverted sphere. Thus, using simplified models for the buckled geometry of a plate the energy of the crease has been found; and by a balance of this energy with the bending energy in the remainder of the plate, an empirical relationship between the central force and the deformation of the plate has been found that agrees with the experimental and numerical results.
ABSTRACT: Wrinkling of thin membranes due to different in-plane loading and boundary conditions has drawn a lot of attention among researchers in the field of structural engineering since the development of tension field theory for the designs of thin webs for early aircraft structures. More recently, prestressed lightweight membrane structures have been proposed for future space missions, for example solar sails, the Next Generation Space Telescope sunshield and some space-based radar systems. These structures are often partially wrinkled during operation. The formation of wrinkles alters the load paths and structural stiffness of the membranes. More importantly its occurrence degrades the surface accuracy of these structures, which is a key design parameter. This dissertation provides two methods to predict the details of wrinkles, namely wrinkle wavelength and amplitude in these membrane structures. Both of these proposed methods exploit the key observation, shown by physical models, that the main parameter which governs the wrinkle details is the bending stiffness of the membrane. The first method models the membrane using thin shell elements available in the commercial non-linear finite element code ABAQUS. The analysis uses a buckling prediction analysis to obtain the initial imperfections that, once introduced in the structure, would induce the formation of wrinkles. This analysis predicts the final wrinkle shapes and the out-of-plane deformation of the membrane, which quantify the wrinkle details. Compressive stresses are allowed to develop in this model. A simple analytical wrinkle model is the proposed second method, based on the assumption that a membrane is able to resist a small compressive stress once it has wrinkled. This critical wrinkling stress is a function of the bending stiffness and wrinkle wavelength. The wrinkle amplitude can be predicted by considering the total strain in the membrane, as the sum of two components, a material strain and a wrinkling strain.

Two membrane structures subjected to in-plane loads are investigated. The first structure is a classical rectangular membrane under shear. The second structure is a square membrane loaded with tension forces at its four corners. In the first case, the wrinkle pattern consists of primarily of wrinkles at 45 degrees and the state of stress in the membrane can be readily determined by tension field theory. The predicted wrinkle wavelength is inversely proportional and the amplitude is directly proportional to the imposed shear angle. In the second case, two wrinkling regimes are identified by varying the corner load ratio. The first regime occurs for symmetric and moderately asymmetric loading; it is characterised by small, radial corner wrinkles. The second regime occurs for strongly asymmetric loading with the formation of a single, large diagonal wrinkle in addition to small radial corner wrinkles. Several simple equilibrium, no-compression stress fields are proposed to capture the behaviour of this wrinkled membrane. Analytical solutions for predicting the wrinkle details are hence derived. The analytical predictions are validated against experimental measurements and detailed finite element simulation results. It is shown that thin shell finite element simulations can provide very detailed and accurate predictions of wrinkle details, although they are computationally expensive. The simple theory provides an alternative solution to obtain this information and is useful for preliminary design of thin membrane structures.

http://www-civ.eng.cam.ac.uk/abstract/lennonabs.htm
ABSTRACT: A lobed parachute with meridional cords adopts a shape where the cords take the shape of the isotensoid curve. The isotensoid is the three dimensional surface that has zero hoop stress and carries load only in the meridional direction. This dissertation investigates the equilibrium and stability of inflated membrane structures. Structures that adopt the shape and the isotensoid curve are of particular interest. It is shown that the isotensoid has two forms, the existing axisymmetric form and a polygonal form that is introduced in this dissertation. It is shown analytically that both forms are in equilibrium and these results are supported by finite element analyses. The inflated shape of these structures depends on stability considerations in addition to the equilibrium requirement. The potential energy for inflated structures is proportional to the negative of the
enclosed volume hence the configuration with the largest enclosed volume will be the most stable configuration. Two example problems show the importance of stability considerations in inflated membranes. The first example concerns the stability of a membrane structure, such as a “pumpkin” balloon, with longitudinal lobes separated by load bearing meridional cords in the shape of isotensoid curves. A deformation mode is postulated and calculations show that structures in this mode can have a larger enclosed volume than structures in the nominal configuration. The relationship between the volumes in the normal and deformed configurations depends on the lobe size and the number of lobes. The volume initially decreases with increasing perturbation size, showing that the nominal configuration is stable for an infinitesimal perturbation. However, for large numbers of lobes only a small perturbation is required for the deformed configuration to be more stable than the nominal configuration. The second example concerns the inflated shape of a structure made from two identical, circular membrane sheets, joined along their edges. The final shape of the structure approximates a polygonal isotensoid in the region away from the apex, with excess material forming folds which separate the sides of the isotensoid. It is shown that the polygonal isotensoid with the minimum number of sides encloses the maximum volume hence is the most stable. This surface requires more material than an axisymmetric isotensoid, which is provided by the membrane pulling inwards during inflation. Elastic stretching near the apex limits the size of the polygonal isotensoid and a geometric constraint at the transition to uniaxial stress can be used to impose a limit on the minimum number of sides of the isotensoid, hence determining the number of folds. Finite element analyses are used to support the work on the shape of the inflated membrane. These analyses confirm the expected shape and the stress distribution in the inflated membrane. Additional analyses are used to study the radius of the transition which is used in conjunction with the method for predicting the number of folds.

http://www-civ.eng.cam.ac.uk/abstract/aberleabs.htm
ABSTRACT: The low shear stiffness of certain gridshells can result in a different behaviour than that generally observed for shell structures. This thesis investigates the nonlinear behaviour of such shear-weak gridshells. The current methods of analysis of these structures are reviewed and the importance of various parameters on their pre- and post-buckling behaviour is studied. To model the individual gridshell members, new stability functions and bowing expressions that allow for the effect of axial loads on the bending stiffness and the change in effective axial stiffness due to bending moments, are derived and verified by numerical and experimental studies. These new formulations, based on power series, are applicable for any degree of shear stiffness and any axial load. This is followed by the presentation of a solution procedure, which combines the Dynamic Relaxation method with different iteration control procedures. The new element formulations, together with the proposed solution procedures are implemented into an essentially new computer program. This program is verified against examples found in the literature, and by comparison with the results obtained from buckling experiments conducted on a 1.2m span gridshell model made of thermoplastic polyester. The program is then employed to assess the post-buckling behaviour of a 12m span shear-weak gridshell model built in Japan, and the results are compared to the available experimental values of this structure. The study indicates that the limit load along with the imperfection sensitivity, and the sensitivity to asymmetric loading of gridshells are directly dependent on their in-plane and out-of-plane shear stiffnesses, and also on the size of the loaded area.

Galletly, D., 2001, “Modelling the equilibrium and stability of slit tubes”
http://www-civ.eng.cam.ac.uk/abstract/galletlyabs.htm
ABSTRACT: A novel shell structure, a bi-stable composite slit tube, is presented. This structure is formed like a coilable tape measure; unlike tape measures, however, it is stable in both the extended form and the coiled form, without any need for a spindle or casing to hold it in either position. The structure is initially modelled linearly, as a beam. Various applications of this model are presented: an algorithm for rapidly locating the
second equilibrium point, the investigation of the strain state as the path is followed from one equilibrium state to the second, and generalised plots throughout longitudinal curvature--transverse curvature space. Various examples (two composites with layups which are anti-symmetric about the middle layer, one which is symmetric about the middle layer, and an isotropic case) are presented. The inability of this model to determine the stability of an equilibrium is noted, as the results for the anti-symmetric and symmetric cases appear to be similar, whilst their experimental behaviour is very different. The model is then extended to incorporate non-linear geometric effects, and stability criteria are determined. The examples considered for the original model are re-evaluated using the new model; the equilibrium locations for the anti-symmetric and isotropic cases are found to be unchanged, whilst the symmetric case develops more twist. The stability of the anti-symmetric layups, and the instability of the symmetric layup and the isotropic case, are accurately predicted. The structure is then modelled as a shell of arbitrary cross-section. An expression for this cross-sectional shape is derived, and the same examples once again examined. The stability of the anti-symmetric layups, and the instability of the symmetric and isotropic cases, are again predicted correctly. The constant transverse curvature assumption of the extended beam model is found to be valid for cross-sectional angles greater than about 180 degrees. Various reasons for the disparity between the experimental and theoretical results are then investigated, including inaccuracies in the material properties and inelasticity in the matrix. It is thought that matrix inelasticity is the cause of the difference and initial results to support this are presented.

ABSTRACT: (page not found)

Bulbul, M.Y.I., 1999, “The geometric nonlinear behavior of spade structures with imperfect laterally loaded slender members”
http://www civ.eng.cam.ac.uk/abstract/myibabst.htm
ABSTRACT: Imperfections in geometric nonlinear reticulated space structures can have significant effects on their stiffness characteristics and load carrying capacity. These imperfections can be defined as deviations from the theoretical node geometry of the structure or imperfections within the length of the elements spanning between these nodes. An analytical model is presented by which the spatial behaviour of a beam-column element with an initial sinusoidal profile supporting a lateral load of general triangular distribution along its length is described. Nonlinear force-deformation equations are developed in the natural coordinate system of the element based on the conventional beam-column theory. A tangent stiffness matrix consistent with the equilibrium equations is also derived. Using a Eulerian frame of reference, appropriate transformations are employed to express the derived quantities in the fixed global coordinate system allowing for large displacement and rotations in the structure. The beam-column formulations are implemented in a geometric nonlinear analysis program, developed by the author, using an incremental iterative algorithm based on automatic load incrementation in a modified version of the arc-length method. A general stability analysis is incorporated in the program, based on a consistent tangent stiffness matrix formulated at each successive equilibrium state. The numerical algorithm developed is applied to the analysis of four 1000mm-span reticulated shallow domes tested by the author for various lateral load configurations. These included a uniform pressure loading designed to emulate the triangular distribution of lateral loading along the elements length expected in full size structures. Using the as-built geometry, good agreement between the numerical predictions and the experimental results was obtained for the cases of vertical nodal loading as well as the pressure loading.

King, S.A., 1999, “Nonlinear and chaotic dynamics of thin-walled open-section deployable structures”
http://www civ.eng.cam.ac.uk/abstract/kingabst.htm
ABSTRACT: This dissertation studies the behaviour of straight, thin-walled shell-beams with a curved cross-section, or "ribs". Recent proposals for the design of large deployable structures exploit the structural simplicity and robustness of ribs as deployment actuators on spacecraft. Under dynamic loading, the low torsional rigidity of ribs, however, may cause coupling between flexural and torsional modes of vibration. Modal interactions of this type, which exhibit an energy-transfer from one mode to another, can be many orders greater than the magnitude of input excitation and may lead to catastrophic failure of the structure. An identification and prediction of nonlinear dynamic effects in ribs is critical to ensure that excessive vibrations do not compromise their performance. This dissertation describes research into the nonlinear dynamic behaviour of cantilevered ribs subjected to sinusoidal base excitation. Regions of nonlinear resonance with single- and multi-mode periodic and aperiodic responses are studied. A finite-element model is developed to predict natural frequencies and mode shapes, to investigate flexural and torsional buckling, to characterise geometric nonlinearities quantitatively, and to simulate nonlinear dynamic behaviour at primary resonance. A series of ribs were constructed and tested to validate the results from the finite-element model and to establish three different types of energy-transfer between modes. These include subharmonic resonances, combination resonances and nonresonant interactions between widely separated modes. It was found that subregions of some nonlinear resonance zones exhibit aperiodic motion. Lyapunov exponents and correlation dimensions are used both to characterise the observed aperiodic motion of the ribs and to establish whether chaotic motion exists. Correlation dimension estimates show, in conjunction with dimension theory, that the bending-torsional instability is low-dimensional and that it can, in principle, be modelled with as few as two or at most three degrees of freedom. An algorithm is developed to calculate the moment-curvature relationships from the axis of a flexible rib, whose deflected shape has been determined from the finite-element model. These relationships are used with analytical expressions to derive the strain energy in the rib. A two-degree-of-freedom analytical model of the dynamic system is developed using Lagrange's equations and the assumed-modes method. The resulting equations of motion are integrated numerically to investigate the possible complexities in the system response.

http://www-civ.eng.cam.ac.uk/abstract/milesabs.htm

ABSTRACT: Subsea oil and gas exploration is increasingly moving into deeper water, where trenching of a pipeline for protection and to mitigate against upheaval buckling becomes increasingly impractical. In addition, the exploration of new reservoirs at higher temperatures and pressures than before leaves a submarine pipeline on the seabed more susceptible to lateral thermal buckling. A novel small-scale compressible base model, with an expanded polystyrene base compressed beneath a silicone rubber strip, has been developed to represent the constrained thermal loading of a pipeline lying on the seabed. This physical model is used, in addition to a nonlinear finite-element analysis, for a case study of a real buckled pipeline. Dimensional analysis is used to provide a means of comparing the post-buckled behaviour of the model strip with that of the full-size pipeline. There is good agreement between the results of the post-buckled behaviour for the physical and finite-element models, and these results compare well with the survey data for the buckled real pipeline. General results from the physical model are also presented for strips with differing geometric and material properties, laid both straight and on a scaled lay-away curve. A useful measure of the evolution of a buckle, the free end
displacement is introduced. This is the axial displacement of the free end of a cut pipe, constrained to remain straight while undergoing thermal loading. This measure used in a study of the parameters which affect the far-post-buckling behaviour of a beam on a frictional foundation. The phenomenon of buckle lobe extinction, when a buckle lobe stops growing, is discovered for certain combinations of beam bending stiffness, axial friction coefficient and lateral friction coefficient. When the buckle length, buckle amplitude and free end displacement are formed into non-dimensional groups with these three parameters, curves for many parameter combinations are found to fall onto a single curve. The conditions for buckle lobe extinction, in terms of these dimensionless groups, may be determined directly from this universal curve. Finally, the closely-related problem of the stability of a pipeline being built up a slope is investigated. A case study is made of a real pipeline, incorporating numerical and physical models and also a simplified analytical model. These models correlate well with each other, and enable the conditions for collapse of the real pipeline to be predicted.

http://www-civ.eng.cam.ac.uk/abstract/memeabs.htm
ABSTRACT: The focus of this dissertation is the small free vibration of thin elastic hyperboloidal shells of revolution, which are often used as cooling towers in thermal power stations. The aim of the present study is to obtain a comprehensive understanding of such phenomena, in order to develop design charts that map the different regimes of structural behaviour of these shells. The work begins with the simpler case of the cylindrical shell and encompasses tests on a range of simplified models that have been proposed in the literature, but which have not been assessed thoroughly hitherto. A first-order approximation theory for the analysis of cylindrical shells has been developed. The proposed theory aims to bridge the gap between the classical Love-Kirchhoff theory, which permits an accurate description of the shell behaviour, and the simplified version of Vlasov which only considers the effects of longitudinal stretching and circumferential bending. A direct analogy is established between the shell behaviour and the behaviour of a Timoshenko beam mounted on a Pasternak foundation. Approximate explicit formulae are derived for the fundamental frequency of the beam-foundation system, and by analogy for the shell. Criteria defining the domains of validity for the proposed theory are established. Attention is then turned to shells with slightly curved meridians (waisted, nearly-cylindrical shells) and finally to hyperboloidal shells, both of which exhibit various complex degenerate-case effects. A simple model of waisted, nearly-cylindrical shells demonstrates cross-over phenomena when geometric parameters are varied. Further investigation shows that these phenomena are replaced by curve-veering when a more accurate shell model is used. Hyperboloidal shells predominantly demonstrate curve-veering phenomena, however there are particular geometries at which cross-over occurs. Most of the above phenomena are dominated by membrane effects. The sensitivity of these phenomena to the shell geometric parameters is examined and explained in simple terms. An experimental investigation, using a small-scale silicone rubber model shell, confirms some main points of the analysis.

Parthasrathi Mandal, 1997, “Buckling of thin cylindrical shells under axial compression”
http://www-civ.eng.cam.ac.uk/abstract/mandalabs.htm
ABSTRACT: Thin-walled cylindrical shell structures are widely used in many industries. Due to the increasing use of high-strength materials in construction, and optimisation methods in analysis, the design of such structures is often buckling-critical. Unfortunately, the theoretical predictions (by classical theory) for buckling loads are often much higher than those found from experimental studies conducted since the 1930s. Moreover, there is large scatter of the experimental buckling loads of identical specimens, tested in a similar fashion. The concepts of non-linearity and imperfection-sensitivity are widely accepted as explanations for these features of shell buckling. Some simple experiments on self-weight buckling of thin, open-top, fixed-base, small-scale silicone rubber cylindrical shells are presented in this dissertation. The thicker shells buckled at almost the
heights predicted by the simple classical theory. But in general the buckling heights were found to be proportional to thickness raised to the power of approximately 1.5 compared to 1.10 as in the classical theory. Moreover, the results showed very little scatter, although there was no conscious attempt to manufacture very accurate shells, and indeed, there were measurable imperfections in terms of thickness variations. These observations somehow defy the accepted hypothesis of imperfection-sensitivity. Much of this dissertation reports various attempts to resolve this paradox. The most successful of these involved a non-linear finite-element analysis, which showed that there is post-buckling plateau load corresponding to the experimental buckling loads. Although no formal explanation of this plateau load is presented here, the recurrence of this feature for more than one shell suggests that the post-buckling, unusually is something like a classical phenomenon, in the sense that there exists a plateau load much like the eigenvalue predictions of classical theory, and with small scatter. In an attempt to find out the relationship of our experimental results to the vast experimental data in the literature, it was found out that the slope of the best-fit line through the large quantity of test data in the literature has also a slope of approximately 1.5. However, the scatter in the literature data is much greater than in the present experiments. The most obvious explanation of the difference is that the open-topped shells in the present study are statically determinate, whereas the usual closed-ended shells used in the tests in the literature are statically indeterminate: the possibility of high initial stresses, may explain the scatter.

ABSTRACT: Tape-springs are straight, thin-walled strips with a curved cross-section. Following recent proposals for large deployable structures exploiting the structural simplicity and robustness of such springs as deployment actuators, this dissertation begins by investigating the formation of elastic folds in a tape-spring. It is shown that the spring deforms by forming an elastically deformed region with zero transverse curvature and uniform longitudinal curvature. It is also shown that the process of formation and growth of elastic folds belongs to a wide class of propagating instabilities. It is characterised by a high peak moment and a lower propagation moment. A compact characterisation of the moment-rotation relationship for an elastic fold is presented. A key feature is that the bending moment on either side of a fold located anywhere along a uniform tape-spring, but far away from the ends of the spring, is constant, whereas this moment increases near a rigid support. Compact and accurate two-dimensional theories are developed to simulate the self-actuated deployment of tape-springs that are either coiled around a circular hub, or folded into a zig-zag pattern. It is shown that conservative energy formulations are appropriate for coiled springs, where the velocity field is smooth, but not for springs with localised folds. To simulate the motion of such localised folds a non-conservative impulse-momentum formulation is proposed, and it is found that this model can accurately predict both the steady motion of the folds along the tape-spring and their rebound against the end supports. The use of tape-springs in deploying a panel of similar inertia properties to an actual satellite radar panel is investigated. Deployment of the panel to approximately its intended configuration is governed by the value of the fold propagation moment in the tape-spring, whereas the high peak moment controls “locking out” of the panel; the velocity field of the deploying springs is similar to that of self-actuated coiled tapes. It is demonstrated, by theory and experiment, that mounting tape-springs in pairs, with their centres of curvature in opposite directions, results in an energy well which traps the kinetic energy of the panel on lock-out. The panel does not overshoot its fully deployed configuration and collision with other parts of the spacecraft is thus prevented. Disturbing torques applied by the panel to the spacecraft can also be computed.

ABSTRACT: More than a hundred years after the publication of Love's seminal paper on the vibrations and deformation of a thin elastic shell, engineers, scientists, and mathematicians continue to struggle with some of the more complicated issues relating to such structures, despite the advent in recent years of extremely powerful computers and appropriate software. In particular the buckling of cylindrical shell structures under axial loading has received a great deal of attention since the turn of the century. This case has been addressed from a number of different points of view. However, none of these have yielded wholly satisfactory solutions to the stability problems faced. In this thesis a new approach is proposed for analysing some of the more challenging examples relating to shell buckling. It is suggested that a careful examination of a heavily deformed shell structure in the post-buckling regime - and the processes leading up to this state of deformation - will establish some of the principles involved in its loss of stability. The complex deformation patterns observed experimentally after buckling may be reduced to a much more elementary description consisting of inextensional and transitional regions. Hence in this dissertation two relatively simple shell inversion problems exhibiting corresponding representative features are studied in detail. Experiments investigating the inversion of a cylindrical shell under a radial point load are outlined. Due to a free boundary large elastic inextensional deformations may occur. Some straightforward empirical formulae are found that well describe the characteristics of the deformed geometry; and the applied load is established as a function of the deformation. The inversion of a spherical shell under a radial point load is considered as a means of examining some of the basic features observed in the experiments performed, whilst eliminating the complexities arising from the lack of symmetry in the cylindrical case. A 'simple model' is detailed which clearly highlights the major components of the total strain energy of the deformed surface and their origin. A number of formulae are found that relate the loading and peak stresses to the radial displacement under the load. The results from this model are confirmed using a finite-element analysis, which also provides a more comprehensive description of the overall stress state of the shell. The finite-element method is likewise applied to the case of the cylindrical shell as an extension of the experiments. Findings from the latter are employed to confirm the validity of the numerical analysis. A detailed account is given of the distribution of stresses and strains over the deformed surface; and the similarities with the case of the spherical shell are outlined. Finally, an analytical model is established for the case of the cylindrical shell using the empirical formulae. The derivation of a condensed expression (Equation 6.61) for the total strain energy is presented. It is shown that the model represents well the relevant data obtained numerically. Notably, it is discovered that the two terms of Equation 6.61 correspond to the two most prominent regions of the deformed shell surface.

ABSTRACT: Mechanical damage to oil and gas pipelines is considered to be the most serious cause of in-service failures in real pipelines. Damage in the form of combined dents and gouges may be of arbitrary shape and size and has from time to time resulted in failures at very low pressures. Full size experiments on pipes with dents and gouges have identified dent size, gouge size and pipe material fracture toughness as the main factors which influence failure. These tests have however exhibited much scatter. This experimental study has focused on understanding the problem through small-size testing on model pipes. An experimental model material was selected and pipe dimensions were carefully scaled to ensure that the small-size pipe was an exact model of a real pipeline. Damage was also appropriately scaled but cracks were specifically excluded. Model testing concentrated on 'short dents'. The gouge length, gouge depth, dent depth, gouge position and gouge orientation were varied extensively. A few tests were carried out with dents formed under non-zero pressure. Tests showed that the position of the gouge relative to the dent, and the gouge depth are the most relevant parameters affecting failure pressures. Zones of high straining were identified using photoelasticity and strain gauging. The off-centre and long gouges which failed at low pressures were observed to pass through these regions of high
straining. Nonetheless, failures occurred at pressures generally higher than those observed in full-size tests and very little scatter was observed. From comparison of the full-size and small-size tests, the importance of initial cracks was established. Cracks are now believed to be responsible for the transition from a stable yielding type failure to a fracture dependent type failure in combined dent and gouge defects resulting in low pressure failures. The Battelle Flow Stress Dependent Model for gouges of infinite length has been shown to be the best method for predicting failure in pipes with short central axial gouges. Model testing, using an equivalent pipeline steel and the correct D/t ratio, is the cheapest known method of determining burst pressures and understanding the behaviour of pipes containing dents and gouges.

Maltby, T.C., 1993, “The upheaval buckling of buried pipelines”
http://www-civ.eng.cam.ac.uk/abstract/tcmabs.htm

ABSTRACT: Upheaval buckling is a serious problem which can be encountered during the operation of buried, submarine, oil and gas pipelines. These pipelines are usually operated at high temperatures and pressures (well above the conditions under which the pipe was laid), and the resulting axial expansion can cause significant axial compressive loads in the pipe wall. Under certain circumstances buckling can occur, with potentially disastrous consequences. An important requirement for pipeline design is therefore to ensure that upheaval buckling does not occur. Most previous models of pipeline buckling have been based on the rigid base model; which is an old railway-track model that has been modified to suit the pipeline conditions. According to this model, a so-called minimum, buckling load can be calculated, and provided that the axial load is kept below this value, then buckling should not occur. In practice however, this model is unsatisfactory because buckling does occur at axial loads well below the so-called minimum value. The model is useful for analysing the post-buckling profile of the pipeline, but a better theory is required to explain the buckling process. A number of modified buckling models have been proposed in the literature. However, despite the volume of literature available on this subject, there appears to be very little experimental data published to verify the numerous theoretical models. The purpose of this project has been to perform a number of experiments on a small-scale model of a buried pipe, in order to determine various aspects of the upheaval buckling behaviour. These aspects included: the force-displacement interaction of the pipeline and the soil, and the behaviour of the pipeline due to various combinations of horizontal and axial loading. A simplified buckling model has been developed, and the results have been discussed in relation to this model. The model concentrates on the conditions under which buckling is initiated, and takes into account the force-displacement interaction between the pipe and the soil. The effect of cyclic loading was also investigated. Under repeated loading, the pipeline can displace by an incremental creep mechanism. A simple design model is suggested for the creep phenomenon.

ABSTRACT: A Two-Surface discrete computational model has been developed which is suitable for the analysis of general doubly curved, elastic, deep, classical, and then shell structures. The stretching effects are modelled by means of either a pin-jointed truss network or the constant strain triangular (CST) finite element, while the bending effects are modelled by a system of overlapping hinged facets, which cover the truss or CST network exactly, like scales. The two surfaces are automatically coupled by the compatibility condition that the two surfaces must be coincident, sharing the same nodes and degree of freedom. The principal innovation has been the development of the hinged bending elements, which, although based on a simple physical analogy, are closely related to both the finite difference and finite element methods. The hinged bending elements are based on local quadratic overlapping assumed displacement functions, which results in constant local stress representation, and permits simple rectangular Cartesian translational nodal degrees of freedom to be employed. This is a significant advantage over most other currently available thin shell finite elements, which employ
The use of rotational and higher order degrees of freedom has, in general, resulted in considerable difficulties in the implementation and application of shell finite elements. This, together with the complexities of shell theories and geometry has ensured that no single finite element has so far achieved acceptance by the engineering community. The Two-Surface model has been applied to a range of linear elastic small-deflection “benchmark” shell problems, including flat plate, cylindrical and hemispherical shell problems. These problems test various aspects of the performance of the model, including stress evaluation, bending stretching interaction, cost of analysis, and numerical control of analyses. The method has been extended to model geometrically nonlinear large-deflection problems, and also shell vibration problems. A limited experimental programme has been undertaken to test the performance of the nonlinear version of the model. The Two-Surface model is simple in concept, implementation and application, and performs competitively against some standard shell finite elements that appear in the literature, and which employ up to four times as many degrees of freedom per node.

http://www.structures.eng.cam.ac.uk/phdabs/p-a-hodgetts
ABSTRACT: This thesis starts with a thorough literature survey on work carried out on both shell and lattice hyperbolic paraboloids, leading to the observation that further investigations of collapse behaviour is justified. Existing methods of analysis, including their development are also researched. A suitable experimental program is drawn up, which involves the testing of four model structures. A detailed account of the rig design and the experimental procedure is given. Against these findings an attempt is made to predict the behaviour of the model structures, using the linear membrane theory in conjunction with an appropriate shell analogy. It is found that what appears to be realistic boundary conditions, produces answers that are either nonsensical or totally unrealistic. Attempts at using more sophisticated methods of shell analysis are also unsuccessful, due to the huge algebraic complexities which quickly appear. Buckling predictions made by previous researchers are not validated by the experimentation. A thorough numerical analysis is then carried out with success. It is found that advanced methods of iteration control are required for certain analyses. A full discussion includes a detailed comparison between experimental results and those predicted by analysis. Reasons for discrepancies are given. Finally, there is a last review the entire research work and the major conclusions drawn. A simplified design aid, suitable for preliminary design, is outlined, based on the findings of the research work. Suggestions for suitable further research are also given.

Kamel Sayed Kandil, 1989, “Interaction between local and Euler buckling modes in thin-walled columns”
http://www.structures.eng.cam.ac.uk/phdabs/k-s-kandil
ABSTRACT: The stability of the buckling process in thin-walled columns depends on non-linear interaction between different buckling modes. This dissertation aims at understanding these phenomena by means of relatively simple conceptual models. The results of the ‘exact’ analysis for the classical buckling of a general rectangular tube, loaded in axial compression, are examined with a view to understanding them in simple, physical terms. Computer graphics are used to re-plot these results according to various hypotheses. On this basis, it is found that most of the results can be reproduced to a satisfactory first approximation by considering one set of plates as ‘active’ and the other as ‘passive’. Some simple, rational approximate formulae are presented. These give a very good description of the exact curves. A simple approach to predict the classical buckling stress (for a given half wavelength) of lipped channel cross-sections, loaded in axial compression, is proposed. The main idea is to consider each of the four classical buckling modes for these cross-sections as existing separately. This approach is verified against algorithm which uses an ‘exact’ matrix where the correlation is very good. Two simple models for the interactive buckling in thin-walled columns are developed. The first is based on the van der Neut two-flange model and has the virtue of being capable of taking account of
the initial overall and local imperfections and material plasticity. The second, which, is based on a Perry-type analysis, produces a simple post-buckling analysis for columns with general cross-sectional geometries. The results of two series of tests conducted small-scale silicone rubber lipped channel models and aluminium thin-walled lipped channel columns are reported. In the latter series, different types of initial imperfections were identified and measured. In the main tests, the columns were loaded over a wide range of positive and negative eccentricities about the minor axis; in addition, several stub (short) columns of different lengths were also tested between rigid flat platens. The theoretical classical and interactive buckling analyses described above are used to examine these results; the theoretical predictions are presented along with the corresponding experimental observations. These analyses are also compared with the experimental results of other researchers. The results of both the present experimental investigation and those of other researchers establish the validity of the present theoretical analyses.

http://www-structures.eng.cam.ac.uk/phdabs/a-affan-1
ABSTRACT: This dissertation is concerned with the behaviour of square-on-square double-layer space grids (DLSG’s) and in particular their collapse mechanisms after initial buckling. A detailed review of the methods used for collapse analysis of these structures is conducted, which shows, that their collapse can be of progressive nature. An outline of the remedies that have been suggested to make safe their collapse behaviour is given, and it traces the line for further study. The present investigation starts by describing the redundancy in these regular pin-jointed assemblies in terms of unit states of self stress. This enables us to understand, by means of the extended Maxwell rule, how it is that mechanisms of collapse can occur when relatively few bars in the assembly have failed. The influence of boundary conditions on the mechanisms of collapse and its progressive nature is also investigated. This method of analysis is verified by detailed examination of several previously reported experimental results, and some conclusions can be drawn. The pre-stressing of statically indeterminate assemblies by means of lack-of-fit is investigated in the hope of changing their collapse characteristics. The unit state of self-stress has been used to explain a method of selecting the bars that can be short-ended/lengthened in order to impose a prescribed state of self-stress, and the scope for achievable patterns of bar tensions has been described. A by-product of the investigation is an algorithm which calculates the required lack-of-fit to impose an initial state if self stress which maximises the load-carrying capacity of indeterminate trusses. Using the formulae derived for pre-stress, a statistical analysis is developed to estimate initial bar tensions due to random lack-of-fit in order to obtain realistic estimate of the load-factor of an assembly before initial failure. Furthermore, we have argued and demonstrated how backlash at the bar-joint connection may have a beneficial effect in reducing substantially initial bar tensions due to the inevitable lack-of-fit on account of manufacturing errors of bars. An extensive experimental program has been conducted to verify the assumptions adopted and formulae derived in this dissertation.

http://www-structures.eng.cam.ac.uk/phdabs/f-a-fathelbab
ABSTRACT: Considerable improvements in the technology of space frame joints have been achieved in recent years. The conventional procedure for the analysis and study of space structure stability assumes that the joints of these structures behave as either pure pins or are fully rigid despite the fact that the joints of most space structures are semi-rigid. The actual behaviour of joints has been shown to have a significant effect on the behaviour of space structures, especially for shallow single layer lattice domes. In this thesis the development of a general space frame member tangent stiffness matrix is reported. This matrix incorporates, in addition to the effects of axial force and bowing, the effects of joint characteristics. An algorithm for following the pre and post
buckling behaviour of shallow single layer lattice domes has also been developed. The tangent stiffness matrix and the new algorithm have been implemented in a computer program for the geometrically nonlinear analysis of space frames. Results obtained using the modified computer program, have been tested against the available published results. The computer program developed is then used to analyse and study the stability of a number of experimental shallow single layer lattice dome models. In these tests, various combinations of member size, joint type, and load pattern were tested. The results of all these tests along with the corresponding computer predictions are presented in this thesis. The ability of the program to model accurately the observed experimental behaviour is clearly demonstrated as is clearly demonstrated as is the significant influence that joint bending stiffness has on behaviour of shallow single layer lattice domes. In particular, realistic levels of joint bending stiffness are shown to produce a considerable improvement in load carrying capacity as compared with predictions based on pin jointed behaviour.

http://www-structures.eng.cam.ac.uk/phdabs/d-t-hatzis

ABSTRACT: Initial geometric imperfections and small loads applied laterally to the members of space frames can have similar and significant effects on the behaviour of such structures. In particular, their presence in shallow, single layer, lattice domes has been shown to lead to considerable reductions in the stiffness and the strength of the domes. An analytical model is presented, that enables the effects of geometric imperfections and lateral loads to be directly incorporated in the equilibrium equations that describe the spatial behaviour of beam-columns, and then by differentiating these equations with respect to deformations, in the derived expressions for their stiffness. The new analytical model obtained, has been incorporated in an already available computer program for the geometrically nonlinear analysis of space frames. This program us is used in this thesis to analyse some standard problems and to reproduce solutions found in the literature or obtained with alternative methods. The results of a series of tests, conducted on shallow, single layer, lattice domes containing members with geometric imperfections or lateral loading are reported. The modified computer program was used for the analysis of these test structures, and the computer predictions are presented along with the corresponding experimental observations.

Kamalarasa, S., 1987, “Buckle propagation in submarine pipelines”

http://www-structures.eng.cam.ac.uk/phdabs/s-kamalarasa

ABSTRACT: The main interest in this thesis has been directed towards the predication of the buckle propagation pressure (Pp) in submarine pipelines. Several empirical formulae for Pp has been derived by various researchers in the past; however, the few who analysed the problem have treated the buckling of the pipe as a problem concerning the collapse of a ring, thus neglecting the longitudinal stretching effects. The present work clearly distinguishes the longitudinal stretching effects from cumferential bending effects. A satisfactory way of incorporating the mechanical properties of the material, without actually measuring them, has been presented. A simple theoretical model, based on a ‘plastic beam on a plastic foundation’ has been developed, and a definite method for the prediction of the buckle propagation pressure has been suggested.

Kollek, Richard John, 1987, Collapse mechanisms of locally loaded reinforced concrete shells”

http://www-structures.eng.cam.ac.uk/phdabs/richard-john-kollek

ABSTRACT: Experiments are presented on the local lateral loading of steel-reinforced micro-concrete hollow cylinders supported by heavily reinforced end diaphragms. The tests exhibit three distinct ultimate modes of failure; global flexural beam collapse, more localised ovalisation, and local punching shear/flexure interaction. The theoretical work concentrates on the behaviour of locally loaded shells, wide beams and arches in plane strain, and axisymmetric and domes. Families of kinematically admissible symmetrical mechanisms are
developed for each case and analysed using the upper bound theorem of plasticity assuming rigid plastic material behaviour, the modified Mohr-Coulomb failure criterion for concrete and the associated flow law. The concept of the shear/flexure interactive failure zone is developed to provide a range of solutions from pure punching shear to pure flexural failure. Calculation of the internal energy dissipation in the narrow interactive zone is facilitated by consideration of the instantaneous centre of relative rotation between the rigid blocks surrounding the zone. The optimum position of the interactive zone is found by variational calculus for a given instantaneous centre and boundary conditions. It is explicitly defined for beams and arches, but numerical analysis is required for the axisymmetric cases. The remaining dissipation terms are substituted into the work equation and provide the upper bound load for any chosen mechanism. By placing the instantaneous centre in different positions, the regimes of ultimate behaviour are explored for certain pertinent cases of beams, arches, slabs and domes. Particular consideration is given to the effect of shell dimensions, material properties and support and loading conditions. Comparisons are made between the present theory, simpler theory and experimental data on beams, arches, slabs and domes. The insight provided by these comparisons is used to illuminate the more complicated ultimate behaviour of the locally loaded cylinders investigated in the present experiments.

Mofflin, D.S., 1984, “Plate buckling in steel and aluminium”

ABSTRACT: Consideration is given to the ultimate strength in compression of both stiffened and unstiffened plates, as well as to plate assemblages. The work is primarily concerned with local buckling, although overall and interactive buckling has also been studied. The effects of a rounded material stress-strain curve have been examined, in particular the behaviour of aluminium alloys. Attention is given to the effects of initial out of flatness and residual stresses. Tests are reported on 76 aluminium plates with controlled initial out of flatness and residual stress. Two alloys were studies, namely 5083-M and 6082-TF. Some specimens were transversely welded. Their sizes ranged from 20 < b/t < 85, corresponding to a non-dimensional slenderness range of 0.58 < β < 2.85. Comparison is made with theoretical predictions and design rules. The results indicate the importance of the roundness of the stress-strain curve on the ultimate strength of non-welded plates. A simple method is described for predicting the complete load-shortening curve of simply supported rectangular plates in uniaxial compression. The method is developed by considering the plate to be comprised of two non-buckling edge zones and a buckling centre zone. It is applicable to either steel or aluminium type materials. Results are in close agreement with other theories and experiments. A full analysis Finite Strip program has been developed to analyse the buckling behaviour of both plates and plate assemblages. The method takes proper account of large deflection theory, elasto-plastic behaviour, residual stresses, HAZ softening and initial out-of-flatness. Different material types can be considered. The method is applicable to local, overall, and interactive buckling problems, loaded in either uniaxial compression or bending. The predicted results compare closely with experiments.

See, T., 1984, “Large displacement of elastic buckling of space structures”

ABSTRACT: Light weight space structures are a product of structural optimisation and are thus prone to suffer from elastic instability. For simple structures with only a few effective degrees-of-freedom the failure mode and the associated failure load can be calculated, but the problems associated with stability are often intractable for a complex space structure particularly when it is also sensitive to small initial imperfections in geometry. A nonlinear stiffness matrix based computer program is used to investigate the stability of such structures, whose likely failure modes are determined by examining the tangent stiffness matrix of the structure near its collapse load. For a structure whose exact initial geometry is known the actual behaviour under any given load can be calculated. Where the imperfections are unknown the initial geometry is altered by adding those combinations
of small imperfections that will excite the likely failure modes. A separate analysis for each of these cases reveals the degree of imperfection sensitivity of the respective failure mode in the structure. Limit point behaviour is correctly analysed because the program is geometrically nonlinear but the present procedure can also take into account possible bifurcation behaviour. Experiments on four different model structures were performed, in which both bifurcation type and limit point behaviour were observed. Separate tests on a large dome produced a snap-through collapse in one case and collapse involving member buckling in another. Where the exact initial geometry was unknown the addition of a suitable set of imperfections produced results in agreement with the experiments. In cases where more significant real imperfections could be measured before the tests, good agreement was obtained between experiment and analysis.

Whaley, Brian, 1982, “The application of the reflective Moire method to the buckling and bending of steel plates”
http://www-structures.eng.cam.ac.uk/phdabs/B%20Whaley.pdf

ABSTRACT (cannot cut and paste)

ABSTRACT: Whilst working in the aerospace industry, the author realised that the structural use of thin cylindrical shells was hampered by a lack of understanding of their buckling behaviour. This dissertation embodies research which examines this behaviour in physical, as opposed to mathematical terms. The work proceeds from a simplified re-working of classical methods of analysis. The physical behaviour of the perfect shell is discussed in terms of the interaction of stretching and bending effects, and the details of the interaction are investigated for a variety of buckling modes. The simplified method also gives a more immediate derivation of standard classical results and suggest the adoption of a second dimensionless geometric parameter for long cylindrical shells under radial (and hydrostatic) pressure, in addition to the well-known parameter of Batdorf, and hence a common load ordinate for a unified plot of theoretical curves and experimental values. Imperfection sensitivity of short cylindrical shells under hydrostatic pressure is discussed, and a theoretical curve devised to allow for it. Finally, conclusions are drawn concerning the differing roles played by longitudinal and circumferential shell stiffeners. Two loading cases of practical importance are examined experimentally using cylindrical shell specimens moulded in Silicone RTV rubber by a centrifugal casting technique which is described.

Bradfield, C.D., 1977, “Problems in strength of stiffened steel compression panels”

ABSTRACT: The dissertation describes work on the failure, in compression, of elements of stiffened steel panels. Attention is directed to geometries where local buckling and yielding interact, and where analysis should account for the presence of residual stresses and initial out-of-flatness and out-of-straightness of the structure. Tests are described on plates loaded in compression, constrained by transverse stiffeners to buckle with a short buckle length, giving aspect ratios of 0.4 to 1.0. Strength was found to rise as aspect ratio was reduced. Residual stresses due to welding were measured, and were not as expected from previous work. Measurements made on steel box-girder bridges are examined to determine the magnitudes, form and variability of initial out-of-flatness and out-of-straightness of plates and stiffeners. For plates, the variations in compressive strength due to varying out-of-flatness are considered, and compared with strength due out-of-flatness are considered, and compared with strength variations due to the variability of material properties. Values are proposed for incorporation in design rules. A method for the analysis of a single stiffener, loaded in compression is described. The governing equations are written in finite difference form and solved numerically.
In the plastic range, an approximate full-section yield criterion is used in an extension of the Ilyushin “method of successive elastic solutions”. Initial out-of-flatness may be included in the analysis. The method has been too used to examine the performance of plain flat stiffeners, including the effect of rotational restraint to the supported unloaded edge. A rig for testing single stiffeners in compression is described. Boundary conditions are those appropriate to a stiffener in eccentrically stiffened plating. In tests on a single bulb flat stiffener, the effects of initial out-of-flatness, eccentric loading and restraint to the supported unloaded edge were examined. Tests are described on single welded splices to plain flat and bulb flat stiffeners. Despite an apparent eccentricity of loading the performance of the splice is satisfactory. Tests covered plain flat and single sided bulb flat stiffeners and their splices.

Reddy, B.D., 1977, “The elastic and plastic buckling of circular cylinders in bending”
http://www.structures.eng.cam.ac.uk/phdabs/B%20D%20Reddy_Abstract.pdf
ABSTRACT: An analytical and experimental study of the buckling of circular cylinders in bending is carried out, with emphasis on the elastic-plastic problem. A review of past work on this problem shows that many of its aspects require further investigation. A set of linear equations is derived, and used to investigate the bifurcation characteristics of both linear-elastic as well as elastic-plastic cylinders subjected to end moments. In most general case, and J2 incremental theory is used. The replacement of the tangent modulus in the general buckling equation by the elastic modulus reduces this equation to Donnell’s linear stability equation. In the treatment of the elastic problem, the circumferential distribution of lateral buckling displacement is approximated by a Gaussian distribution, and results are obtained from a relatively simple analysis for both the cases of pure bending as well as combined bending and internal pressure. These results compare very well with those obtained by others in more rigorous analyses. Some of the results of the elastic buckling analysis are then made use of in the treatment of the corresponding elastic-plastic problem. New results are presented for the bifurcation of elastic-plastic problem cylinders under pure bending. These results are compared with corresponding results for elastic-plastic axially compressed cylinders. The results of an experimental study of the collapse of cylinders in pure bending are presented. The tubes tested were thick enough to buckle in the plastic range. Collapse of these specimens was due mainly to wrinkling on the compressive side though a small amount of cross-sectional ovalisation also occurred. Measurements of the ripples are presented and discussed. The presence of these ripples before collapse took place indicated the presence of initial imperfections. A comparison between experimental critical strains and various theoretical strains shows that the experimental values are closest to deformation theory predictions for axially compressed cylinders. A similar conclusion is reached with regard to the comparison of experimental and theoretical critical stresses.

Mohr, G.A., 1976, “Analysis and design of plate and shell structures with finite elements”
ABSTRACT: The main emphasis in this work is upon the development and application of simple finite displacement element solutions with particular reference to design oriented problems in slabs and shells. In the work of element development a new approach to bending elements is employed and this is also recommended for future work. Several other new elements, as well as variations in the derivation and working of many established elements, are also presented. An attempt is also made to extend the present understanding of the convergence behaviour of displacement elements and a simple modification of the Southwell Plot is suggested for extrapolating monotonically convergent solutions. An iterative procedure for the uniform strength design of slabs is developed and much used, showing consistent agreement with the fibre optimum theory developed by Lowe and Melchers, and further more detailed work is worthwhile in this area. For the design of shells an iterative optimality criterion approach is developed and used to yield a new and apparently feasible solution for the design of an arch dam. Finally, however, it is an improved method that is recommended for future work in
this area. Finally, a number of other slab and shell problems are investigated leading to recommendations for future work upon structural shell analysis, incipient buckling problems and composite constructional systems.

Rogers, N.A., 1975, “Local buckling of welded steel outstands”

http://www-structures.eng.cam.ac.uk/phdabs/N%20A%20Rogers_Abstract.pdf

ABSTRACT: The design of plain flat outstands (beam or column flanges, plain flat stiffeners in stiffened plating) is based on setting limits to the outstand slenderness. For the plastic design of beams and columns, the width-thickness ratio of the compression flanges is limited to prevent buckling and enable to fully-plastic moment of the section to be developed and maintained over considerable rotations. For conventional elastic design, the allowable slenderness is slightly higher, but must still be sufficiently low that the outstand strength in compression is equal to the material yield stress. In this stocky region, the effect of residual stresses on strength is small. For more complex outstand shapes (bulb flats, angles, tees), past practice has been to assume these sections to be fully effective. Following the collapse of a number of box-girder bridges, and the setting up of the Merrison Committee, an allowable stress for outstands in stiffened plating can be calculated, based on the elastic critical stress for torsional buckling of the outstand. Since little was known about the effect of initial imperfections on the strength of outstands, the Merrison Committee also recommended stringent tolerances on the allowable out-of-straightness of such members. Detailed information (both experimental and theoretical) concerning the behaviour of outstands in compression is limited, especially in the more slender range where initial imperfections and residual stresses are more important. This dissertation contains details of a theoretical analysis for predicting the load-deflection characteristics of slender simply supported plain flat outstands in compression, including the effect of welding stresses and initial imperfections. A comprehensive experimental study of hinged plain flat outstands in compression is also described, and the results enable a design curve of strength against slenderness to be drawn. The agreement between experimental and predicted strengths is quite good. For bulb flats, high rolling residual stresses and a considerable variation in the yield stress across the section have been found. Compression tests have been conducted on the bulb-flat cruciform columns to investigate the effect of different imperfection shapes on strength. The results indicate that a relaxation in the Merrison fabrication tolerance could be made. Finally, a design method is presented for outstand failure in stiffened steel compression panels. This is based on calculating an “affective slenderness” for the outstand restrained by the plating, and entering in the strength curve derived from the results of tests on simply-supported outstands.

ABSTRACT: Two problems are considered in this dissertation:

i. the effect of web buckling on the behaviour of hybrid plate girders, and
ii. the residual stresses induced in steel structures fabricated by welding.

Part I describes an experimental investigation into the behaviour and strength of hybrid girders having high yield strength steel flanges and mild steel webs. The project set out to consider whether the limits specified by current British Standards for webs in mild steel girders could be used for hybrids and whether the design philosophy of these standards could be applied to hybrids. The webs of the test specimens were either unstiffened or transversely stiffened and were designed to the limits permitted by current standards. They were subjected to a wide range of loading conditions to study the effect of moment-shear interaction. The results are compared with predictions of available theories. Part II describes an experimental and theoretical investigation into the residual stresses caused by welding. The wide ranging experimental programme of Chapter 6 first considers the relationship between the heat input to a weld and the shrinkage force and then studies the effect of various welding (intermittent welding and multi-pass welding) and of specimen geometry. A study of the
welding residual stresses to be expected in the Rising Sector Gates of the Thames Barrier structure is described in Chapter 7. The stresses were measured on a full-scale specimen. A numerical method for determining welding residual stresses in free plates is developed in Chapter 8. The problem is treated as one of two-dimensional elastoplastic thermal stress analysis. A finite difference approximation is used to solve the governing differential equation of the problem and plasticity is allowed for using the method of successive elastic solutions. The relationship between the welding parameters and the shrinkage force is obtained theoretically and the effect of coincident two-pass welding is examined.

Gilbert, R.B., 1973, “Topics in the elastic buckling of plates and columns”
ABSTRACT: The thesis is divided into two parts, the first of which considers the buckling of anisotropic plates, and the second is concerned with a problem in the buckling of an elastic box column. Anisotropic materials are manufactured by incorporating layers of stiff glass of carbon fibres in flexible matrices of epoxy or other polymeric resins. Plates made from such materials have bending and stretching rigidities much greater than their transverse shearing rigidities, which are determined by the low shearing moduli of the resin matrices. Because of this it has been suggested that a “thick-plate” analysis of their behaviour is necessary, as conventional “thin-plate” theory neglects the transverse shearing strains. This thesis examines the small deflection buckling of anisotropic thick plates, the eigen-values being found by a novel numerical method derived from the technique known as Dynamic Relaxation. It is found that the buckling-loads may be considerably over estimated by a thin-plate analysis, and that the magnitude of the error is strongly dependant upon the boundary conditions. An elastic box column may either buckle locally or by overall flexure. It has been shown that a small “local” imperfection can substantially reduce the load-carrying capacity of the column, particularly when the buckling-loads for the two modes acting separately are nearly the same. In the second part of the thesis the effects of both local and overall (column-axis) imperfections behaviour is characterised by the value of a single, combined imperfection parameter. The analysis has been performed by considering the finite-deflection behaviour of a simplified model system but the results agree well with the results of a number of tests on small-scale rubber box columns.

Gill, J.I., 1972, “Computer aided design of shell structures using the finite element method”
ABSTRACT: The object of the research described in this dissertation is to develop and evaluate computer techniques for the design of shell structures. A computer aided design system for thin elastic shells is described. Shell surfaces are defined geometrically using an existing surface design program, MULTIPATCH, which is based on the surface patches proposed by S.A. Coons. The structural design system, SHELL, provides facilities for preparing data for a finite element analysis, performing an analysis and examining the result in printed or pictorial form. Interactive computer graphics is used extensively during both input and output. A new algorithm for automatically triangulating a surface for a finite element analysis is described. The density of triangular elements on any part of the surface depends on an “element density function” whose values are interpolated from values specified by the designer at the corners of the patches which define the surface. The algorithm produces near-equilateral triangles which are well graded in regions of varying density. The designer defines loads and boundary conditions in terms of the patch definition of the surface, and these are automatically mapped on to the finite element idealisation. An interactive method for obtaining a near-minimum bandwidth for a structural stiffness matrix is described. The method utilises the ability of an engineering designer to appraise the overall structure of a finite element layout and decide on a near-optimum node order. The main disadvantages of previous methods of bandwidth reduction are overcome. Lengthy finite element analyses may be run as batch-processing jobs and the results may be examined interactively using convenient graphics.
facilities. The data pertaining to a given structure is stored in a single magnetic disc file to which all phases of
the design system have access. Having evaluated the results of analysis, the designer can modify the geometric
definition or the structural data and run a further analysis. The techniques developed, as incorporated into an
integrated computer system, accelerate the design process by drastically reducing the amount of input data
required for an analysis and by providing convenient output facilities. The evaluation of the system on a number
of structures is described and suggestions are given for further work.

ABSTRACT: This work is concerned with the effect of local buckling on the rotation capacity of composite
steel concrete beams in regions of negative bending. Experiments were made in which both stiffened and
unstiffened beams were subjected to a moment gradient in negative bending. The sizes of the joists varied so
that a wide range of flange and web slenderness ratios could be investigated. In only a few tests were true
composite steel-concrete specimens used; many had the reinforced concrete slab simulated by rolled steel flat.
Comparison between the test results and existing theories on local buckling in plane steel structures revealed
that much of the existing work can be applied to composite beams. Not all of the past work, however, agreed
well with the observations, and it is concluded that the applicability of some existing recommendations for
plastically designed member should be re-examined. An approximate method, deriving from the upper bound
theorem of limit analysis, of predicting the moment-rotation characteristics of a locally buckling I-shape is
presented. Two buckling mechanisms for unstiffened sections, and one for a stiffened section are analysed.
Extension of the analysis to composite and cover-plated beams is discussed. The predicted curves are compared
with actual characteristics as observed by the author and by others. Reasonable agreement is found for the
unstiffened shapes, and it is concluded that the method provide a useful tool for further research. Both the actual
and predicted behaviour of the longitudinally stiffened sections showed significant improvements over their
unstiffened counterparts. There were too few results, however, for definite conclusions to be drawn. Tentative
conclusions are given to aid the development if design recommendations, and to act as guides for future studies.

Gunaratnam, D.J., 1968, “Finite elastic-plastic displacements of shells”
ABSTRACT: A detailed theoretical and experimental study is presented for large deflection elastic and elastic-
plastic behaviour of thin spherical shells subjected to uniform external pressure, and concentrated inward load
applied at the apex through a rigid boss. The theoretical study is carried out using the rate problem, This is a
boundary value problem for the rates of stress velocities and rates of surface tractions which takes geometry
changes into account. The rate problem is first derived for a general continuum in terms of Cartesian tensors.
The corresponding rate equations for an axisymmetric shell are then derived in terms of generalised stress rates,
and strain rates. In the elastic region the governing differential equations are linear in the rates and are solved
numerically by expressing it in finite difference form. By solving a sequence of such rate problems the entire
load-deflection characteristic of the shell is determined to any desired stage. In the plastic region the governing
equations are non-linear, and are solved using the strain-bound iteration technique. The experimental study was
carried out on aluminium and P.V.C. hemispherical shells. The theoretical results are in fair agreement with
previous and present experimental results. Further the results show that the boss size does influence the
buckling behaviour of spherical shells under point load. Also an initial external pressure is shown to cause
dramatic collapse under point load. Finally in the sixth chapter the rate equations are derived for a general shell.

ABSTRACT: The dissertation is concerned with the ultimate strengths in compression of columns up of thin plates. The columns are proportioned in such way that local buckling occurs when the section is still entirely elastic. The ultimate average stress of short columns is then primarily determined by the plastic yielding of the plates in their post-buckled range, but in the case of longer columns, this ultimate stress is somewhat reduced because of a tendency towards overall buckling. The dissertation is divided into two parts, the first containing an account of the theoretical derivation of ultimate stresses, the second, a description of the experimental research carried out to support the theory. The theory has involved essentially the development of two computer programs. The first predicts the post-buckled behaviour of a short thin-walled rectangular column under uniform axial compression, giving information about the regions of plasticity within the plates at various applied strains and evaluating the ultimate stress. The second obtains the internal bending moment – curvature relationship if the column at stages in its post-buckled range. From the variation of this latter parameter with the average applied axial stress the interaction curve of ultimate stress versus slenderness-ratio for the column may be derived. Interaction curves are presented for sections with various values of yield stress, and the effect of initial geometrical imperfections is also demonstrated. Experimental interaction curves have been obtained by performing tests on model columns cut from square-section thin-walled drawn tubing and they appear to be in good agreement with the theoretical curves.

http://www-structures.eng.cam.ac.uk/phdabs/A%20T%20Ractliffe_Abstract.pdf

ABSTRACT: The dissertation covers work by the author over the past three years and is concerned with the post-buckled behaviour of rectangular plates compressed primarily in one direction into the plastic regime. Particular emphasis is placed on the study of ultimate strength, and it sensitivity to residual welding stresses, initial imperfections, boundary conditions and material properties. The “load-shedding” problem in plate buckling is investigated experimentally for the first time with particular reference to the problem of assessing the strength of built-up columns and other structural members made from welded plates. Chapter 1 states the problem and reviews the present state of knowledge in this field. Chapter 2 presents a simplified analysis of the simply-supported square plate which takes into account residual stresses, initial imperfections and work-hardening. Typical results are shown graphically. Chapter 3 describes a rigorous method based on strain energy. Unfortunately lack of time curtailed work on the computer program and no result emerged, but the method embodies some novel ideas and is presented as a powerful approach which will take into account a fairly general loading system and boundary conditions, in addition to accommodating residual stresses and work-hardening. Chapter 4 moves on to experimental work and the design of a test rig to simulate clamped or simply-supported boundary conditions in an individual plate. Another feature discussed is the stiffening of a testing machine in order to observe behaviour after the ultimate load. Chapters 5 – 7 describe actual tests on steel cruciform columns, and plates in steel, H30WP-alloy and Chapter 8 discusses these results and compares theory with experiment. Appendices are devoted to topics indirectly connected to the main thesis, including the measurement and prediction of residual stresses, material properties, elasto-plastic theory etc.

The main results to emerge are:

a) Local buckling strength is adversely affected by residual stresses and imperfections, most severely when the elastic critical stress is of the same order as the yield stress.

b) In plates of certain sizes, intrinsic instability arises i.e. at or beyond the maximum load the effective load may fall off catastrophically under no further compression, with possible serious consequences for the rest of the structure.

c) Boundary conditions do not greatly affect the ultimate strength of plates.

d) Further evidence, experimental and theoretical, emerges to suggest that the BS449 and 153 “effective width” rules may not be very reliable.
Massey, Campbell, 1965, The inelastic lateral stability of mild steel I beams”
http://www-structures.eng.cam.ac.uk/phdabs/Campbell%20Massey_Abstract.pdf

ABSTRACT: A basic assumption in the proportioning of structures for ultimate strength by plastic design methods is that large inelastic rotations, and consequent redistribution of moments, are possible at certain regions. This assumption implies that premature failure by buckling does not occur. It is the purpose of this dissertation to examine the phenomenon of lateral buckling of beams, more particularly mild steel I beams, which have been strained beyond yield by bending in the plane of maximum rigidity. Existing theories are studied critically and modified where necessary, a programme of uniform bending tests on small scale model steel I beams is described and the result are correlated with theoretical predictions. First, a new theory to describe the reduction in torsional rigidity with increase in primary bending moment beyond yield is formulated and supported experimentally. Then the lateral stability in the inelastic range generally is discussed, with a comparison of theoretical and experimental findings, a variation of the Southwell Plot is developed and used for inelastic stability predictions. Rotation capacity is next examined and a relation between laterally unsupported length and amount of possible rotation before collapse is determined. It is also shown that sufficient rotation may be possible in cases where the full plastic moment of the beam cannot be developed before it becomes unstable. The effect of residual stresses is studied theoretically and it is shown quantitatively how much stresses precipitate the onset of instability in the plastic range. Beams with non uniform are then discusses and examined analytically by means of an approximate method of calculation, based on the moment are principles, which is developed for the purpose. Finally, a theory is formulated to predict the required force applied horizontally at mid span to prevent lateral instability up to the full plastic moment. This theory is also supported experimentally.

Augsti, Giuliano, 1964, “Some problems in structural instability with special reference to beam of I-section”

ABSTRACT: This thesis consists of two Parts: Part I is concerned with the basic types of elastic buckling and post-buckling; Part II with the theory of instability in the inelastic range and the actual behaviour and practical design of I-section metal beam-columns. Semi-rigid models with one or two degrees of freedom are used in Part I to present and illustrate the different cases: namely, the models are constituted by a rigid compressed strut loaded at the top and either pinned or ball-ended at the bottom (one or two degrees of freedom respectively); a similar model illustrated the lateral-torsional buckling of deep beams, but in this case the load is applied at one end at 90 degrees to the limb, which is restrained at the other end by two cylindrical hinges. Different behaviours are obtained by changing the elastic restraints; for each case the complete equations of equilibrium, valid for any value of the rotations, are written. For the “strut” models, the load-deformation curves are plotted in both cases of perfectly vertical or slightly inclined (“imperfect”) strut, the loading force being vertical. It is noted in particular that in the second case separate paths of equilibrium exist, which tend to touch each other in the “bifurcation points” as the imperfections tend to vanish; in the “perfect” case, the buckled branches of the equilibrium path can be either rising or falling, depending on the restraints. Only perfect “deep beam” models are studied, and it is noted that the torsional and lateral bending stiffnesses have different importance in determining the post-buckling strength. General conclusion from the different examples are derived at the end of Part I, and these are put in relation with the results of more general researches. The first Chapter of Part II deals with the general principles and fundamental cases of inelastic buckling, presenting firstly a critical synthesis of the present knowledge and then examples again obtained by means of a semi-rigid strut model, with a variety of inelastic stress-strain relationships. The rest of Part II (Chapter 5 to 8) deals with an investigation on I-section “beam-columns”, and comprise

(i) a search of literature, with particular emphasis on practical design procedure;
(ii) description and results of two groups of experiments, respectively on aluminium-alloy and mild-steel miniature stanchions, subjected to a compressive axial load and one end moment acting in the plane of the web;

(iii) comparison of the experimental results with theoretical and empirical predictions, and proposal of a simple empirical “interaction curve”, which fits the experimental results to the “rotation capacity” of beam-columns, that is, the ability to withstand end rotations with out excessive decrease of strength.

Wasti, Syed Tanvir, 1964, Finite plastic deformations of spherical shells”
http://www-structures.eng.cam.ac.uk/phdabs/Syed%20T%20Wasti_Abstract.pdf
ABSTRACT: A detailed theoretical and experimental study of the behaviour of copper, aluminium and steel hemispherical shells tested under concentrated loads at the apex and under water pressure is presented. There shells are not “perfect”, but obtained commercially. The description of loading apparatus designed to test shells under the above conditions, and suitable for use in a small laboratory, is given in Chapter I. Chapter III deals specifically with the starting point of the present investigation – the work of Reissner and Ashwell. The result of 39 tests on shallow and deep shells are given. Short notes on the shells written during each experiment comprise of Chapter II. Theoretical load-deflexion relationships are derived in Chapter IV on the basis of several postulated collapse mechanisms, and reasonable agreement is obtained for some of the theoretical analyses. The need for a convenient method of designing shells has also been borne in mind. Close attention is paid to the way in which, a shell deform under increasing load, and it is shown that the work done on thick shells at least is plastic almost from the very beginning. A cine-film has been obtained, showing the outward propagation of circular yield-hinges along the shell from the apex. Finally in Chapter V, some observations are made on the problem of the inextensional large-deflexion behaviour of spherical shells.

Grundy, Paul, 1961, “The strength of elastically restrained steel tubular struts”
http://www-structures.eng.cam.ac.uk/phdabs/Paul%20Grundy_Abstract.pdf
ABSTRACT: Current design methods of struts in trusses are examined and it is found that there is no exact general solution of the ultimate strength based upon elastoplastic material. One solution is found for tubular struts bent in single curvature with end restraints for equal rotational stiffness, which is the worst condition for moments of a given magnitude. In the analysis only struts at collapse are considered. For each strut configuration the end rotational stiffnesses necessary for the strut to be at collapse are found using an adjacent equilibrium criterion. The solutions are found using an electronic computer to integrate the moment-curvature functions, and charts of results applicable to all practical lengths of tubular struts are found. A supplementary analysis shows the effect of the stiffness of end restraint and a safe method of including the effect of initial curvature in the inelastic analysis. A further analysis develops the idea of an “elastic hinge” to compare the collapse load conditions of struts in single curvature with struts of other shapes. A significant reduction in the necessary end stiffness of restraint is found for unsymmetrical struts. The design and operation of a testing rig for small tubular struts is described and the results of fifty eight tests are given. The single curvature tests are compared with the theory, which is found to be conservative, and the reasons for this are discussed. The tests show the significance of various factors, in particular that the nett initial central deflection before the load is applied is the most significant factor affecting the proximity if the collapse load to the squash load, and the load generally falls steeply with contraction after the collapse load is obtained.

Thompson, J.M.T., 1961, “The elastic instability of spherical shells”
ABSTRACT: Part I of the dissertation represent an investigation into the well-known discrepancy between experimental and theoretical (eigenvalue) analyses of elastic shell instability. The buckling and post-buckling of
a ‘perfect’ and ‘imperfect’ complete spherical shell under uniform external pressure are studied. An electrolytic method, applicable to the manufacture of thin shells of various profiles, is developed for the production of near-perfect metallic specimens. The shells are suitable for instability and model stress analyses. Pressure tests on electroplated copper, and polyvinyl chloride shells confirm the reported premature experimental failures. Many types of ‘imperfection’ were eliminated from the shells, and the magnitudes of the remaining imperfections are assessed. The ‘classical’ nature of the experimental snap is demonstrated, and the rotationally symmetric post-snapping states are analysed. The initial and post-buckling behaviours of a perfect shell are analysed theoretically by a well established energy method. The use of a digital computer allows a considerable advance over previous theoretical treatments, and the uniqueness of the post-buckling states is discussed. The experimental and theoretical post-buckling analyses show good agreement equilibrium states in the field of shell instability. Theoretical analyses of an imperfect shell, together with the experimental shell, together with experimental conclusions, show that middle-surface and thickness irregularities can, and in many cases do represent the primary cause of the premature failures. Loading imperfections are unimportant. Part II represents a unified presentation of several fundamental stability concepts of large-deflection elasticity. Four theorems concerning the stability of the system, which includes both a general structure and its loading device, are established. The first theorem incorporates the ‘classical’ stability concept, which identifies the ‘critical’ condition with the existence of an ‘adjacent position of equilibrium’. Used conjointly the theorems are a powerful tool in any investigation into the stability of a structure, for which the load-deflection characteristics are known. This practical usefulness of the theorems is demonstrated in several examples.

Cotterell, B., 1960, “Thermal buckling of circular plates”
http://www-structures.eng.cam.ac.uk/phdabs/B%20Cotterell_Abstract_1.docx.pdf
ABSTRACT: (cannot cut and paste)

ABSTRACT: The investigation into the elastic-plastic behaviour of mild steel plates has aimed at determining the ultimate load carrying capacity of square and circular plates loaded in the plane of the plate. It has been restricted to the simplest of boundary conditions by assuming simple supports along the perimeter of the plate and strain hardening effects have been excluded, the analysis being confined to an elastic perfectly plastic material obeying a Johansen Yield Criterion of constant maximum stress. The ultimate load has been obtained from the intersection of an elastic-plastic loading path, which occurs subsequent to the elastic-plastic buckling of the plate, and a rigid plastic unloading line. For stocky plates, whose elastic critical stress is equal to or greater than the yield stress, it has been shown that the ultimate load is equal to the yield load. It has also been shown that the ultimate load is related to the magnitude of the initial imperfections in the plate, this load being a maximum for an ideal initially plane plate. The problem of the behaviour of circular plates has been limited to a theoretical investigation. Experiments were not carried out owing to the difficulty of applying radial loads of large magnitude to a plate of this shape. The theoretical investigation, however, has been supplemented by suggesting an elastic-plastic loading path for a circular plate with clamped edges. Extensive experiments have been carried out on square plates and the theory has been verified to large transverse deflexions of such plates. There experiments have been conducted on thin walled tubes of square cross-section where the walls of the tube have been found to approximate the conditions of a simply supported plate. Tests have also been carried out on the webs of I sections though these experiments have not proved too successful owing to the effects of elastic restraints along the unloaded edges. The general analysis developed in this dissertation has been compared with previous solutions for the ultimate strength of plates in compression.
Ariaratnam, S.T., 1959, “The collapse load of elastic-plastic structures”
http://www-structures.eng.cam.ac.uk/phdabs/S%20T%20Ariaratnam_Abstract.pdf

ABSTRACT: The investigation is concerned with the overall stability and collapse behaviour of elastic-plastic structures. The discussions are restricted to plane rigid-jointed frames loaded in their plane. Fundamental ideas put forward intuitively by previous investigators and verified by them using specific numerical examples, are proved rigorously for structures in general. It is shown that the elastic critical loads play a significantly part in determining the stability of elastic-plastic structures. The critical loads are defined as eigenvalues in terms of a variational problem. Using this definition some useful results concerning critical loads are established for structures generally. The “Southwell Method” for predicting critical loads of struts from experimental observations, is extended to the problem of plane frameworks which buckle within and out of their plane. A proof of Hoff’s Convergence Criterion for stability of elastic frameworks is presented as an appendix to the main body of the analysis. The collapse behaviour of elastic-plastic structures which fail through frame instability is explained in mathematical terms. The general procedure adopted is the study of the equilibrium problem of the response of a structure to proportional loading in relation to the associated eigenvalue buckling problem, the solutions being obtained as series in the buckling modes using the Theorem of Minimum Potential Energy. The special case of the collapse of frames, in which the external loading does not excite in the deflexions a component in the first buckling mode, is discussed by considering the problem of the slender symmetrically loaded symmetrical frame. Equations for the stability analysis of elastic-plastic structures are developed in a form suitable for evaluation on a digital computer. Empirical methods for predicting collapse loads are reviewed and suggestions for possible improvements made where necessary. The result of an experimental investigation on frame instability in the plastic range is presented. The programme consists of tests on a series of model multi-story frames of rectangular and tubular members under the action of vertical and horizontal loading in the plane of the frames.

Ellis, John Stewart, 1957, “The plastic behavior of tubular compression members”

ABSTRACT: The problem was to investigate theoretically and experimentally the plastic behaviour of mild steel compression members of an annular cross-section when subjected to end loads of equal and unequal end eccentricities. In order to provide a theoretical answer to this problem, it was first necessary to specify a collapse criterion. This was used to find the critical length of a compression member under a known thrust and subjected to end loads of equal or unequal eccentricities. It was then necessary to compute the physical characteristics of compression members on the point of collapse. These computations were made for a comprehensive range of axial loads and ratios of end eccentricities. An electronic digital computer was used in this work, and the results are expressed as graphs in which all the quantities are non-dimensional. It should be noted that the theory does not take into account the effect of shear, strain history, residual stresses, shakedown, fatigue and local buckling. A total of fifteen stanchion tests were conducted, using specimens of an annular cross-section with an outside diameter of 4.5 in. and thickness of 0.138 or 0.25. The lengths of the specimens were either 5 ft. or 9 ft., and three types of loading were used: (1) single curvature bending with equal end eccentricities, (2) single curvature bending with no moment at one end, and (3) single curvature bending with equal but opposite end eccentricities. The agreement between the plastic theory and the experimental collapse loads is considered to be good. It would appear that considerable economy will result from using the plastic theory to analyse stanchions rather than the elastic one. A method of analysing stanchions in a framework is advanced.

Ashwell, Derek George, 1953, “The finite deformation of thin plates and shells”

ABSTRACT: This investigation is concerned with the elastic-plastic response of thin plates and shells subjected to compressive loadings in their plane. The effects of elastic-plastic transverse shear are neglected. The plate and shell equations are developed in the form of a variational problem for a given boundary condition. The plate and shell equations are solved under the assumption of perfect plasticity. The results are presented in a form suitable for the use of a digital computer. It is shown that the solution of a given problem can be obtained by a series of calculations using the computer. The agreement between the theoretical and experimental results is considered to be good.
ABSTRACT: A number of fundamental large-deflexion problems in the elastic bending, compression, and torsion of thin plates and thin-walled members are investigated in detail. From the general equations for the extensional bending of thin plates an equation is obtained governing the bending of rectangular plates into certain types of surfaces of revolution. This equation is applied in turn to the pure bending about one axis of initially curved and corrugated plates, to flat-square, or rectangular plates loaded by distributed bending moments applied to all four edges, and to plates with initial curvature loaded by compressive forces parallel to the axis of curvature. All these problems exhibit the type of instability characteristics of thin-walled structures which depend in curvature of their stiffness. Curves are drawn showing the deformation suffered by the plates, the critical loads are found, and the post-buckling behaviour is described. The final chapter considers the finite torsion of a twisted elastic cantilever. It is well known that the displacement of such a cantilever relative to its support is a rotation about its flexural axis, to so-called axis of twist. It is here shown that, by considering the distortion of the cantilever without reference to its support, an axis of distortion can be found that is, in general, quite different from the accepted axis of displacement. General expressions are derived for the determination of the axis of distortion, and it is found that the finite deformation of thin-walled sections depends on the position of both axes, in a manner which is described. Various experiments are described which were designed to test the analyses of all types of problem considered in the dissertation and their results are found to confirm them satisfactorily.

Gross, Nicol, 1950, “Experiments on curved thin-walled tubes”
http://www-structures.eng.cam.ac.uk/phdabs/N%20Gross_Abstract.pdf

ABSTRACT: The stresses and the flexibility of curved thin-walled tubes have been estimated in the past by Karman’s approximate analysis, but experiments have shown that misleading results are obtained when the radius of curvature is not considerably larger than the radius of the tube. In this dissertation, Karman’s analysis is extended to pipe bends in which the radius of curvature and the pipe radius are of the same order of magnitude, by introducing the second and the third approximations for the shape of the deformed centre-line, as well as a correction of Karman’s assumption that this deformation does not alter the length of the centre-line. By measuring strains, for the first time, not only on the outside but also on the inside surface of curved tubes, this extension was checked for the usual small-radius pipe bends and was also applied to an extreme case. The measurements of the strain confirmed that the largest stress occurred on the inside surface, that it was a stress in the transverse direction, and that it was induced in the cross-section where, from similarity with curved bars, the stress-free axis was assumed to be. It was also found that after local yielding has taken place, the load can be roughly doubled before unduly large deflexions occur. A comparison of the behaviour of seamless and pressed-welded pipe bends showed that neither the flexibility nor the stresses are significantly influenced by the presence of the weld. Experiments are also described in which the pipe-bends were subjected to uniform internal pressure, strain measurements being taken for the first time inside pipes under high water-pressure. The stresses can be estimated by assuming that the pipe-bend behaves like a thin-walled torus of circular cross-section. But initial deviations from circularity superimpose additional bending stresses. In the course of comparing the behaviour of seamless and pressed-welded bends when they were subjected to internal pressure, it was found that the ultimate pressure that could be sustained was lower in the latter because of imperfections in the weld.

Neal, Bernard George, 1948, “The lateral instability of mild steel beams of rectangular cross-section bent beyond the elastic limit”
http://www-structures.eng.cam.ac.uk/phdabs/B%20G%20Neal_Abstract.pdf

ABSTRACT: It is well known that a thin deep beam, loaded in a vertical plane so as to cause flexure about the stronger, or primary principal axis of the cross-section, may fail by buckling laterally out of that plane.
type of instability is characterised by the development of twist in the beam. A component of the applied load then causes flexure about the weaker, or secondary principal axis, and lateral deflection occurs. The critical load causing instability in an initially straight beam therefore depends on the flexural rigidity of the beam about its secondary principal axis, and its torsional rigidity. Values of the critical load have been calculated for many loading systems and types of end-constraint for beams that behave elastically under the applied loads. This dissertation discusses rectangular section beams of mild steel in which yield occurs in the more highly strained outer fibres before the critical condition causing lateral instability is reached. For such beams the secondary flexural rigidity decreases progressively as the load increased above the value at which yield first occurs. The torsional rigidity, however, remains constant at its elastic value. In the first part of the dissertation the reduction of the secondary flexural rigidity is calculated, and the critical lateral buckling moment is estimated for a beam bent by pure terminal couples, the ends of which are prevented from twisting but a free to rotate about the secondary principal axis. Experimental confirmation of the results is given. In the second part of the dissertation the calculations are extended to problems in which the primary bending moment varies linearly along the beam, so that a constant shear force exists. The two particular examples considered are a simply supported beam with a central concentrated load, and a cantilever. No experimental evidence in support of these calculations is available.

End of Ph.D. theses about buckling of beams, plates and shells from Cambridge University Structures Research Group (CURSG)
=======================================================================

ABSTRACT: (none given)

ABSTRACT: The problem of optimal design of rotationally symmetrical shells of uniform stability stiffened by ribs was discussed in the current paper. The structure was modelled in ANSYS software and solved by FEM method. The formulation of uniform local stability was successfully verified by the linear buckling solution. The optimization tasks were solved numerically using the modified Particle Swarm Optimization algorithm. The critical loading multiplier was increased by determining the optimal shape of the meridian, distribution of a wall thickness in a coat of shell and the placement of ribs inside the shell.

References listed at the end of the paper:

ABSTRACT: A three-dimensional (3D) method of analysis is presented for determining the free vibration frequencies of joined hemispherical-cylindrical shells of revolution with a top opening. Unlike conventional shell theories, which are mathematically two-dimensional (2D), the present method is based upon the 3D dynamic equations of elasticity. Displacement components $u_r$, $u_\theta$, and $u_z$ in the radial, circumferential, and axial directions, respectively, are taken to be periodic in $\theta$ and in time, and algebraic polynomials in the $r$ and $z$ directions. Potential (strain) and kinetic energies of the joined shells are formulated, and the Ritz method is used to solve the eigenvalue problem, thus yielding upper bound values of the frequencies by minimizing the frequencies. As the degree of the polynomials is increased, frequencies converge to the exact values. Convergence to four-digit exactitude is demonstrated for the first five frequencies. Natural frequencies are presented for different boundary conditions. The frequencies from the present 3D method are compared with those from 2D thin shell theories.

“Eigen value and buckling load measurement of stiffened panel using FEM”, IJME, Vol. 1, Special Issue 1, 2014 (NCETADM-2014)

ABSTRACT: One of the main failure modes of an aircraft is buckling. Stringers are often bonded to composite panel skins to help increase the panel’s buckling strength; however, if there is a defect in the bond between the stringer and the panel, the structure may be weakened. Developing analysis tools that can accurately simulate the behaviour of composite materials is critical to the successful design and use of composite structures. The pre-design of aircraft wing structures relies on finite element models of significantly reduced complexity in which only spar and rib components are explicitly modelled, whereas the wing skin-stringers stiffened panels are implicitly represented by stiffness-equivalent elements. This conventional procedure enables a fast solution technique for large problems. The panel was loaded beyond buckling and strains, and out-of-plane displacements were extracted. The experimental data were compared with the strains and out-of-plane deflections from a high-fidelity non-linear element analysis. The test data indicated that the panel buckled at the
linear elastic buckling Eigen value when continuous load is applied. This value is obtained from graph. References listed at the end of the paper

ABSTRACT: The design of deep submersible pressure hull’s structure is one of the core technologies of submersible development of human history. Submersible pressure hulls with fiber-reinforced multilayer constructions have been developed in the recent years as substitutes for classical metallic ring-stiffened pressure hulls; strength and stability are its top priority. This paper investigates the optimum design of a composite elliptical deep-submerged pressure hull under hydrostatic pressure to minimize the buoyancy factor of the submersible pressure hull under constraints on the failure criteria and the buckling strength of the hulls to reach the maximum operating depth. The thickness and the fiber orientation angles in each layer, the radii of the ellipse, and stringers dimensions were taken as design variables and determined in the design process. The optimization procedures are performed using commercial finite element analysis software ANSYS. Additionally, a sensitivity analysis is performed to study the influence of the design variables on the structural optimum design. Results of this study provide a valuable reference for designers of underwater vehicles.

ABSTRACT: The method of solving static problems of nonlinear deformation, buckling, and postbuckling behavior of thin elastic inhomogeneous shells is based on the geometrically nonlinear equations of the 3D thermoelasticity theory and use of the moment finite-element scheme. A unified model has been created based on the universal spatial finite element with additional variable parameters. The model considers the multilayer structure of a material and geometrical features of structural elements of an inhomogeneous shell: casing of varying thickness, ribs, cover plates, cavities, channels, holes and sharp bends of the mid-surface. In a number of the authors’ works the reliability of linear and nonlinear solutions for a wide class of inhomogeneous shells has been numerically justified by analyzing their convergence and comparing them with those obtained by other authors. This paper is devoted to the comparative analysis of finite-element models and results of calculation of thin elastic shells using the moment finite-element scheme, and LIRA and SCAD program complexes. The effect of different types of weakening on nonlinear deformation and buckling of shells was studied on the example of isotropic panels under uniform pressure.

ABSTRACT: An imperfection sensitivity analysis of cold-formed steel members in compression is presented. The analysis is based on Koiter’s approach and Monte Carlo simulation. If the modes interaction is correctly accounted, than the limit load and the erosion of critical buckling load can be easily evaluated. Thousands of imperfection can be analysed with very low computational cost and an effective statistical evaluation of limit performance can be carried out. The analysis is done on pallet rack uprights in compression, based on an intensive experimental study carried out at the Politehnica University of Timisoara.

Yuan-Hung Kuo, Bo-Siou Wei and Jeff Measamer (McDermott International Inc.), “A study on suction pile shell buckling and soil failure utilizing predicted and real-time monitored suction pressures during installation”, International Society of Offshore and Polar Engineers, 25th International Offshore and Polar Engineering Conference, 21-26 June, Kona, Hawaii, USA, 2015

ABSTRACT: Suction piles have been widely used for subsea foundations, since they are reliable and cost effective for subsea installation. Traditionally, suction piles were designed to sustain installation pressure against upper and lower limits derived from soil failure and tubular buckling. This traditional approach does not take into account the variation between the predicted required suction pressure and the real installation suction pressure and assumes the real suction pressure time history will fall into the zone between the predicted upper bound and lower bound pressure curves. For the traditional tubular buckling check, the thin plate effect and the
pile geometric imperfection are not well considered and experimented; therefore, the buckling capacity of the piles with large D/t ratios may be overestimated in certain circumstances. Recent studies on piles with large diameters have suggested that those piles often fail in plate buckling modes instead of tubular buckling mode during pile installation. In this paper, we presents the in-situ pump-in pressure history extracted from the real-time monitoring data during suction pile installation. The installation pressure curve is distinct from the predicted curve based on soil friction theory both in shape and in magnitude. The actual required suction pressure built overtime is found to be greater than the upper bound pressure curve and is dangerously close to the lower bound pressure curve of soil plug heave failure, even when the pile self-penetration depth falls into the predicted range. This observation suggests that the required pump-in pressure curve for a suction pile installation is not well predicted using traditional approach. The soil uncertainty cannot explain enough for the pressure curve deviation because a considerably large suction pressure is also observed at the initiation of the pressure-forced penetration minutes after the self-weight penetration stops. This initial large suction pressure suggests the initial soil setup effect was not fully understood before and this excessive pressure jump may fail the suction pile at this stage when the pile unbraced buckling length is at the longest. Lastly, in addition to developing the allowable suction pressure envelops using industrial codes specifically for plate and shell buckling, this paper recommends to structurally stiffen a suction pile so that the allowable structural buckling pressure curve is always greater than the soil-failure-based allowable suction pressure curve. Through this approach, the pile installability and structural integrity can be ensured. In the case when the soil plug failure occurs, the structurally sound pile will be still retrievable and reusable.

ABSTRACT: This paper discusses macro-geometrical, micro-geometrical and biomechanical features of eggshell, and proposes its inspiration for bionic design of submersible pressure hull. The results show that eggshell has excellent bionic performance on the weight-strength ratio, the span-thickness ratio, the aesthetic characteristics, the distribution of material and so on. The pressure endurance of the eggshell under uniform pressure is quite remarkable. Bionic design based on eggshell structure can effectively coordinate variable features of deep-sea pressure hull such as strength, stability, reserve buoyancy, streamline shape, space utilization in the crust and occupant comfort.

ABSTRACT: The material, form and geometric shape of egghave been designed in a way that nobody could
ever break an egg squeezing it lengthwise. This research is based on the pattern of human palm. Two soft and concave seating bases are built in order to hold the two ends of the chicken egg. Different chicken eggs with various geometric shapes were examined by Zwick compression strength test while they were raw, baked and empty. The maximum failing force (breaking of the egg) was 988 Newton. Static linear and nonlinear analysis and modeling of material and geometry is done by Ansys software or with Shell181 element. Early results show that chicken egg content has no effect on its load-application capacity and the reason of breaking are exceeded orbital tensile stresses. With the same thickness, eggs with length to width ratio of 1.4 have the highest load-application capacity and eggs with length to width ratio of 1.7 have the lowest load-application capacity.

ABSTRACT: ANSYS 14.0 structural analysis software is used in order to make a ring rib-reticulated shell for the overall stability analysis. Considering the geometric nonlinear analysis and initial geometric imperfections influence, obtain a key node of the load-displacement curve and assess the ultimate strength of the structure. The results showed that the structure meets the "Space grid rules" for monolayer shells stability requirements. And it is found that load distribution form and initial geometry defect has a great deal with bearing capacity of single-layer lattice shell stability by comparison.

ABSTRACT: We propose a method of modelling sail type structures which captures the wrinkling behaviour of such structures. The method is validated through experimental and analytical test cases, particularly in terms of wrinkling prediction. An enhanced wrinkling index is proposed as a valuable measure characterizing the global wrinkling development on the deformed structure. The method is based on a pseudo-dynamic finite element procedure involving non-linear MITC shell elements. The major advantage compared to membrane models generally used for this type of analysis is that no ad hoc wrinkling model is required to control the stability of the structure. We demonstrate our approach to analyse the behaviour of various structures with spherical and cylindrical shapes, characteristic of downwind sails over a rather wide range of shape and constitutive parameters. In all cases convergence is reached and the overall flying shape is most adequately represented, which shows that our approach is a most valuable alternative to standard techniques to provide deeper insight into the physical behaviour. Limitations appear only in some very special instances in which local wrinkling-related instabilities are extremely high and would require specific additional treatments, out of the scope of the present study.

ABSTRACT: The influence of alternating curvature on the dynamic instability domains of shells under combined static and dynamic loading is studied. It is shown that the range of safe harmonic loads for shells of revolution with sinusoidal generatrix can be extended compared with cylindrical shells.

ABSTRACT: Results are presented of investigations into determining the limit of the magnitudes of uniform external pressure, which when exceeded may cause the possible stability loss of equilibrium states of geometrically perfect ideally elastic spherical shells. Results of calculations of pressures corresponding to this boundary and understanding the necessary conditions of instability of the shells under consideration are close qualitatively and quantitatively to the lower boundary of their experimentally determined critical values. Investigations are performed based on the dynamic criterion of stability and equations of the unperturbed motion of shells linearized in the vicinity of the equilibrium states under consideration.

ABSTRACT: This project analyzes the effect of delamination size on the localized critical buckling load of a partially delaminated composite plate sublaminate under uniform, uniaxial compression. The plate being analyzed is a square, 24-layered, symmetric graphite/epoxy laminate composite of uniform thickness, with a centrally-located circular delamination between the fourth and fifth layers. A model, based on the code outlined in Reference (1), was built in the symbolic computation program Maple to conduct this analysis. The model first applies Classical Laminate Plate Theory to define the composite behavioral response to compression. It then applies the Ritz variational method to minimize the total potential energy of the system and create an expression from which the critical buckling load of the composite sublaminate can be predicted. The potential energy term is initially expressed in terms of known geometric dimensions and material properties, and unknown polynomial coefficients. The Newton-Raphson method solves for the values of the polynomial coefficients, which can then be substituted back into the sublaminate stress, strain, and displacement equations to fully describe the sublaminate behavior. By conducting this analysis at various loads, a load-strain plot illustrates the critical buckling load as a maximum point in the resulting curve. This process was repeated for delaminations of various diameters to understand the relationship between delamination size and the compressive-tolerance capabilities of composites. This analysis was validated by recreating the results of a model created in the Reference (1) study. After verifying the Maple model, the initial study was able to be expanded to support the goals of this project. Ultimately the project determined that as the delamination size increases, the strength of the composite can be severely reduced.

ABSTRACT: Free vibration of simply supported circular cylindrical shell made of Functionally Graded Material (FGM) under internal pressure was investigated. The effective material properties are assumed to vary continuously along the thickness direction according to a volume fraction power law distribution. First order shear deformation theory based on Love's first approximation theory was utilized in the equilibrium equations. The effects of FGM parameters such as material configuration and power law exponent, internal pressure as well as geometrical parameters such as thickness to radius and length to radius ratios on the vibration behavior were investigated. The validation of the results was achieved by comparing with those available in the literature. The results show that the vibration characteristics of Functionally Graded (FG) shells are greatly influenced by FGM parameters. Moreover, internal pressure and geometrical parameters considerably influence the frequency behavior regarded to different values of FGM parameters.

PARTIAL INTRODUCTION: The static stability analysis as a key problem for design of single-layer reticulated shells has become attractive to many researchers since late 1980s. Instead of traditional analytical method based upon “continuum theory”, the procedure of whole-course response analysis based upon non-linear finite element analysis and method for tracing equilibrium path was developed, by which the structural behavior along with the whole loading course of a complicated structure such like reticulated shell can be revealed clearly by the complete load-deflection curve, and the critical load can be accurately obtained. The effects of some practical factors such like the initial geometric imperfection of the structure and the unsymmetrical distribution of load can also be considered in this procedure. Based upon such a procedure, systematical elastic complete load-deflection analyses for different types of reticulated shells with varying geometric and structural parameters have been carried out. By nearly 20 years effort, the elastic stability of reticulated shells has been solved up to now [1-2]. Recently, the problem of elasto-plastic stability of reticulated shells gradually has become more attractive to researchers [3-4]. However, the analysis on elasto-plastic stability is much more complicated than elastic analysis because of distinguished characteristics between elastic stability and elasto-plastic stability. Plastic instability of reticulated shells exhibits obvious nonlinear and non-conservation features, it will be found that some new phenomena and mechanism of instable behaviors not seen before. Taking into consideration of material nonlinearity, the elasto-plastic stability performance of reticulated shells will change greatly, which
will be recognized only by plentiful elasto-plastic whole-course response analysis.

Four kinds of single-layer latticed domes constructed widely (Kiewitt 8, Kiewitt 6, Geodesic and Schwedler), are studied systematically with the software ANSYS, in which more than 144 cases of elasto-plastic whole-course analysis were carried out with different initial imperfection, geometric, structural and load parameters… References listed at the end of the paper:

ABSTRACT: Thin-walled cylindrical shells subjected to axial compression are sensitive to initial geometrical imperfections. Firstly, the influence of a single dimple imperfection on the load-carrying capacity of cylindrical shells is investigated by varying the amplitudes, directions and positions of the dimple imperfection. Then a single delta function is introduced to describe the profile of the dimple imperfection in a more general form, which enables to analyze conveniently the effect of the imperfect zone area on the load-carrying capacity of cylindrical shells. Thereafter, a surrogate-based optimization framework of determining the worst realistic imperfection is proposed to study the reduction of the buckling load of cylindrical shells based on a finite number of dimple imperfections. The possible dimple imperfections may be introduced during the service of cylindrical shells. Finally the effectiveness of the present method is demonstrated by an illustrative example.

ABSTRACT: Stiffened shells are very sensitive to initial imperfections, especially for geometrical imperfections. In this study, based on a 3-m-diameter orthogrid stiffened shell, post-buckling and imperfection sensitivity analyses are performed by use of explicit dynamic method. Result indicates that stiffened shell with outward hyperbolic generatrix shape shows a lower imperfection sensitivity as compared to the cylindrical one. Then, a framework of surrogate-based optimization including load-carrying capacity and imperfection sensitivity for stiffened shells is introduced, and the illustrative example demonstrates that the proposed framework has the potential to provide robust optimum design for realistic stiffened shells.

ABSTRACT: An optimization framework of determining the worst realistic imperfection was proposed by the present authors to study the reduction of the load-carrying capacity of unstiffened cylindrical shells. However, with regard to stiffened shells, especially when cutouts are included, the dimple combination pattern should be judged in a more rational manner. In this study, node coordinates are utilized to describe the position of each dimple-shape imperfection for Worst Multiple Perturbation Load Approach (WMPLA), which is an improvement of the MPLA using an optimization algorithm to find the application positions that will reduce the buckling load. Further, a novel method to determine the density of possible positions of dimple-shape imperfections is proposed based on eigenmode shape for stiffened shells without cutout. In addition, the effects of cutouts on the proposed method are investigated in detail. The effectiveness of the proposed method is demonstrated by comparison of several conventional methods to obtain improved knockdown factors (KDFs).

ABSTRACT: Axial compression of metallic and composite spherical shells, and aluminium conical frusta were performed under both quasi-static and dynamic loading conditions. Quasi-static tests were conducted on an INSTRON machine and the impact tests on the gravity drop hammer setup. Spherical shells of different radii and thicknesses, and frusta of different semi-apical angles and different slenderness ratios were tested to identify various failure modes and to study the energy absorption capacities. Analysis was carried out in each case and the results obtained have been compared with experiments. A comparative study of the results obtained from the quasi-static and impact tests is also presented. A brief description of the work done on spherical shells and conical frusta is given below.

SUMMARY: Occurrence of non-axisymmetric collapse modes in axial compression of thin tubes has been studied both experimentally and with the help of FE simulation. Variables considered are tube diameter to thickness ratio, annealing, variation in tube wall thickness, eccentricity, and boundary conditions. It is seen that amongst other factors, a certain combination of thickness eccentricity and unsymmetrical in plane end conditions favours formation of diamond mode.

ABSTRACT: The present paper deals with the experimental and computational study of axial collapse of the aluminum metallic shells having combined tube-frusta geometry between two parallel plates. Shells were having bottom two third lengths as frusta and remaining top one third lengths as tube. Shells were compressed to recognize their modes of collapse and associated energy absorption capability. An axisymmetric Finite Element computational model of collapse process is presented and analysed, using a non-linear FE code FORGE2. Six noded isoparametric triangular elements were used to discretize the deforming shell. The material of the shells was idealized as rigid visco-plastic. To validate the computational model experimental and computed results of the deformed shapes and their corresponding load-compression and energy-compression curves were compared. With the help of the obtained results progress of the axisymmetric mode of collapse has been presented, analysed and discussed.

ABSTRACT: Composite domes made of short, randomly oriented glass fiber mats with polyester resin were subjected to axial compression in an Instron machine, in both empty and foam filled conditions. The domes were of different sizes and their generator was a parabola. The mechanics of deformation and the energy absorbing characteristics of the shells were studied, and their load compression curves are presented. The effect of foam filling on the response of the domes is discussed. Based on the experimental observations analytical expressions were formulated to find the average crush load and total strain energy by considering the energy absorbed in different mechanisms involved in the crushing process. The results thus obtained were compared with experimental results and these match well. Some conical shells made of the same material, height and diameter as those of domes were also subjected to axial compression, and their behavior is compared with those of the corresponding domes.

ABSTRACT: The paper presents experimental and analytical studies on axial compression of aluminium spherical shells having Radius/wall thickness \((R/t)\) ratios between 23 and 135. Quasi-static compressive load was applied centrally and with offset through a indenter having diameter of 22 mm. Testing was carried out on an INSTRON machine having 250 T capacity. Shells having different radius and wall thickness were tested, to classify their modes of collapse and their corresponding energy absorption mechanism. In experiments shells of lower \(R/t\) values were found to collapse due to formation of an inward dimple associated with a rolling plastic hinge in central as well as in offset loading. On the other hand, shells of higher \(R/t\) values were collapsed initially with formation of an axisymmetric inward dimple, but in later stage of compression showed buckling of non-symmetric shape consisting of integral number of lobes and stationary plastic hinges. The stationary hinges were formed between consecutive lobes. Experimental observations are used to propose an analytical model for prediction of load–compression and energy–compression curves. The results obtained from analytical model compared with the experimental results and found match fairly well.

ABSTRACT: Composite materials present striking potentials to be tailored for advanced engineering applications. Thin walled composite panels are one of the most utilized structural elements in construction. The increasing use of the composites necessitates for the precise and viable methods of analysis- the life prediction being an important issue. The initiation and propagation of failure until final fracture of the structure assesses the life of the structure. Unnoticed internal failures may lead to fatal collapse, thus making first ply and progressive failure of much concern to researchers. This paper addresses the various literatures that have been published so far associated with the progressive failure of the composite laminated shells; also it reflects the five failure theories working behind. ABSTRACT: An experimental and numerical study of the buckling behavior of cantilevered shells with opening and stiffening is presented in this paper. Unlike previous experimental studies, the present work focuses on shell slenderness as well as opening and stiffening reflecting the main geometric characteristics of wind turbine towers. The specimens can be classified as medium slenderness shells affected mainly by inelastic effects and secondarily by geometric imperfections. Both load–displacement curves as well as strain measurements are presented and compared with numerical predictions by finite element analyses, accounting for both inelastic effects and geometrical nonlinearity as well as for contact interaction between the various parts of the specimens. A good agreement between numerical and experimental results was found in terms of load–displacement curves and ultimate load. Due to the influence of the shape and size of geometric imperfections, a complete match of the numerically obtained strains to the corresponding experimental ones was not possible. The provided stiffening was found to be able to compensate the strength loss due to the presence of the cut-out.

ABSTRACT: Objective of this paper is to compare linear buckling analysis formulations, available in commercial finite element programs. Modern steel design codes, including Eurocode 3, make abundant use of linear buckling loads for calculation of slenderness, and of linear buckling modes, used as shapes of imperfections for nonlinear analyses. Experience has shown that the buckling mode shapes and the magnitude of buckling loads may differ, sometimes significantly, from one algorithm to another. Thus, three characteristic examples have been used in order to assess the linear buckling formulations available in the finite element programs ADINA and ABAQUS. Useful conclusions are drawn for selecting the appropriate algorithm and the proper reference load in order to obtain either the classical linear buckling load or a good approximation of the actual geometrically nonlinear buckling load.

ABSTRACT: Surface wrinkling of a cylindrical shell supported by a soft core subjected to axial compression is investigated via combined experimental, computational and theoretical efforts. Our experiments show that the post-bifurcation deformation mode of the system is axisymmetric when the modulus ratio of the surface layer to the core is small while a non-axisymmetric wrinkling pattern appears when the modulus ratio is large. Our nonlinear finite element simulations have confirmed this experimental finding. A theoretical analysis based on Koiter’s elastic stability theory is carried out to reveal the mechanisms underpinning the phenomenon of morphological evolution. The critical buckling analysis shows that the first bifurcation mode is axisymmetric for arbitrary modulus ratios of the shell to the core. Post-bifurcation analysis reveals that the system will evolve into a diamond-like mode when the modulus ratio is large enough but keep the axisymmetric mode if the modulus ratio is smaller than a critical value. The results can guide the creation of controlled surface wrinkles on a cylindrical surface under compression. Besides, the analysis approach presented here may be adopted to understand the wrinkling patterns observed in some natural systems generated by, for instance, differential growth.

ABSTRACT: Buckling mode interaction of elastic systems in the presence of, thus obtaining results with questionable validity in the post-buckling range. In order to acquire additional insight into this issue, in the first part of the present paper, two different versions of the well-known 2-DOF Augusti model, whose independent buckling modes are both stable, are studied analytically without any simplifying assumptions with respect to the magnitude of deformation, in order to accurately demonstrate the coupling phenomena in the presence of imperfections in the pre- and post-buckling range. Depending on the nature of the structure’s rotational springs, its post-buckling equilibrium path may be either stable or unstable. Afterward, the elastic response of two examples of laced built-up columns is illustrated numerically, one characterized by interaction between in-plane global and local buckling and the other by in- and out-of-plane global buckling, featuring similar response to that of the two 2-DOF models, respectively, thus demonstrating occurrence of such behavior in actual structural systems.

ABSTRACT: An approximate analytical method for quantifying the lateral resistance offered by inclined cables to guyed towers, such as the pylons of cable-stayed bridges, is presented first. For this purpose, an analytical expression was derived for the evaluation of the pylon's effective buckling length. Taking into account the cables’ inclination and prestressing and approximating the nonlinearity caused by sag using Dischinger's formula, the cables were substituted by horizontal translational springs of equivalent stiffness. Then, an analytical solution of the linear buckling load of the equivalent spring model was obtained. The presented analytical method can be very useful at the preliminary design stage. Then, the approximate results were compared to the ones extracted from geometrically nonlinear finite element analysis with imperfections (GNIA) of both the more exact cable–pylon model and the spring–pylon model. The results show that the critical buckling load is predicted with very good accuracy for a wide range of values of cable inclination and pretensioning and indicate an unstable post-buckling behavior. In- and out-of-plane buckling of pylons with single or multiple levels of cables, in either a fan or a harp arrangement, with either a fixed or a hinged base, is addressed. A parametric analysis showed a strong imperfection sensitivity leading to significantly smaller ultimate loads of the imperfect structures compared to the linear buckling loads.

Stelios Vernardos and Charis Gantes, “Preliminary feasibility investigation of initial imperfections is well known to have a detrimental effect on the response of a wide range of structural systems. This has been demonstrated mostly analytically for simple models, assuming small displacements sandwich type shells for wind turbine towers”, 8th Hellenic National Conference on Steel Structures, Tripoli, Greece (year not given, probably 2015; abstract not given).

ABSTRACT: A methodology is presented on assessing the effectiveness of flexible joints in mitigating the consequences of faulting on buried steel pipelines through a comprehensive analysis that incorporates the uncertainty of fault displacement magnitude and the response of the pipeline itself. The proposed methodology is a two-step process. In the first step the probabilistic nature of the fault displacement magnitude is evaluated by applying the Probabilistic Fault Displacement Hazard Analysis, considering also all pertinent uncertainties. The second step is the “transition” from seismological data to the pipeline structural response through the fault displacement components as the adopted vector intensity measure. To mitigate the consequences of faulting on pipelines, flexible joints between pipeline parts are proposed as innovative measure for reducing the deformation of pipeline walls. Thus, the mechanical behavior of continuous pipelines and pipelines with flexible joints is numerically assessed and strains are extracted in order to develop the corresponding strain hazard curves. The latter are a useful engineering tool for pipeline – fault crossing risk assessment and for the effectiveness evaluation of flexible joints as innovative mitigating measures against the consequences of faulting on pipelines.

ABSTRACT: The effectiveness of the numerical methods GMNIA and MNA/LBA proposed in EN1993-1.6 for the design of steel shells is studied for cylindrical steel shells with an unreinforced or reinforced rectangular cutout chamfered elliptically at the four ends and for the corresponding shells without cutout. Moreover, another design method proposed in the literature and denoted here as MNA/GNA, which is based on a modified slenderness, is also evaluated. GMNIA is considered as the most reliable analysis type, provided that a judicious choice of shape and amplitude of initial imperfections is made. Thus, GMNIA results are used as basis for comparison, except for shells without cutout where the EN1993-1.6 normative strengths could serve the same purpose as well. For shells without cutout it is found that the modified slenderness gives similar results to the corresponding results of the conventional slenderness definition. In the case of unreinforced cutout the modified slenderness gives better results, thus the use of MNA/GNA is recommended. However, in the case of reinforced cutout the GMNIA results are approximated better by employing the conventional slenderness, thus MNA/LBA is more appropriate.

ABSTRACT: An analytical solution is presented to predict the mean axial collapse forces of fiber reinforced conical shells under thermal loading, in which the fibers wrapped orientation is arbitrary; Analytical method and finite element simulate; The influences of thermal loading, fibers wrapped orientations, geometrical eccentricity factor and proportionality coefficient on the axial collapse force of fiber reinforced conical shells are given. The collapse loading Pm of fiber-reinforced conical shells appears in the maximum value under different thermal environment when the fibers wrapped direction equals 45°. By optimizing the wrapping orientation of fiber layers, the capability of energy absorption of fiber-reinforced conical shells can be enhanced.

ABSTRACT: We consider the point indentation of a pressurized, spherical elastic shell. Previously it was shown that such shells wrinkle once the indentation reaches a threshold value. Here, we study the behaviour of
this system beyond the onset of instability. We show that rather than simply approaching the classical “mirror-buckled” shape, the wrinkled shell approaches a new, universal shape that reflects a nontrivial type of isometry. For a given indentation depth, this “asymptotic isometry”, which is only made possible by wrinkling, is reached in the doubly asymptotic limit of weak pressure and vanishing shell thickness.

ABSTRACT: A simple and effective in situ method for strengthening or healing thin-wall structures is presented. In this method, a liquid-state gap-sealing foam is injected within the enclosed spaces of a structure.
After injection it expands to fill and pressurize the cavities, then solidifies in few hours. The stiff pressurized foam enhances load carrying capacity both by supporting part of the load, and by retarding the buckling of thin-wall structural components. A simple demonstration of the proposed technique is provided by load-testing thin-wall beverage cans, and also both intact and damaged aluminum honeycomb, filled with commercially available gap-sealing polyurethane foam. By adding foam, the structures’ peak load and energy absorption were significantly enhanced. The injected foam partially restored the original undeformed shape during unloading, highlighting the potential advantage to apply this method for multiple-use energy absorbing components.

ABSTRACT: We present a straightforward method for fabricating nanochannels that exploits a type of thin film instability called folding, which emerges during post-instability evolution of surface wrinkles. In our experiments, a flat PDMS substrate was uniaxially stretched and treated with oxygen plasma for varying durations, resulting in formation of a stiff-oxidized skin of varying thickness on the surface. Thereafter, the stretch was released to induce a compressive strain, defined as the change in length per unit of the initial length of the substrate, in the skin. At small strain levels, wrinkles appeared on the substrate surface, forming open channels with a specific wavelength and amplitude. Further increase in the strain level triggered the transition from wrinkles to folds, creating well-defined closed channels with a diameter in the nanoscale range. The characteristic dimensions of the channels such as wavelength, amplitude, and diameter were robustly tunable by changing the duration of oxygen plasma treatment and strain level. Furthermore, the configuration of the channels was switchable from open to closed and vice versa by controlling the strain level.

ABSTRACT: A hierarchical modeling of planar steel frames that is based on a weak coupling of shell and beam computational models is studied in detail. A shell finite element is used to compute failure response of a representative part of each column and each beam of a frame under consideration; elasto-plasticity, geometrical nonlinearity and material softening (along with a localization limiter) are taken into account. The computed results, which naturally include local buckling and/or localized material failure effects, are further incorporated into a beam inelastic stress-resultant constitutive model; the embedded-discontinuity-in-rotation Euler-Bernoulli finite element is considered in this work. The designed beam finite element formulation can be effectively used for the failure analysis of the steel frame. Important issues of such weak coupling concept are presented and results of several numerical simulations are discussed. A concept for analysis of steel frames, which couples shell and beam models, has been studied. The resulting steel frame analysis takes into account local buckling and localized material failure. The concept has large potential for practical applications.

ABSTRACT: Nonlinear finite element (FE) collapse pressure predictions are compared to experimental results for submarine pressure hull test specimens with and without artificial corrosion and tested to collapse under external hydrostatic pressure. The accuracy of FE models, and their sensitivity to modeling and solution procedures, are investigated by comparing FE simulations of the experiments using two different model generators and three solvers. The standard FE methodology includes the use of quadrilateral shell elements, nonlinear mapping of measured geometric imperfections, and quasi-static incremental analyses including nonlinear material and geometry. The FE models are found to be accurate to approximately 11%, with 95% confidence, regardless of the model generator and solver that is used. Collapse pressure predictions for identical FE models obtained using each of the three solvers agree within 2.8%, indicating that the choice of FE solver does not significantly affect the predicted collapse pressure. The FE predictions are found to be more accurate for corroded than for undamaged models, and neglecting the shell eccentricity that arises due to one-sided shell thinning is found to significantly decrease the resulting accuracy of the FE model.

ABSTRACT: The subject of the numerical investigation is an ellipsoidal head with a central (axis-symmetrical) nozzle. The nozzle is loaded by axial load force. The ellipsoidal head is under axial-symmetrical compression load. The numerical FEM model is elaborated. The calculation will provide the critical loads and equilibrium paths for the sample head. The investigation will measure the influence of the diameter of the nozzle on the critical state of the ellipsoidal head.

ABSTRACT: We have developed a facile procedure that can create asymmetrical building blocks by uniformly deforming nanospheres into $C_{\infty v}$ symmetry at low cost and high quality. Concave polystyrene-carbon (PS-C) core–shell nanospheres were produced by a very simple microwave-assisted alcohol thermal treatment of spherical PS-C nanoparticles. The dimensions and ratio of the concave part can be precisely controlled by temperature and solvents. The concavity is created by varying the alcohol-thermal treatment to tune the swelling properties that lead to the mechanical deformation of the PS-C core–shell structure. The driving force is attributed to the significant volume increase that occurs upon polystyrene core swelling with the incorporation of solvent. We propose a mechanism adapted from published models for the depression of soft capsules. An extrapolation from this model predicts that the rigid shell is used to generate a cavity in the unbuckled shell, which is experimentally confirmed. This swelling and deformation route is flexible and should be applicable to other polymeric nanoparticles to produce asymmetrical nanoparticles.

Konstantinos Tsavdaridis and Christopher Pilbin (School of Civil Engineering, University of Leeds), “Finite Element modelling of steel connections with web openings: Aseismic design and avoidance of progressive collapse”, The 7th European Conference on Steel and Composite Structures, Napoli, Italy, September 2014
PARTIAL INTRODUCTION: Events of extreme loading on structures such as the 1994 Northridge, California earthquake and the 2001 attack on the World Trade Centres, New York have not only lead to loss of life but highlighted structural deficiencies and lack of existing knowledge of the progressive collapse behaviour. As a result, Governmental bodies such as the GSA [1] and DoD [2] have established design codes and guidelines to reduce the possibility of progressive collapse through the promotion of redundancy, ductility and continuity in structural systems. The design codes do not provide guidelines for the complete prevention of progressive collapse but rather mitigate a ‘disproportionate’ area of collapse. In collapse scenarios, following the removal of a load bearing column, the ability for the beams and columns to develop catenary action is essential for the structure to resist further collapse. Beam-to-column connections should provide sufficient ductility to sustain large rotations and allow structural members to carry loads in tension. . . . In order to enhance the ductility of post Northridge connections, researchers suggested the weakening of the beam to shift the stresses away from the column’s face. One method to achieve this is by removing portions of the flanges or the web weakening the beam locally, referred to as Reduced Beam Section (RBS) and Reduced Web Section (RWS), respectively. . . . ABSTRACT: Liquid storage steel tanks are vertical above-ground cylindrical shells and as typical thin-walled structures, they are very sensitive to buckling under wind loads, especially when they are empty or at low liquid level. Previous studies revealed discrepancies in buckling resistance of empty tanks between the design method proposed by the American Standard API 650 and the analytical formulas recommended by the European Standard EN1993-1-6 and EN1993-4-2. This study presents a comparison between the provisions of current design codes by performing all types of numerical buckling analyses recommended by Eurocodes (i.e. LBA-linear elastic bifurcation analysis, GNA-geometrically nonlinear elastic analysis of the perfect tank and GNIA-geometrically nonlinear elastic analysis of the imperfect tank). Such analyses are performed in order to evaluate the buckling resistance of two existing thin-walled steel tanks, with large diameters and variable wall thickness. In addition, a discussion is unfolded about the differences between computational and analytical methods and the conservatism that the latter method imposes. An influence study on the geometric imperfections and the boundary conditions is also conducted. Investigation on the boundary conditions at the foot of the tank highlights the sensitivity to the fixation of the vertical translational degree of freedom. Further, it is indicated that the imperfection magnitude recommended by the EN1993-1-6 is extremely unfavorable when applied to large diameter tanks. Comments and conclusions achieved could be helpful in order to evaluate the safety of the current design codes and shed more light towards the most accurate one.

ABSTRACT: Stiffened shells are affected by numerous uncertainty factors, such as the variations of manufacturing tolerance, material properties and environment aspects, etc. Due to the expensive experimental cost of stiffened shell, only a limited quantity of statistics about its uncertainty factors are available. In this case, an unjustified assumption of probabilistic model may result in misleading outcomes of reliability-based design optimization (RBDO), and the non-probabilistic convex method is a promising alternative. In this study, a hybrid non-probabilistic convex method based on single-ellipsoid convex model is proposed to minimize the weight of stiffened shells with uncertain-but-bounded variations, where the adaptive chaos control (ACC) method is applied to ensure the robustness of search process of single-ellipsoid convex model, and the particle swarm optimization (PSO) algorithm together with smeared stiffener model are utilized to guarantee the global optimum design. A 3 m-diameter benchmark example illustrates the advantage of the proposed method over RBDO and deterministic optimum methods for stiffened shell with uncertain-but-bounded variations.

“Nonlinear contact between inner walls of deep sea pipelines in buckling process”, J. Ocean Univ. China

ABSTRACT: In order to study buckling propagation mechanism in deep sea pipelines, the contact between pipeline’s inner walls in buckling process was studied. A two-dimensional ring model was used to represent the pipeline and a nonlinear spring model was adopted to simulate the contact between inner walls. Based on the elastoplastic constitutive relationship and the principle of virtual work theory, the coupling effect of pipeline’s nonlinear large deformation and wall contact was included in the theoretical analysis with the aid of MATLAB, and the application scope of the theoretical model was also discussed. The calculated results show that during the loading process, the change in external pressure is closely related to the distribution of section stress, and once the walls are contacting each other, the external pressure increases and then remains stable after it reaches a specific value. Without fracture, the pipeline section will stop showing deformation. The results of theoretical calculations agree well with those of numerical simulations. Finally, in order to ensure reliability and accuracy of the theoretical results, the collapse pressure and propagation pressure were both verified by numerical simulations and experiments. Therefore, the theoretical model can be used to analyze pipeline’s buckling deformation and contact between pipeline’s inner walls, which forms the basis for further research on three-dimensional buckling propagation.

ABSTRACT: Imperfection sensitivity of cylindrical shells subjected to axial compressive load is investigated by means of nonlinear buckling analysis and post-buckling analysis. Nonlinear buckling analysis involves the determination of the equilibrium path (or load-deflection curve) up to the limit point load by using the Newton-Raphson approach, whereas post-buckling analysis involves the determination of the equilibrium path beyond the limit point and up to the collapse load by using the arc-length approach. Limit point loads evaluated from these two approaches for various imperfection magnitudes show an excellent agreement, which clearly confirms the numerical results obtained. Finally, the influence of L/D and R/t ratios on post-buckling behavior of isotropic and composite cylindrical shells is briefly highlighted.

“Apparent strain of a pipe at plastic bending buckling state”, Journal of the Brazilian Society of Mechanical Sciences and Engineering, Vol. 37, No. 6, pp 1811-1818, November 2015
ABSTRACT: An expression for apparent strain of a pipe at plastic bending buckling status is proposed in the present paper. The material of the pipe is considered as a rigid-perfectly plastic one, and the cross section of the pipe during the pipe-bending process assumes to be elliptic gradually. The energy rate for the pure bending of the elliptic pipe is proposed firstly, and the energy rate of cross-sectional ovalizing of the pipe is derived
afterward. Furthermore, both the energy rates are combined to analyze the pipe bending buckling. As a result, an apparent strain expression of a pipe at the plastic bending buckling status is proposed. The predicted result of the new strain expression of pipe bending at buckling status is compared with the available test data and shows that the new formula is reasonable.

ABSTRACT: A parametric study on circular thin-walled pipes subjected to pure bending is performed. Both straight and curved pipes are considered. Ratio D/t, initial pipe curvature and internal pressure are the parameters varying in the analyses. The study is mainly FEA-based. It is found that negative curvatures (opposite to bending moment) considerably increase stiffness and buckling limit of the pipe when no internal pressure is acting and, similarly, positive curvatures decrease the stiffness and buckling limit. For internal pressurised pipes the effects of initial pipe curvature are less relevant. Results show that this phenomenon is in relationship with the cross-section deformation due to bending moment, which undergoes relevant ovalisation for no pressurised pipes and little ovalisation for pressurised pipes.

ABSTRACT: This paper presents results from a recent combined experimental-analytical study of the inelastic response and the sequence of events that lead to collapse of pipes bent under internal pressure. Experimental results from stainless steel 321 seamless tubes with D/t of 52 are reported. The tubes were loaded by pure bending at fixed values of pressure ranging from zero to a value that corresponds to 0.75 times the yield pressure. The moment-curvature response is governed by the inelastic characteristics of the material. Bending induces some ovalization to the tube cross section while, simultaneously, the internal pressure causes the circumference to grow. Following some inelastic deformation, small amplitude axial wrinkles appear on the compressed side of the tube, and their amplitude grows stably as bending progresses. Eventually, wrinkling localizes, causing catastrophic failure in the form of an outward bulge. Pressure increases the wavelength of the wrinkles as well as the curvature at collapse. The onset of wrinkling is established by a custom bifurcation buckling formulation. The evolution of wrinkling and its eventual localization are simulated using a FE shell model. The material is represented as an anisotropic elastic-plastic solid using the flow theory, while the models are assigned initial geometric imperfections that correspond to the wrinkling bifurcation mode. It will be shown
that all aspects of the observed behavior including the failure by localized bulging can be successful reproduced by the models developed.

ABSTRACT: This paper deals with the combined effect of pressure and geometric imperfection on buckling of stressed thin films on a semi-infinite rigid substrate. Analytical approximate solutions are proposed by using the total potential energy of the system and the Rayleigh–Ritz’s method, and their stabilities are also determined. The present analytical approximate solutions agree very well with the numerical solutions obtained via the improved shooting method. The effect of pressure mismatch together with imperfection on the critical stress (above which the film buckles) and on the film-center deflection is characterized. It is found that, compared with the classical case of the Euler column buckling, the equilibrium solutions and critical stress of the film are strongly dependent on the linear combination of the pressure mismatch and imperfection amplitude.

ABSTRACT: This paper investigates the delamination buckling of an orthotropic film with compressive prestress bonded to an orthotropic substrate. The buckled film detached from the film/substrate structure is solved in the closed form except for the resultant force and bending moment at the ends of the buckled film, which are obtained by matching the solutions for the buckled film and the film/substrate structure in which the buckled part of the film is removed. Special attention is paid to the effects of parameters of orthotropic materials on delamination buckling based on a numerical analysis. The energy release rate and mode mixity induced by buckling are evaluated, and the growth and arrest of the interface crack under mixed loading induced by buckling are discussed based on the energy criterion.

Bahramibabamiri (Department of Mechanical Engineering, Malayer University, Malayer, Iran), “The effect of different geometrical imperfection of buckling of composite cylindrical shells subjected to axial loading”, International Journal of Mechanical and Materials Engineering, Vol. 10, No. 6, December 2015

ABSTRACT: The effects of geometric properties, lamina lay-up, amplitudes of imperfection and parametric research of the shape (square, circular) and the dimensions (axial and circumferential sizes, diameter) of the opening on the strength of the cylinders under compression were studied. The measurement of imperfections on the cylindrical surface is achieved using the interpolation method and Fourier series. The analysis indicates that the critical load is sensitive to the circumferential size of the opening. The function (critical load-circumferential size of the opening) is linear for large openings and independent of the geometrical imperfections of the shell. However, for small openings, it is necessary to take into account the coupling between the initial geometrical imperfections and the openings. The linear approach does not fit due to the importance of the evolution of the displacements near the openings. Also, it was shown that the buckling behaviour of thin composite cylindrical shells can be evaluated accurately via modelling to determine the imperfections and the material properties in FEM.

Dynamic buckling response of long plates for the prediction of local plate buckling of corrugated core sandwich columns”, Journal of Applied Mechanics, Vol. 82, No. 11, 111008, September 2015 (12 pages)

ABSTRACT: An analytical model predicting the dynamic local buckling failure of plates with a large dimension in the longitudinal direction compressed at a constant rate was proposed. The model began with the hypothesis that the proposed analytical approach could be an alternative methodology to approximate the dynamic local plate buckling response of constituent plates of corrugated core sandwich columns. Prior to the model development, four preliminary finite-element (FE) simulations were conducted to observe the typical dynamic response of the sandwich columns having thin core web plates or thin face sheets. From the simulations, several wrinkles with a regular pattern were generated, and then one of the wrinkles grew excessively to a failure. Accordingly, the proposed model considered an imaginary patch plate on a long plate

“Spiral welded tubes – imperfections, residual stresses, and buckling characteristics”, Eighth International Conference on Advances in Steel Structures, Lisbon, Portugal, July 22-24, 2015

ABSTRACT: Spiral Welded Tubes (SWTs) are manufactured from steel coil, which is de-coiled and levelled by using cold rolling. The edges of the plate material are bevelled and set for welding containing preheating, if required. The coil is then cold formed into a spiral with a series of rollers and welded into a continuous tube. The rolling equipment applies a significant force to the plate material during production that can increase geometric imperfections in the tube wall. At the spiral welds a high or low imperfection can exist and weld shrinkage could cause local imperfections. Internal residual stresses are the main drawback of SWTs compared with longitudinally welded tubes (LWTs). SWTs offer cost benefits when compared with other types of tubes and they have successfully been used for low-pressure applications, water supply, and structural components. The aim of this paper is to investigate the imperfections, residual stresses, and buckling characteristics of SWTs in comparison with LWTs.

ABSTRACT: This study examines the buckling of a single strip of material, modeled as a two-dimensional (2D) micropolar solid. The effects of material microstructure are incorporated by modeling the material using micropolar theory. By setting the micropolar constants to zero, the equations of classical elasticity are obtained and these results are compared to the buckling analysis performed by previous authors on elastic materials. In the limiting case, when the thickness of the strip becomes small in comparison to the overall length, the micropolar beam equations are developed. Because buckling analysis requires the consideration of geometric nonlinearity, nonlinear micropolar equations are derived using a variational procedure, which also results in variationally consistent boundary conditions. Due to the complexity of micropolar theory, its application has been limited to linear analysis with a few exceptions.

ABSTRACT: The high-polymeric degree or molecular-weight of self-made polyethoxydisiloxane (PEDS) was successfully used to synthesize aerogels with several advantageous mechanical characteristics, compared with those based on conventional tetraethylorthosilicate (TEOS) aerogel preparation methods. The first advantage is their lower initial values of bulk modulus (K0), compared with those prepared via the two-step method; this is due to release of internal stress during the shrinkage of wet gel. Secondly, a collapse index n of -0.125 is obtained by the collapse law; this implies a new buckling destruction model. This is different from those prepared via the two-step method, and suggests that a hierarchical filament structure, formed by the connection of nano-particles, constitutes the solid skeleton of pores. In this paper, average aerogel pore sizes between 16.0 and 39.3 nm are analyzed by the combination of Mercury Intrusion Porosimetry (MIP) and Nitrogen Adsorption–Desorption (NAD). The microstructure and morphology of the aerogels are demonstrated by Transmission Electron Microscopy (TEM) and Field Emission Scan Electron Microscopy (FE-SEM).
M. Mohammadi and M. Fooladi Mahani (Department of Mechanical Engineering, Shahid Bahonar University of Kerman, Kerman, Iran), “An analytical solution for buckling analysis of size-dependent rectangular micro-plates according to the modified strain gradient and couple stress theories”, Acta Mechanica, Vol. 226, No. 10, pp 3477–3493, October 2015

ABSTRACT: In this study, a size-dependent Kirchhoff plate model is developed for determining the critical buckling loads of rectangular micro-plates. Modified strain gradient theory with three length scale parameters is used. It should be noted that this theory is reduced to modified couple stress theory by setting two length scale parameters to zero. Using the variational approach and the principle of minimum total potential energy, the nonlinear form of the governing equations and all possible boundary conditions are determined. It is assumed that the micro-plate is simply supported on two opposite edges. The stability equations are solved analytically, and the critical buckling loads are obtained based on the modified strain gradient and modified couple stress theories. Also, the effects of length scale parameters, dimensions and loading states on the buckling loads are investigated in detail.

References listed at the end of the paper:

ABSTRACT: In this article, an analytical method for buckling analysis of thin functionally graded (FG) rectangular plates is presented. It is assumed that the material properties of the plate vary through the thickness of the plate as a power function. Based on the classical plate theory (Kirchhoff theory), the governing equations are obtained for functionally graded rectangular plates using the principle of minimum total potential energy. The resulting equations are decoupled and solved for rectangular plate with different loading conditions. It is assumed that the plate is simply supported along two opposite edges and has arbitrary boundary conditions along the other edges. The critical buckling loads are presented for a rectangular plate with different boundary conditions, various powers of FGM and some aspect ratios.

“Buckling analysis of orthotropic rectangular plate resting on Pasternak elastic foundation under biaxial in-plane loading”, Mechanics of Advanced Materials and Structures, DOI: 10.1080/15376494.2015.1059528
ABSTRACT: In this study, buckling of rectangular orthotropic plates resting on Pasternak elastic foundation under biaxial in-plane loading by the power series method (the method of Frobenius) was analyzed. Similar to many studies, two opposite edges of loading is simply supported and two other edges is assumed clamped. In order to extract the characteristic equations of orthotropic rectangular plate under in-plane loading resting on a pasternak elastic foundation, the classical plate theory by considering the interaction between plate and foundation is used. The results showed that in the aspect ratio of less than 2, existing Pasternak foundation caused to increase the buckling load severely, but by increasing the aspect ratio, the effect of foundation is negligible. Applying the in-plane load in the y-direction caused to decrease the buckling load, but by increasing the aspect ratios the effect of the load is negligible.

Marcos A. Reyes-Martinez, Alfred J. Crosby and Alejandro L. Briseno (Polymer Science and Engineering, University of Massachusetts, Amherst, Massachusetts, USA), “Rubrene crystal field-effect mobility modulation via conducting channel wrinkling”, Nature Communications, Vol. 6, Article No. 7948, May 2015, DOI: 10.1038/ncomms7948
ABSTRACT: With the impending surge of flexible organic electronic technologies, it has become essential to understand how mechanical deformation affects the electrical performance of organic thin-film devices. Organic single crystals are ideal for the systematic study of strain effects on electrical properties without being concerned about grain boundaries and other defects. Here we investigate how the deformation affects the field-effect mobility of single crystals of the benchmark semiconductor rubrene. The wrinkling instability is used to apply local strains of different magnitudes along the conducting channel in field-effect transistors. We discover that the mobility changes as dictated by the net strain at the dielectric/semiconductor interface. We propose a model based on the plate bending theory to quantify the net strain in wrinkled transistors and predict the change in mobility. These contributions represent a significant step forward in structure–function relationships in organic semiconductors, critical for the development of the next generation of flexible electronic devices.

“Buckling behavior of bidirectional composite flat panels with delamination in hygrothermal field”, Acta
ABSTRACT: Hygrothermal influence on the buckling behavior of bidirectional glass/epoxy composite panels
having delaminations was studied numerically and verified by conducting several experiments. First-order shear
deformation theory was used to develop a finite element model for numerical predictions with an 8-noded
quadratic isoparametric element that takes care of the effects of delamination area and hygrothermal conditions
of composite panels. Verification of results of the numerical analysis was done by conducting several
experiments showing the effects of various parameters like temperature, moisture, area of delaminations,
orientations of fibers, stacking sequence and boundary conditions on the buckling characteristics of
bidirectional glass/epoxy composite panels. Experimental buckling loads were calculated using an INSTRON
8862 universal testing machine for hygrothermally treated composite panels having delaminations. It was
observed that there is a good comparison of predicted and experimental buckling loads. The effects of various
parameters on the buckling behavior of composite panels are presented. The buckling results can be utilized as a
tool for detection of delamination damage in composite plates subjected to hygrothermal environment.

ABSTRACT: In industrial applications structural efficiency is primary concern, this brings about the need of strong and lightweight materials. Due to their high specific strength, fibre reinforced polymers find wide application in these areas. Panels made of composite materials are widely used in aerospace structures.
automobile, civil, marine and biomedical industries because of their good mechanical properties, impact resistance, excellent damage tolerance and also low fabrication cost. In this Paper, buckling and post-buckling analysis was performed on composite stiffened panel to obtain the critical load and modes of failures, with different parameters like ply-orientation, different composite materials, and stiffeners and by changing the number of stiffeners was derived. To analyze the post buckling behaviour of composite stiffened panels the nonlinear finite element analysis is employed and substantial investigations are undertaken using finite element (FE) model. Effect of critical parameters on buckling behaviour is studied and parametric studies were conducted with analytical tool to understand the structural behaviour in the post buckling range.

ABSTRACT: This paper models the effect of material parameter randomness on the initial buckling load of rectangular, specially orthotropic, composite laminates. The basic formulation for stability analysis is based on classical laminate theory. A perturbation technique is used to obtain the solution of the governing equation. The effects of aspect ratio and change in standard deviation of the input parameters have been investigated for several laminate configurations. The solution has also been checked with the help of Monte Carlo simulation.

ABSTRACT: Carbon nanotube (CNT) arrays have shown the remarkable ability to react as foam-like structures and exhibit localized buckling coordinated within specific regions. Here, we report on the low-cycle compression of bulk vertically aligned CNT arrays to observe initiation and growth of the buckling as a function of compressive strain. A critical strain is found above which the buckling region length increased and below which it remained at or below the applied strain. As previously observed, the buckling region of the CNT array propagates from the surface where growth occurred, which, in the test specimen, is a free surface and later receives compressive contact by a polished silicon substrate. The results are corroborated with nanoindentation on the surfaces, which indicate a stiffening of the near surface with increasing applied strain. Observation and results of the buckling region nature are important for applications of nanotube arrays as energy absorbing cushions, tunable dampers, thermal contacts, or in sliding contact.

ABSTRACT: The local buckling behavior of vertically aligned carbon nanotubes (VACNTs) has been investigated and interpreted in the view of a collective nanotube response by taking van der Waals interactions into account. To the best of our knowledge, this is the first report on the case of collective VACNT behavior regarding van der Waals force among nanotubes as a lateral support effect during the buckling process.
local buckling propagation and development of VACNTs were experimentally observed and theoretically analyzed by employing finite element modeling with lateral support from van der Waals interactions among nanotubes. Both experimental and theoretical analyses show that VACNTs buckled in the bottom region with many short waves and almost identical wavelengths, indicating a high mode buckling. Furthermore, the propagation and development mechanism of buckling waves follow the wave damping effect.

ABSTRACT: In many engineering structures different energy absorption systems may be used to improve crashworthiness capability of the system and to control damages that may occur in a system during an accident. Therefore, extensive research has been done on the energy-absorbing cells. In this paper, energy absorption in tapered thick walled tubes has been investigated. As a practical case, studies have been focused on the crush element of Siemens ER24PC locomotive. To investigate performance of this part at collision time, it has been modeled in Abaqus software and its collision characteristics have been evaluated. Considering that the crash element is folded at time of collision, an analytical approach has been presented for calculation of instantaneous folding force under axial load. Basis of this method is definition and analysis of main folding mechanism and calculation of average folding force. This method has been used for validation of the results of numerical solution. Since sheet thickness of the crash element is high and may be ruptured at time of collision, some damage models have been used for numerical simulations. One of the three damage models used in this paper is available in the software and coding has been done for two other damage models and desirable damage model has been specified by comparing results of numerical solution with results of laboratory test. In addition, authenticity of the desirable damage model has been studied through ECE R 66 standard. To improve crashworthiness characteristic some attempts, such as use of metal foam and creation of trigger in suitable situations to reduce maximum force resulting from collision, have been performed. Finally though different simulation optimal crush element has been introduced and its performance and efficiency have been evaluated.

ABSTRACT: The buckling of hybrid boron nitride–carbon nanotubes (BN–CNTs) with various BN compositions and locations of the BN domain is investigated using molecular dynamics. We find that BN–CNTs with large BN composition (>38%) only undergo local shell-like buckling in their BN domain. Although similar local shell-like buckling can occur in BN–CNTs with a relatively small BN composition, it can transfer to the global column-like buckling of the whole BN–CNT with increasing strains. The critical strains for local shell-like and global column-like buckling decrease with increasing BN composition. In addition, critical strains and buckling modes of the global column-like buckling of BN–CNTs also strongly depend on the location of their BN domain. As a possible application of the buckling of BN–CNTs, we demonstrate that the BN–CNT can serve as a water channel integrated with a local natural valve using the local buckling of its BN domain.

ABSTRACT: When a flexible pipe is subjected to high external hydraulic pressure, the innermost carcass layer serves to resist buckling and collapse. The maximum external pressure that the carcass layer can withstand before buckling collapse must be considered during pipe design. To study this problem, a strain energy equivalence method is proposed to transform a representative volume element (RVE) of the carcass layer, which has a complex geometry, into a homogeneous shell with an equivalent thickness. To obtain the strain energy, a finite element model of the RVE is developed, and the analytical equations for the homogeneous shell are derived for the same uniform-strain boundary conditions. Radial compression tests on three different carcass layer test pieces are performed to verify the safety and effectiveness of the proposed equivalence method. The strain energy equivalence method is found to give conservative results when compared to other equivalence approaches. The advantages of the method for designing a collapse-resistant carcass layer in engineering practice are also discussed.

ABSTRACT: Bases of asymptotic theory of beams, plates and shells are stated. The comparison with classic theory is conducted. New classes of thin bodies problems, for which hypotheses of classic theory are not applicable, are considered. By the asymptotic method effective solutions of these problems are obtained. The effectiveness of the asymptotic method for finding solutions of as static, as well as dynamic problems of beams, plates and shells is shown.

Under increasing compression, an unbuckled shell is in a metastable state which becomes increasingly precarious as the buckling load is approached. So to induce premature buckling a lateral disturbance will have to overcome a decreasing energy barrier which reaches zero at buckling. Two archetypal problems that exhibit a severe form of this behaviour are the axially-compressed cylindrical shell and the externally pressurized spherical shell. Focussing on the cylinder, a non-destructive technique was recently proposed to estimate the ‘shock sensitivity’ of a laboratory specimen using a lateral probe to measure the nonlinear load-deflection characteristic. If a symmetry-breaking bifurcation is encountered on the path, computer simulations showed how this can be suppressed by a controlled secondary probe. Here, we extend our understanding by assessing in general terms how a single control can capture remote saddle solutions: in particular how a symmetric probe could locate an asymmetric solution. Then, more specifically, we analyse the spherical shell with point and ring probes, to test the procedure under challenging conditions to assess its range of applicability. Rather than a bifurcation, the spherical shell offers the challenge of a de-stabilizing fold (limit point) under the rigid control of the probe.

ABSTRACT: Two buckling modes (out-of-surface and in-surface buckling) of micro/nanowires on elastomeric substrates are observed. Here, theoretical analysis and numerical simulations are presented to discover the critical factors that govern the competition between the two buckling modes. The aim is to fabricate buckled structures in selectable manner, instead of studying the buckling behavior of each individual buckling mode. The result shows the material properties have large influence on the critical buckling strain, but no significant influence on buckling competition behavior, the buckling mode is mainly determined by the micro/nanowires cross-section morphology. For cross-sections with equal moment of inertia in in-surface and normal-to-surface directions, in-surface buckling is always favorable. However, micro/nanowires with unequal moment of inertia,
e.g. ellipse, rectangle and trapezoid, are usually fabricated in practical micro/nanofabrication such as through electrospinning and etching, and their influence on buckling modes is investigated.

“The influence of imperfections and nonlinearities on the failure and B2 stress index of thin-walled pipes”,
Journal of Pressure Vessel Technology, Vol. 137, No. 6, December 2015
ABSTRACT: The effects of imperfections and nonlinearities on the failure mode and the B2 stress index of thin-walled straight pipes are investigated with finite element (FE) analyses. The analyses were performed for pipes made of an ideal elastic–plastic material and the austenitic steel X6CrNiNb18-10. The B2 index is calculated from the instability bending moments obtained by limit load analyses. The effects of initial imperfections as well as the D/t-ratio and the yield stress on the B2 stress index are studied. As a first result, it is noted that thin-walled straight pipes and imperfections fail due to local plastic buckling. Further analyses show that the type of imperfections, the ovality, the D/t-ratio, and the yield stress have significant influences on the B2 index. The obtained B2 indices for thin-walled straight pipes with D/t > 40 and possible technical imperfections are considerably higher than 1.0. The results have been compared with those of other investigations.

ABSTRACT: Most common studies on the strength of plates under compressive longitudinal loading are related to plates having unrestrained edges which lead to a zero net load in the transverse direction. In ships, the framing system and the continuity of the plating in the transverse direction tend to induce rather different boundary conditions on the “unloaded” edges, which results in a completely different state of stresses when the external loads are applied. This is due to the surge of a significant level of induced membrane stresses in the direction perpendicular to loading. In this work, the behavior of long restrained plates under compressive axial loading is analyzed and compared with the one of plates having other boundary conditions. The finite element method is applied for the nonlinear analysis of the plates using a commercial package. Fifty-six cases are considered corresponding to different levels of plate slenderness which ranges between 0.35 and 3.46 covering the practical range of structural plates used in the shipbuilding industry. Various shapes of initial imperfections are considered in order to establish the minimum level of resistance. Also, the influence of the magnitude of the distortions associated to each mode is discussed. The study conducted to the establishment of the minimum compressive strength of restrained plates and it defines the expected range of strength’s variation due to the magnitude level of distortions. The biaxial state of stresses resulting from these boundary conditions is characterized and its dependence from the plate’s slenderness is quantified for the most common type of the hull plating.

“Analytical solution for the axisymmetric buckling of cylindrical shells”, International Journal of Mechanics
ABSTRACT: Closed-form analytical solutions for thin shell buckling problem are useful in a wide range of analysis and design problems. In this paper, the profile of a cylindrical shell in the post-buckling regime of axisymmetric deformation is analysed, and the solution is shown to be a Jacobi elliptic sine function, for any load and axial deformation. The exact solution of the non-linear differential equation for the thin elastic shell profile holds for any deformation, up to the limit in which the shell is almost flattened by the applied load. Closed-form expressions are derived also for the load dependent axial deflection and stored energy. The analytical solution of the buckling loads and deformed profile are found to agree well with an equivalent numerical solution. Results show that an axially compressed cylindrical shell exhibits ideal behaviour for a safety shock energy absorber.

ABSTRACT: Geometrically nonlinear FEM analysis of multilayered composite plates and shells is performed in order to resolve the stability problem of the structures being under the influence of temperature field. The Riks-Wempner-Ramm algorithm with a specially modified multi-choice unloading condition has been implemented in authors’ numerical code. As the representation of multilayered medium the Equivalent Single Layer approach with the First Order Shear Deformation kinematics is employed. The effectiveness of the proposed model is examined in numerical examples with reference solutions available in the literature. Presented study proves that the proposed approach can be very effective in the analysis of stability of thin-walled thermally loaded panels.

ABSTRACT: The buckling of axially compressed beams resting on elastic foundation is considered, accounting for discontinuous (unbonded) contact between beam and subgrade which is the case of real structural response. Using Galerkin’s method a two-region contact/non-contact configuration was revealed as the only possible post-buckling deformation for both pinned – pinned and fixed – fixed boundary conditions, a fact strongly contradicting relevant results where continuous contact was assumed.

ABSTRACT: This paper considers the minimum buckling load and mode shape of a simply supported beam on an elastic foundation. Solutions are obtained by solving the eigenvalue problem delivered by a finite-element formulation and by using the analytical solutions involving (1) trials and (2) rounding of real numbers to integers as described by Hetényi [Hetényi, M. (1946). Beams on Elastic Foundations, University of Michigan Press, Ann Arbor, MI]. The comparison shows that the solution by rounding can lead to overestimation of the buckling load close to the transition zone between mode shapes. The paper explains the reason for the overestimation and offers a simple direct algorithm that always leads to the correct mode shape and minimum buckling load.

ABSTRACT: This paper concerns the efficiency study of the arc-length algorithm in the geometrically non-linear analysis of thermally loaded multilayered shells. The thermal loading is considered as the one-way thermo-mechanical coupling effect. Two implementations of the arc-length method are examined: the path-following technique available in NX-Nastran and the Riks-Wempner-Ramm algorithm adopted in the authors’ computer code SHLTH. It is shown that the appropriate unloading condition in each step of the analysis plays the crucial role in obtaining a proper solution. The algorithm offered in NX-Nastra tends to fail, whereas the authors’ code enables to find the solution in required temperature range.

ABSTRACT: With the availability of user oriented software tools, dedicated architectures, such as the parallel computing platform and programming model CUDA (Compute Unified Device Architecture) released by NVIDIA, one of the main producers of graphics cards, and of improved, highly performing GPU (Graphics Processing Unit) boards, GPGPU (General Purpose programming on GPU) is attracting increasing interest in the engineering community, for the development of analysis tools suitable to be used in validation/verification and virtual reality applications. For their inherent explicit and decoupled structure, explicit dynamics finite element formulations appear to be particularly attractive for implementations on hybrid CPU/GPU or pure GPU architectures. The issue of an optimized, double-precision finite element GPU implementation of an explicit dynamics finite element solver for elastic shell problems in small strains and large displacements and rotations, using unstructured meshes, is here addressed. The conceptual difference between a GPU implementation directly adapted from a standard CPU approach and a new optimized formulation, specifically conceived for GPUs, is discussed and comparatively assessed. It is shown that a speedup factor of about 5 can be achieved by an optimized algorithm reformulation and careful memory management. A speedup of more than 40 is achieved with respect of state-of-the art commercial codes running on CPU, obtaining real-time simulations in some cases, on commodity hardware. When a last generation GPU board is used, it is shown that a problem with
more than 16 millions degrees of freedom can be solved in just few hours of computing time, opening the way to virtualization approaches for real large scale engineering problems.

ABSTRACT: In this paper, the geometric nonlinear bending response of channel-section beams of finite length is investigated by using energy methods. The basic assumptions used in the present study are that the total strain energy of a channel-section beam subjected to pure bending can be simplified into a two-stage analysis process. One is the local bending response of the web behaving as the plate; the other is the overall bending response as a beam with flattened section. Analytical solutions for both static and dynamic instabilities of channel section beams of finite length subjected to pure bending about its minor axis are derived by applying the minimum potential energy principle. To validate the analytical solution developed, geometric nonlinear finite element analyses are also conducted. Good agreement between the present solution and the FEA results is demonstrated. The effect of beam's length on the critical load is also discussed.

ABSTRACT: The present study deals with the dynamic stability behavior of laminated composite and sandwich plates subjected to in-plane static and periodic compressive loads based on a recently developed inverse hyperbolic zigzag theory by the authors. The present model satisfies the traction-free boundary conditions on the surfaces of the plate and interlaminar continuity conditions at the layer interfaces, thus obviating the need for a shear correction factor. An efficient Co continuous isoparametric serendipity element with seven field variables is employed for the usual discretization of the plate structure. The effect of span-thickness ratio, modular ratio, boundary conditions, static load factor, and thickness ratios are examined by solving a variety of numerical problems on laminated composite and sandwich structures. The principal instability regions of plate structures are obtained using Bolotin’s approach and are represented either in the nondimensional load amplitude-excitation frequency plane or load amplitude-load frequency plane. The evaluated results are compared with the available published results based on various deformation theories. The prediction of accurate results at the cost of less computational effort ensures the efficiency of the present models for a wide range of applications

ABSTRACT: Corrugated tubes with sinusoidal patterns were studied to improve the energy absorption properties of traditional circular tubes and reduce the initial peak force. The effects of the radius-thickness ratio, wavelength, and amplitude of corrugated tubes under an axial impact were determined using the LS-DYNA. The numerical simulations show that tube deformation can be classified into three crushed modes, namely,
dynamic asymptotic buckling, dynamic plastic buckling, and transition buckling. The theoretical equation for dynamic plastic buckling was developed to predict the impact force using certain assumptions. The theoretical prediction results are consistent with the findings of the numerical simulations.

ABSTRACT: Weak formulations of mixed state equations of closed laminated cylindrical shells are presented in the Hamilton System. The Hamilton canonical equation of closed cylindrical shell is established. By means of applying the transfer matrix method and taking the advantage of Hamiltonian matrix in the calculation, a unified approach and three-dimensional thermoelastic solutions are obtained for the buckling analysis of closed thick laminated cylindrical shells. All equations of elasticity can be satisfied and all elastic constants can be taken into account. Numerical results are given to compare with those of FEM calculated using SAP5. The principle and method suggested here have clear physical concepts. The equations and boundary conditions proposed in this paper are weakened. The solutions and results given here may serve as a benchmark for other numerical procedures.

ABSTRACT: Background: Nowadays, because of construction and repair costs, maintenance of structures is indispensable. Several factors such as design and calculation errors, lack of proper installation, change structures application, fatigue, corrosion and events such as earthquake, fire and environmental conditions reduce their durability, which renew and restore to its original function is inevitable. One of the proper materials for strengthening is Carbon Fibre Reinforced Polymer (CFRP). This paper presents an investigation on the effect of CFRP for strengthening of short steel box-shaped members with initial horizontal and vertical deficiency. Thirteen specimens with variety of parameters such as length, width and position of deficiency, and strengthening techniques were investigated to study amount of CFRP and strengthening methods to reform the performance. Three-dimensional (3D) modeling and nonlinear static analysis method using ABAQUS software were utilized. The results of research on the use of CFRP fibers to strengthening of short steel box-shaped members with initial deficiency indicate, the fibres have significant effects on increasing load bearing capacity and ductility and, also prevent deficiency propagation.

T.-P. Chang (Dept. of Construction Engineering, National Kaohsiung First University of Science and Technology, Taiwan), “Nonlinear vibration of single-walled carbon nanotubes under magnetic field by stochastic finite element method”, International Journal of Structural Stability and Dynamics, August 2015, DOI: 10.1142/S0219455415500467
ABSTRACT: In the present study, we investigate the statistical nonlinear dynamic behaviors of a single-walled carbon nanotube (SWCNT) subjected to a longitudinal magnetic field by considering the effect of geometric nonlinearity. We consider both the Young's modulus of elasticity and mass density of the SWCNT as stochastic with respect to the position to actually characterize the random material properties of the SWCNT. In addition, we use the theory of nonlocal elasticity to investigate the small scale effect on the nonlinear vibration of the SWCNT. By using the Hamilton's principle, the nonlinear governing equations of the SWCNT subjected to a longitudinal magnetic field are derived. We utilize the stochastic finite element method along with the perturbation technique to compute the statistical response of the SWCNT. Some statistical dynamic response of the SWCNT, such as the mean values and standard deviations of the midpoint deflections, are computed and checked by the Monte Carlo simulation, besides, the effects of the small scale coefficients, magnetic field and the elastic stiffness of matrix on the statistical dynamic response of the SWCNT are studied and discussed.
ABSTRACT: The objective of this study was to evaluate three potential core alternatives for glass fiber reinforced polymer (GFRP) foam-core sandwich panels. The proposed system could reduce the initial production costs and the manufacturing difficulties while improving the system performance. Three different polyurethane foam configurations were considered for the inner core, and the most suitable system was recommended for further prototyping. These configurations consisted of high-density polyurethane foam (Type 1), a bidirectional gridwork of thin, interconnecting, GFRP webs that is in-filled with low-density polyurethane foam (Type 2), and trapezoidal-shaped, low-density polyurethane foam utilizing GFRP web layers (Type 3). The facings of the three cores consisted of three plies of bidirectional E-glass woven fabric within a compatible polyurethane resin. Several types of small-scale experimental investigations were conducted. The results from this study indicated that the Types 1 and 2 cores were very weak and flexible making their implementation in bridge deck panels less practical. The Type 3 core possessed a higher strength and stiffness than the other two types. Therefore, this type is recommended for the proposed sandwich system to serve as a candidate for further development. Additionally, a finite element model (FEM) was developed using software package ABAQUS for the Type 3 system to further investigate its structural behavior. This model was successfully compared to experimental data indicating its suitability for parametric analysis of panels and their design.

ABSTRACT: There are vast possibilities in fibre architecture design of 3D woven reinforcement. This paper considers the application of Genetic Algorithm (GA) in 3D woven composites optimisation. A set of real and integral variables, representing 3D fibre architecture, are formulated into a mixed integer Genetic Algorithm. The objective function is evaluated through automation of the unit cell based finite element analysis, by using the open source pre-processor TexGen and the commercial solver ABAQUS. The mixed integer Genetic Algorithm is adapted to a micro-population, aiming to improve computational efficiency. The study uses statistical tests to quantify the performance of the Genetic Algorithm schemes and the choice of parameters. The proposed approach was applied to the optimisation of 3D woven composites for maximum buckling resistance for the case of a landing gear brace. This study demonstrated that the optimisation converged to the optimum design within 20 iterations, considering 300 out of 7000 permissible solutions. In terms of buckling performance, the optimum design performed twice as well as cross-ply laminated composites and at least 50% better than known orthogonal 3D woven composites.

ABSTRACT: The paper investigates the effects of creep of the core material on the geometrically nonlinear behavior of sandwich panels with debond at one of the core–face interfaces within the framework of the high-order sandwich panel theory (HSAPT). The theoretical model accounts for the viscoelasticity of the core via an incremental exponential law that corresponds to the rheological generalized Maxwell model obtained from the expansion of the relaxation moduli into Prony series. The HSAPT structural modeling accounts for the deformability of the core in shear and through its thickness, as well as for the large displacements of the facesheets. An incremental time-stepping analysis is conducted, which accounts for the time variations of the stresses, deformations, and the geometrically nonlinear effects. The incremental governing equations and the stresses and deformations fields through the thickness of the core are derived, and the capabilities of the model are studied numerically. The results show that creep of the core leads to significant variations in the deformations and stresses over time, which when combined with the geometrically nonlinear effects of the debonded facesheet, can have an important influence on the performance of sandwich panels under sustained loads. It is shown that stress relaxation due to creep and/or contact may restrain the buckling of the debonded facesheet in some cases.

ABSTRACT: Not only straight pipes, but also the curved ones are used in an actual pipeline. In designing such a pipeline, it is important to know the buckling strength of the pipe under various kinds of loads. Especially, it is well known that the buckling moment will be reduced by increasing the pipe’s length. However, comprehensive studies for the buckling strength of straight and curved pipe under bending loads are still limited. In this research, the previous research for the buckling strength of pipe under bending moments was reviewed. It is well known that the cross-sectional oval deformation takes place and the buckling strength of pipe is reduced due to this deformation. Therefore, secondly, the buckling phenomenon for a straight pipe under a pure bending moment was investigated by nonlinear FEA, considering the effect of a cross-sectional oval deformation by changing the varying of pipes, that is, the length-to-diameter ratio \((L/D)\) varying from about 5 to 20 and the diameter-to-thickness ratio \((D/t)\) varying from about 50 to 200. Thirdly, the buckling phenomenon for curved
pipe was also investigated by changing the \( R/D \) from 50 to 200 where \( R \) is the curvature radius of curved pipe. From the results of the calculations for the straight pipe, the reduction rate of the buckling moment due to the oval deformation of pipe was clarified for various values of \( L/D \) and \( D/t \), not only in elastic buckling, but also in elasto-plastic buckling. For the curved pipe, it was explained that the buckling moment will be reduced by lowering the value of \( R/D \).

“Buckling phenomenon for imperfect pipe under pure bending”, Journal of Marine Science and Technology, First online, 11 June 2015, pp 1-8

ABSTRACT: The buckling phenomenon for imperfect pipe under bending has been investigated by nonlinear FEA, considering the effect of a cross sectional oval deformation by changing the variables of pipes, that is, \( L/D \) varying from 2.5 to 20, \( D/t \) varying from 50 to 200, and imperfection (\( \delta_o/t \)) varying from 0.05 to 0.5. As well as the elastic buckling, the elasto-plastic buckling was investigated. From the calculation results, the followings were found. The reduction of buckling moment due to imperfection is larger in short pipe than in long pipe. The effect of imperfection for pipes with large values of \( D/t \) is larger than those with small values of \( D/t \) if \( L/D \) of both pipes is same. The effects of imperfection for elastic analysis are larger than elasto-plastic analysis. The buckling moment reduces more by the imperfection of buckling mode than by that of oval mode.

Gronchi, 18, 67100, L’Aquila, Italy), “Semi-analytical approach for the study of linear static behaviour and buckling of shells with single constant curvature”, Continuum Mechanics and Thermodynamics, Vol. 27, No. 4, pp 767-785, September 2015

ABSTRACT: A model of linear, internally constrained shell with single, constant curvature is used to describe the behaviour of existing structures, such as barrel shells. A linear, elastic, isotropic material is considered. Observing that in the shell two families of mono-dimensional interacting beams can be recognized: straight longitudinal beams and transversal arches, a non-conventional semi-analytical approximate solution, which uses the method of separation of variables, is proposed. By using an integral procedure, reduced differential, ordinary equations, capable of describing the behaviour of the shell, are obtained. Both linear static behaviour and longitudinal buckling of the shell are investigated. The approximate solution proposed leads to results that match those of a finite element model and permits to give a description of shells similar to that of beams on elastic soil. With regard to the linear static behaviour of the shell, a “short” and a “long” characterization is proposed and original graphical abaci are obtained with the purpose of facilitating the classification. An extensive study is then performed in order to analyse the buckling of the shells.

ABSTRACT: The elastic limit analysis for elliptical and circular tubes under lateral force is conducted in the present paper, and elastic–perfect plastic material model is employed. An analytical expression for describing the elastic limit load of elliptical and circular tubes under lateral force is obtained. It shows that the critical load for elliptical and circular tubes under lateral force increases with the plastic yielding strength of the tube material, the ratio of the wall thickness to radius, the wall thickness and the length of the tube, as well as the degree of deviation from circular tube monotonously. The experimental results from available literature for both steel and aluminum tubes are cited to verify the proposed expression, and it shows that the expression reflects the loading capacity of elliptical and circular tubes quite well, which indicates the proposed expression is a reasonable formula.

ABSTRACT: This paper is focused on the buckling and the vibration analyses of microstructured struc-
tures, i.e., elements composed of repetitive structural cells. The relationship between the discrete and the
equivalent nonlocal continuum is specifically addressed from a numerical and a theoretical point of view. The
microstructured beam considered herein is modeled by some repetitive cells composed of finite rigid segments
and elastic rotational springs. The microstructure may come from the discreteness of the matter for small-
scale structures (such as for nanotechnology applications), but it can also be related to some larger scales as for civil
engineering applications. The buckling and vibration results of the discrete system are numerically obtained
from a discrete-element code, whereas the nonlocal-based results for the equivalent continuum can be

23. Yin H., Wen G., Liu Z., Qing Q.: Crash worthiness optimization design for foam-filled multi-cell thin-walled structures. Thin Walled Struct. 73, 8–17 (2014)
analytically performed. It is shown that Eringen’s nonlocal elasticity coupled to the Euler-Bernoulli beam theory is relevant to capture the main-scale phenomena of such a microstructured continuum. The small-scale coefficient of the equivalent nonlocal continuum is identified from the specific microstructure features, namely, the length of each cell. However, the length scale calibration depends on the type of analysis, namely, static versus dynamic analysis. A perfect agreement is found for the microstructured beam with simply supported boundary conditions. The specific identification of the equivalent stiffness for modeling the equivalent clamped continuum is also discussed. The equivalent stiffness of the discrete system appears to be dependent on the static-dynamic analyses, but also on the boundary conditions applied to the overall system. Satisfactory results are also obtained for the comparison between the discrete and the equivalent continuum for other type of boundary conditions.

ABSTRACT: This paper presents the treatment of elastically restrained ends for the axially loaded beam-buckling problem for the central finite difference beam model, the microstructured beam model, and Eringen’s nonlocal continuous beam model. The equivalence between the central finite difference beam model and the microstructured beam model is established herein, and these equivalent systems are regarded as belonging to one class of discrete systems since they become indistinguishable. Also, the continualized form of the discrete system is obtained by adopting the continualization method that is based on an exponential displacement function. Three approaches are then proposed for matching the discrete system with Eringen’s nonlocal continuous system for the beam-buckling problem. The approaches depend on the assumption made on the constancy/or varying Eringen’s small length scale coefficient $e_0$ as well as which one of the discrete or continuum system is taken as the reference system.

ABSTRACT: We use the Mindlin plate theory and the finite element method to delineate the effect of fixing points on a transverse normal to the mid-surface of the plate on the localization of buckling modes in clamped–clamped rectangular plates made of linear elastic, homogeneous and either isotropic (monolithic) or orthotropic (fiber-reinforced composite) materials. The in-plane loads considered on the bounding edges are: (i) normal tractions on the length, (ii) normal tractions on the width, (iii) equal normal tractions on the length and the width (equal biaxial loading), (iv) shear (tangential), and (v) combined same normal and shear tractions on all sides. It is found that clamping points on a transverse normal passing through the mid-point of a line parallel to the short side increases the critical buckling load of plates of only low aspect ratios over that of the corresponding plates unconstrained at interior points. However, for plates of all aspect ratios (thickness/length) fixing points on a transverse normal divides it into two regions with negligible transverse deflections in only one of the two regions. Only for loads (i)–(iii) the dividing line is parallel to the short side of the plate. For both thin and thick isotropic plates the slope of the dividing line is found to monotonically increase with an increase in the aspect ratio of a plate until it reaches a saturation value. A parameter based on the modal strain energy is used to quantify the degree of localization of a buckling mode. For an isotropic plate the degree of localization is found to increase with the increase in the aspect ratio for load cases (i)–(iii) but is found to be moderate for load cases (iv) and (v). For an orthotropic layer the degree of localization with an increase in the aspect ratio of the plate increases more for the 90° lamina than that for the 0° and the 45° laminae. Also, the mode localization in the (45°, 45°) laminate is stronger than that in the (0°, 90°) laminate for the five load cases. However, moderate degree of mode localization is found in symmetric and anti-symmetric cross-ply and angle-ply laminates.

ABSTRACT: This paper presents a comprehensive review of the various methods employed to study the static, dynamic and stability behavior of Functionally Graded Material (FGM) plates. Both analytical and numerical methods are considered. The review is carried out with an emphasis to present stress, vibration and buckling characteristics of FGM plates predicted using different theories proposed by several researchers without considering the detailed mathematical implication of various methodologies. The effect of variation of material properties through the thickness, type of load case, boundary conditions, edge ratio, side-to-thickness ratio and the effect of nonlinearity on the behavior of FGM plates are discussed. The main objective of this paper is to serve the interests of researchers and engineers already involved in the analysis and design of FGM structures.

“Regular and chaotic oscillations of a Timoshenko beam subjected to mechanical and thermal loadings”,
Continuum Mechanics and Thermodynamics, Vol. 27, No. 4, pp 719-737, September 2015

ABSTRACT: Dynamics of a Timoshenko beam under an influence of mechanical and thermal loadings is analysed in this paper. Nonlinear geometrical terms and a nonuniform heat distribution are taken into account in the considered model. The mathematical model is represented by a set of partial differential equations (PDEs) which takes into account thermal and mechanical loadings. The problem is simplified to two PDEs and then reduced to ordinary differential equations (ODEs) by means of the Galerkin method taking into account three modes of a linear Timoshenko beam. Correctness of the analytical model is verified by a finite element method. Then, the nonlinear model is studied numerically by a continuation method or by a direct numerical integration of ODEs. An effect of the temperature distribution on the resonance near the first natural frequency and on stability of the solutions is presented. The increase of mechanical loading results in hardening of the resonance curve. Thermal loading may stabilise the beam dynamics when the temperature is decreased. The elevated temperature may transit dynamics from regular to chaotic oscillations.

ABSTRACT: Auxetic metamaterials are synthetic materials with microstructures engineered to achieve negative Poisson's ratios. Auxetic metamaterials are of great interest because of their unusual properties and various potential applications. However, most of the previous research has been focused on auxetic behaviour of elastomers under elastic deformation. Inspired by our recent finding of the loss of auxetic behaviour in metallic auxetic metamaterials, a systematic experimental and numerical investigation has been carried out to explore the mechanism behind this phenomenon. Using an improved methodology of generating buckling-induced auxetic metamaterials, several samples of metallic auxetic metamaterials have been fabricated using a 3D printing technique. The experiments on those samples have revealed the special features of auxetic behaviour for metallic auxetic metamaterials and proved the effectiveness of our structural modification. Parametric studies have been performed through experimentally validated finite element models to explore the auxetic performance of the designed metallic metamaterials. It is found that the auxetic performance can be tuned by the geometry of microstructures, and the strength and stiffness can be tuned by the plasticity of the base material while maintaining the auxetic performance.

ABSTRACT: Variations of manufacturing process parameters, environment aspects, and imperfections may significantly affect the quality and performance of stiffened shells. The reliability-based design optimization (RBDO) of stiffened shells, considering all these uncertainty factors simultaneously, is extremely time-consuming, even if the surrogate-based technology is used. Therefore, a hybrid bi-stage framework for RBDO of stiffened shells is presented to release the computational burden, where two main sources of uncertainties are considered: variations of material properties and geometric dimensions are described as random variables, while various forms of imperfections of stiffened shells are covered by the single perturbation load approach. The basic idea of the proposed method is to combine the efficiency of smeared stiffener method with the accuracy of finite element method, and then narrow the design window efficiently with little accuracy sacrifice. The adaptive chaos control method is used to ensure the robustness of the search process of the most probable target point. The numerical example illustrates the advantage of the proposed method over other RBDO approaches from the point of view of computational cost, accuracy and robustness of the result.

ABSTRACT: Under increasing compression, an unbuckled shell is in a metastable state which becomes increasingly precarious as the buckling load is approached. So to induce premature buckling a lateral disturbance will have to overcome a decreasing energy barrier which reaches zero at buckling. Two archetypal problems that exhibit a severe form of this behaviour are the axially-compressed cylindrical shell and the externally pressurized spherical shell. Focussing on the cylinder, a non-destructive technique was recently proposed to estimate the ‘shock sensitivity’ of a laboratory specimen using a lateral probe to measure the nonlinear load deflection characteristic. If a symmetry-breaking bifurcation is encountered on the path, computer simulations showed how this can be suppressed by a controlled secondary probe. Here, we extend our understanding by assessing in general terms how a single control can capture remote saddle solutions: in particular how a symmetric probe could locate an asymmetric solution. Then, more specifically, we analyse the spherical shell with point and ring probes, to test the procedure under challenging conditions to assess its range of applicability. Rather than a bifurcation, the spherical shell offers the challenge of a de-stabilizing fold (limit point) under the rigid control of the probe.

ABSTRACT: The purpose of this paper is to develop a general mathematical model for laminated curved structure of different geometries using higher-order shear deformation theory to evaluate in-plane and out of plane shear stress and strains correctly. Subsequently, the model has to be validated by comparing the responses with developed simulation model (ANSYS) as well as available published literature. It is also proposed to analyse thermal buckling load parameter of laminated structures using Green–Lagrange type non-linear strains for excess thermal distortion under uniform temperature loading. Laminated structures known for their flexibility as compared to conventional material and the deformation behaviour are greatly affected due to combined thermal/aerodynamic environment. The vibration/buckling behaviour of shell structures are very different than that of the plate structures due to their curvature effect. To model the exact behaviour of laminated structures mathematically, a general mathematical model is developed for laminated shell geometries. The responses are evaluated numerically using a finite element model-based computer code developed in MATLAB environment. Subsequently, a simulation model has been developed in ANSYS using ANSYS parametric design language code to evaluate the responses. Vibration and thermal buckling responses of laminated composite curved panels have been obtained based on proposed model through a customised computer code in MATLAB environment and ANSYS simulation model using ANSYS parametric design language code. The convergence behaviour are tested and compared with those available in published literature and ANSYS results. Finally, the investigation has been extended to examine the effect of different parameters (thickness ratios, curvature ratios, modular ratios, number of layers and support conditions) on the free vibration and thermal buckling responses of laminated curved structures.

PARTIAL ABSTRACT: We study the fabrication of thin polymeric shells based on the coating of a curved surface by a viscous fluid. Upon polymerization of the resulting thin film, a slender solid structure is delivered after demolding. This technique is extensively used, empirically, in manufacturing, where it is known as
rotational molding, as well as in the food industry, eg for chocolate-eggs. This problem is analogous to the Landau-Levich-Derjaguin coating of . . .

ABSTRACT: Thin spherical shells range from nanometer-sized viruses to space vehicles. A pressure differential between the inner and outer part of the shell can result in the buckling and catastrophic failure of the structure. We revisit this classic buckling problem, depressurizing thin elastic shells, which are arrested from within by a concentric spherical mandrel. As a result, buckling is constrained to occur within the gap between the two. Above a critical pressure, dimples appear sequentially on the surface of the shell to form a robust periodic pattern. We perform precision desktop experiments to construct the bifurcation diagram of the process, and explore a range of geometric and material properties. A scaling analysis enables us to rationalize the dependence of the size of the dimples on both the radius of the shell and the radial gap between the shell and the inner rigid mandrel. Moreover, we characterize the process of nucleation and progression of the dimpled pattern front. Particular emphasis is given to the patterns obtained in the strongly nonlinear post-buckling regime where a network of sharp ridges forms.

PARTIAL ABSTRACT: We introduce a new class of pre-stressed bilayer shells, whose surface morphology can be used to smoothly tune their optical transmittance by pneumatic actuation. Each sample is fabricated by pressurizing a disk made out of an optically clear silicone-based rubber to bulge it into a nearly hemispherical pre-strained shell. The surface of this shell is then taken as a substrate and coated with a thin layer of a polymer suspension with black micron-sized dye particles, which, upon curing, can make the samples opaque. The . . .

ABSTRACT: A thin flat rectangular plate supported on its edges and subjected to in-plane loading exhibits stable post-buckling behaviour. However, the introduction of a nonlinear (softening) elastic foundation may cause the response to become unstable. Here the post-buckling of such a structure is investigated and several important phenomena are identified, including the transition of patterns from stripes to spots and back again. The interaction between these forms is of importance for understanding the possible post-buckling behaviours of this structural system. In addition, both periodic and some localized responses are found to exist as the dimensions of the plate are increased and this becomes relevant when the characteristic wavelengths of the buckle pattern are small compared to the size of the plate. Potential application of the model range from macroscopic industrial manufacturing of structural elements to the understanding of micro- and nano-scale deformations in materials.

“Buckling of a spherical shell under external pressure and inward concentrated load: Asymptotic solution”, Mathematics and Mechanics of Solids, Published online before print, March 21, 2016,
DOI: 10.1177/1081286516635872

ABSTRACT: An asymptotic solution is suggested for a thin isotropic spherical shell subject to uniform external pressure and concentrated load. The pressure is the main load and a concentrated lateral load is considered as a perturbation that decreases buckling pressure. First, the post-buckling solution of the shell under uniform pressure is constructed. A known asymptotic result for large deflections is used for this purpose. In addition, an asymptotic approximation for small post-buckling deflections is obtained and matched with the solution for large deflections. The proposed solution is in good agreement with numerical results. An asymptotic formula is then derived, with the load-deflection diagrams analyzed for the case of combined load. Buckling load combinations are calculated as limiting points in the load-deflection diagrams. The sensitivity of the spherical shell to local perturbations under external pressure is analyzed. The suggested asymptotic result is validated by a finite element method using the ANSYS simulation software package.

ABSTRACT: In the present work, in order to tackle the linear elastic buckling problem, we develop a shape optimization process based on a free-form optimization method to optimize a shell structure under out-of-plane and in-plane shape variations. The free-form optimization method is a node-based method in which mesh regularity can be maintained and shape design parameterization is not required. It has the advantages of sufficient efficiency for treating large-scale problems and the ability to realize a smooth shape. The buckling coefficient in buckling mode 1 is set as the objective function in the shape optimization problem. We consider repeated eigenvalues and volume constraint for the whole optimization process. Three numerical examples are presented in this work to illustrate the shape optimization algorithm and to show that it can increase the buckling strength substantially, especially under shape variation in the out-of-plane direction.

ABSTRACT: The post-buckling behavior of elastic–plastic cylindrical shells under external pressure and twisting moment is unstable. The effect of stabilization of the post-buckling behavior is in most cases obtained by changing geometry of the structure. In this paper an alternative concept of modification of the post-buckling behavior is applied, namely modification of post-buckling path is achieved by application of additional loadings acting on the structure without changing the shape or sizes of the optimized element. Calculations are performed using ANSYS code for elastic–plastic shells of different length and thickness for the whole range of load from a pure external pressure to a pure twisting moment. It turned out that the active stabilizing force can always stabilize the post-buckling paths whereas the passive and ‘mixed’ variant of stabilizing loads are able to stabilize the post-buckling paths only for thicker elastic–plastic shells and for limited states of loading.

ABSTRACT: An investigation has been undertaken on the buckling strength of concrete arch dams in the form of thin shells of single and double curvature. When subjected to the hydrostatic pressure exerted by the retained water, the shell experiences predominantly compressive internal actions, which can result in buckling failure of the thin shell. There are many factors influencing the buckling strength of the arch dam. These include the shape of the valley, the geometry of the arch surface, the degree of bulging of the arch, shell-thickness variation and support conditions. The present study makes use of FEM modelling to determine the influence of key parameters on the critical buckling pressure of cylindrical and elliptic-paraboloidal arch dams. For cylindrical arch dams, design curves giving information on factors of safety against buckling are presented. By comparing the results for the elliptic paraboloid with those for the parabolic cylindrical arch, the benefits of double curvature are evaluated.

ABSTRACT: The cross-sectional behaviour of laminated glass (LG) is characterised by a significant zigzag effect owing to the large stiffness mismatch between the glass and polymer layers. The approach incorporated in current glass design standards is based on the use of a monolithic model with an effective thickness, which suffers several sources of inaccuracy and limitations. In this paper, laminated shell elements with an alternating stiff/soft lay-up are enhanced and used to model LG structures, so as to accurately reproduce the through-thickness behaviour of LG with a minimal number of zigzag displacement parameters per node. In order to consider the influence of loading rate and temperature on the response of LG, a linear viscoelastic material model is adopted to simulate the polymer interlayer, which is formulated based on a recursive formula for stress calculation. Finally, several applications of the proposed modelling approach for two-ply and multi-ply LG structures are presented, considering typical deflection, stability and creep problems, where the benefits of the proposed approach are demonstrated through comparisons against monolithic shell models based on an effective thickness as well as 3D continuum models.

ABSTRACT: This paper proposes a kinematic model for sandwich plates and shells, utilising a novel zigzag function that is effective for symmetric and asymmetric cross-sections, and employing a piecewise through-thickness distribution of the transverse shear strain. The proposed model is extended to large displacement analysis using a co-rotational framework, where a 2D local shell system is proposed for the direct coupling of additional zigzag parameters. A 9-noded co-rotational shell element is developed based on the proposed approach, which utilises the MITC method for overcoming locking effects. Several linear/nonlinear analysis examples of sandwich structures demonstrate the effectiveness of the proposed approach.

ABSTRACT: We demonstrate the existence of spurious modes in finite elements with incompatible modes when a geometrically nonlinear displacement analysis with small displacements and strains is performed. The spurious modes are a direct consequence of the incompatibility of the elements with displacement boundary conditions. We derive a critical compressive strain condition analytically, and show that the critical strain can be quite small, with small displacements, if the geometric aspect ratio of the elements is large but still practical. In numerical examples we give further insight and results in correspondence with the analytical theory, and demonstrate that spurious modes can be triggered in practical small strain analyses when using elements with incompatible modes.

ABSTRACT: We investigate the possibilities for simplification of previously proposed refined linearized equations of perturbed motion to identify, by dynamic method, the buckling mode shapes of isotropic spherical shells undergoing external hydrodynamic pressure. In the analysis of classical flexural buckling shapes of spherical shells, it is shown that preserving of nonconservative parametric terms in governing equations of formulated problem, which are related with loading of the shell with follower pressure practically does not affect the value of critical load and the resulting buckling mode shapes in shell.

ABSTRACT: In this research, buckling analysis of a two-dimensional, functionally graded, cylindrical shell that has been embedded in an outer elastic medium in the presence of combined axial and transverse loading based on third-order shear deformation shell theory is numerically investigated. Variations of the shell properties are considered to be continuous through length and thickness. Winkler–Pasternak foundation and simply supported boundary conditions have been applied. The problem has been solved using the generalized differential quadrature method. Geometrical, load, and foundation parameters beside functionally graded power indexes effects on the critical buckling load have been studied.

ABSTRACT: The aim of this experimental research work is to investigate the effect of axial crack length on the buckling behavior of cracked cylindrical shells subjected to axial compression loading. The crack on the cylindrical strucutures is assumed to be a percentage of the axial length of the cylindrical shell structure. The magnitude of the crack length-to-cylinder axial length is varied between 0.05 and 0.15. Cylindrical specimens are made from mild steel with radius-to-thickness ratio ranging from 25 to 100. The axial length of the
specimens was assumed to be constant. Results indicate that the crack length strongly affect the buckling behavior of the axially compressed cylinder. Also, it was revealed that the buckling load of the cylindrical specimens with high value of radius-to-thickness ratio is more sensitive to the effect of change in crack length as compared to cylinder with low value of radius-to-thickness ratio.

ABSTRACT: In this paper, the buckling analysis of thin walled composite cylindrical shells with and without cutouts is investigated by applying axial load on Glass Fiber Reinforced Plastic (GFRP) shell. The effect of cutout not only introduces stress concentration but also significantly reduces the buckling strength. The column is fixed at one end and load is applied at the other end. The Static and Eigenvalue buckling analysis is done on shell model. The circular, elliptical and rectangle cutouts are considered on cylindrical shell. The buckling analysis is repeated in each case. The compressive stress, buckling load factor and lateral strain of each case for cylindrical shell is obtained from ANSYS software. The buckling load decreases for shell with cutout when compared to the value of the shell without a cutout. Stress and lateral strain increases for shell with cutout when compared to the shell without a cutout. The buckling load value is maximum in circular cutout and minimum in the rectangular cutout.

ABSTRACT: The buckling load make reduce the bearing in shells. This is one of the disadvantages of the shell. Key factors influencing the buckling load of the shell are the types of structures. In this paper, the effect of the ratio of radius to thickness ratio of length to thickness of the skin buckling load of laminated composite materials is investigated. It should be added, the shell is below the static water pressure. Therefore, the interaction effects of axial load and the static water pressure is also analyzed. It must be understood, to do this by a geometric nonlinear analysis. Also, the software ANSYS is used.

Thorpe, Maria Anastasia. Deformation and buckling of isolated and interacting thin shells in an elastic medium. Degree: 2016, University of Manchester. URL: http://www.manchester.ac.uk/escholar/uk-ac-man-scw:294750
This thesis 'Deformation and buckling of isolated and interacting thin shells in an elastic medium', is submitted by Maria Thorpe to The University of Manchester for the degree of PhD in September 2015. This thesis aims to model the effects of interaction and buckling upon pairs of micro-shells embedded within an elastic medium under far field hydrostatic pressure. This analysis is motivated by the role shell buckling plays in the nonlinear nature of the pressure relative volume curve of elastomers containing micro-shells. Current models of the effective properties of these types of composites assume shells are in a dilute distribution within the host medium, and as such assume shells will buckle at the pressure of the associated isolated embedded shell model. For composites with a high volume fraction of micro-shells, or in poorly mixed composites, the dilute distribution model may provide a first approximation to the effective properties of the composite, however, interaction between shells must be considered to find a more accurate model. We begin the process of modelling the buckling of interacting embedded shells by considering the buckling of an isolated embedded thin spherical shell. For a host medium undergoing far field hydrostatic pressure we demonstrate the parameter ranges in which Jones et al. thin shell buckling theory agrees with the thin shell buckling theory of Fok and Allwright. We then use scalings to increase the range of validity of the thin shell approximation used in the Jones et al. theory to include composites with a high contrast between medium and shell materials. This enables more accurate predictions of buckling pressures of embedded shells under far field axially symmetric pressures to also be found, as is demonstrated for an embedded shell under far field axial compression. We model the linear elastic deformation of pairs of embedded micro-shells using the Boussinesq-Papkovich stress function method, before employing the thin shell linear analysis method developed in previous chapters to calculate the critical buckling pressure and buckling patterns of the pair of embedded shells.

ABSTRACT: The present work investigates stress analysis and buckling analysis of cylindrical shell. It had been wide applications in the industry especially in mechanical and nuclear applications.. etc. The most common type of failure which may be happen in this type of structure was the buckling when was subjected to
external hydrostatic pressure which represents the aim of this work. The buckling happen due to transfer major amount of strain energy into bending energy which leads to sudden failure in the structure. To avoid this type of failure the cylindrical shell must be stiffened by adding stiffeners rings along the shell from internal or external surface. In this work two types of stiffeners existed, longitudinal and circumferential stiffeners based on the direction of the installation on the shell surface. In this work the critical pressure due to buckling was calculated numerically by using ANSYS15 for both stiffened and un-stiffened cylinder for various location and installing types, strengthening of the cylinder causes a significant increase in buckling pressures than non reinforced cylinder. Also the deflection for stiffened cylinder is function to mode shape and increasing with increasing the mode number because when the mode is increased, the strength of cylinder is increased and this leads to lower deflection. Also the stress analysis due to buckling for different depths of sea water was done to find the critical depth which may be the stresses exceeded the elastic limit. And from stress analysis results, it is observed that there is not a huge difference in stresses between stiffened shell and un-stiffened shell in similar boundary and loading condition so the value of stresses in stiffened shell is a little lower compared to un-stiffened shell.

Luis Miguel dos Santos Laim, “Experimental and numerical analysis on the structural behaviour of cold-formed steel beams subjected to fire”, Ph.D dissertation, Department of Civil Engineering, University of Coimbra, Portugal, 2013. ABSTRACT: The steel construction is increasingly an important technology for civil building. Actually, the steel industry is constantly in search of more and better uses for steel. The uses of hot-rolled, welded and cold-formed steel elements in the construction of buildings are ones of the solutions that can easily replace the traditional technology of construction. Indeed, cold-formed steel is one of which are becoming a very popular material in construction because they provide a high strength to weight ratio, are easy to produce, transport and assembly when compared to thicker hot-rolled steel members. Another advantage is the great variety of profiles available on the market which allow the building of different member cross-sections.
However, they may behave poorly under fire conditions, especially when they are unprotected in fire case, due to the combination of the high thermal conductivity of steel and section factor of these structural members (small wall thickness), both of which lead to a rapid rise of temperature in steel in fire situation. In addition, cold-formed steel members usually have complex buckling behaviour, involving local, distortional, global buckling and their interactions. Studies on fire performance of cold-formed steel members are still fairly rare, are mostly of a numerical nature and are based on the structural behaviour of single and short elements at elevated temperatures. Hence, this research work intended to study the behaviour of cold-formed galvanized steel beams under fire conditions, basing on the results of a large programme of experimental tests. Four-point bending tests on cold-formed steel C-, lipped I-, R- and 2R-section beams were performed, both under fire conditions, under flexural loading conditions and under simply supported boundary conditions (roller and pinned supports) with different restraining conditions, including no restraints, partial axial restraint to the thermal elongation of the beam (15 kN/mm) and partial rotational restraint at the beam supports (150 kN.m/rad). In other words, it was investigated the influence of the cross-sections, the axial restraining to the thermal elongation of the beam and the rotational stiffness of the beam supports. These beams, commonly used in CFS buildings, had a span of 3000 mm and were made of one or more cold-formed steel profiles (channel, U, and lipped channel, C, profiles), which were 2.5 mm thick, 43 mm wide and 250 mm tall for C sections and 255 mm for the U sections. On the other hand, as reference, four-point bending tests on the same type of beams at room temperature and under simply supported boundary conditions were also carried out to assess their ultimate bending strength and to compare with the failure modes. A numerical study was still performed by the finite element program ABAQUS. So a great number of numerical simulations aimed to carry out a parametric study outside the bounds of the original experimental tests, in other words, to find out the effect of thickness (from 1.5mm to 3.5mm) and height (from 200mm to 300mm) of the beam cross-sections, of the beam spans (from 2000mm to 5000mm) and of other values of axial (from zero to infinite) and rotational stiffness (from zero to 1200kN.m/rad) of the surrounding structure to the beam. Finally, the results of the experimental tests and the numerical simulations were the basis of an analytical study for the development of simplified calculation equations for fire design of cold-formed steel beams. The main conclusions of this research study were that the cold-formed steel beams commonly used in this kind of buildings may have a quite low fire resistance (less than 30 minutes), but high critical temperatures (higher than 350 oC - limitation enforced by Eurocode 3, Part 1.2) in most of the cases. On the other hand, the critical temperature may drop significantly (30% in some cases) with the axial restraint to thermal elongation of the beam. This decreasing is however minimized when the rotational restraint at beam supports is relevant comparing with rotational stiffness of the beam.

ABSTRACT: Aluminium stiffened panels are the basic elements of many structures with requirements of high strength/weight ratio. They are used in a wide variety of applications such as airplane wings and fuselage, ships and off-shore structures. Friction Stir Welding (FSW) process has been used in the manufacturing of such structures as an alternative of other joining techniques, such as riveting or fusion welding processes, with many
advantages. The understanding of the effects of FSW processes in the structural behaviour of stiffened panels is a relevant research area, useful to avoid conservative design choices often motivated by an attempt to compensate for structural analysis uncertainties.

The present work focuses on the numerical simulation of FSW processes, aiming to predict its effects, and also on the numerical simulation of the longitudinal compression of aluminium stiffened panels, including these effects. The numerical model for FSW was firstly developed to simulate single plates’ joining and subsequently validated using data from experiments, also performed in the scope of this work. The validated model was afterwards adapted to simulate FSW operations on stiffened panels. Sensitivity analyses performed showed an insignificant variation in the results coming from models using distinct heat input distributions related to the geometry of the tool. On the contrary, both models showed significant sensitivity to the variations of the mechanical boundary conditions that simulate the clamping system, although the single plate model was seen to be more affected by this modelling parameter.

The simulations regarding the longitudinal compression of the panels included the study of the influence of each one of the welding effects (distortion, residual stresses and material softening) on the structural behaviour. The numerical modelling of these welding effects was performed adopting two different procedures: using the results from FSW numerical analyses; and using a simplified methodology based on the literature. Regarding the compression of the panels, other modelling details were also tested and compared, such as: the numerical solving methodology; the plastic behaviour definitions of the material and the welding effects on the transversal edges. All the mentioned welding effects were able to affect the panel behaviour and, namely, the collapse load. Finally, a complementary study on initial geometrical imperfection was performed using distinct deformed shapes obtained from eigenvalue analyses and applied with different magnitudes. The variation of the collapse load with the increase of the imperfection magnitude revealed to be dependent on the shape of that imperfection.

Gary Han Chang, “Reduced order fluid-structure interaction models for thin shells with non-zero Gaussian curvatures to understand the response of aneurysms to flow”, Ph.D dissertation, Dept. of Mechanical and Industrial Engineering, University of Massachusetts Amherst, 2016

ABSTRACT: In this thesis, a reduced-order model is constructed to study the physiological flow and wall shear stress conditions for aneurysms. The method of local proper orthogonal decomposition (POD) is used to construct the reduced-order modes using a series of CFD results, which are subsequently improved using a QR-factorization technique to satisfy the various boundary conditions in physiological flow problems. This method can effectively construct a computationally efficient physiological model, which allows us to examine the fluid velocities and wall shear stress distributions over a range of different physiological flow parameters. Aneurysms are the dilation, bulging, or ballooning-out of part of the wall of a human artery. Repetitive forces on an existing aneurysm can lead either to its gradual expansion or to a devastating event of rupture. Traditionally, clinicians use the largest diameter as the sole parameter for standard risk stratification outside of clinical trials. However, there seems to be no safe small aneurysm size and a more accurate answer depends on the exact distributions of material and geometrical properties of the aneurysms. Aneurysms can have a very non-uniform distribution of thickness, modulus, and failure tension. We focus on the thins-shell fluid-structures interactions (FSI) with thickness inhomogeneity by studying the influence of one or multiple thin spots on the flow-induced instabilities of flexible shells of revolution with non-zero Gaussian curvatures. The results show that for shells with positive Gaussian curvatures conveying fluid, the existence of a thin spot results in a localized flow-induced buckling response of the shell in the neighborhood of the thin spot, and significantly reduces the critical flow velocity for buckling instability. For shells with negative Gaussian curvatures, the buckling response is extended along the shell’s characteristic lines and the critical flow velocity is only slightly reduced. Finally, the shell model with non-uniform thickness is combined with the ROM of hemodynamic loads. We show that based on a growth and remodeling (G&R) model, the rate of aneurysmal wall’s elastin degradation
can be predicted efficiently with various degrees of thickness inhomogeneity.

Lassila, T., Manzoni, A., Quarteroni, A., Rozza, G., 2014. Model Order Reduction In Fluid Dynamics: Challenges And Perspectives,

ABSTRACT: The complex configurations of soft materials are vital for many biological systems because they allow them quickly response to environmental stimuli and therefore achieve some necessary living functions. Such stimulus-sensitive properties are ascribed to the large deformation resulted from the bending, folding and buckling and have attracted the scientists to explore their essences in a variety of scenarios relating to mechanical force, temperature, humidity, pH value, electricity, magnetism to van der Waals force. Up to date, some exciting achievements have been made and successfully applied to soft robot, sensor, nano-reactor and artificial organ. However, there are still many challenging problems to be well addressed in future. This research aims to investigate the bending, folding and buckling of soft materials via theoretical analysis, numerical simulation and experimental validation. The retractile behaviours of a spherical shell perforated by sophisticated apertures, attributed to the buckling-induced large deformation are studied. The buckling patterns observed in experiments are reproduced in computational modeling by imposing velocity-controlled loads and eigenmode affine geometric imperfection. It is found that the buckling behaviours are topologically sensitive with respect to the shape of dimple and the buckliball featured with rounded-square apertures has the maximal volume retraction ratio. Afterwards, a kirigami approach is used to fold a patterned planar sheet into a buckliball under a certain thermal stimulus. By minimizing the potential strain energy, we obtain a critical temperature, below which this bilayer sheet exhibits identical principal curvatures everywhere in the self-folding procedure and above which the buckling occurs. The applicability of the theoretical analysis to the self-folding of sheets with a diversity of patterns is verified by the finite element method. Finally, the opening and closure of pine cones is revealed, which is attributed to the self-bending of its scales. It undergoes three states of humidity-driven deformation in terms of Föppl–von Kármán plate theory. Both numerical simulation and experimental data support the theoretical analysis and indicate the longitudinal principal curvature and transverse principal curvature bifurcate at a critical humid value which relies on the thickness and shape of scales.

The findings in this dissertation are significant not only for understanding the principle of natural structures with stimuli-responsive properties, but also for offering a novel way to design and fabricate functional shape-morphing structures for a variety of applications.

ABSTRACT: In this paper, a novel foam-filled double ellipse tube (F-DET) is proposed. First, the circle and ellipse tubes with three different configurations (hollow, foam-filled, double foam-filled) are investigated under axial and oblique impact by using the nonlinear finite element code LS-DYNA. The numerical results showed that the F-DET tube has the best crashworthiness performance than tubes with other configurations. Then to optimize the F-DET tube, the Kriging model about the radial rate $f$, thickness of wall $t$ and foam density $\rho_f$ is constructed. Based on the Kriging model, the multiobjective particle swarm optimization (MOPSO) algorithm is utilized to achieve the optimized F-DET tube, foam-filled ellipse (F-ET) tube and foam-filled double circle (F-DCT) tube on the maximizing specific energy absorption (SEA) and minimizing peak crush force (PCF) under multiple loading angles. It can be found that the F-DET tube has better crashworthiness performance than F-ET tube and F-DCT tube. This indicates F-DET tube can be a potential energy absorber under the multiple loading cases.

ABSTRACT: Lightweight magnesium alloys and polyurethane foams have attracted much attention in the automotive industry due to their potential to reduce vehicle weight. This study conducted quasi-static/dynamic three-point bending tests to investigate the energy absorption characteristics and deformation behaviour of empty and polyurethane foam-filled magnesium alloy AZ31B thin-walled beams, and to make comparisons with mild steel DC04 beams. The results showed that both deformation/fracture modes and energy absorption capacity of the thin-walled beams subjected to bending loads depend on the strain rate and other parameters, such as the beam material’s strength and ductility, foam density and wall thickness. Both the DC04 beams and AZ31B extruded beams showed a positive effect of strain rate on the energy absorption capacity. A beam filled with a higher density foam achieves higher bending resistance, but fractures at a smaller deflection. The experiments demonstrated that AZ31B significantly outperforms DC04 in terms of energy absorption and specific energy absorption for the foam-filled beams, when the beams are subjected to bending loads at a deflection of 250 mm. However, this gain could be weakened when the performance is assessed at a larger fracture deflection because the foam-filled AZ31B beams tend to fracture at smaller deflections. For applications that require limited deformation, there is a possibility to develop lightweight auto-body structures such as rocker rails by substituting foam-filled AZ31B structures for mild steel structures, while maintaining or exceeding their current crashworthiness and safety.

ABSTRACT: Auxetic materials are modern class of materials that have recently been gaining popularity within the research community due to their enhanced mechanical properties. Unlike conventional materials, they exhibit a negative Poisson's ratio when subjected to a uniaxial loading. This present research experimentally investigates the crush response and energy absorption performances of auxetic foam-filled square tubes under axial loading. For comparison, the crush response and energy absorption of empty and conventional foam-filled square tubes have also been examined with respect to deformation modes and force displacement curve. Standard compression tests were conducted on a series number of thin-walled tube samples. An additional compression test on conventional and auxetic foam has also been conducted to observe the behavior of foam itself. It is evident that the auxetic foam-filled square tubes are superior to empty and conventional foam-filled square tubes in terms of energy absorption capacity. It shows that such tube is preferable as an impact energy absorber due to their ability to withstand axial loads effectively. Furthermore, it is found that the load capacity increases as the crush length increases. The primary outcome of this study is design information for the use of auxetic foam-filled square tubes as energy absorbers where impact loading is expected particularly in crashworthiness applications.

ABSTRACT: This present study investigates experimentally and numerically the crush response and energy absorption performances of auxetic foam-filled square tubes under quasi-static axial loading. Three different structures: empty, conventional and auxetic foam-filled square tubes have been compared and examined with respect to the deformation modes and load-displacement curves. Standard compression tests were conducted on the tubes to evaluate the influence of auxetic foam in the energy absorption of empty tubes. Moreover, results from computer simulation have also been supplemented to further examine the abovementioned effect. It is discovered that the auxetic foam-filled square tube is superior to empty and conventional foam-filled square tubes in terms of all studied crashworthiness indicators.

ABSTRACT: As a class of widely observed materials in nature, hierarchical micro structures maybe of superior mechanical properties. In this study, we incorporate the concept of hierarchy into honeycomb structures for enhancing their crashworthiness performance. Hierarchical honeycombs are constructed by replacing every vertex of a regular hexagonal network with a smaller hexagon topology and repeating this process for
constructing fractal-appearing honeycombs with higher order of structural hierarchy. To examine the crashing characteristics the hierarchical honeycombs with the first-order and second-order structures were investigated under an out of the cross-sectional plane loading. A parametric study on structural variables ($\gamma_1$, $\gamma_2$) which are defined by $\gamma_i = L_i / L_0$ ($L_0$ is the edge length of regular honeycomb cell, $L_i$ is the edge length of $i$-th order hexagon in hierarchical honeycombs) and oblique-wall angles $\theta$ which is defined by the angle of oblique-wall edge to the vertical direction are undertaken with three different densities. A comparison between regular honeycombs and hierarchical honeycombs was conducted. The results showed that the out-of-plane energy absorption of the first-order hierarchical honeycombs with $0.04 \leq \gamma_1 \leq 0.2$ and the second-order hierarchical honeycombs with $0.15 \leq \gamma_1 \leq 0.2$ and $0.04 \leq \gamma_2 \leq 0.08$, as well as the hierarchical honeycombs with oblique-wall angle $\theta$ from $30^\circ$ to $50^\circ$ have better overall performance. Further, it was found that the specific energy absorptions (SEA) of the first-order hierarchy with $\gamma_1 = 0.08$ and the second-order hierarchy with $\gamma_1 = 0.20$, $\gamma_2 = 0.06$ were improved about $81.3\%$ and $185.7\%$, respectively. Moreover, their corresponding peak forces ($P_{\text{max}}$) do not increase much compared with the regular honeycomb under the same density, indicating that hierarchical honeycombs can be an ideal lightweight structure for designing crashworthy structures.

ABSTRACT: Thermoplastic composites are likely to emerge as the preferred solution for meeting the high-volume production demands of passenger road vehicles. Substantial effort is currently being directed towards the development of new modelling techniques to reduce the extent of costly and time consuming physical testing. Developing a high-fidelity numerical model to predict the crush behaviour of composite laminates is dependent on the accurate measurement of material properties as well as a thorough understanding of damage mechanisms associated with crush events. This paper details the manufacture, testing and modelling of self-supporting corrugated-shaped thermoplastic composite specimens for crashworthiness assessment. These specimens demonstrated a $57.3\%$ higher specific energy absorption compared to identical specimen made from thermoset composites. The corresponding damage mechanisms were investigated in-situ using digital microscopy and post analysed using Scanning Electron Microscopy (SEM). Splaying and fragmentation modes were the primary failure modes involving fibre breakage, matrix cracking and delamination. A mesoscale composite damage model, with new non-linear shear constitutive laws, which combines a range of novel techniques to accurately capture the material response under crushing, is presented. The force-displacement curves, damage parameter maps and dissipated energy, obtained from the numerical analysis, are shown to be in a good qualitative and quantitative agreement with experimental results. The proposed approach could significantly reduce the extent of physical testing required in the development of crashworthy structures.

ABSTRACT: An integrated design concept for crashworthy fuselage using sine-wave beam and strut is proposed and investigated. The finite element model of aircraft fuselage is built first. The structures above cabin floor, occupant and seat are simplified as two rigid blocks. The fuselage frame is redesigned, and the sine-wave beam is arranged under the frame. The impact dynamic performance of the aircraft with bottom sine-wave beam structure is studied and compared with that of conventional type. To obtain better crashworthiness performance, different rigidity of strut is combined with the sine-wave beam bottom structure. Numerical simulation result shows that the proposed sine-wave beam bottom structure could not only dissipate more proportion of impact kinetic energy but also reduce the initial peak acceleration. The structure and rigidity of strut have great influence on the crashworthiness performance. To give a better fuselage structure, both of the strut and bottom structure should be properly integrated and designed.

ABSTRACT: This paper describes a test program on austenitic stainless steel beam-columns. Two types of section were investigated: cold-formed square hollow section and welded H section. Twelve material tensile coupon tests and four stub column tests were conducted to provide the material properties of the specimens. The overall initial geometric imperfections were measured. Ten beam-columns were tested between pin-ended conditions with sideway supports. Results from the tests, including the strengths, the load-deformation responses, and the failure modes were presented. The test strengths and the strengths of all the previous available test specimens were compared with the design strengths predicted using Eurocode (EN 1993-1-4:2006) and American code (SEI/ASCE 8-02). It is shown that the design strengths predicted by these two design codes are generally conservative, and the performance of the American code is better than that of the Eurocode. A modified design rule based on the American code was proposed. Comparison of the predicted strengths with the tests strengths shows that the proposed method offers improved accuracy and reduced scatter.

ABSTRACT: Cold-formed steel members have been widely used in residential and commercial buildings as primary load bearing structural elements. They are often made of thin steel sheets and hence they are more susceptible to local buckling. The buckling behaviour of cold-formed steel compression members under fire conditions is not fully investigated yet and hence there is a lack of knowledge on the fire performance of cold-formed steel compression members. Current cold-formed steel design standards do not provide adequate design guidelines for the fire design of cold-formed steel compression members. Therefore a research project based on extensive experimental and numerical studies was undertaken to investigate the local buckling behaviour of light gauge cold-formed steel compression members under simulated fire conditions. First a series of 91 local buckling tests was conducted at ambient and uniform elevated temperatures up to 700 °C on cold-formed lipped and unlipped channels. Suitable finite element models were then developed to simulate the behaviour of tested
columns and were validated using test results. All the ultimate load capacity results for local buckling were compared with the predictions from the available design rules based on AS/NZS 4600, BS 5950 Part 5, Eurocode 3 Parts 1.2 and 1.3 and the direct strength method (DSM), based on which suitable recommendations have been made for the fire design of cold-formed steel compression members subject to local buckling at uniform elevated temperatures.

“Dynamic axial crashing of tailor-welded blanks (TWBs) thin-walled structures with top-hat shaped section”, Advances in Engineering Software, Vol. 96, pp 70-82, June 2016, DOI: 10.1016/j.advengsoft.2016.02.003
ABSTRACT: In this paper, dynamic axial crashing analysis of tailor-welded blanks (TWBs) thin-walled structures with top-hat shaped section under front impact is presented. The crash tests are performed through a sled test in order to model a car-to-car front impact. The strain rate dependence of both high strength steels (DP590 and DP780) is considered to study its influence on acceleration and energy absorption involved into high speed impacting process. The FE model about the front dynamic crashing is conducted, and different weld line modeling types on the dynamic simulation results such as acceleration history are compared. It demonstrates that coincide node (CN) model is considered appropriate for simulating the dynamic impacting. Additionally, the effects of weld line locations and spotweld spacing are also performed. It may be concluded that the material and thickness properties of front end have certain influence on the crashworthiness performance of TWBs. The simulation results show that the acceleration curves of three TWB combinations are insensitive to spotweld spacing. A comprehensive analysis including the crash mode, the acceleration curves and the energy absorption is carried out for crashworthiness assessment. The obtained results can provide some insightful guide information and fundamental supports for light-weight and crashworthiness design of TWBs to a certain extent.

ABSTRACT: Large and small cylindrical shells have long been used as tanks and silos to store materials such as oil and its derivatives. The radius-to-thickness ratio of these shells is 500:2000; as a result, buckling collapse of these thin-walled structures is of major concern for designers. The present study examined inelastic buckling behavior of cylindrical shells near the base, known as elephant foot buckling. This form of buckling occurs under high internal pressure exerted simultaneously with axial compression. The buckling of cylindrical shells subjected to combined axial loads and internal pressure was experimentally studied and tested and a new method of strengthening steel cylindrical shells using fiber-reinforced polymer (FRP) composite materials is presented. The proposed method was studied by numerical methods using a nonlinear algorithm, and the results were evaluated for resistance to buckling of cylindrical shells. The results provide effective and useful information for use in retrofitting cylindrical shell tanks.
Wenfeng Du and Nasim Uddin, “Innovative composite structural insulated panels (CSIPs) folded shell structures for large-span roofs”, Materials and Structures, Vol. 50, No. 51, February 2017
DOI: 10.1617/s11527-016-0924-3

ABSTRACT: Composite structural insulated panels (CSIPs) have the potential to construct lighter large-span roof structures due to high strength-to-weight ratio. However, the drawback of large deflection severely limits their applications. Two effective methods improving the stiffness of CSIPs were investigated in this paper at first. One is the method of folding, which improves the moment of inertia of cross-section areas using the principle of folded panels. The other is the method of curving, which transforms structural bending moments into axial forces using the principle of arches. Then an innovative CSIPs folded shell structure was proposed by combining the advantages of above two methods together. The mechanical behaviors of the CSIPs folded shell structure were studied comparing with CSIPs folded panels and CSIPs thin shells. The static analysis results showed the maximum vertical displacement of the CSIPs folded shell structure under self-weight was 11.054 mm, which was much less than that of CSIPs folded panel (129.17 mm) and that of CSIPs thin shell (89.78 mm). The results of geometrical nonlinear analysis demonstrated that the CSIPs folded shell structure has 5 times larger nonlinear buckling load capacity than the CSIPs thin shell. CSIPs folded shell structures have excellent structural configurations and extensive application prospects in large-span roof structures.

ABSTRACT: In this paper, the buckling analysis of thin walled composite cylindrical shells with and without cutouts is investigated by applying axial load on Glass Fiber Reinforced Plastic (GFRP) shell. The effect of cutout not only introduces stress concentration but also significantly reduces the buckling strength. The column is fixed at one end and load is applied at the other end. The Static and Eigenvalue buckling analysis is done on shell model. The circular, elliptical and rectangle cutouts are considered on cylindrical shell. The buckling analysis is repeated in each case. The compressive stress, buckling load factor and lateral strain of each case for cylindrical shell is obtained from ANSYS software. The buckling load decreases for shell with cutout when compared to the value of the shell without a cutout. Stress and lateral strain increases for shell with cutout when compared to the shell without a cutout. The buckling load value is maximum in circular cutout and minimum in the rectangular cutout.

ABSTRACT: Curved micromechanical beams are a versatile platform for exploring multistable behavior, with potential applications in mechanical based logic elements and electrical and optical switches. Here we demonstrate bidirectional electrostatic actuation of a bistable, latched, micromechanical beam by the same electrode, which was used for the snap-through switching of the device. The release of the mechanically-latched beam is achieved by pre-loading the structure using a rising voltage applied to the electrode, followed by a sudden decrease of the voltage. This abrupt removal of the loading results in a transient response and dynamic snap-back of the beam.

ABSTRACT: To get a strong, stiff and weight efficient cylindrical shell, a carbon fiber reinforced orthogrid-core sandwich cylinder was designed and fabricated. The core is made up of orthogonal grids and manufactured by interlocking method. The sandwich cylinder is fabricated by filament winding method. Free vibration test combining with theoretical analysis and numerical simulation was carried out to reveal the vibration responses and estimate the modulus of the wound laminate. Uniaxial compression test was performed to reveal the strength and failure mode. Without end flanges, laminate delamination at the end controls the peak load. Delamination of skins induces interfacial debonding and dimpling of inner skin finally. An engineering method based on the average strain at the peak load is proposed to predict the load capacity of the cylinder. Compared with stiffened cylinder, the orthogrid sandwich cylinder is stiffer and stronger. Meanwhile, its making process is simplified and the mechanical ability is comparable with other lattice-core sandwich cylinders.

ABSTRACT: The nonlinear free vibration and postbuckling behaviors of multilayer functionally graded (FG) porous nanocomposite beams that are made of metal foams reinforced by graphene platelets (GPLs) are investigated in this paper. The internal pores and GPL nanofillers are uniformly dispersed within each layer but both porosity coefficient and GPL weight fraction change from layer to layer, resulting in position-dependent
elastic moduli, mass density and Poisson's ratio along the beam thickness. The mechanical property of closed-cell cellular solids is employed to obtain the relationship between coefficients of porosity and mass density. The effective material properties of the nanocomposite are determined based on the Halpin-Tsai micromechanics model for Young's modulus and the rule of mixture for mass density and Poisson's ratio. Timoshenko beam theory and von Kármán type nonlinearity are used to establish the differential governing equations that are solved by Ritz method and a direct iterative algorithm to obtain the nonlinear vibration frequencies and postbuckling equilibrium paths of the beams with different end supports. Special attention is given to the effects of varying porosity coefficients and GPL's weight fraction, dispersion pattern, geometry and size on the nonlinear behavior of the porous nanocomposite beam. It is found that the addition of a small amount of GPLs can remarkably reinforce the stiffness of the beam, and its nonlinear vibration and postbuckling performance is significantly influenced by the distribution patterns of both internal pores and GPL nanofillers.

ABSTRACT: The new Reference Resistance Design (RRD) method, recently developed by Rotter [1], for the manual dimensioning of metal shell structures effectively permits an analyst working with only a calculator or spreadsheet to take full advantage of the realism and accuracy of an advanced nonlinear finite element (FE) calculation. The method achieves this by reformulating the outcomes of a vast programme of parametric FE calculations in terms of six algebraic parameters and two resistances, each representing a physical aspect of the shell’s behaviour. The formidable challenge now is to establish these parameters and resistances for the most important shell geometries and load cases. The systems that have received by far the most research attention for RRD are that of a cylindrical shell under uniform axial compression and uniform bending. Their partial algebraic characterisations required thousands of finite element calculations to be performed across a four-dimensional parameter hyperspace (i.e. length, radius to thickness ratio, imperfection amplitude, linear strain hardening modulus). Handling so many nonlinear finite element models is time-consuming and the quantities of data generated can be overwhelming. This paper illustrates a computational strategy to deal with both issues that may help researchers establish sets of RRD parameters for other important shell systems with greater confidence and accuracy. The methodology involves full automation of model generation, submission, termination and processing with object-oriented scripting, illustrated using code and pseudocode fragments.

ABSTRACT: The nonlinear axisymmetric post-buckling behavior of perfect thin spherical shells subject to external pressure and their asymmetric bifurcations are characterized providing results for a structure/loading combination with an exceptionally nonlinear buckling response. Immediately after the onset of buckling, the buckling mode localizes into a dimple at the poles. The relations among the pressure, the dimple amplitude and the change in volume of the shell are determined for large deflections. These results allow accurate evaluation of criteria such as the Maxwell condition for which the energy in the unbuckled and buckled states are the same and evaluation of the influences of pressure versus volume controlled loadings. Non-axisymmetric bifurcation from the axisymmetric state which occurs deep into the post-buckling regime in the form of multi-lobed dimples is also established and discussed.

Michael Rotter, “Shell buckling transformed: Mechanics, design processes and their inter-relation”, Stahlbau, Vol. 86, No. 4, pp 315-324, April 2017, DOI: 10.1002/stab.201710478 (Dedicated to Professor Herbert Schmidt on his 80th birthday)
ABSTRACT: This paper, in honour of Professor Herbert Schmidt, provides a brief description of two parallel but connected historical developments in the field of the buckling of thin metal shells, an area in which Professor Schmidt has made very significant contributions over the last four decades. The developments in shell buckling mechanics have been enormous over the last century, in addressing challenging practical problems and in changing from difficult mathematics to universal access for competent engineers. The second development has been in design calculations for practising engineers, moving from crude empiricism based on simple tests into a complete framework that can house all computational predictions in a structured manner, permitting very complex problems to be fully characterised. These two fields are quite separate, especially in the early part of the 20th century, and still lie somewhat apart, but the problems encountered in practical engineering continue to influence the development of shell buckling mechanics, whilst the conceptual framework for practical design is evolving to accommodate the most complex of findings in structural mechanics.

ABSTRACT: Thin-walled cylindrical shells are commonly used in numerous branches of industry. Since they are subjected to axial load, the most common cause of their failure is buckling. This paper provides numerical analysis and experimental verification of the buckling of the thin-walled aluminium alloy cylindrical shell with special regard to the influence of dent, positioned in the middle of the shell. Numerical simulation was performed using ANSYS 16.2, and experimental verification was performed by means of hydraulic press Armavir, PSU-50, which was used to subject the specimen to the increasing axial load until the occurrence of buckling. Comparing the results it was concluded that there is significant decrease of the buckling resistance if compared the values of the specimen with no dent, and the specimen with 2 mm deep dent. On the contrary, resistance of the 2 mm and 4 mm dented specimen is quite similar. Position and shape of the deformations occurred due to buckling are matching if experimental and numerical results are compared.

ABSTRACT: Buckling and post buckling of cylindrical shells under hydrostatic pressure is regarded as important issue in structure of submarines. These cylindrical shells have variable thickness due to construction process which effected by pressure of buckling and its destruction. In this paper, effects of changing thickness on buckling and destruction pressure under external hydrostatic pressure of a shell are studied. Results of buckling pressure of cylindrical shell have been obtained with theoretical relations and finite element method. Then, using machining process a sample of cylindrical shell with variable thickness has been produced. Buckling pressure and post buckling of the constructed sample have been obtained with the reservoir under closed-ended hydrostatic pressure. Changes of the test sample size have been considered with closed-ended testing apparatuses which are used for new evaluation of buckling. In this research, results of the pressure have been obtained in terms of the volume change. At the end, results of the finite element method have been compared with results of the analytical solutions and experimental data. Results show that the shell with variable thickness has buckling pressure close to shell bucking pressure with mean thickness.

ABSTRACT: We compute nonlinear force equilibrium solutions for a clamped thin cylindrical shell under axial compression. The equilibrium solutions are dynamically unstable and located on the stability boundary of the unbuckled state. A fully localized single dimple deformation is identified as the edge state—the attractor for the dynamics restricted to the stability boundary. Under variation of the axial load, the single dimple undergoes homoclinic snaking in the azimuthal direction, creating states with multiple dimples arranged around the central circumference. Once the circumference is completely filled with a ring of dimples, snaking in the axial direction leads to further growth of the dimple pattern. These fully nonlinear solutions embedded in the stability boundary of the unbuckled state constitute critical shape deformations. The solutions may thus be a step towards explaining when the buckling and subsequent collapse of an axially loaded cylinder shell is triggered.

ABSTRACT: Shells are among the most frequent structural components which are used in construction and industrial projects. Shell structures are composed of shell bearing elements and mainly used in oil and gas tanks, offshore marine platforms, silos, funnels, cooling towers, ship and aircraft body, etc. Despite the frequent use of steel cylindrical shells, their construction and assembling process has caused main problems. In these structures,
there is no possibility for the integrated construction due to their large shell extent and they are built using a number of welded curved panel parts; hence, some geometrical imperfections emerge. Most of these imperfections are caused by the process of welding, transportation, inappropriate rolling, as well as installation and implementation problems. These imperfections have a direct impact on the structural behavior of shells during the buckling and external compressive load. Since in most shell tanks during operation, there is high possibility for the suction (vacuum) state, compressive forces in their thin wall cause buckling and failure. In this research, the imperfections made in steel cylindrical tanks being constructed in one of the refinery site are introduced and evaluated using a field study. Relying on the statistical inference, they are classified and then, by studying the effective factors and origin in their generation, the common imperfections are identified. Later, the impact of common imperfections on the buckling behavior is experimentally evaluated under uniform external pressure. Then, nonlinear numerical analysis of the test specimens is performed. Finally, experimental results, finite element and analytical relations are compared.

ABSTRACT: Shell structures are susceptible to various types of imperfections and damage such as cracking, corrosion, chemical attack and time-dependent material degradation, which may impair their structural integrity and affect their service life. The effects of cracks are important considerations in the design of cylindrical shell structures as they influence on load carrying capacity and safety. This present work is a finite element investigation on the vibration, buckling and fracture analysis of a cracked cylindrical shell subjected to a time varying rotating speed. The effects of crack length, orientation of crack and length-diameter ratio of the cylindrical shell are investigated under free-vibration and buckling. The fracture parameters like stress intensity factor and J-integral of the cracked shell are also studied considering the influence of crack length and crack orientation. Results reveal that the crack length and crack orientation can affect the vibration, buckling behaviour of the cylindrical shell significantly.

ABSTRACT: Shell structures are widely used in civil, mechanical, aerospace and marine engineering applications (e.g. offshore oil tanks, automotive industry, aircraft and submarines). Like other types of structures, they are susceptible to various types of defect and damage such as cracking, corrosion, chemical attack and time-dependent material degradation, which may impair their structural integrity and affect their service life. The presence of cracks in a cylindrical structure can considerably affect its behavior. The effects of these imperfections on load carrying capacity and safety are thus important considerations in the design of cylindrical shell structures. This present work presents a finite element study on the vibration, buckling and fracture behavior of a cracked cylindrical shell with clamped type supports and subject to a time varying rotating speed. Vibration, linear elastic buckling and fracture parameters of a cracked cylindrical shell with
time-varying rotating speed are analyzed. The effects of constant rotating speed, crack length and orientation of crack and length-diameter ratio of the cylindrical shell on the free-vibration and buckling behaviors are investigated.

Arash Ghaedizadeh, Jianhu Shen, Xin Ren and Yi Min Xie (Centre for Innovative Structures and Materials, School of Engineering, RMIT University, GPO Box 2476, Melbourne 3001, Australia), “Tuning the performance of metallic auxetic metamaterials by using buckling and plasticity”, Materials, Vol. 9, No. 1, 54, 2016, doi:10.3390/ma9010054

ABSTRACT: Metallic auxetic metamaterials are of great potential to be used in many applications because of their superior mechanical performance to elastomer-based auxetic materials. Due to the limited knowledge on this new type of materials under large plastic deformation, the implementation of such materials in practical applications remains elusive. In contrast to the elastomer-based metamaterials, metallic ones possess new features as a result of the nonlinear deformation of their metallic microstructures under large deformation. The loss of auxetic behavior in metallic metamaterials led us to carry out a numerical and experimental study to investigate the mechanism of the observed phenomenon. A general approach was proposed to tune the performance of auxetic metallic metamaterials undergoing large plastic deformation using buckling behavior and the plasticity of base material. Both experiments and finite element simulations were used to verify the effectiveness of the developed approach. By employing this approach, a 2D auxetic metamaterial was derived from a regular square lattice. Then, by altering the initial geometry of microstructure with the desired buckling pattern, the metallic metamaterials exhibit auxetic behavior with tuneable mechanical properties. A systematic parametric study using the validated finite element models was conducted to reveal the novel features of metallic auxetic metamaterials undergoing large plastic deformation. The results of this study provide a useful guideline for the design of 2D metallic auxetic metamaterials for various applications.

ABSTRACT: The buckling and layer failure characteristics of composite laminated cylinders subjected to hydrostatic pressure were investigated through finite element analysis for underwater vehicle application. The Tsai-Wu failure criteria were used as the failure criteria for the buckling analysis. A sensitivity analysis was conducted to research the influence of the number of elements on the critical buckling pressure. ANSYS, a finite element program, successfully predicted the buckling pressure with 5.3–27.8% (linear) and 0.3–22.5% (nonlinear) deviation from experimental results. The analysis results showed that the cylinders can carry more pressure after a slight decrease in pressure and recovery of the supporting load. For layer failure analysis, it was found that the failure that occurred in the 0° layer was more serious than that in the 90° layer within the neighboring layers at the inner layers (nos. 1–7) and outer layers (nos. 8–24).

ABSTRACT: Micro-buckling of unidirectional fiber-reinforced composites is investigated in this paper by means of an explicit representation of a geometrically imperfect fiber within the context of kinematical and material non-linear behavior. Two types of fiber imperfections are considered: a helicoidal shape, identified as 3D imperfection; and a sinusoidal plane shape (2D imperfection). Both imperfection models are characterized by a maximum misalignment angle of the fiber with respect to the ideal or perfect configuration, as is usually considered in this field. A total of 816 cases were computed in terms of imperfection type (either 2D or 3D), fiber volume fraction, fiber arrangement (square or hexagonal array), orientation for 2D models, matrix yield stress, and misalignment angle. Two load cases, with constrained and unconstrained transverse strain, were considered. Assuming periodic boundary conditions, homogenization was carried out to obtain macroscopic stresses. Numerical results are compared with an analytical model available in the literature. The results show a high imperfection-sensitivity for small misalignment angles; on the other hand, the type of imperfection and the fiber arrangement do not have a large influence on the results. In addition, it was found that this problem is governed by fiber volume fraction and matrix yield stress only for small imperfections, whereas for large misalignment angles, a change in fiber volume fraction produces small changes in micro-buckling stress.

Loads. Results show that the FML layup has a significant effect on the buckling loads of FML cylindrical composite fiber orientation, stacking sequence of layers and geometric parameters. Afterward, the effects of FML parameters such as metal volume fraction (MVF), experimental and analytical data for buckling behavior of FML cylindrical shells in the literature, the proposed calculation and finite element approaches. The governing equations are derived based on the first-order shear deformation theory and solved by the Navier solution method. Also, the buckling load of a FML cylindrical shell is calculated using linear eigenvalue analysis in commercial finite element software, ABAQUS. Due to lack of experimental and analytical data for buckling behavior of FML cylindrical shells in the literature, the proposed model is simplified to the full-composite and full-metal cylindrical shells and buckling loads are compared with the available results. Afterwards, the effects of FML parameters such as metal volume fraction (MVF), composite fiber orientation, stacking sequence of layers and geometric parameters are studied on the buckling loads. Results show that the FML layup has a significant effect on the buckling loads ofFML cylindrical shells.
shells in comparison to the full-composite and full-metal shells. Results of this paper hopefully provide a useful guideline for engineers to design an efficient and economical structure.

ABSTRACT: In this paper, non-linear dynamics analysis of functionally graded material (FGM) shell structures is investigated using the higher order solid-shell element based on the Enhanced Assumed Strain (EAS). With this element, a quadratic distribution of the shear stress through the thickness is considered in an enhancing part. Material properties of the shell structure are varied continuously in the thickness direction according to the general four-parameter power-law distribution in terms of the volume fractions of the constituents. Performance and accuracy of the present higher order solid-shell element are confirmed by comparing the numerical results obtained from finite element analyses with results from the literature.

ABSTRACT: We report the results of an experimental and numerical investigation into the buckling of thin elastic rings confined within containers of circular or regular polygonal cross section. The rings float on the surface of water held in the container and controlled removal of the fluid increases the confinement of the ring. The increased compressive forces can cause the ring to buckle into a variety of shapes. For the circular container, finite perturbations are required to induce buckling, whereas in polygonal containers the buckling occurs through a linear instability that is closely related to the canonical Euler column buckling. A model based on Kirchhoff–Love beam theory is developed and solved numerically, showing good agreement with the experiments and revealing that in polygons increasing the number of sides means that buckling occurs at reduced levels of confinement.

http://journals.rudn.ru/structural-mechanics/article/view/14617

ABSTRACT: В настоящей статье рассматривается устойчивость функционально-градиентных эпитрохоидальных оболочек под давлением и тепловой среды. Свойства материала принимаются как зависящие от температуры. Конечно-элементные решения получены с помощью программного комплекса ANSYS. Линейные задачи на собственные значения устойчивости решается с помощью блочного метода Ланцоша. Влияние различной геометрии и параметров материала на критическую температуру функционально-градиентных эпитрохоидальных оболочек под давлением и тепловой средой наглядно показано. В конце, изменение напряжений, перемещений, вращений и деформаций изучены и представлены.

ABSTRACT: In the present study, the size-dependent buckling behavior of carbon nanotubes (CNTs) is investigated on the basis of orthotropic shell model. Due to the nature of carbon nanotubes, their properties differ in various directions; therefore, they must be treated as anisotropic shells. Moreover, due to the small dimensions of CNTs, material length scale parameter must be included to predict the mechanical behavior of CNTs more accurately; accordingly this study is carried out on the basis of the new modified couple stress theory. CNT buckling affects the stability of nanocomposites and nanoactuators and small dimensions and different properties affect the CNT stability. In this article, using minimum potential energy principle, the equilibrium equations and boundary conditions are derived. Then, the buckling response of simply supported CNTs under combined loading is studied and the critical buckling load of the orthotropic CNT is calculated for various structural and geometrical conditions. Finally, the molecular dynamics (MD) simulation is performed to investigate the axial buckling behaviour of defective CNTs.

ABSTRACT: Perforated steel thin plates are commonly used in structural engineering. Due to their geometric characteristics, these panels can suffer the undesired buckling phenomenon. In this context, the present work associates the computational modeling and the constructal design method to evaluate the influence of the geometric configuration in the plate buckling behavior, using the exhaustive search method to determine which geometries conduct to superior mechanical behavior. To do so, numerical models are employed to solve elastic and elasto-plastic buckling of plates having a centered perforation. Different hole types (longitudinal oblong, transversal oblong, elliptical, rectangular, diamond, longitudinal hexagonal, or transversal hexagonal) with different shapes (variation of characteristics dimensions of each hole type) are analyzed. Limit curves to avoid buckling were obtained, as well as the definition of the geometries that can improve up to 107% the plate performance.

ABSTRACT: Composite lattice structures are shells that are reinforced by unidirectional helical and hoop ribs. Their main advantage over contemporary composite structures is their superior stiffness to mass ratio. However, their application in industry is still limited. In this paper, the lattice structure concept was applied for the case of a small business aircraft. Emphasis here is given at the initial stages of the design. More specifically, the buckling modes for bending loads were calculated by utilizing a continuum unit cell model which was correlated with finite element models for a cylindrical small fuselage structure and two scaled down versions.

ABSTRACT: Cell-generated mechanical forces drive many of the tissue movements and rearrangements that are required to transform simple populations of cells into the complex three-dimensional geometries of mature organs. However, mechanical forces do not need to arise from active cellular movements. Recent studies have illuminated the roles of passive forces that result from mechanical instabilities between epithelial tissues and their surroundings. These mechanical instabilities cause essentially one-dimensional epithelial tubes and two-dimensional epithelial sheets to buckle or wrinkle into complex topologies containing loops, folds, and undulations in organs as diverse as the brain, the intestine, and the lung. Here, I highlight examples of buckling and wrinkling morphogenesis, and suggest that this morphogenetic mechanism may be broadly responsible for sculpting organ form.

Nunes (King Abdullah University of Science and Technology (KAUST), Biological and Environmental Science and Engineering Division (BESE), Thuwal, Saudi Arabia), “Evolution of regular geometrical shapes in fiber lumens”, Scientific Reports, Vol. 7, Article number: 9171, August 2017, doi:10.1038/s41598-017-09134-z

ABSTRACT: The geometry of polymeric hollow fibers for hemodialysis or desalination is a key factor determining their performance. Deformations are frequently observed, but they are rather random. Here we were able to exactly control the shape evolution of the internal channels or lumens of polymeric hollow fibers, leading to polygonal geometries with increasing number of sides. The elasticity of the incipient channel skin and instabilities during fiber formation are affected by the internal coagulant fluid composition and flow rate; and highly influence the polygonal shape. We propose a holistic explanation by analyzing the thermodynamic, kinetic and rheological aspects involved in the skin formation and their synergy.

ABSTRACT: In this research work, an exact analytical solution for frequency characteristics of the free vibration of rotating functionally graded material (FGM) truncated conical shells reinforced by eccentric FGM stringers and rings has been investigated by the displacement function method. Material properties of shell and stiffeners are assumed to be graded in the thickness direction according to a simple power law distribution. The change of spacing between stringers is considered. Using the Donnell shell theory, Leckhinsky smeared stiffeners technique and taking into account the influences of centrifugal force and Coriolis acceleration the governing equations are derived. For stiffened FGM conical shells, it is difficult that free vibration equations are a couple set of three variable coefficient partial differential equations. By suitable transformations and applying Galerkin method, this difficulty is overcome in the paper. The sixth order polynomial equation for $\omega$ is obtained and it is used to analyze the frequency characteristics of rotating ES-FGM conical shells. Effects of stiffener, geometrics parameters, cone angle, vibration modes and rotating speed on frequency characteristics of the shell forward and backward wave are discussed in detail. The present approach proves to be reliable and accurate by comparing with published results available in the literature.

ABSTRACT: The main aim of this paper is to investigate analytically nonlinear buckling and post-buckling of functionally graded stiffened circular cylindrical shells filled inside by Pasternak two-parameter elastic foundations in thermal environments and under axial compression load and external pressure by analytical approach. Shells are reinforced by closely spaced rings and stringers. The material properties of shell and the stiffeners are assumed to be continuously graded in the thickness direction. Using the Reddy third order shear deformation shell theory, stress function method and Lekhnitskii smeared stiffeners technique, the governing equations are derived. The closed form to determine critical axial load and post-buckling load-deflection curves are obtained by Galerkin method. The effects of temperature, stiffener, foundation, material and dimensional parameters on the stability behavior of shells are shown. The accuracy of the presented method is affirmed by comparisons with well-known results in references. The results shown for thick cylindrical shells, the use of TSDT for determining their critical buckling load is necessary and more suitable.

ABSTRACT: The mechanics of a fascicle insertion into the skin by a mosquito of the type *aedes aegypti* has been studied experimentally using high-speed video (HSV) imaging, and analytically using a mathematical model. The fascicle is a polymeric microneedle composed of a ductile material, chitin. It has been proposed that the mosquito applies a non-conservative follower force component in addition to the Euler compressive load in order to prevent buckling and penetrate the skin. In addition, the protective sheath surrounding the fascicle (labium) provides lateral support during insertion. The mechanics model presented approximates the fascicle as a slender column supported on an elastic foundation (labium) subjected to non-conservative (Beck) and
conservative Euler loads simultaneously at the end. Results show that the lateral support of the fascicle provided by the labium is essential for successful penetration by increasing the critical buckling load by a factor of 5. The non-conservative follower force application increases the buckling load by an additional 20% and may or may not be necessary for successful penetration. Experimental results showing the importance of the labium have been cited to validate the model predictions, in addition to the video observations presented in this work. This understanding may be useful in designing painless needle insertion systems as opposed to miniaturized hypodermic needles.

ABSTRACT: Thin walled tubes are often used for load-bearing structures, in nature and in engineering, because they offer good resistance to bending and torsion at relatively low weight. However, when loaded in bending they are prone to failure by buckling. It is difficult to predict the loading conditions which cause buckling, especially for tubes whose cross sections are not simple shapes. Insights into buckling prevention might be gained by studying this phenomenon in the exoskeletons of insects and other arthropods. We investigated the leg segments (tibiae) of five different insects: the locust (Schistocerca gergaria), American cockroach (Periplaneta americana), death's head cockroach (Blaberus discoidalis), stick insect (Parapachymorpha zomproi) and bumblebee (Bombus terrestris audax). These were tested to failure in cantilever bending and modelled using finite element analysis (FEA). The tibiae of the locust and the cockroaches were found to be approximately circular in shape. Their buckling loads were well predicted by linear elastic FEA, and also by one of the analytical solutions available in the literature for elastic buckling. The legs of the stick insect are also circular in cross section but have several prominent longitudinal ridges. We hypothesised that these ridges might protect the legs against buckling but we found that this was not the case: the loads necessary for elastic buckling were not reached in practice because yield occurred in the material, causing plastic buckling. The legs of bees have a non-circular cross section due to a pollen-carrying feature (the corbicula). We found that this did not significantly affect their resistance to buckling. Our results imply that buckling is the dominant failure mode in the tibia of insects; it likely to be a significant consideration for other arthropods and any organisms with stiff exoskeletons. The interactions displayed here between material properties and cross sectional geometry may provide insights for the biomimetic design of engineering structures using thin walled tubes.

ABSTRACT: This thesis deals with shell structures in shape of a cylinder and an arch. First a cylindrical shell is examined analytically and numerically to see how the shell behaves under meridional- and circumferential compression and torsion. Afterwards imperfections are implemented by using an eigenmode as initial geometry to see how this affects the buckling stress. It is seen that the imperfection reduces the buckling stress as expected and the larger the scaling factor of the eigenmode is the lower is the buckling stress. Afterwards, a study of shells in the shape of an arch is analysed in order to determine the optimal geometry when considering buckling and yielding. Here a circular, parabolic and catenary cross sectional geometry is analysed when exposed to an inside suction, self weight and line load on top of the arc. The results shows that the different shapes have a large influence on the buckling stress. It is also concluded that the support type is of importance since they might increase or decrease the stresses. Finally, imperfections are implemented in the arch and the
results show that the different types of imperfection have different influence on the buckling stress.

ABSTRACT: A typical mechanical failure mode observed in slender percutaneous instruments, such as needles and guidewires, is buckling. Buckling is observed when the axial compressive force that is required to penetrate certain tissue types exceeds the critical load of the instrument and manifests itself by sudden lateral deflection of the instrument. In nature, several organisms are able to penetrate substrates without buckling while using apparatuses with diameters smaller than those of off-the-shelf available percutaneous needles and guidewires. In this study we reviewed the apparatuses and buckling prevention strategies employed by biological organisms to penetrate substrates such as wood and skin. A subdivision is made between buckling prevention strategies that focus on increasing the critical load of the penetration tool and strategies that focus on decreasing the
penetration load of the substrate. In total, 28 buckling prevention strategies were identified and categorized. Most organisms appear to be using a combination of buckling prevention strategies simultaneously. Integration and combination of these biological buckling prevention strategies in percutaneous instruments may contribute to increasing the success rate of percutaneous interventions.

ABSTRACT: This paper presents the effect of stiffeners on the free vibration response of delaminated composite shallow cylindrical shells employing the finite element method. An eight-noded isoparametric shell element based on the first-order shear deformation theory is combined with a three-noded isoparametric curved beam element in the present formulation. The stiffeners follow the nodal lines of the shell wherein the stiffness and mass of the stiffeners are lumped at the corresponding nodal points of the shell elements considering curvature and eccentricity. The generalized dynamic equilibrium equation is derived from Lagrange’s equation of motion, wherein Coriolis effect for moderate rotational speeds is neglected. The multi-point constraint algorithm has been used to model delamination at the desired locations wherein the compatibility of deformation and equilibrium of stress resultants are ensured at the delamination crack front. Numerical results are presented for cantilevered long, intermediate and short cylindrical shells as defined by Aas-Jakobsen’s parameters, and the influence of important parameters like location of delamination, twist angle, rotational speed, number of layers and eccentricity of the stiffeners is studied. The mode shapes for a typical composite un-stiffened and stiffened long cylindrical shell at different rotational speeds and twist angles are also presented.

ABSTRACT: We study a Brownian dynamics simulation model of a biopolymeric shell deformed by axial forces exerted at opposing poles. The model exhibits two distinct, linear force-extension regimes, with the response to small tensions governed by linear elasticity and the response to large tensions governed by an effective spring constant that scales with radius as \( R^{-0.25} \). When extended beyond the initial linear elastic regime, the shell undergoes a hysteretic, temperature-dependent buckling transition. We experimentally observe this buckling transition by stretching and imaging the lamina of isolated cell nuclei. Furthermore, the interior contents of the shell can alter mechanical response and buckling, which we show by simulating a model for the nucleus that quantitatively agrees with our micromanipulation experiments stretching individual nuclei.

Fahimeh Mehralian, Yaghoub Tadi Beni and Yaser Kiani (Faculty of Engineering, Shahrekord University, Shahrekord, Iran), “Molecular dynamics study on the thermal buckling of carbon nanotubes in the presence of pre-load”, Materials Research Express, Vol. 4, No. 1, January 2017, https://doi.org/10.1088/2053-1591/aa576a

ABSTRACT: This paper presents a molecular dynamics (MD) study on the thermally induced buckling of pre-compressed carbon nanotubes (CNTs) using AIREBO interatomic potential. CNTs are compressed at a certain ratio of their critical buckling strain and then undergo a uniform temperature rise. In order to evaluate the chirality effects, armchair and zigzag CNTs are investigated. The results demonstrate that critical buckling temperature depends strongly on the geometrical parameters such as chirality, diameter and aspect ratio. The armchair CNTs, due to their bond configuration, show higher resistance to thermal buckling than zigzag ones. Moreover, the buckling mechanism is strongly affected by the length of CNTs. At small aspect ratios, radial limit load shell buckling occurs while by increase in aspect ratio above the critical one different behaviors emerge. Due to the strong thermal oscillation of carbon atoms, increase in temperature changes perfect nanotubes to defective ones.

Fattahi (Department of Mechanical Engineering, Bandar Anzali Branch, Islamic Azad University, Bandar Anzali, Iran), “An anisotropic calibrated nonlocal plate model for biaxial instability analysis of 3D metallic carbon nanosheets using molecular dynamics simulations”, Materials Research Express, Vol. 4, No. 6, June 2017, https://doi.org/10.1088/2053-1591/aa6bc0

ABSTRACT: Based upon an interlocking hexagonal arrangement of carbon atoms, it is possible to have a mechanically stable three-dimensional (3D) carbon structure including metallicity which provides a wide range of applications. In the present study, a novel calibrated size-dependent plate model using nonlocal continuum...
theory of elasticity with an exponential distribution of the shear deformation is constructed to anticipate accurately the nonlinear instability response of biaxially loaded 3D metallic carbon nanosheets. Explicit expressions for the size-dependent equilibrium curves are proposed via a two-stepped perturbation technique. After that, the critical biaxial buckling loads obtained by the developed nonlocal plate model are matched with those evaluated by some molecular dynamics (MD) simulations of biaxial instability of square 3D metallic carbon nanosheets to catch the proper value of nonlocal parameter. It is indicated that by using the proposed calibrated nonlocal plate model, the error in prediction of the biaxial instability behavior of 3D metallic carbon nanosheets reduces significantly.

ABSTRACT: This paper deals with the theoretical analysis of free vibration and biaxial buckling of magneto-electro-elastic (MEE) microplate resting on Kelvin–Voigt visco-Pasternak foundation and subjected to initial external electric and magnetic potentials, using modified strain gradient theory (MSGT). Kirchhoff plate model and Hamilton's principle are employed to extract the governing equations of motion. Governing equations were analytically solved to obtain clear closed-form expression for complex natural frequencies and buckling loads using Navier's approach. Numerical results are presented to reveal variations of natural frequency and buckling load ratio of MEE microplate against different amounts of the length scale parameter, initial external electric and magnetic potentials, aspect ratio, damping and transverse and shear stiffness parameters of the visco-Pasternak foundation, length to thickness ratio, microplate thickness and higher modes. Numerical results of this study illustrate that by increasing thickness-to-material length scale parameter ratio, both natural frequency and buckling load ratio predicted by MSGT and modified couple stress theory are reduced because the non-dimensional length scale parameter tends to decrease the stiffness of structures and make them more flexible. In addition, results show that initial external electric and initial external magnetic potentials have no considerable influence on the buckling load ratio and frequency of MEE microplate as the microplate thickness increases.

Jiyoon Nam, Bowook Seo, Youngjoo Lee, Dong-Ho Kim and Sungjin Jo, “Cross-buckled structures for stretchable and compressible thin film silicon solar cells”, Scientific Reports, Vol. 7, Article Number 7575, August 2017, doi:10.1038/s41598-017-08012-y

ABSTRACT: Increasing interests in stretchable electronic devices have resulted in vigorous research activities, most of which are focused on structural configurations. Diverse structural configurations are available for stretchability, including stiff-island, serpentine, and buckled structures. With easily deformable shapes and simple fabrication processes, buckled structures have the potential to realize stretchability. However, conventional buckled structures exhibit stretchability only in a single-axis direction. In the present study, a new type of cross-buckled structure, which can overcome the limitations of conventional buckled structures is developed. The stretchable thin film solar cells with the cross-buckled structure showed stable mechanical and electrical characteristics under both stretching and compressing conditions. The cross-buckled structure for stretchable electronic devices is expected to broaden the fields of wearable electronics, stretchable displays, and biocompatible applications.

ABSTRACT: We present a novel cellular metamaterial constructed from Origami building blocks based on Miura-ori fold. The proposed cellular metamaterial exhibits unusual properties some of which stemming from the inherent properties of its Origami building blocks, and others manifesting due to its unique geometrical construction and architecture. These properties include foldability with two fully-folded configurations, auxeticity (i.e., negative Poisson’s ratio), bistability, and self-locking of Origami building blocks to construct load-bearing cellular metamaterials. The kinematics and force response of the cellular metamaterial during folding were studied to investigate the underlying mechanisms resulting in its unique properties using analytical modeling and experiments.

ABSTRACT: Programmable stiff sheets with a single low-energy folding motion have been sought in fields ranging from the ancient art of origami to modern meta-materials research. Despite such attention, only two extreme classes of crease patterns are usually studied; special Miura-Ori-based zero-energy patterns, in which crease folding requires no sheet bending, and random patterns with high-energy folding, in which the sheet bends as much as creases fold. We present a physical approach that allows systematic exploration of the entire space of crease patterns as a function of the folding energy. Consequently, we uncover statistical results in origami, finding the entropy of crease patterns of given folding energy. Notably, we identify three classes of extreme classes of crease patterns ranging from the ancient art of origami to modern meta-materials research.

ABSTRACT: A large number of references dealing with the geometric stiffness matrix of the DKT finite element exist in the literature, where nearly all of them adopt an inconsistent form. While such a matrix may be part of the element to treat nonlinear problems in general, it is of crucial importance for linearized buckling analysis. The present work seems to be the first to obtain an explicit expression for this matrix in a consistent way. Numerical results on linear buckling of plates assess the element performance either with the proposed explicit consistent matrix, or with the most commonly used inconsistent matrix.

ABSTRACT: Tiny concentrations of suspended particles may alter the behavior of an evaporating droplet remarkably, leading to partially viscous and partially elastic dynamical characteristics. This, in turn, may lead to some striking mechanical instabilities, such as buckling and rupture. Here, we report certain non-trivial implications of the consequent morpho-dynamics (macro to nano scales), when such an evaporating droplet is encapsulated in a confined environment. Compared to unconfined scenario, we report non-intuitive suppression of rupturing beyond a critical confinement. We attribute this to confinement-induced dramatic alteration in the evaporating flux, leading to distinctive spatio-temporal characteristics of the internal flow leading to preferential particle transport and subsequent morphological transitions. We present a regime map quantifying buckling-non-buckling pathways. These results may turn out to be of profound importance towards achieving desired morphological features of a colloidal droplet, by aptly tuning the confinement space, initial particle concentration, as well as the initial droplet volume.

ABSTRACT: Currently, lattice composite structures have many applications in aerospace industries. The present research analyzed the effect of an external skin consisting of a lattice’s cylindrical shell on the buckling strength of composite materials, both numerically and experimentally. Two classes of specimens, with and without external skins, were fabricated using the filament winding process. To find the buckling strength of the fabricated samples, tests were carried out. For validation of the experimental results, the finite element method was used to test the shells under the same testing conditions. The results of the experimental and numerical tests showed good agreement with one another, revealing that the lattice cylindrical shell specimen with the outer skin had a much higher buckling strength than the one without the outer skin (≈50%). The added weight of the outer skin was negligible compared to the overall weight of the lattice cylindrical shell, and the external skin had a tremendous positive effect on the buckling strength to weight ratio of the lattice composite structures.

ABSTRACT: We explore how thermal fluctuations affect the mechanics of thin amorphous spherical shells. In flat membranes with a shear modulus, thermal fluctuations increase the bending rigidity and reduce the in-plane elastic moduli in a scale-dependent fashion. This is still true for spherical shells. However, the additional coupling between the shell curvature, the local in-plane stretching modes, and the local out-of-plane undulations leads to novel phenomena. In spherical shells, thermal fluctuations produce a radius-dependent negative effective surface tension, equivalent to applying an inward external pressure. By adapting renormalization group calculations to allow for a spherical background curvature, we show that while small spherical shells are stable, sufficiently large shells are crushed by this thermally generated “pressure.” Such shells can be stabilized
by an outward osmotic pressure, but the effective shell size grows nonlinearly with increasing outward pressure, with the same universal power-law exponent that characterizes the response of fluctuating flat membranes to a uniform tension.

ABSTRACT: This contribution provides simulated results of cross-sectional deformations observed in carbon nanotubes under high pressure. Molecular dynamics (MD) simulations were performed to explore radial buckling characteristics of multi-walled carbon nanotubes, and confirmed a variety of large-amplitude deformation modes. The energetically stable deformation mode turned out to be strongly dependent on the diameter of the innermost tube and the number of concentric walls. Critical buckling pressure obtained by MD simulations was compared with that estimated from a continuum elastic approximation, by which the validity of the continuum approximation was assessed.

[NOTE: “particle morphology” includes buckling.]

ABSTRACT: Powders of nanoparticles are volatile, i.e. easily disperse in air, which makes their handling difficult. Granulation of nanoparticle powders provides a solution to that issue, and it is generally performed by spray drying the nanoparticles that have been suspended in a liquid. Spray drying of a colloidal suspension consists of atomising the suspension into droplets by a fast flowing and hot gas. Once the droplets dried, the resulting dry grains/microparticles can be used in a wide range of applications – food, pharmaceutics, fillers, ceramics, etc. It is well known that the grains resulting from spray-drying may be spherical but may also exhibit other diverse morphologies. Although different influencing parameters have been identified, no clear overview can be found in the literature for the driving mechanisms of grain shaping. In the present work, we review the assumptions made in the literature to explain the different morphologies. We analyse the orders of magnitude of the different effects at stake and show that the grain shape does not result from a hydrodynamic instability but is determined by the drying stage. However, we emphasize that neither the drying time nor the associated Péclet number are critical parameters for the determination of shape morphology. In light of those results, we also review and discuss the single droplet experiments developed to mimic spray drying. Generalising our previous works, we further analyse how the control of morphology can be achieved by tuning the colloidal interactions in the suspension. We detail the model we have developed that relates the colloidal interaction potential to a critical pressure exerted by the solvent as it flows, and we provide a quantitative prediction of the grain shape. Finally, we offer perspectives with regard to spray drying of systems such as molecular solutions, widely performed in e.g. the pharmaceutical industry.
ABSTRACT: The present paper discusses reliability of dynamic buckling of single layer reticulated domes under dead and seismic loads. First, several domes with different safety factors for dead load are designed based on elasto-plastic buckling analysis. Second, the dynamic buckling loads obtained based on dynamic nonlinear analysis of these domes are analyzed aiming at formulating a mathematical expression for buckling loads in terms of related structural variables. Then, an equation for the dynamic buckling load is formulated explicitly in terms of the related variables. Third, concerning dynamic buckling under dead and seismic loads, a performance function for reliability is expressed in terms of seismic input acceleration intensity as action and buckling strength as resistance. Fourth, a trial is performed to evaluate an approximate value of reliability index using a performance function, then solved successively using AFOSM method, and the values of reliability index for reticulated domes using 50-year and 100-year reference periods are searched considering the related stochastic properties. Finally, the paper discusses the relationship between reliability index and safety factor for dead load in the two cases of reference period from a viewpoint of structural design for ordinary structures.

ABSTRACT: In this paper a physically based and deterministic design procedure for spherical shells under external pressure is introduced. Within the new design concept the membrane energy of a sphere is incrementally reduced by means of perturbation cutouts, until a bending energy dominate state is identified. The threshold between membrane energy state and bending energy state represents a robust plateau for the buckling pressure. A comprehensive numerical investigation was performed in order to study the influence of radius-to-thickness ratio (R/t) as well as the dome height-to-base radius ratio (H/r). The results verify that both geometric properties ratios significantly influence the lower-bound buckling pressure, especially if plastic buckling occurs. Improved shell buckling design factors are given in the form of an simple analytic equation. The corresponding threshold KDFs were validated with a large number of buckling experiments and deliver much higher KDFs than currently used empirical guidelines. Based on the new design criterion lower-bound estimation for the buckling pressure of a tori-spherical bulkhead and the inner dome of the cryogenic upper stage ESC-A from the European space launch-vehicle Ariane 5 are determined.

ABSTRACT: The buckling behaviour of thin shell structures under load has been a persistent challenge to engineering designers and researchers over many decades. In this article I consider two unusual experimental studies on the buckling of thin-walled elastic cylindrical shells, each of which sheds intriguing light on the buckling phenomena. The classical theory of buckling of thin cylindrical shells under axial compression predicts that the buckling stress will be proportional to \( t/R \) – the ratio of thickness to radius – other things being equal. But collected results of experimental studies from many laboratories, when plotted on log–log scales, show clearly that the buckling stress is actually proportional to \( (t/R)^1.5 \), with the measured buckling stresses being scattered through a factor of about 4 for shells with \( R/t > 200 \). Such scatter is commonly judged to be in accord with Koiter’s theory of ‘imperfection sensitivity’. But that theory lays no claim to an understanding of the empirical 1.5-power law. I claim that a key to this situation is the experimental performance of some small-scale open-topped silicone rubber shells, buckling under their own weight, which clearly demonstrates a 1.5-power law, but with very little scatter. The buckling mode of these shells involves almost entirely inextensional deformation, with a single small dimple growing near the base, separated from the rest of the shell by a narrow boundary layer that accounts for almost all of the dimple’s elastic strain energy. A straightforward, simple analysis of the mechanics of the dimple is consistent with the experimental 1.5-power law. As noted above, experimental buckling loads of shells that are closed at both ends also show the empirical 1.5-power law, but now with significant statistical scatter. A second aim of the paper is to throw light on that phenomenon. I venture to attribute it to the effect of the boundary conditions of the shell. I adduce support for this view from experimental observations on the buckling of a shell with special, frictional end-fittings. That feature produces significantly higher collapse loads, and with much smaller scatter, than for corresponding shells with fixed boundaries; and it permits striking pre-buckled deformations to occur, of a kind not previously noted. It will be appreciated that neither of the two parts of this article depends on the widely accepted theory of imperfection-
sensitivity; hence my choice of title. It is a pleasure for me to submit this article to a special publication in honour of Michael Rotter, with whom I have discussed matters of this sort through three decades.

Wang Xiang, “Cellular cavity structure and its building technology for shell structure with thin sheet materials”, Ph.D dissertation, Darmstadt University, 2017
ABSTRACT: This research investigates a new structure concept and its building techniques for shell structures that can be built with thin sheet materials. Shell structures have been a desired structure type for both architects and structural engineers due to its efficient load-bearing behavior and also the elegant curved geometry. In the past decades, innovational structure concepts such as grid-shells and spatial framework structures have continuously pushed the development of shell structures towards a comprehensive type of structures which provides a better structural behavior of building materials.
This dissertation argues for a material-driven design methodology of the new shell structure design through a well-rounded revisit of the development of shells in the past decades. And a new type of industrial materials has been selected for the innovational structure concept of the novel type of shells.
The research is based on a comprehensive analysis of the materials’ application in the existing industrial and architectural design, as well as the theoretical analysis of the materials’ behavior and the corresponding fabrication techniques and structural consideration in designs. A novel structure concept is then generated with also the inspiration of the natural cellular structures.
The main focus of the architectural analysis is the design procedure of the cellular cavity structure, including the form-finding process, the structural consideration of the stability problem of thin materials, the possible simple fabrication with the materials form a planar sheet form. At the same time, a collaborative design process is also discussed to enable a better cooperation between both architects and engineers.
A novel shell was finally built as a demonstrator of such a structure concept. With a dome which reaches a span of 5 meters and a height of 2.5 meters and was built only with 1mm paperboard as major materials, the load-bearing capacity and the construction details of the cellular cavity structure is tested and evaluated.
Finally, through the comparison with the recent parallel research and the popular experimental shell designs in the past several years, the cellular cavity structure is positioned into a series of relevant research fields. With the analysis of the limitations of this research, future works are also defined for the improvement and future development of this Ph.D. research.

ABSTRACT: The performance of recently proposed flag-based energy harvesters is strongly limited by the chaotic response of flags to strong winds. From an experimental point of view, the detection of flag chaotic dynamics were scarce, based on the flapping amplitude and the maximal Lyapunov exponent. In practice, tracking the flapping amplitude is difficult and flawed in the large oscillation limit. Also, computing the maximal Lyapunov exponent from time series of limited size requires strong assumptions on the attractor geometry, without getting insurance of their reliability. For bypassing these issues, (1) we use a time series which takes into account the whole dynamic of the flag, by using the flapping moment which integrates its displacements, and (2) we apply an algorithm of detection of chaos based on recurring values in time series.

ABSTRACT: We measure the response of cylindrical shells to poking and identify a stability landscape, which fully characterizes the stability of perfect shells and imperfect ones in the case where a single defect dominates. We show that the landscape of stability is independent of the loading protocol and the poker geometry. Our results suggest that the complex stability of shells reduces to a low dimensional description. Tracking ridges and valleys of this landscape defines a natural phase-space coordinates for describing the stability of shells.
References listed at the end of the paper:
[14] Note that in the situations where during the buckling process several dimples are formed (more common at high axial loads), $D_{p}^S$ only indicates the depth of the dimple in the direction of the poker and the other dimples are not taken into account.
[15] For load-controlled compression, the shell is totally crushed when buckling is induced; thus, $D_{p}^S$ cannot be measured.
[17] A violent drop in the poking force is observed for axial loads of $F_0^A 1/4859$ or $F_0^A 1/41084$ N in Fig. 2(a). In these two cases the force drops to zero significantly faster than the axial loading rate. We did not observe any rate dependence of the mechanical response in the loading rate range that we tested (0.1 to 10 mm= min).

Van Vinh Nguyen, “Direct strength method for the design of cold-formed steel sections under localized loading”, Ph.D dissertation, Civil Engineering, The University of Sydney, 2017
ABSTRACT: The main objective of the thesis is the development of the Direct Strength Method (DSM) for the design of cold-formed steel sections under general localised loading. In order to calibrate the DSM equations, it is necessary to have three main input variables which are the buckling load, the yield load and the experimental data.
The first objective of this research is the development of the Finite Strip Method (FSM) theory for analysis of thin-walled sections under localised loading with general end boundary conditions to determine the buckling load as described in Chapters 3 and 4 of the thesis. The theory is included in Version 2.0 of the THIN-WALL-2 program which can be used for analysing structural members under generalised loading conditions as described in Chapter 5.
The second objective is the formulation of plastic mechanism models to estimate the yield load of thin-walled sections subjected to localised loading. In order to establish these models, observations are performed from
experiments to ascertain the failure modes of structural members under localised loading with different cross-sections, load cases and flange fastening conditions. From the data, new simple plastic mechanism models are built-up based on the concept of the balance between the internal energy of the structural member and the external energy of the applied loads to estimate the yield load as described in Chapter 6.

The third objective is collating the experimental data of thin-walled sections under localised loading. The data is collected from previous literature for different types of cross-sections: un-lipped plain-C, lipped plain-C, SupaCee and Dimond Hi-Span channel (DHS) sections subjected to all load cases. In addition, both flange fastened and unfastened conditions are assembled in the experimental database as described in Chapter 6.

From these three input variables, the DSM design equations are proposed for structural members under general localised loading. The method is a consistent and simplified model generalised for all localised load cases. It includes both an inelastic reserve component as observed in testing and a yield load component. Also, a reliability analysis calibration is performed to validate the accuracy of the DSM predictions with the collected experimental data as described in Chapter 7.

SUMMARY: The thin walled structures are used in many area, such as aircraft, space vehicles, and missiles thanks to providing lower weight than the thicker structure. However, when the lower weight is providing, there can be some lost of the strength of the structure. One of the possible problem that coming with having thin walled structures is the buckling. The shell structures under compression load may have some deformation. The loading type which causes to the buckling may be the axial compression loading, torsional loading, bending loading, hydrostatic or external pressure. In this thesis, the consideration is only given to the axially compressed cylinders thanks to the most cylinders are under this type of loading and more sensitive the structures under that type of loading.

When the structure under compressive load, at a point, it suddenly start to buckle. This point is the critical point for that structure. At that point, the structure has the deformation. This deformed shape can still carry the loading but, of course, it is lower than the critical load value. The behavior, after buckling, called post buckling behavior. This implies that the buckled structure can be still used with the lower buckling strength.

The phenomena buckling is studied for decades. For the derive the critical buckling load under axially compressed cylinders, the stability theory is used and both energy and the Donnell approaches is provided in the thesis. As the result of the derivation, the critical stress value is $\frac{Et}{r} \sqrt{3(1 - \mu^2)}$. Since the stress value is the ratio of the force to area of the load applied. For the cylindrical shell structure, area that the load applied is $2\pi rt$. Therefore the buckling load formula is obtained as $2\pi \frac{Et^2}{\sqrt{3(1 - \mu^2)}}$.

Keep in mind that, this formula is only valid for the medium length cylinder. As it is seen form the critical load formula, it is highly depended to the thickness of the shell structure. The shorter cylinders are behaves plate like and longer cylinders behave like the Euler column. The length range of the cylinder is decided with the help of the Batdorf parameter.

After the theoretical part the analysis are presented. To be able to making numerical analysis, first of all the optimization of the some parameters should be made. Those parameters are mesh density, element type, constrain and load type etc. After the suitable parameters are chosen, the analyses are made and compared to the theoretical value. The computer program used the linear eigenvalue analysis for buckling prediction. The lowest eigenvalue is provides to calculate the critical eigenvalue. When it is multiplied with the applied load, the result is the critical load value.

For the verification of the numerical study, the obtained value is compared with the analytic solution. Also, some papers are found and the cylinders in those papers are modeled and the results are compared.

Then, the some addition properties are given to the cylinder to see the effect of them. These additions are used to increase the strength of the structure. For instance, the composite material is used in terms of aluminum. For the same mass, the composite material have higher critical value. When the effect of stringer and ring stiffened structure is investigated, it is realized that the effect of the ring is lower than the ring since the load is applied to the longitudinal direction. In addition, the shell cylinders are used as tank, for that reason, effect of the internal
pressure is investigated. As it is expected, the internal pressure provide higher critical load value.
After the investigation of the stiffeners, composite material, and internal pressure, the inertia relief load is applied to the same model. Inertia relief load is applied for simulating the free structures like spacecraft, aircraft, or rocket. This kind of load is applied for the static, dynamic, or buckling analysis. Obtained buckling shape is shown in the thesis. The critical value that is obtained is the critical thrust value, as the cylinder is considered as the rocket body. Obtained value is low but it is sourced from the lack of the internal pressure or some structural components like stiffeners.
After all the analysis are performed, to see the buckling behavior, an experimental study is performed. For the test specimens, the Coca-Cola can is used. The top and bottom side of the cans are cut off and the buckling test is performed with the two aluminum plate placed to the top and bottom side of the cylinder. Although there is a significant difference. It can be sourced because of the high sensitivity of the buckling. The load eccentricity has a great influence. Therefore, the analysis are made with the eccentric loading.

ABSTRACT: Material efficiency in modern tank constructions often is achieved by combining thin plates with
light and heavy ring stiffeners. While the plates are designed to resist hydrostatic pressure, the stiffeners are designed against wind and external pressure. Axial buckling may occur due to high roof loads and wind since very thin plates are prone to a loss of stability.

Test results in the 60s and 70s revealed that closely spaced ring-stiffeners may greatly enhance the axial buckling behavior, allowing for knock-down factors greater unity. However, until today, no design procedure is available allowing for adopting the beneficial effect of ring stiffeners under axial compression into practical design.

In this paper a design procedure is proposed that closes this gap in current design codes. One outcome of the conducted literature study revealed that test results of unstiffened shells may be more closely approximated and is shortly presented. The design procedure for ring-stiffened shells was then developed from lower bound curves deduced from categorized buckling tests.

The results of a parametrical study, that was conducted over a wide range of r/t-values, is presented. Imperfection depths up to 10t were examined using a stiffener spacing of one buckling half-wave. Especially highly slender stiffened cylinders benefit from ring-stiffening, showing up to 380% strength gains.

Imperfection depths proposed by the current design code were found to be too conservative.

Yang Zhou, Ilinca Stanciulescu, Thomas Eason and Michael Spottswood, “Fast approximations of dynamic stability boundaries of slender curved structures”, ABSTRACT: Curved beams and panels can often be found as structural components in aerospace, mechanical and civil engineering systems. When curved structures are subjected to dynamic loads, they are susceptible to dynamic instabilities especially dynamic snap-through buckling. The identification of the dynamic stability boundary that separate the non-snap and post-snap responses is hence necessary for the safe design of such structures, but typically requires extensive transient simulations that may lead to high computation cost. This paper proposes a scaling approach that reveals the similarities between dynamic snap-through boundaries of different structures. Such identified features can be directly used for fast approximations of dynamic stability boundaries of slender curved structures when their geometric parameters or boundary conditions are varied. The scaled dynamic stability boundaries of half-sine arches, parabolic arches and cylindrical panels are studied.

ABSTRACT: Shells are important structural elements widely used in various engineering applications ranging from outer space to deep oceans such as rockets, aircrafts, missiles, submarines and automobiles etc. A huge amount of research efforts has been devoted to vibration analysis and dynamic behaviors of the shells. Furthermore, a large variety of shell theories and computational methods have been proposed and developed by researchers. For different cases different computational approaches have been used in literature to study the vibration characteristics of shells. This review is aimed to provide contemporarily relevant survey of papers on vibrational characteristics of shells and identification of various methods and approaches that have been used to study its vibration characteristics. Focus has been kept to important and prominent studies and its compilation in a single paper to help future researchers to identify relevant literature quickly and easily and also help them to apply these approaches to study vibration characteristics of other built up and coupled structures.

ABSTRACT: The purpose of this paper is to establish the mathematical model on the elastic-plastic transitions occurring in the rotating spherical shells based on compressibility of materials. The paper investigates the elastic-plastic stresses and angular speed required to start yielding in rotating shells for compressible and incompressible materials. The paper is based on the non-linear transition theory of elastic-plastic shells given by B.R. Seth. The elastic-plastic transition obtained is treated as an asymptotic phenomenon at critical points & the solution obtained at these points generates stresses. The solution obtained does not require the use of semi-empirical yield condition like Tresca or Von Mises or other certain laws. Results are obtained numerically and depicted graphically. It has been observed that Rotating shells made of the incompressible material are on the safer side of the design as compared to rotating shells made of compressible material. The effect of density variation has been discussed numerically on the stresses. With the effect of density variation parameter, rotating spherical shells start yielding at the internal surface with the lower values of the angular speed for incompressible/compressible materials.

Abdullah Mahmoud, “Analysis and design of spirally welded thin-walled steel tapered cylindrical shells under bending with application to wind turbine towers”, PhD dissertation, Johns Hopkins University, Baltimore, 2017
ABSTRACT: An important obstacle restricting the growth of wind-generated energy is the production of taller towers for wind turbines that can harvest energy from the steadier, stronger winds at higher elevations. Currently, the need to transport wind turbine tower sections to the construction site constrains the diameter of the section, which then limits the height of the tower. This limitation can be avoided if the tower sections are made on-site, and one potential method for on-site manufacturing is automated spiral welding. This thesis, which focuses largely on computational modeling for design, is part of a larger research effort to advance the application of spirally welded tubes (SWTs) in wind tower structures. With the new manufacturing technique, a wider range of tower diameters and thicknesses, and potentially more optimal thin-walled sections can be employed. Thin-walled shells are one of the most advanced and efficient forms of large structures; however, their behavior can be unstable and extremely sensitive to imperfections. For decades, the structural design of such shell structures relied on elastic buckling “knockdown factors” obtained from experimental results, but with the expansion in the capabilities of computational modeling, today design is working to leverage the power of shell finite element models that are geometrically and materially nonlinear with imperfections included (i.e. “GMNIA” analysis models). This thesis explores the analysis and design of spirally welded tapered cylindrical steel shells and complements experimental results conducted as a companion to this effort within the larger SWT effort. The thesis includes an introduction and historical background on the development of research on thin shells; a summary of relevant experimental work completed in the literature and in the SWT project; careful examination of geometric imperfections in the world of shells in general and spirally welded shells in particular; provides a practical finite element modeling protocol for predicting the flexural strength and collapse behavior of thin-walled spirally welded tapered steel tubes; validates the proposed modeling protocols for GMNIA models with SWT test results; extends the results to provide standard “reference resistance” curves that can be used for future GMNIA analyses by structural designers; and highlights the application to an archetype 3MW wind turbine tower using both classical and new analysis-based.

ABSTRACT: We investigate the elastic buckling of a triangular prism made of a soft elastomer. A face of the prism is bonded to a stiff slab that imposes an average axial compression. We observe two possible buckling modes which are localized along the free ridge. For ridge angles $\Phi$ below a critical value $\Phi^* \approx 90^\circ$, experiments reveal an extended sinusoidal mode, while for $\Phi$ above $\Phi^*$, we observe a series of creases progressively invading the lateral faces starting from the ridge. A numerical linear stability analysis is set up using the finite-element method and correctly predicts the sinusoidal mode for $\Phi < \Phi^*$, as well as the associated critical strain $\varepsilon^*(\Phi)$. The experimental transition at $\Phi^*$ is found to occur when this critical strain $\varepsilon^*(\Phi)$ attains the value $\varepsilon^*(\Phi^*) = 0.44$ corresponding to the threshold of the subcritical surface creasing instability. Previous analyses have focused on elastic crease patterns appearing on planar surfaces, where the role of scale invariance has been emphasized; our analysis of the elastic ridge provides a different perspective, and reveals that scale invariance is
not a sufficient condition for localization.

ABSTRACT: Inspired by the differential-growth-driven morphogenesis of leaves, flowers, and other tissues, there is increasing interest in artificial analogs of these shape-shifting thin sheets made of active materials that respond to environmental stimuli such as heat, light, and humidity. But how can we determine the growth patterns to achieve a given shape from another shape? We solve this geometric inverse problem of determining the growth factors and directions (the metric tensors) for a given isotropic elastic bilayer to grow into a target shape by posing and solving an elastic energy minimization problem. A mathematical equivalence between bilayers and curved monolayers simplifies the inverse problem considerably by providing algebraic expressions for the growth metric tensors in terms of those of the final shape. This approach also allows us to prove that we can grow any target surface from any reference surface using orthotropically growing bilayers. We demonstrate this by numerically simulating the growth of a flat sheet into a face, a cylindrical sheet into a flower, and a flat sheet into a complex canyon-like structure.

ABSTRACT: The rapid growth of the human cortex during development is accompanied by the folding of the brain into a highly convoluted structure\(^1\)–\(^3\). Recent studies have focused on the genetic and cellular regulation of cortical growth\(^4\)–\(^8\), but understanding the formation of the gyral and sulcal convolutions also requires consideration of the geometry and physical shaping of the growing brain\(^9\)–\(^15\). To study this, we use magnetic resonance images to build a 3D-printed layered gel mimic of the developing smooth fetal brain; when immersed in a solvent, the outer layer swells relative to the core, mimicking cortical growth. This relative growth puts the outer layer into mechanical compression and leads to sulci and gyri similar to those in fetal brains. Starting with the same initial geometry, we also build numerical simulations of the brain modelled as a soft tissue with a growing cortex, and show that this also produces the characteristic patterns of convolutions over a realistic developmental course. All together, our results show that although many molecular determinants control the tangential expansion of the cortex, the size, shape, placement and orientation of the folds arise through iterations and variations of an elementary mechanical instability modulated by early fetal brain geometry.

ABSTRACT: Predicting the large-amplitude deformations of thin elastic sheets is difficult due to the complications of self contact, geometric nonlinearity, and a multitude of low-lying energy states. We study a simple two-dimensional setting where an annular polymer sheet floating on an air-water interface is subjected to different tensions on the inner and outer rims. The sheet folds and wrinkles into many distinct morphologies that break axisymmetry. These states can be understood within a recent geometric approach for determining the gross shape of extremely bendable yet inextensible sheets by extremizing an appropriate area functional. Our analysis explains the remarkable feature that the observed buckling transitions between wrinkled and folded shapes are insensitive to the bending rigidity of the sheet.

ABSTRACT: In order to examine the accuracy of the enhanced double directors shell model for the functionally graded material (FGM) shell structures, a series of benchmark static tests are tackled using finite elements method. For implementing the discrete double directors shell model (DDDSM) within the Enhanced Strain Technique (EST), four parameters are used for enhancing the membrane strain. The vanishing of transverse shear strains on top and bottom faces is considered in a discrete form. The mechanical properties of
the shell structure are assumed to vary continuously in the thickness direction by a simple power-law
distribution in terms of the volume fractions of the constituents. A comparison with the exact solutions
presented by several authors for shell structures indicates that the present model accurately estimates the stress-
strain responses.

strain enhanced solid-shell element for laminated composite structures analysis”, in Multiphysics Modelling
and Simulation for Systems Design and Monitoring, pp 497-506, 2015, Springer
ABSTRACT: This paper presents a free from locking higher order solid-shell element based on the Enhanced
Assumed Strain (EAS) for laminated composite structures analysis. The transverse shear strain is divided into
two parts: the first one is independent of the thickness coordinate and formulated by the Assumed Natural Strain
(ANS) method; the second part is an enhancing part which ensures a quadratic distribution through the
thickness. This permit to remove the shear correction factors and improves the accuracy of transverse shear
stresses. Also, volumetric locking is completely avoided by using the optimal parameters in the EAS method.
Comparisons of numerical results with those extracted from literature show the performance of the developed
finite element.

with enhanced solid-shell element”, in Advances in Acoustics and Vibration, pp 291-300, 2017, Springer
ABSTRACT: This paper presents the non linear dynamic response of multilayer composites with an enhanced
solid-shell element. The transverse shear and transverse normal locking are treated using the Assumed Natural
Strain formulation (ANS). For the enhanced part, one, three and five parameters are examined. Comparisons of
numerical results with those extracted from literature show the good performance of the developed formulation
in the isotropic case. The three enhancement choices give the same results in the multilayer composite case.

Amin Taraghi Osguei, Mohamad Taghi Ahmadian, Mohsen Asghari and Nicola Maria Pugno, “A shell model
for free vibration analysis of carbon nanoscroll”, Materials (MDPI), Vol. 10, p 387, 6 April 2017
ABSTRACT: Carbon nanoscroll (CNS) is a graphene sheet rolled into a spiral structure with great potential for
different applications in nanotechnology. In this paper, an equivalent open shell model is presented to study the
vibration behavior of a CNS with arbitrary boundary conditions. The equivalent parameters used for modeling
the carbon nanotubes are implemented to simulate the CNS. The interactions between the layers of CNS due to
van der Waals forces are included in the model. The uniformly distributed translational and torsional springs
along the boundaries are considered to achieve a unified solution for different boundary conditions. To study the
vibration characteristics of CNS, total energy including strain energy, kinetic energy, and van der Waals
energy are minimized using the Rayleigh-Ritz technique. The first-order shear deformation theory has been
utilized to model the shell. Chebyshev polynomials of first kind are used to obtain the eigenvalue matrices. The
natural frequencies and corresponding mode shapes of CNS in different boundary conditions are evaluated. The
effect of electric field in axial direction on the natural frequencies and mode shapes of CNS is investigated. The
results indicate that, as the electric field increases, the natural frequencies decrease.

Jorge Yarasca and J.L. Mantari, “N-objective genetic algorithm to obtain accurate equivalent single layer models with layerwise capabilities for challenging sandwich plates”, Aerospace Science and Technology, Vol. 70, pp 170-188, July 2017

ABSTRACT: This paper presents refined equivalent single layer plate theories develop by an effective N-objective optimization method, considering multiple displacements and stresses as output parameters. The refined plate theories reported belong to Best Theory Diagrams (BTDs), in which the minimum number of terms that have to be used to achieve a desired accuracy can be read. Maclaurin, high order zig-zag, trigonometric, exponential and hyperbolic terms are employed in order to investigate their influence on several static mechanical studies for sandwich plates. The used refined models are develop via the Unified Formulation developed by Carrera. The governing equations are derived from the Principle of Virtual Displacement (PVD), and Navier-type closed form solutions have been obtained in the case of simply supported plates subjected to binuisoidal transverse pressure. BTDs have been constructed using the Axiomatic/Asymptotic Method (AAM) and genetic algorithms (GA). The results are compared with the layer-wise solution in several benchmarks proposed in the literature. It is shown that the ESL plate models can accurately describe the displacement field and the mechanical stress fields predicted by a LW model with less computational effort, even for extreme theoretical cases. Furthermore, the method presented allows the user to analyze the influence of numerous test functions in a single run. The combined use of CUF, AAM and GA is a powerful tool to evaluate the accuracy of any structural theory.

composite plates employing polynomial, zig-zag, trigonometric and exponential thickness expansions”.

Composite Structures, Vol. 176, pp 860-876, June 2017

ABSTRACT: This paper presents Best Theory Diagrams (BTDs) for plates considering all the displacement and stress components as objectives. The BTD is a diagram in which the minimum number of terms that have to be used to achieve the desired accuracy can be read. Maclaurin, zig-zag, trigonometric and exponential expansions are employed for the static analysis of cross-ply composite plates. The Equivalent Single Layer (ESL) approach is considered, and the Unified Formulation developed by Carrera is used. The governing equations are derived from the Principle of Virtual Displacement (PVD), and Navier-type closed form solutions are adopted. BTDs are obtained using the Axiomatic/Asymptotic Method (AAM) and genetic algorithms (GA). The results show that the BTD can be used as a tool to assess the accuracy and computational efficiency of any structural models and to draw guidelines to develop structural models. The inclusion of the multiobjective capability extends the BTD validity to the recognition of the role played by each output parameter in the refinement of a structural model.

ABSTRACT: The effects of the hydroelastic coupling on structures in contact with fluid are pronounced when composite materials are used due to the low composite density. This paper presents an analytical solution for the free vibration analysis of thick rectangular composite plates in contact with a bounded fluid. The plate displacement field is analyzed using Carrera Unified Formulation in order to consider displacement theories of arbitrary order. The displacement variables are approximated using the Ritz method. Analysis considering any of the classical boundary conditions is performed using suitable functions in the Ritz series. The fluid kinetic energy is obtained by considering an inviscid and incompressible fluid, and thus the velocity potential is applicable. The kinetic and potential energy of the plate are also obtained, and the energy functional is used to derive the eigenvalue problem. Validation is performed with results in the open literature and by using 3D finite element software. The influence of the fiber orientations on the natural frequencies is discussed, as well as the influence of the plate and fluid domain geometry. Certain natural frequencies are seen to be independent of the fluid domain depth, depending on the symmetric or antisymmetric nature of the normal mode.

ABSTRACT: A so far unavailable quasi-3D trigonometric shear deformation theory for the bending analysis of functionally graded plates is presented. This theory considers the thickness-stretching effect ($\epsilon_{zz}$ not = 0) by modeling the displacement field with just four unknowns and rich trigonometric shear strain shape functions. The principle of virtual works is used to derive the governing equations and boundary conditions. Results from this theory are compared with the CPT, first-order shear deformation theory (FSDT), and other quasi-3D HSDTs. In conclusion, this theory is more accurate than the CPT and FSDT and behaves as well as quasi-3D HSDTs having much less number of unknowns.

ABSTRACT: This paper develops a coupling approach which integrates the meshfree method and isogeometric analysis (IGA) for static and free-vibration analyses of cracks in thin-shell structures. In this approach, the domain surrounding the cracks is represented by the meshfree method while the rest domain is meshed by IGA. The present approach is capable of preserving geometry exactness and high continuity of IGA. The local refinement is achieved by adding the nodes along the background cells in the meshfree domain. Moreover, the equivalent domain integral technique for three-dimensional problems is derived from the additional Kirchhoff-Love theory to compute the J-integral for the thin-shell model. The proposed approach is able to address the problems involving through-the-thickness cracks without using additional rotational degrees of freedom, which facilitates the enrichment strategy for crack tips. The crack tip enrichment effects and the stress distribution and displacements around the crack tips are investigated. Free vibrations of cracks in thin shells are also analyzed. Numerical examples are presented to demonstrate the accuracy and computational efficiency of the coupling approach.

References listed at the end of the paper:
ABSTRACT: An extended isogeometric thin shell analysis (XIGA) for the analysis of through-the-thickness cracks in thin shell structures is developed. The discretization is based on Non-Uniform Rational B-Splines (NURBS). The proposed XIGA formulation can reproduce the singular field near the crack tip and the discontinuities across the crack. It is based on the Kirchhoff-Love theory where C1-continuity of the displacement field is required. This condition is satisfied by the NURBS basis functions. Hence, the formulation eliminates the need of rotational degrees of freedom or the discretization of the director field facilitating the enrichment strategy. The performance and validity of the formulation is tested by several benchmark examples.

ABSTRACT: NURBS-based isogeometric analysis was first extended to thin shell/membrane structures which allows for finite membrane stretching as well as large deflection and bending strain. The assumed non-linear kinematics employs the Kirchhoff–Love shell theory to describe the mechanical behaviour of thin to ultra-thin structures. The displacement fields are interpolated from the displacements of control points only, and no rotational degrees of freedom are used at control points. Due to the high order $C^k$ ($k \geq 1$) continuity of NURBS shape functions the Kirchhoff–Love theory can be seamlessly implemented. An explicit time integration scheme is used to compute the transient response of membrane structures to time-domain excitations, and a dynamic relaxation method is employed to obtain steady-state solutions. The versatility and good performance of the present formulation are demonstrated with the aid of a number of test cases, including a square membrane subjected to static pressure, the inflation of a spherical shell, the inflation of a square airbag in excitations, and a dynamic inflation of a rubber balloon. The mechanical contribution of the bending stiffness is also evaluated.

ABSTRACT: This thesis presents two new methods in finite elements and isogeometric analysis for structural analysis. The first method proposes an alternative alpha finite element method using triangular elements. In this method, the piecewise constant strain field of linear triangular finite element method models is enhanced by additional strain terms with an adjustable parameter $\alpha$, which results in an effectively softer stiffness formulation compared to a linear triangular element. In order to avoid the transverse shear locking of Reissner-Mindlin plates analysis the alpha finite element method is coupled with a discrete shear gap technique for triangular elements to significantly improve the accuracy of the standard triangular finite elements. The basic idea behind this element formulation is to approximate displacements and rotations as in the standard finite element method, but to construct the bending, geometrical and shear strains using node-based smoothing domains. Several numerical examples are presented and show that the alpha FEM gives a good agreement compared to several other methods in the literature. Second method, isogeometric analysis based on rational splines over hierarchical T-meshes (RHT-splines) is proposed. The RHT-splines are a generalization of Non-Uniform Rational B-splines (NURBS) over hierarchical T-meshes, which is a piecewise bicubic polynomial over a hierarchical T-mesh. The RHT-splines basis functions not only inherit all the properties of NURBS such as non-negativity, local support and partition of unity but also more importantly as the capability of joining geometric objects without gaps, preserving higher order continuity everywhere and allow local refinement and adaptivity. In order to drive the adaptive refinement, an efficient recovery-based error estimator is employed. For this problem an imaginary surface is defined. The imaginary surface is basically constructed by RHT-splines basis functions which is used for approximation and interpolation functions as well as the construction of the recovered stress components. Numerical investigations prove that the proposed method is capable to obtain results with higher accuracy and convergence rate than NURBS results.

ABSTRACT: This paper presents an alternative alpha finite element method using triangular meshes (AaFEM) for static, free vibration and buckling analyses of laminated composite plates. In the AaFEM, an assumed strain field is carefully constructed by combining compatible strains and additional strains with an adjustable parameter $\alpha$ which can produce an effectively softer stiffness formulation compared to the linear triangular element. The stiffness matrices are obtained based on the strain smoothing technique over the smoothing domains and the constant strains on triangular sub-domains associated with the nodes of the elements. The discrete shear gap (DSG) method is incorporated into the AaFEM to eliminate transverse shear locking and an improved triangular element termed as AaDSG3 is proposed. Several numerical examples are then given to demonstrate the effectiveness of the AaDSG3.

[80] A.J.M. Ferreira, A formulation of the multiquadric radial basis function method for the analysis of laminated composite plates,

ABSTRACT: Isogeometric analysis (IGA) aims at simplifying the Computer Aided Design (CAD) and Computer Aided Engineering (CAE) pipeline by using the same functions to describe the geometry (CAD) and the unknown fields (Analysis). IGA can be based on a variety of CAD descriptions, the most widely used today being Non-Uniform Rational B-Splines (NURBS). In this paper, we investigate the suitability of NURBS-based isogeometric analysis within a third-order shear deformation theory for the simulation of the static, dynamic and buckling response of laminated composite plates. The method employs NURBS basis functions to both represent the geometry (exactly) and the unknown field variables. One of the main advantages of the present method is directly inherited from IGA, that is to easily increase the approximation order. To avoid using a shear correction factor, a third order shear deformation theory (TSDT) is introduced. It requires C1-continuity of generalized displacements and the NURBS basis functions are well suited for this requirement. Several numerical examples are used to demonstrate the performance of the present method compared with other published ones.

ABSTRACT: In this paper, a node-based smoothed finite element method (NS-FEM) using 3-node triangular elements is formulated for static, free vibration and buckling analyses of Reissner–Mindlin plates. The discrete weak form of the NS-FEM is obtained based on the strain smoothing technique over smoothing domains associated with the nodes of the elements. The discrete shear gap (DSG) method together with a stabilization technique is incorporated into the NS-FEM to eliminate transverse shear locking and to maintain stability of the present formulation. A so-called node-based smoothed stabilized discrete shear gap method (NS-DSG) is then proposed. Several numerical examples are used to illustrate the accuracy and effectiveness of the present method.

ABSTRACT: A four-node quadrilateral shell element with smoothed membrane-bending based on Mindlin-Reissner theory is proposed. The element is a combination of a plate bending and membrane element. It is based on mixed interpolation where the bending and membrane stiffness matrices are calculated on the boundaries of the smoothing cells while the shear terms are approximated by independent interpolation functions in natural coordinates. The proposed element is robust, computationally inexpensive and free of locking. Since the integration is done on the element boundaries for the bending and membrane terms, the element is more accurate than the MITC4 element for distorted meshes. This will be demonstrated for several numerical examples.

ABSTRACT: Isogeometric finite element analysis has become a powerful alternative to standard finite elements due to their flexibility in handling complex geometries. One major drawback of NURBS based isogeometric finite elements is their less effectiveness of local refinement. In this study, we present an alternative to NURBS based isogeometric finite elements that allow for local refinement. The idea is based on polynomial splines and exploits the flexibility of T-meshes for local refinement. The shape functions satisfy important properties such as non-negativity, local support and partition of unity. We will demonstrate the efficiency of the proposed method by two numerical examples.

ABSTRACT: An alternative alpha finite element method (αFEM) using triangular elements is proposed that significantly improves the accuracy of the standard triangular finite elements and provides a superconvergent solution in the energy norm for the static analysis of two-dimensional solid mechanics problems. In the αFEM, the piecewise constant strain field of linear triangular FEM models is enhanced by additional strain terms with an adjustable parameter \( \alpha \) which results in an effectively softer stiffness formulation compared to a linear triangular element. The element is further extended to the free and forced vibration analyses of solids. Several numerical examples show that the αFEM achieves high reliability compared to other existing elements in the literature.

ABSTRACT: A four-node quadrilateral shell element with smoothed membrane-bending based on Mindlin–Reissner theory is proposed. The element is a combination of a plate bending and membrane element. It is based on mixed interpolation where the bending and membrane stiffness matrices are calculated on the boundaries of the smoothing cells while the shear terms are approximated by independent interpolation functions in natural coordinates. The proposed element is robust, computationally inexpensive and free of locking. Since the integration is done on the element boundaries for the bending and membrane terms, the element is more accurate than the MITC4 element for distorted meshes. This will be demonstrated for several numerical examples.

ABSTRACT: A cell-based smoothed discrete shear gap method (CS-FEM-DSG3) using three-node triangular
element was recently proposed for static, free vibration and buckling analyses of stiffened Mindlin plates. The CS-FEM-DSG3 element is a significant improvement of the original DSG3 element by using smoothing technique to soften the stiffness of the DSG3 element while it has still inherited the locking-free feature of the former. In this paper, the CS-FEM-DSG3 is further extended for the static and free vibration analyses of stiffened flat shells by combining the original plate element CS-FEM-DSG3 with Allman’s plane stress element and a linearly isotropic two-node stiffened beam element. The compatibility of displacement field of stiffeners and shell is applied at the contact positions. Numerical results of the proposed element are compared with those of some existing methods to demonstrate the accuracy and reliability of the proposed method.

ABSTRACT: The edge-based strain smoothing technique is combined with the three-node Mindlin plate element (MIN3) to give a so-called the edge-based smoothed three-node Mindlin plate element (ES-MIN3) for static and free vibration analyses of plates. In the formulation of the ES-MIN3, the MIN3 together with a shear stabilized technique is used to compute the strains and to avoid the shear locking. Then the strain smoothing technique on the smoothing domains associated with edges of elements is used to smooth the strains on the adjacent elements. This strain smoothing technique can provide proper softening effect, which will effectively relieve the stiff behavior of the MIN3 and thus improve significantly the accuracy of solutions. The numerical examples demonstrated that the ES-MIN3 is free of shear locking, passes the patch test and shows three superior properties such as: (1) be a strong competitor to others existing plate elements in the static analysis; (2) can give high accurate solutions in free vibration analysis; (3) can provide accurately the values of high frequencies of plates by using only coarse meshes.

ABSTRACT: The paper presents an extension of the Edge-based Smoothed Finite Element Method (ES-FEM-T3) using triangular elements for the dynamic response analysis of two-dimension fluid-solid interaction problems based on the pressure-displacement formulation. In the proposed method, both the displacement in the solid domain and the pressure in the fluid domain are smoothed by the gradient smoothing technique based on the smoothing domains associated with the edges of the triangular elements. Thanks to the softening effect of the gradient smoothing technique used in the ES-FEM-T3, the numerical solutions for the coupled systems by the ES-FEM-T3 are improved significantly compared to those by some other existing FEM methods.

ABSTRACT: A cell-based smoothed discrete shear gap method (CS-FEM-DSG3) was recently proposed and proven to be robust for free vibration analyses of Reissner-Mindlin shell. The method improves significantly the accuracy of the solution due to softening effect of the cell-based strain smoothing technique. In addition, due to using only three-node triangular elements generated automatically, the CS-FEM-DSG3 can be applied flexibly for arbitrary complicated geometric domains. However so far, the CS-FEM-DSG3 has been only developed for analyzing intact structures without possessing internal cracks. The paper hence tries to extend the CS-FEM-DSG3 for free vibration analysis of cracked Reissner-Mindlin shells by integrating the original CS-FEM-DSG3 with discontinuous and crack–tip singular enrichment functions of the extended finite element method (XFEM) to give a so-called extended cell-based smoothed discrete shear gap method (XCS-FEM-DSG3). The accuracy and reliability of the novel XCS-FEM-DSG3 for free vibration analysis of cracked Reissner-Mindlin shells are investigated through solving three numerical examples and comparing with commercial software ANSYS.

ABSTRACT: Nowadays, stiffened plates have been widely used in many branches of structural engineering such as aircraft, ships, bridges, buildings etc. In comparison with common bending plate structures, stiffened plates not only have larger bending stiffness but also use less amount of material. Hence, it usually has higher economic efficiency. However, to obtain high effectiveness in solving the design problems of the stiffened plate, the reliability-based optimization problems need to be established together with the ordinary numerical computing methods. Therefore, the paper presents an approach to establish and solve the reliability-based optimization problem for the stiffened Mindlin plate. To analyze the behavior of Mindlin plate, we use the recently proposed CS-DSG3 element. The random variables are chosen to be elastic modulus, density of mass and external force. The design variables are the thickness, the width and the height of the stiffened plate. The objective function can be the strain energy or the mass of the structure and subjected to the constraints of displacement or vibration frequency. The reliability-based optimization algorithm used in this paper is a three-step closed loop: 1) Estimating the random variables by the Reliability Index (RI) method; 2) Solving the optimization problem using Sequential Quadratic Programming (SQP) method; 3) Checking and estimating the reliability by the first-order reliability method (FORM) in which the limit state function is the limit of displacement or vibration frequency of the structure.

SUMMARY: Smart materials are material classes, which have several properties, such as coupling electrical and mechanical properties, changing properties from one surface to the other across the thickness, high strength and stiffness, moisture resistance, etc. Some of the most popular and common types of smart materials are as follows:

Piezoelectric materials are materials in which a voltage is produced when load/stress is applied and vice versa. Carbon nanotube-reinforced composites are a class of new materials, which are being developed to take advantage of electrical conductivity and the high tensile strength of carbon nanotube materials. Regarding mechanical properties, carbon nanotubes are the stiffest and strongest materials yet discovered in terms of elastic modulus and tensile strength. This strength leads to the covalent sp2 bonds formed between the individual carbon atoms.

Shape memory alloys (SMA) are materials that through stress changes (pseudo-elasticity) or temperature changes, large deformation can be produced and recovered. This is due to the martensitic phase change and induced elasticity at higher temperatures. And this phenomenon is called the shape memory effect.

The smart materials offer a considerable interest in many practical applications, such as micro-electromechanical systems (MEMS), automotive sensors, actuators, transducers, active damping devices and smart material systems, especially in the medical and aerospace industries. With these complex problems, i.e., coupling problems, Nano-structures, etc., it is very difficult or impossible to find exact solutions or analytical solutions by solving the partial differential equations (PDEs). Hence, approximated solutions or numerical solutions are considered to be the most suitable in order to analyze and simulate these problems.

For numerical methods, isogeometric analysis (IGA) has been recently proposed as a useful numerical method of computational analysis with the aim of integrating Finite Element Analysis (FEA) and Computer Aided Design (CAD) into one model. Data generated from CAD can be used directly for FEA. It means that the IGA uses Non-Uniform Rational B-Splines (NURBS), which are commonly used in CAD in order to describe both the geometry and the unknown variables for analyzed problems. Hence, the exact geometry is expressed in both design and mechanical analysis. Therefore, the process of re-meshing in IGA can be omitted. And an advantage of NURBS is its ability to easily control the continuity, as C^{p-1} continuity is obtained by using p-th order NURBS.

In this thesis, IGA is developed for analyzing and simulating smart plate structures. Four main contributions have been obtained from the results of the research as follows:

Firstly, a simple and effective formulation using IGA based on higher-order shear deformation theory (HSDT) is presented to investigate dynamic control of piezoelectric composite plates. There are two field variables, which need to be approximated, including mechanical displacement field and electrical potential field. In composite plates, the mechanical displacement field is approximated according to the HSDT model with five
degrees of freedom per each control point using isogeometric elements based on Non-Uniform Rational B-Spline (NURBS) basis functions. These achieve naturally any desired degree of continuity through the choice of the interpolation order, so that the method easily fulfils the C1-continuity requirement of the HSDT model. To simulate numerical results, NURBS with quadratic, cubic and quartic functions are considered. Besides, the electric potential is assumed to vary linearly through the thickness for each piezoelectric sublayer. Finally, governing equations of piezoelectric composite plates for static, free vibration analyses and dynamic control are expressed. In control section, a displacement and velocity feedback control algorithm is used for the active control of the static deflection and of the dynamic response of the plates through a closed-loop control with bonded or embedded distributed piezoelectric sensors (the bottom layer) and piezoelectric actuators (the top layer). The displacement feedback control is based on the actuator, and the velocity feedback control gives the velocity component. The accuracy and reliability of the proposed method is verified by comparing its numerical predictions with those of other available numerical approaches.

Secondly, IGA based on a generalized shear deformation theory for geometrically nonlinear transient analysis of smart piezoelectric functionally graded material (FGM) plates is developed. In this part, the electrical field is assumed to be independent on each layer and the mechanical displacements are approximated by the generalized higher order shear deformation theory. The nonlinear transient formulation for plates is formed with the total Lagrange approach based on the von Kármán strains. For nonlinear transient solution, Newmark’s method and Newton-Raphson method are used to find displacements, velocities and accelerations at each time step. Besides, thermo-piezoelectric effects are also considered. Temperature distributions of the bottom surface and top surface of piezoelectric FGM model are assumed to be constant. The temperature variation along the thickness is obtained by solving the one-dimensional steady state heat equation. The material properties vary through the thickness of FGM and are assumed to follow the rule of mixture. To consider the interactions among the constituents, the Mori-Tanaka scheme is used. For numerical results, many examples are investigated and compared to other available numerical methods to show the accuracy and effectiveness of the present method. The effects of volume fraction exponents on frequencies and displacements of the piezoelectric FGM plates are examined. And the effects of thermo-electro-mechanical loads on the behavior of the plates are also studied.

Thirdly, IGA based HSDT is proposed to investigate the static and dynamic vibration behavior of functionally graded carbon nanotube-reinforced composite plates. The material properties of functionally graded carbon nanotube-reinforced composites (FG-CNTRCs) are assumed to be graded through the thickness direction according to several linear distributions of the volume fraction of carbon nanotubes. Four distributions are considered UD (uniform), FG-V, FG-O and FG-X. For the FG-V type, the top surface of the CNTRC plate is CNT-rich. In FG-X, the top and the bottom surface of CNTRC plate are CNT-rich. And in case of FG-O, the CNT-rich zone is in the middle of the CNTRC plate. The displacements of the CNTRC plates are approximated according to the third-order shear deformation theory. Numerical results proved the high accuracy and reliability of the proposed method in comparison with other available numerical approaches. Fourthly, an efficient computational approach based on a generalized unconstrained approach in conjunction with IGA are proposed for dynamic control of smart piezoelectric composite plates. A new function for the unconstrained third order shear deformation theory (UHSDT) is introduced. In this theory, there are seven degrees of freedom per control point. Constant gains of the displacement feedback control and velocity feedback control are used in active control analysis in order to predict geometrically nonlinear transient response of the piezoelectric composite plates. An optimization procedure using genetic algorithm (GA) is considered to search optimal design for actuator input voltages. Various numerical examples are investigated to demonstrate the effectiveness of the proposed method.

ABSTRACT: The cell-based strain smoothing technique is combined with the well-known three-node Mindlin plate element (MIN3) to give a so-called the cell-based smoothed MIN3 (CS-MIN3) for static and free vibration analyses of plates. In the process of formulating the system stiffness matrix of the CS-MIN3, each triangular element will be divided into three sub-triangles, and in each sub-triangle, the stabilized MIN3 is used to compute the strains and to avoid the transverse shear locking. Then the strain smoothing technique on whole the triangular element is used to smooth the strains on these three sub-triangles. The numerical examples demonstrated that the CS-MIN3 is free of shear locking, passes the patch test and shows four superior properties such as: (1) be a strong competitor to many existing three-node triangular plate elements in the static analysis, (2) can give high accurate solutions for problems with skew geometries in the static analysis, (3) can give high accurate solutions in free vibration analysis, (4) can provide accurately the values of high frequencies of plates by using only coarse meshes.

ABSTRACT: A n-sided polygonal cell-based smoothed finite element method (nCS-FEM) was recently proposed to analyze the elastic solid mechanics problems, in which the problem domain can be discretized by a set of polygons with an arbitrary number of sides. In this paper, the nCS-FEM is further extended to the free and forced vibration analyses of two-dimensional (2D) dynamic problems. A simple lump mass matrix is proposed and hence the complicated integrations related to computing the consistent mass matrix can be avoided in the nCS-FEM. Several numerical examples are investigated and the results found of the nCS-FEM agree well with exact solutions and with those of others FEM.

ABSTRACT: An edge-based smoothed finite element method (ES-FEM-T3) using triangular elements was recently proposed to improve the accuracy and convergence rate of the existing standard finite element method (FEM) for the solid mechanics analyses. In this paper, the ES-FEM-T3 is further extended to the dynamic analysis of 2D fluid–solid interaction problems based on the pressure-displacement formulation. In the present coupled method, both solid and fluid domain is discretized by triangular elements. In the fluid domain, the standard FEM is used, while in the solid domain, we use the ES-FEM-T3 in which the gradient smoothing technique based on the smoothing domains associated with the edges of triangles is used to smooth the gradient of displacement. This gradient smoothing technique can provide proper softening effect, and thus improve significantly the solution of coupled system. Some numerical examples have been presented to illustrate the effectiveness of the proposed coupled method compared with some existing methods for 2D fluid–solid interaction problems.

ABSTRACT: In this paper, a combined scheme of edge-based smoothed finite element method (ES-FEM) and node-based smoothed finite element method (NS-FEM) for triangular Reissner–Mindlin flat shells is developed to improve the accuracy of numerical results. The present method, named edge/node-based S-FEM (ENS-FEM), uses a gradient smoothing technique over smoothing domains based on a combination of ES-FEM and NS-FEM. A discrete shear gap technique is incorporated into ENS-FEM to avoid shear-locking phenomenon in Reissner–Mindlin flat shell elements. For all practical purpose, we propose an average combination (aENS-FEM) of ES-FEM and NS-FEM for shell structural problems. We compare numerical results obtained using aENS-FEM with other existing methods in the literature to show the effectiveness of the present method.

ABSTRACT: In this paper, a suitable and simple computational formulation based on Isogeometric Analysis (IGA) integrated with higher-order shear deformation theory (HSDT) is introduced for size-dependent buckling analysis of functionally graded material (FGM) nanoplates. The material properties of FGM based on the Mori–Tanaka schemes and the rule of mixture are used. The differential nonlocal equations are utilized to take into account size effects. The nonlocal governing equations are approximated according to IGA based on HSDT, which satisfies naturally the higher-order derivatives continuity requirement in weak form of FGM nanoplates. The effect of nonlocal approach on the behaviors of the FGM nanoplates with several volume fraction
exponents is investigated to show the reliability of the proposed method.

ABSTRACT: Isogeometric analysis (IGA) based on HSDT is used to simulate buckling analysis of nanoplates. The material properties of nanoplates based on the Mori–Tanaka schemes and the rule of mixture are utilized. The differential nonlocal equations with size effect are utilized. The nonlocal governing equations are approximated according to IGA, that satisfies naturally the higher-order derivatives continuity requirement in weak form of nanoplates. Several numerical results are presented to demonstrate the reliability of the proposed method.

ABSTRACT: A novel and effective formulation that combines the eXtended IsoGeometric Approach (XIGA) and Higher-order Shear Deformation Theory (HSDT) is proposed to study the free vibration of cracked plates. XIGA utilizes the Non-Uniform Rational B-Spline (NURBS) functions with their inherent arbitrary high order smoothness, which permit the C1 requirement of the HSDT model. Two numerical examples are provided to show excellent performance of the proposed method compared with other published solutions in the literature.

ABSTRACT: A cell-based smoothed discrete shear gap method (CS-FEM-DSG3) using triangular elements was recently proposed to improve the performance of the discrete shear gap method (DSG3) for static and dynamics analyses of Mindlin plates. In this paper, the CS-FEM-DSG3 is incorporated with spring systems for dynamic analyses of composite plates on the Pasternak foundation subjected to a moving mass. The composite plate-foundation system is modeled as a discretization of triangular plate elements supported by discrete springs at the nodal points representing the Pasternak foundation. The position of the moving mass with specified velocity on triangular elements at any time is defined, and then the moving mass is transformed into loads at nodes of elements. The accuracy and reliability of the proposed method is verified by comparing its numerical solutions with those of other available numerical results. A parametric examination is also conducted to determine the effects of various parameters on the dynamic response of the composite plates on the Pasternak foundation subjected to the moving mass.

ABSTRACT: In this paper, equilibrium and stability equations of functionally graded material (FGM) plate under thermal environment are formulated based on isogeometric analysis (IGA) in combination with higher-order shear deformation theory (HSDT). The FGM plate is made by a mixture of two distinct components, for which material properties not only vary continuously through thickness according to a power-law distribution but also are assumed to be a function of temperature. Temperature field is assumed to be constant in any plane and uniform, linear and nonlinear through plate thickness, respectively. The governing equation is in nonlinear form based on von Karman assumption and thermal effect. A NURBS-based isogeometric finite element formulation is utilized to naturally fulfill the rigorous C1-continuity required by the present plate model. Influences of gradient indices, boundary conditions, temperature distributions, material properties, length-to-thickness ratios on the behaviour of FGM plate are discussed in details. Numerical results demonstrate excellent performance of the present approach.

ABSTRACT: The cell-based smoothed discrete shear gap method (CS-FEM-DSG3) using three-node triangular elements was recently proposed to improve the performance of the discrete shear gap method (DSG3) for static and free vibration analyses of isotropic Mindlin plates. In this paper, the CS-FEM-DSG3 is further extended for static and free vibration analyses and dynamic control of composite plates integrated with piezoelectric sensors and actuators. In the piezoelectric composite plates, the electric potential is assumed to be a linear function through the thickness of each piezoelectric sublayer. A displacement and velocity feedback control algorithm is used for active control of the static deflection and the dynamic response of the plates through closed loop control with bonded or embedded distributed piezoelectric sensors and actuators. The accuracy and reliability of the proposed method is verified by comparing its numerical solutions with those of other available numerical results.

ABSTRACT: Growing bacterial biofilms exhibit a number of surface morphologies, e.g., concentric wrinkles, radial ridges, and labyrinthine networks, depending on their physiological status and nutrient access. We explore the mechanisms underlying the emergence of these greatly different morphologies. Ginzburg-Landau kinetic method and Fourier spectral method are integrated to simulate the morphological evolution of bacterial biofilms. It is shown that the morphological instability of biofilms is triggered by the stresses induced by anisotropic and heterogeneous bacterial expansion, and involves the competition between membrane energy and bending energy. Local interfacial delamination further enriches the morphologies of biofilms. Phase diagrams are established to reveal how the anisotropy and spatial heterogeneity of growth modulate the surface patterns. The mechanics of three-dimensional microbial morphogenesis may also underpin self-organization in other development systems and provide a potential strategy for engineering microscopic structures from bacterial aggregates.

ABSTRACT: The control of surface wrinkling patterns at the microscale is a concern in many applications. In this letter, we regulate surface wrinkling patterns on a film–substrate system by introducing microbeads atop the film. Both experiments and theoretical analysis reveal the changes in surface wrinkles induced by microbeads. Under equibiaxial compression, the film–substrate system without microbeads bonded on its upper surface often buckles into global, uniform labyrinths, whereas the labyrinthine pattern locally gives way to radial stripes emanating from the microbeads. This
regulation of surface wrinkles depends on the sizes and spacing of microbeads. We combine the finite element method and the Fourier spectral method to explore the physical mechanisms underlying the phenomena. This study offers a viable technique for engineering surfaces with tunable functions.

ABSTRACT: Biofilm morphogenesis not only reflects the physiological state of bacteria but also serves as a strategy to sustain bacterial survival. In this paper, we take the Bacillus subtilis colony as a model system to explore the morphomechanics of growing biofilms confined in a defined geometry. We find that the growth-induced stresses may drive the occurrence of both surface wrinkling and interface delamination in the biofilm, leading to the formation of a labyrinthine network on its surface. The wrinkles are perpendicular to the boundary of the constraint region. The variation in the surface undulations is attributed to the spatial stress field, which is isotropic in the inner regime but anisotropic in the vicinity of the boundary. Our experiments show that the directional surface wrinkles can confer biofilms with anisotropic wetting properties. This study not only highlights the role of mechanics in sculpturing organisms within the morphogenetic context but also suggests a promising route toward desired surfaces at the interface between synthetic biology and materials sciences.

ABSTRACT: The global growth in wind energy suggests that wind farms will increasingly be deployed in seismically active regions, with large arrays of similarly designed structures potentially at risk of simultaneous failure under a major earthquake. Wind turbine support towers are often constructed as thin-walled metal shell structures, well known for their imperfection sensitivity, and are susceptible to sudden buckling failure under compressive axial loading. This study presents a comprehensive analysis of the seismic response of a 1.5-MW wind turbine steel support tower modelled as a near-cylindrical shell structure with realistic axisymmetric weld depression imperfections. A selection of 20 representative earthquake ground motion records, 10 ‘near-fault’ and 10 ‘far-field’, was applied and the aggregate seismic response explored using lateral drifts and total plastic energy dissipation during the earthquake as structural demand parameters. The tower was found to exhibit high stiffness, although global collapse may occur soon after the elastic limit is exceeded through the development of a highly unstable plastic hinge under seismic excitations. Realistic imperfections were found to have a significant effect on the intensities of ground accelerations at which damage initiates and on the failure location, but only a small effect on the vibration properties and the response prior to damage. Including vertical accelerations similarly had a limited effect on the elastic response, but potentially shifts the location of the plastic hinge to a more slender and, therefore, weaker part of the tower. The aggregate response was found to be significantly more damaging under near-fault earthquakes with pulse-like effects and large vertical accelerations than far-field earthquakes without these aspects.

ABSTRACT: The length-dependent behaviour domains of thin elastic cylindrical shells under uniform bending have recently received significant research attention. Ovalization is known to affect very long cylinders that undergo significant cross-sectional flattening before failing by local buckling. This effect is restrained by the end boundary conditions in shorter cylinders, which instead fail by local buckling at moments close to the
classical analytical prediction. In very short cylinders, however, even this local buckling is restrained by the end boundary, and failure occurs instead through the development of a destabilizing meridional fold on the compressed side. Although this is a limit point instability under bending, ovalization does not play any role at all. This ‘very short’ length domain has only recently been explored for the first time with the aid of finite element modelling. A brief overview of the non-linear buckling behaviour of very short elastic cylinders under uniform bending is presented in this paper. Two types of edge rotational restraint are used to illustrate the influence of a varying support condition on the stability in this short length range. It is shown that short cylinders under bending do not suffer at all from local short-wave buckling. Additionally, when the meridional dimension of such cylinders becomes particularly short, the resulting numerical models may predict indefinite stiffening without a limit point, even when the shell is modelled using more complete 3D solid continuum finite elements. Idealized weld depressions, which are realistic representations of a systemic manufacturing defect, are used to demonstrate only a very mild sensitivity to geometric imperfections at such short lengths owing to a pre-buckling stress state dominated by local compatibility bending. The topic should be of interest to researchers studying shell problems dominated by local bending with computational tools and designers of multi-segment shells with very close segment spacing.

ABSTRACT: Efforts are ongoing to characterise a comprehensive resistance function for cylindrical shells under uniform bending, a ubiquitous structural system that finds application in load-bearing circular hollow sections, tubes, piles, pipelines, wind turbine support towers, chimneys and silos. A recent computational study by Rotter et al. (2014) demonstrated that nonlinear buckling of perfect elastic cylinders under bending is governed by four length-dependent domains – ‘short’, ‘medium’, ‘transitional’ and ‘long’ – depending on the relative influence of end boundary conditions and cross-section ovalisation. The study additionally transformed its resistance predictions into compact algebraic relationships for use as design equations within the recently-developed framework of Reference Resistance Design (RRD). This paper extends on the above to present a detailed computational investigation into the imperfection sensitivity of thin elastic cylindrical shells across the most important length domains, using automation to carry out the vast number of necessary finite element analyses. Geometric imperfections in three forms – the classical linear buckling eigenmode, an imposed cross-section ovalisation, and a realistic manufacturing ‘weld depression’ defect – are applied to demonstrate that imperfection sensitivity is strongly length-dependent but significantly less severe than for the closely-related load case of cylinders under uniform axial compression. The axisymmetric weld depression almost always controls as the most deleterious imperfection. The data is processed computationally to offer an accurate yet conservative lower-bound algebraic design characterisation of imperfection sensitivity for use within the RRD framework. The outcomes are relevant to researchers and designers of large metal shells under bending and will appeal to computational enthusiasts who are encouraged to adopt the automation methodology described herein to explore other structural systems.

ABSTRACT: Liquid storage tanks are vulnerable to a wide variety of failures under severe seismic excitation. Among all failure modes shell buckling and anchor bolt failures are the most critical forms of damage. Sometimes combination of different modes intensifies or accelerates liquid storage tank’s damage. Although the effect of each different failure modes has been studied separately by a number of researchers, few studies may have considered combination of main failure modes concurrently. Hence, in this paper, a cylindrical steel tank has been selected in order to study multiple damages due to dynamic loadings on the tank. All anchor bolts and steel thin wall and reinforced concrete pedestal have been modeled counting material and geometric non-linearity. The methodology for finite element modeling of fluid-structure interaction has included applying the added-mass strategy, followed by performing the numerical analyses. A suite of ground motions has been selected and matched to the target spectrum. Afterwards, incremental dynamic analyses have been conducted to obtain fragility curve according to simultaneous modes of failure. The results have indicated that anchor bolt failures along with shell buckling significantly have contributed to more flexible behavior of the thin-walled steel tank and distribution of buckling to uppermiddle part of tank which might increase seismic effects on the tank. Also, the design of steel tanks needs more considerations beyond current codes in major earthquake prone zones.
WMPLA [5]. Validated by the buckling tests of a 5 m-diameter stiffened shell [6] and five 1-m-diameter unstiffened shells [7], WMPLA has showed significantly higher prediction accuracy in the actual buckling load than NASA SP-8007 and Single Perturbation Load Approach (SPLA).

ABSTRACT: Steel cylindrical shell structures are used in a large variety of civil engineering applications such as off-shore platforms, tanks, silos, wind turbine towers, etc. The local stability of such structures and their sensitivity to imperfections is a well-known problem. In current engineering practice the design method is based on the selection of an imperfection class for the shell and subsequently calculating a reduction factor, $\chi$, to the resistance of the shell. One such methodology is supplied by the EN1993–1–6; special conditions are given to pressurized tubes subjected to meridional compression. Past studies have focused on the stability of cylindrical shells with internal pressure. The stability problem of a long cylinder considering the internal pressure as a simple static load was addressed. Thus, the approaches considered the fluid as compressible. The purpose of the present work is to investigate numerically the potential benefit of using an incompressible fluid fully enclosed in a circular cylindrical shell. The constraint imposed by the presence of the liquid in the interior of a shell will be referred to as “hydraulic constraint”. As liquids are nearly incompressible, the buckling of a liquid-filled shell has to satisfy the condition that the integral of all the displacements normal to the shell surface is equal to the volume variation of the contained liquid. The volume variation of the shell interior has to be equal to the dilation of the shell due to liquid pressure increments associated to the onset of geometrical instability. Additionally, the weight of the contained liquid causes additional circumferential tension in the cases of vertically placed cylinders. The methodology followed is the numerical analysis of cylindrical shells by means of the ABAQUS Finite Element code and a comparison with the methods given in the Eurocode.

ABSTRACT: Carbon Fiber Reinforced Polymers (CFRPs) have been widely used in numerous applications where high specific stiffness and strength offer structural weight reduction and fuel efficiency. RVS (re-entry vehicle system) structural protection to the weapon system during re-entry. These kinds of structures are realized using filament winding process. In this paper mechanical characterization of CFRP with Carbon Nano-fiber has been prented. Studies are carried out to characterize the strength and Young’s modulus of the composite structure. Carbon Nano-fibers are among the greatly potential reinforcing additives for polymeric composites due to their high axial Young’s modulus, high aspect ratio, large surface area, and excellent thermal and electrical properties. Various studies can be found in the literature regarding the incorporation of CNFs in polymeric matrices and the final mechanical and/or electrical properties of these materials. To prove the technology a composite cylinder having size Length of 600mm, Diameter 300mm and thickness 1.5mm is considered for experimental study. In the present work a method has been developed to analyze composite shell using Layered 46. In addition, 3D layered analysis of composite cylinder with end metallic plates have been performed to predict the Buckling behavior of the Composite shell. Composite shell were fabricated & tested with buckling load condition to verify the design and analysis procedure. It has been observed that the experimental results are in close agreement with the finite element analysis results, also the design stresses were within safe limits. Based on test results, the Longitudinal Strength of CFRP with CNF is achieved 1860 MPa,
Young’s modulus is 118 GPa and improvement against CFRP with epoxy resin (LY556).

ABSTRACT: Being one of the commonest deformation modes for soft matter, shell buckling is the primary reason for the growth and nastic movement of many plants, as well as the formation of complex natural morphology. On-demand regulation of buckling-induced deformation associated with wrinkling, ruffling, folding, creasing and delaminating has profound implications for diverse scopes, which can be seen in its broad applications in microfabrication, 4D printing, actuator and drug delivery. This paper reviews the recent remarkable developments in the shell buckling of soft matter to explain the most representative natural morphogenesis from the perspectives of theoretical analysis in continuum mechanics, finite element analysis, and experimental validations. Imitation of buckling-induced shape transformation and its applications are also discussed for the innovations of sophisticated materials and devices in future.

ABSTRACT: This paper is the first to present the dynamic buckling behavior of spherical shell structures colliding with an obstacle block under the sea. The effect of deep water has been considered as a uniform external pressure by simplifying the effect of fluid–structure interaction. The calibrated numerical simulations were carried out via the explicit finite element package LS-DYNA using different parameters, including thickness, elastic modulus, external pressure, added mass, and velocity. The closed-form analytical formula of the static buckling criteria, including point load and external pressure, has been firstly established and verified. In addition, unprecedented parametric analyses of collision show that the dynamic buckling force (peak force), mean force, and dynamic force redistribution (skewness) during collisions are proportional to the velocity, thickness, elastic modulus, and added mass of the spherical shell structure. These linear relationships are independent of other parameters. Furthermore, it can be found that the max force during the collision is about 2.1 times that of the static buckling force calculated from the analytical formula. These novel insights can help structural engineers and designers determine whether buckling will happen in the application of submarines, subsea exploration, underwater domes, etc.

ABSTRACT: We study the thermal buckling behavior of cylindrical shells reinforced with Functionally Graded (FG) wavy Carbon NanoTubes (CNTs), stiffened by stringers and rings, and subjected to a thermal loading. The equilibrium equations of the problem are built according to the Third-order Shear Deformation Theory (TSDT), whereas the stiffeners are modeled as Euler Bernoulli beams. Different types of FG distributions of wavy CNTs along the radial direction of the cylinder are herein considered, and temperature-dependent material properties are estimated via a micromechanical model, under the assumption of uniform distribution within the shell and through the thickness. A parametric investigation based on the Generalized Differential Quadrature (GDQ) method aims at investigating the effects of the aspect ratio and waviness index of CNTs on the thermal buckling of FG nanocomposite stiffened cylinders, reinforced with wavy single-walled CNTs. Some numerical examples are here provided in order to verify the accuracy of the proposed formulation and to investigate the effects of several parameters—including the volume fraction, the distribution pattern of wavy CNTs, and the cylinder thickness—on the thermal buckling behavior of the stiffened cylinders made of CNT-reinforced composite (CNTRC) material.

and Geoscience, Delf University of Technology, The Netherlands (date not given; the date of the most recent reference is 2017.)

ABSTRACT: Shells tend to be thin because their curvature enables them to carry distributed loads as membrane forces. The property of thinness stems from shells’ capacity to store membrane strain energy without much deformation. As a result, buckling failures often govern the design of shell structures. These buckling failures usually start locally, at a location where a combination of curvature and membrane forces is met. Moreover, shells tend to be imperfection-sensitive structures, that is, real-life shells (with initial geometric imperfections) usually cannot resist loads as high as the theoretically predicted critical buckling load. Advanced finite element analyses can accurately predict these so-called nonlinear buckling loads but require significant time and computation effort. On the other hand, current design equations are simple yet highly inaccurate and often penalize strength significantly. This treatise caters a Python script that executes nonlinear finite element analyses (using ANSYS Mechanical APDL) to generate a database of the nonlinear buckling loads of shell portions with varying membrane forces, curvatures and magnitudes of initial geometric imperfections. The aim, beyond the scope of this treatise, is to perform a parametric regression on said database to device design equation(s) that accurately predict the nonlinear buckling load of linear-elastic shell structures with initial geometric imperfections based merely on the linear elastic results of a geometrically perfect shell model.

ABSTRACT: In this paper, the dynamic plastic buckling of axisymmetric circular cylindrical shells subjected to axial impact is investigated. The von Mises yield criterion is used for the elastic-plastic cylindrical shell made of linear strain hardening material in order to derive the constitutive relations between stress and strain increments. Nonlinear dynamic circular cylindrical shell equations are solved with the finite difference method for three types of boundary conditions and two types loading. Two types of loading are stationary cylindrical shells impacted axially and traveling cylindrical shells impacted on a rigid wall. The growth and improvement of axial and lateral strains and buckling shapes of cylindrical shells are investigated for different boundary and loading conditions, from the viewpoint of stress wave propagation. It is found that the total length of cylindrical shell is affected by the plastic deformation when the plastic wave reaches unimpacted end. Also it is found that shortening and energy absorption are independent of loading and boundary conditions. The buckling shapes are affected by loading and boundary conditions; also peak loads at impacted and unimpacted ends are affected by loading conditions and are independent of boundary conditions. The presented theoretical results are compared with some experimental results and good agreement is obtained.

ABSTRACT: This research presents a study on mechanical buckling of thick-walled cylindrical shell made of functionally graded materials with ring supported under uniform axial and lateral loads. The mechanical properties of shell are variable along the thickness direction. First, the governing equations on the buckling of the FGM cylindrical shell supported with ring are established based on third-order shear deformation theory. Then, the governing characteristic equations were employed using energy method and by applying the Ritz technique. In the following with solving characteristic equations, the critical load buckling of the FGM thick-walled cylindrical shell supported with axial and lateral loads are calculated. The boundary conditions represented by end conditions of the FGM shell are the following: clamped-clamped and free-free. To verify the validity of the proposed analytical method the results of this research are compared with the results that came from using the finite element software. Finally, the effects of the different parameters such as thickness variations, boundary conditions, loading conditions and geometrical parameters of shell and ring on the buckling behavior of FGM thick-walled cylindrical shell are investigated. The results showed that by increasing the FGM volume fraction power in the shell structure, the critical buckling load increases and the location of the ring support has a significant effect on the critical buckling load. The results presented can be used as an important benchmark for researchers to validate their numerical and analytical methods.

ABSTRACT: Cylindrical shells are often used in ship structures at deck plating with a camber, side shell plating at fo̧re and aft parts, and bilge structure part. It has been believed that such curved shells can be modelled fundamentally by a part of a cylinder under axial compression. From the estimations with the usage of cylinder models, it is known that, in general, curvature increases the buckling strength of a curved shell subjected to axial compression, and that curvature is also expected to increase the ultimate strength. We conduct series of elasto-plastic large deflection analyses in order to clarify the fundamentals in buckling and plastic collapse behaviour of cylindrical shells under axial compression. From the numerical results, we derive design formula for predicting the ultimate strength of cylindrical shell, based on a series of the nonlinear finite element calculations for all edges, simply supporting plating, varying the slenderness ratio, curvature and aspect ratio, as well as the following design formulae for predicting the ultimate strength of cylindrical shell. From a number of analysis results, fitting curve can be developed to use parameter of slenderness ratio with implementation of the method of least squares. The accuracy of design formulae for evaluating ultimate strength has been confirmed by comparing the calculated results with the FE-analysis results and it has a good agreement to predict their ultimate strength.

Dmytro Dizhur, Gye Simkin, Marta Glaretton, Giuseppe Loporcaro, Alessandro Palermo and Jason Ingham, “Performace of winery facilities during the 14 November 2016 Kaikoura Earthquake”, Bulletin of the New Zealand Society for Earthquake Engineering, Vol. 50, No. 2, pp 206-223, June 2017 ABSTRACT: In-field post-earthquake performance observations of winery facilities in the Marlborough region, New Zealand, were documented following the 14 November 2016 Kaikoura earthquake and subsequent aftershocks. Observations presented and discussed herein include land damage to vineyards and the performance of winery building facilities, legged and flat-bedded storage tanks, barrel racking systems, and catwalks. A range of winery facilities were instrumented with tri-axial accelerometers to capture seismic excitations during aftershocks, with the specific aim to instrument different storage tanks having varying capacities and support systems to better understand the dynamic performance and actual forces experienced up the height of the tanks during an earthquake, with preliminary results reported herein.

classical theory of shells

Fundamental relations and equilibrium equations are derived for the thermal post-buckling analysis of eccentrically stiffened FG cylindrical shells surrounded by elastic foundation and subjected to thermal radial loading. A two-parameter elastic foundation is introduced based on the Winkler and Pasternak model. The shell is modeled by a two-parameter elastic foundation, and the stiffeners are assumed to be placed on the inner surface of the shell. The material properties of the shell and stiffeners are assumed to depend on the temperature. The Von-Karman nonlinear equations are derived based on the smeared stiffeners technique and the classical theory of shells according to the von-Karman nonlinear equations. By using the Galerkin method, the
thermal post-buckling response of eccentrically stiffened FG thin circular cylindrical shells is obtained. In order to validate the method, the obtained results are compared with available solutions and to continue, the effects of different parameters such as volume fraction exponent, number of stiffeners and elastic foundation parameters, on the thermal post-buckling response of eccentrically stiffened FG thin circular cylindrical shells are considered. Numerical results show that stiffeners and elastic foundation enhance the stability of the FG shells. Moreover, increasing the shell thickness, reducing the volume fraction index, increasing the number of stringer and ring stiffeners and applying stiffer elastic foundation lead to an increase in the thermal post-buckling response of stiffened FG circular cylindrical shells.

ABSTRACT: Recently, the demand for Liquefied Natural Gas (LNG) as power-generating fuel has rapidly increased. On the other hand, the production of a new type of natural gas, due to the development of technologies for gas extraction from shale formations (referred to as “Shale Gas Revolution”), has been expanding mainly in the United States. Due to the increasing demand for this natural gas, the marine transport of LNG is expected to increase significantly. Currently, regarding the transport of American shale gas, which has attracted enormous attention, there are concerns such as restrictions on the dimensions of vessels after the expansion of the Panama Canal and long-distance transport across the Pacific Ocean. Therefore, it is important for LNG carriers to achieve a high level of safety and improve cargo loading space efficiency. Mitsubishi Heavy Industries, Ltd. (MHI) developed the 155 km$^3$ Sayaendo LNG carrier in 2011, and has delivered five vessels of the same model so far. In order to satisfy the needs of our customers, MHI has completed the development of an “Apple-Shaped Tank” that inherits the features of the existing MOSS spherical tank, which has enjoyed a great reputation for reliability. As of April 2016, MHI has received orders for eight new LNG carriers with apple-shaped tanks, and began the manufacturing of aluminum tanks in October 2015.

ABSTRACT: The paper is concerned with the sensitivity analysis of structural responses in context of linear and non-linear stability phenomena like buckling and snapping. The structural analysis covering these stability phenomena is summarised. Design sensitivity information for a solid shell finite element is derived. The mixed formulation is based on the Hu-Washizu variational functional. Geometrical non-linearities are taken into account with linear elastic material behaviour. Sensitivities are derived analytically for responses of linear and non-linear buckling analysis with discrete finite element matrices. Numerical examples demonstrate the shape optimisation maximising the smallest eigenvalue of the linear buckling analysis and the directly computed critical load scales at bifurcation and limit points of non-linear buckling analysis, respectively. Analytically derived gradients are verified using the finite difference approach.

ABSTRACT: In the present article, stability of functionally graded epitrochoidal shells under pressure and thermal environment is examined. Material properties are taken as temperature dependent. Finite element solutions are obtained through commercially available tool ANSYS. The linear eigenvalue buckling problem is solved using Block Lanczos method. The effect of different geometry and material parameters on the critical buckling temperature of functionally graded Epitrochoidal Shells under pressure and thermal environment is demonstrated. Finally, the change of the stresses, displacements, rotations and stains were investigated and presented.

ABSTRACT: Superelastic conducting fibers with improved properties and functionalities are needed for diverse applications. Here we report the fabrication of highly stretchable (up to 1320%) sheath-core conducting fibers created by wrapping carbon nanotube sheets orientated in the fiber direction on stretched rubber fiber cores. The resulting structure exhibited distinct short- and long-period sheath buckling that occurred reversibly out of phase in the axial and belt directions, enabling a resistance change of less than 5% for a 1000% stretch. By including other rubber and carbon nanotube sheath layers, we demonstrated strain sensors generating an 860% capacitance change and electrically powered torsional muscles operating reversibly by a coupled tension-to-torsion actuation mechanism. Using theory, we quantitatively explain the complementary effects of an increase in muscle length and a large positive Poisson’s ratio on torsional actuation and electronic properties.

ABSTRACT: Reverse fault movement is one of the threats for the structural integrity of buried oil-gas pipelines caused by earthquakes. Buckling behavior of the buried pipeline was investigated by finite element method. Effects of fault displacement, internal pressure, diameter-thick ratio, buried depth and friction coefficient on buckling behavior of the buried steel pipeline were discussed. The results show that internal pressure is the most important factor that affecting the pipeline buckling pattern. Buckling mode of non-pressure pipeline is collapse under reverse fault. Wrinkles appear on buried pressure pipeline when the internal pressure is more than 0.4Pmax. Four buckling locations appear on the buried pressure pipeline under bigger fault displacement. There is only one wrinkle on the three locations of the pipeline in the rising formation, but more wrinkles on the fourth location. Number of the wrinkle ridges and length of the wavy buckling increase with the increasing of friction coefficient. Number of buckling location decreases gradually with the decreasing of diameter-thick ratio. A protective device of buried pipeline was designed for preventing pipeline damage crossing fault area for its simple structure and convenient installation. Those results can be used to safety evaluation, maintenance and protection of buried pipelines crossing fault area.

ABSTRACT: There are several methods for considering the interaction between compression and bending for slender steel members. This is covered by the interaction formula and the general method, currently. For stainless steel, the structural design standards have been developed largely in-line and refer to carbon steel design guidelines. The current stainless steel interaction formula of axial force and bending moment given in EN 1993-1-4 was derived on limited results available. On the other hand, the general method may be used without any change for stainless steel according to the Eurocode despite the non-linear stress-strain behaviour, which obviously could lead to some drawbacks. Hence, the main objective of this paper is to compare the analysis results with existing Eurocode design formulas, the general method and some formula taken from
experimental and parametric studies, showing their possible applicability, weaknesses and the need of further development. The conclusions are not applicable for stainless steel only, but they may be used for other non-linear materials such as aluminium alloys to some extent.

ABSTRACT: Induced by proteins within the cell membrane or by differential growth, heating, or swelling, spontaneous curvatures can drastically affect the morphology of thin bodies and induce mechanical instabilities. Yet, the interaction of spontaneous curvature and geometric frustration in curved shells remains still poorly understood. Via a combination of precision experiments on elastomeric spherical bilayer shells, simulations, and theory, we show a spontaneous curvature-induced rotational symmetry-breaking as well as a snapping instability reminiscent of the Venus fly trap closure mechanism. The instabilities and their dependence on geometry are rationalized by reducing the spontaneous curvature to an effective mechanical load. This formulation reveals a combined pressure-like bulk term and a torque-like boundary term, allowing scaling predictions for the instabilities in excellent agreement with experiments and simulations. Moreover, the effective pressure analogy suggests a curvature-induced buckling in closed shells. We determine the critical buckling curvature via a linear stability analysis that accounts for the combination of residual membrane and bending stresses. The prominent role of geometry in our findings suggests the applicability of the results over a wide range of scales.

ABSTRACT: The laminated composite materials are widely used in almost every engineering field due to its high strength, stiffness, corrosion resistance, thermal insulation and many more. Laminated composite cylindrical shells are one the most common structures and depending on their usage they may face several loading condition. One of the most popular failures of these structures is buckling under axial compression. The application of cylindrical shells in variety of structures demands the creation of cutouts in shells, such as for access openings, pipeline passages etc. Hence there will be an invariable reduction in the strength due to the cutouts of the laminated composite cylindrical shell. The effect of cutout is that it not only introduces stress concentration but also significantly reduces buckling load. In present study, the nonlinear buckling analysis of laminated composite cylindrical shells under axial loading has been investigated. The analysis is carried out using ANSYS software. The results show how the imperfections like cutouts affect the buckling behavior of the shells.

ABSTRACT: The paper is concerned by multi-scale methods to describe instability pattern formation, especially the method of Fourier series with variable coefficients. In this respect, various numerical tools are available. For instance in the case of membrane models, shell finite element codes can predict the details of the wrinkles, but with difficulties due to the large number of unknowns and the existence of many solutions. Macroscopic models are also available, but they account only for the effect of wrinkling on membrane behavior. A Fourier-related method has been introduced in order to modelize the main features of the wrinkles, but by using partial differential equations only at a macroscopic level. Within this method, the solution is sought in the form of few terms of Fourier series whose coefficients vary more slowly than the oscillations. The recent progresses about this Fourier-related method are reviewed and discussed.

ABSTRACT: Curvature and mechanics are intimately connected for thin materials, and this coupling between geometry and physical properties is readily seen in folded structures from intestinal villi and pollen grains to wrinkled membranes and programmable metamaterials. While the well-known rules and mechanisms behind folding a flat surface have been used to create deployable structures and shape transformable materials, folding of curved shells is still not fundamentally understood. Shells naturally deform by simultaneously bending and stretching, and while this coupling gives them great stability for engineering applications, it makes folding a surface of arbitrary curvature a nontrivial task. Here we discuss the geometry of folding a creased shell, and demonstrate theoretically the conditions under which it may fold smoothly. When these conditions are violated we show, using experiments and simulations, that shells undergo rapid snapping motion to fold from one stable configuration to another. Although material asymmetry is a proven mechanism for creating this bifurcation of stability, for the case of a creased shell, the inherent geometry itself serves as a barrier to folding. We discuss here how two fundamental geometric concepts, creases and curvature, combine to allow rapid transitions from one stable state to another. Independent of material system and length scale, the design rule that we introduce here explains how to generate snapping transitions in arbitrary surfaces, thus facilitating the creation of programmable multistable materials with fast actuation capabilities.

ABSTRACT: The wind turbine blade is a very important part of the rotor. Wind turbine provides an alternative way of generating energy from the power of wind. Extraction of energy depends on the design of blade. At windy places where the wind speeds are so high, sufficient amount of energy can be harnessed by making use of wind turbines. The blades of such turbines are so designed that they generate lift from wind and thus rotate. In this work, the wind turbine blade is modelled in CATIA V5 and analyzed for five different materials like Structural steel, Epoxy carbon, s-glass, E-glass, Aluminium alloy. Then the work explores the finite element analysis of a Wind Turbine Blade using ANSYS software. The aim of the analysis is to validate the strength of the blade and compare the above materials to select the best material for the wind turbine blade.

Hamed Farokhi, “Nonlinear behaviour of carbon nanotube resonators with applications in mass-sensors”, Ph.D dissertation, Dept. of Mechanical Engineering, McGill University, Montreal, April 2017

ABSTRACT: Recent technological advances have facilitated the development and fabrication of nanoelectromechanical systems (NEMS). NEMS are nano-scale devices consisting of integrated mechanical and electrical components designed to work in different environments for various purposes. A special class of NEMS devices are nanomechanical resonators which have received considerable attention from researchers around the world. Due to their small mass and size, nano resonators are capable of detecting the presence of even one very small particle, since the addition of the particle mass causes a shift in the resonance frequency of such devices. Carbon nanotubes (CNTs) have been considered as suitable candidates to be implemented in nano resonators, due to their small mass, high stiffness, small cross-section, and unique electrical properties. The performance of a nano resonator is directly related to its dynamical behaviour. The objective of this thesis is to perform a comprehensive investigation on the nonlinear behaviour of CNT resonators and to examine their
applications in mass detection. To this end, new nonlinear size-dependent continuum models are developed for doubly clamped and cantilevered CNT resonators taking into account the effects of small size, initial curvature, geometric imperfection, nonlinear damping, and geometrical and inertial nonlinearities; for a special case, the size-dependent continuum model is validated via molecular dynamics simulations. On the electrical part, new nonlinear models are proposed for the electrostatic load distribution in doubly clamped and cantilevered CNT resonators, taking into account the end effects caused due to the finite length; the proposed models are validated employing 3D finite element simulations.

Solving the complete nonlinear model developed for each case is a significantly complicated and challenging task, due to presence of various nonlinearities associated with the large-amplitude motion of the CNT resonator as well as the strong nonlinear coupling between the electrostatic load and the motion of the system. In this thesis, highly optimized and efficient discretization schemes as well as advanced numerical techniques are employed to investigate the nonlinear behaviour of the CNT resonator. The nonlinear static and dynamic responses of the CNT resonator are examined thoroughly, investigating the effect of various parameters, such as DC and AC voltages, length-scale parameter, nonlinear intrinsic damping, number of degrees of freedom, initial curvature, and geometric imperfections; it is shown that the DC voltage acts as a tuning parameter for the nonlinear behaviour of the system. More importantly, it is shown that when a realistic model is employed for the electrostatic load, via taking into account the end effects, the response of the system, in both static and dynamic regimes, changes significantly compared to the model available in the literature. Furthermore, the mass detection sensitivity of the cantilevered CNT resonator is examined in detail and methods are proposed for its enhancement.

ABSTRACT: In this study, the supersonic panel flutter of doubly curved composite sandwich panels with variable thickness is considered under aerothermoelastic loading. Considering different radii of curvatures of the faces in this paper, the thickness of the core is a function of plane coordinates \((x,y)\), which is unique. For the first time in the current model, the continuity conditions of the transverse shear stress, transverse normal stress and transverse normal stress gradient at the layer interfaces, as well as the conditions of zero transverse shear stresses on the upper and lower surfaces of the sandwich panel are satisfied. The formulation is based on an enhanced higher order sandwich panel theory and the vertical displacement component of the faces is assumed as a quadratic one, while a cubic pattern is used for the in-plane displacement components of the faces and the all displacement components of the core. The formulation is based on the von Kármán nonlinear approximation, the one-dimensional Fourier equation of the heat conduction along the thickness direction, and the first-order piston theory. The equations of motion and boundary conditions are derived using the Hamilton principle and the results are validated by the latest results published in the literature.

ABSTRACT: This thesis presents a study on vibration of an axially moving web following a curved path. The web is considered as a simply supported beam travelling axially on a curved guide that consists of a combination of linear and nonlinear elastic supports. The main objective of this work is to investigate the effect of the path curvature on the moving beam vibration and investigate the effect of different parameters on the system’s dynamic response. These parameters include axial speed, applied tension, degree of curvature of the path and stiffness of the path supports. The Galerkin decomposition with a first mode-shape of a straight a pinned-pinned basis function is utilized to realize a mathematical model that describes the static and dynamic behaviors of the axially moving curved beam. Numerical solutions of the developed model are obtained using a fourth-order Runge-Kutta algorithm under MATLAB environment. Fundamental frequencies are calculated results for axially moving curved beams and compared with those for axially moving straight beam. Amplitude-frequency curves are developed to study forced vibration of the axially moving curved beam under an external
force excitation. Poincaré sections and bifurcation diagrams are obtained for three cases: primary, sub-harmonic, and super-harmonic resonance excitations. It is found that the natural frequency of an axially moving beam travelling on a curved elastic support is higher than that of its axially moving straight beam for all considered cases of different path curvatures and different degrees of support stiffness. Forced vibrations of an axially moving beam on a curved elastic support are considered under harmonic excitation. Using the excitation amplitude as a controlling parameter over a wide range of variation, while keeping the excitation frequency fixed, it is found that the system exhibits many types of bifurcations, including period doubling bifurcation, period four bifurcation and many jumps. Compared to an axially moving beam resting on a straight elastic support, the axially moving curved beam showed earlier bifurcation and more swarming bifurcation diagram.

ABSTRACT: Previous research has shown that steel plate shear walls (SPSWs) are efficient lateral force-resisting systems against both wind and seismic loads. A properly designed SPSW can have high initial stiffness, strength, and energy absorption capacity as well as superior ductility. SPSWs have been commonly designed with unstiffened and stiffened infill plates based on economical and performance considerations. Recent introduction and application of corrugated plates with advantageous structural features has motivated the researchers to consider the employment of such elements in stiffened SPSWs with the aim of lowering the high construction cost of such high-performing systems. On this basis, this paper presents results from a numerical investigation of the hysteretic performance of SPSWs with trapezoidally corrugated infill plates. Finite element cyclic analyses are conducted on a series of flat- and corrugated-web SPSWs to examine the effects of web-plate thickness, corrugation angle, and number of corrugation half-waves on the hysteretic performance of such structural systems. Results of the parametric studies are indicative of effectiveness of increasing of the three aforementioned web-plate geometrical and corrugation parameters in improving the cyclic response and energy absorption capacity of SPSWs with trapezoidally corrugated infill plates. Increasing of the web-plate thickness and number of corrugation half-waves are found to be the most and the least effective in adjusting the hysteretic performance of such promising lateral force-resisting systems, respectively. Findings of this study also show that optimal selection of the web-plate thickness, corrugation angle, and number of corrugation half-waves along with proper design of the boundary frame members can result in high stiffness, strength, and cyclic performances of such corrugated-web SPSWs.

ABSTRACT: In this article, we investigate the buckling analysis of plates that are made of functionally graded materials (FGMs) resting on two-parameter Pasternak’s foundations under thermal loads. Three different thermal loads were considered, i.e., uniform temperature rise (UTR), linear and non-linear temperature distributions (LTD and NTD) through the thickness. The mechanical and thermal properties of functionally graded material (FGM) vary continuously along the plate thickness according to a simple power law distribution. Employing an analytical approach, the five coupled governing stability equations, which are derived based on first-order shear deformation plate theory, are converted into two uncoupled partial differential equations (PDEs). Considering the Levy-type solution, these two PDEs are reduced to two ordinary differential equations (ODEs) with variable coefficients. Then, the ODEs are solved using an exact analytical solution, which is called the power series Frobenius method. The appropriate convergence study and comparison with previously published related articles was employed to verify the accuracy of the proposed method. After such verifications, the effects of parameters such as the plate aspect ratio, side-to-thickness ratio, gradient index, and elastic foundation stiffnesses on the critical buckling temperature difference are illustrated and explained. The critical buckling temperatures of functionally graded rectangular plates with six various boundary conditions are reported for the first time and can serve as benchmark results for researchers to validate their numerical and analytical methods in the future.

This paper presents an analytical investigation on the buckling analysis of symmetric sandwich plates with functionally graded material (FGM) face sheets resting on an elastic foundation based on the first-order shear deformation plate theory (FSDT) and subjected to mechanical, thermal and thermo-mechanical loads. The material properties of FGM face sheets are assumed to be graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents. The core layer is still homogeneous and made of an isotropic material. An analytical approach is used to reduce the governing equations of stability and then solved using an analytical solution which is named as power series Frobenius method for symmetric sandwich plates with six different boundary conditions. A detailed numerical study is carried out to examine the influence of the plate aspect ratio, side-to-thickness ratio, loading type, sandwich plate type, volume fraction index, elastic foundation coefficients and boundary conditions on the buckling response of FGM sandwich plates. This has not been done before and serves to fill the gap of knowledge in this area.

ABSTRACT: This paper presents an analytical investigation on the buckling analysis of symmetric sandwich plates with functionally graded material (FGM) face sheets resting on an elastic foundation based on the first-order shear deformation plate theory (FSDT) and subjected to mechanical, thermal and thermo-mechanical loads. The material properties of FGM face sheets are assumed to be graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents. The core layer is still homogeneous and made of an isotropic material. An analytical approach is used to reduce the governing equations of stability and then solved using an analytical solution which is named as power series Frobenius method for symmetric sandwich plates with six different boundary conditions. A detailed numerical study is carried out to examine the influence of the plate aspect ratio, side-to-thickness ratio, loading type, sandwich plate type, volume fraction index, elastic foundation coefficients and boundary conditions on the buckling response of FGM sandwich plates. This has not been done before and serves to fill the gap of knowledge in this area.

ABSTRACT: In this paper, nonlinear vibration and post-buckling analysis of beams made of functionally graded materials (FGMs) resting on nonlinear elastic foundation subjected to thermo-mechanical loading are studied. The thermo-mechanical material properties of the beams are assumed to be graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents, and to be temperature-dependent. The assumption of a small strain, moderate deformation is used. Based on Euler-Bernoulli beam theory and von-Karman geometric nonlinearity, the integral partial differential equation of motion is derived. Then this PDE problem which has quadratic and cubic nonlinearities is simplified into an ODE problem by using the Galerkin method. Finally, the governing equation is solved analytically using the variational iteration method (VIM). Some new results for the nonlinear natural frequencies and buckling load of the FG beams such as the influences of thermal effect, the effect of vibration amplitude, elastic coefficients of foundation, axial force, end supports and material inhomogeneity are presented for future references. Results show that the thermal loading has a significant effect on the vibration and post-buckling response of FG beams. References listed at the end of the paper:

PARTIAL SUMMARY: The main objective of this thesis is to study thermo-mechanical responses and free vibration of plates and shells composed of FGM composites. To this end, methodology used in this thesis is organized as follows.

Firstly, theoretical formulations for free vibration, static and thermal analyses of FGMs are developed based on 3-D elasticity theory and 2-D plate theories. The main approach in formulations based on 3-D elasticity theory is to combine the the equilibrium equations with the stress-strain and strain-displacement relations to derive the governing equations in term of the displacement components. This approach is called Navier method. In case of 2-D theories, the displacements are expanded in terms of thickness and transverse displacement is independent of the transverse coordinate. This causes coupled governing equations to be independent of transverse
displacement. For the first time, thermo-elastic governing equations for a 2-D FGM panel based on third-order-shear deformation theory are derived.

Secondly, for modelisation of variation of volume fraction or fiber orientation, classic form of power-law distribution is introduced. Then, as one of the contributions of this thesis, 1-D and 2-D generalized power-law distributions are presented. By using generalized power-law distribution, it is possible to study the effects of the various kinds of material profiles including symmetric, asymmetric, sigmoidal and classic on mechanical behaviour of FGM structures. To compute effective material properties of composites, rule of mixture and Mori-Tanaka method are used. In case of nanocomposites, Eshelby-Mori-Tanaka method is employed to determine the effective material properties of composites reinforced by various type of carbon nanotubes dispersion.

Thirdly, owing to the complexity of governing equations with variable coefficients initiated from non-homogeneity, it is very rigorous to obtain the exact solutions. Due to non-linear variation of material properties, seeking a powerful numerical method is highly desirable. In this thesis, generalized differential quadrature method (GDQM) is adopted to solve coupled governing differential equations. The 1-D and 2-D GDQM are applied to various problems consisting of thermal, vibration, and static analyses of FGMs. By solving free vibration, static, and thermal problems and by comparing the results with those of other methodologies, accuracy, convergency and efficiency of the methodology are asserted. Less computational efforts of the proposed approach for FGMs problems with respect to other available methods have been found. According to contributions of the thesis into FGMs, significant motivations and findings can be categorized into three parts as follows: 1) 1-D FG fiber-reinforced composites, 2) 2-D FGM composites, and 3) FG carbon nanotubes-reinforced composites.

ABSTRACT: This study investigated influences of vacancy defects on buckling behaviors of open-tip carbon nanocones (CNCs) by molecular dynamics simulations. Effects of vacancy location and temperature on the buckling behaviors were examined in the study. Some interesting findings were attained from the investigations. It was noticed that the CNC with an upper vacancy has comparable degradation in the critical strain and in the critical load with the CNC with a middle vacancy, whereas the CNC with a lower vacancy has lower degradation in the antibuckling ability than the above two CNCs. The antibuckling ability of the CNCs reduces with the growth of the temperature. This temperature effect is more apparent in the perfect CNC than in the vacancy-defect CNCs. It was also observed that the degradation in the antibuckling ability is obvious at a lower temperature, but it decreases as the temperature grows. Besides, all the CNCs (including the perfect and the vacancy-defect CNCs) exhibited a shrinking/swelling buckling mode shape at the studied temperatures. Existence of the vacancies did not alter the buckling mode shape of the CNCs.

ABSTRACT: An analytical algorithm is proposed for studying the stability of a cylindrical shell subjected to nonuniform external pressure. The algorithm is based on a perturbation procedure and Pade approximants. Unlike the commonly used perturbation method, this approach is not limited by the smallness of the perturbation parameter. The approximate formulas obtained are sufficiently accurate and can be used in engineering practice.

James G.A. Croll (Emeritus Professor of Civil Engineering, University College London), “Validation and Design Use of Analytic Lower Bounds for the Unstable Postbuckling of Shells: Experimental, Analytical and

ABSTRACT: Because they so often exhibit extreme forms of nonlinear mode coupling in their imperfection-sensitive response, the buckling design of shells is often thought to require either massive computational power or vast accumulations of test data, or both. Nothing could be further from the truth. Virtually all the information required to predict lower bounds to the imperfection-sensitive buckling loads, for the vast majority of shells, is conveniently contained within a reanalysis of the stiffness (or energy) components characterizing the linearized, classical critical load (eigenvalue) analysis. This chapter briefly outlines the philosophical basis for the "reduced stiffness method," refers to its capacity to predict lower bounds to the scatter of past test results, and illustrates its more recent validation through carefully controlled numerical experiments. It also demonstrates how the understanding of the relative importance of the various energy components within each of the prospective buckling modes provides a powerful guide as to the best choice of rib stiffening or fibre reinforcement to enhance the buckling performance. Although attention is focused on the elastic buckling behaviour, it will be indicated how a simple extension of the reduced stiffness method also allows prediction of lower bounds to elastic-plastic buckling loads of shells.

ABSTRACT: Being one of the commonest deformation modes for soft matters, shell buckling is the primary reason for the growth and nastic movement of many plants, as well as the formation of complex natural morphology. On-demand regulation of buckling-induced deformation associated with wrinkling, ruffling, folding, creasing and delaminating has profound implications for diverse scopes, which can be seen in its broad
applications in microfabrication, 4D printing, actuator and drug delivery. This paper reviews the recent remarkable developments in the shell buckling of soft matters to explain the most representative natural morphogenesis from the perspectives of theoretical analysis in continuum mechanics, finite element analysis, and experimental validations. Imitation of buckling-induced shape transformation and its applications are also discussed for the innovations of sophisticated materials and devices in future.

Jun Young Chung, Ashkan Vaziri and Lakshminarayanan Mahadevan, “Reprogrammable Braille on an elastic shell”, Proceedings of the National Academy of Sciences, Vol. 115, No. 29, 201722342, July 2018

ABSTRACT: We describe a minimal realization of reversibly programmable matter in the form of a featureless smooth elastic plate that has the capacity to store information in a Braille-like format as a sequence of stable discrete dimples. Simple experiments with cylindrical and spherical shells show that we can control the number, location, and the temporal order of these dimples, which can be written and erased at will. Theoretical analysis of the governing equations in a specialized setting and numerical simulations of the complete equations allow us to characterize the phase diagram for the formation of these localized elastic states, elastic bits (e-bits), consistent with our observations. Given that the inherent bistability and hysteresis in these low-dimensional systems arise exclusively due to the geometrical-scale separation, independent of material properties or absolute scale, our results might serve as alternate approaches to small-scale mechanical memories.

ABSTRACT: It is widely acknowledged that tracking the postbuckling response of structures made from thin plates can be problematical. Such difficulty is associated with highly nonlinear effects, including mode jumping, imperfection sensitivity, and their combined interactions. Two widely used techniques that are currently used involve path following and asymptotic expansion. The former is often implemented in commercial finite element codes but can prove unreliable at representing branch switching. The latter is a relatively quick technique due to its recursive nature but is only reliable in the vicinity of bifurcations. Due to the overall complex nonlinearity, analytical closed-form solutions do not exist for path following and exist rarely for quadratic asymptotic expansions where simple forms have been adopted. This paper presents an analytical-based approach that enables the efficient optimal design of “moderately deep” nonlinear postbuckling behavior of laminated composite plates under uniaxial or biaxial loading. It provides a closed-form solution that more reliably reflects a deeper postbuckling response than the state of the art. Subsequently, highly efficient postbuckling optimization is attributed to the newly derived closed-form solution and a recent two-level optimization framework.

SEMC 2016: The Sixth International Conference on Structural Engineering, Mechanics and Computation, 5-7 September 2016, Cape Town, South Africa

Special Session: SS07: Design, Modeling and Analysis of Thin Shell Structures, organized by Krzysztof Magnucki, Poznan University of Technology, Poland

SUMMARY: The purpose of this special session of SEMC 2016 will be to share and exchange the latest knowledge concerning the design and analysis of thin shell structures. The session will cover analytical, numerical and experimental investigations. While the focus will be on stability problems of shells in both the critical and post-critical range, other related subjects will be equally welcome. Contributions are invited on the following topics: Analytical and numerical modeling of the pre-buckling state; Numerical simulations of post-buckling behaviour of shells; Control of buckling and post-buckling behavior; New shell applications; Nonconventional shell forms.

The “Thin-Walled Structures” papers that involve instability in some form are almost numberless. There are numerous other similar papers in other journals not covered in the following list, papers in journals such as Engineering Structures, Journal of Constructional Steel Research, Journal of Composites, International Journal of Solids and Structures, International Journal of Impact Engineering, International Journal of Mechanical Sciences, etc., etc. I cannot possibly include citations of all of them. By far most of the “buckling” papers in Thin-Walled Structures involve shear walls and beam-columns with thin-walled cross sections. I have not included them previously at this website because they are not, in the strictest sense, “shell structures”. However, the physics and mathematics governing their behavior is entirely analogous to that governing shell buckling and post-buckling.

Alembagheri (Department of Civil Engineering, Sharif University of Technology (SUT), P.O Box 11155-9313, Tehran, Iran), “Seismic analysis of steel liquid storage tanks by Endurance Time method”, Thin-Walled Structures, Vol. 50, pp 14-23, January 2012, DOI: 10.1016/j.tws.2011.08.015
ABSTRACT: Endurance Time (ET) method is a time history based method for seismic evaluation of structures using intensifying dynamic excitation as the loading function. In this paper, application of this method in the analysis of steel tanks has been investigated. A methodology for practical application of ET method in seismic assessment of storage tanks has been presented. This methodology has been applied in three-dimensional nonlinear analysis of a particular anchored steel tank using Finite Element method, and results are compared with conventional codified design procedures. Results of the analyses indicate reasonable accuracy of the proposed method in estimation of seismic responses of steel tanks and its applicability in enhancing the design process of steel tanks considering various sources of complicated behavior. Comparative study of seismic response of the tank in anchored and unanchored states utilizing ground motions has been presented. Advantages and limitations of the procedure have also been discussed.

ABSTRACT: This paper presents a detailed investigation into lateral-torsional stability of aluminium extruded I section beams under pure bending. Forty aluminium members of two different alloys 6061-T6 and 6063-T5, representing weak hardening and strong hardening alloys respectively, were tested. Stress–strain relationships were determined by tensile tests with 8 coupons cut from extruded flanges and web. Widths of flanges and lengths of members were herein taken as primary parameters to study lateral-torsional stability of the beams. With rigid lateral-torsional restraint on beam ends, lateral-torsional buckling resistances and load-rotation
relationships were obtained by continuous loading. Comparison of numerical predictions with test results indicated that accurate and reliable replication could be achieved by the described finite element (FE) models. By means of measured material behaviour and geometric properties, the corresponding provisions in Eurocode 9 (CEN 2007) and a design method previously proposed by the authors were evaluated by the test results. It was demonstrated that the proposed calculation method could provide cross-section lateral-torsional buckling resistances that are much closer to the test results than design strengths on the basis of the Eurocode 9 provisions are. Therefore, the proposed design method could be an alternative way of predicting the lateraltorsional buckling resistances of aluminium alloy I-beams.

ABSTRACT: The aluminum tubular structure with hat-shaped cross-section was axially compressed under the dynamic condition. The crush strength was larger for the bonded structure than that for the riveted one. The crush strength level was remarkably dominated by the plastic deformation behavior at the double-walled flange. The method to initiate the first plastic buckling lobe was demonstrated, where the inertia force in the early stage of impact was exploited. The method uses the solid block attached to the structural wall causing the wall bending force. It successfully worked without changing the energy absorption performance of the structure.

ABSTRACT: This paper presents numerical investigation and design of concrete-filled aluminum circular hollow section (CHS) columns. A non-linear finite element model is developed and verified against experimental results. An extensive parametric study was carried out to study the effects of cross-section geometries and material properties on the concrete-filled aluminum CHS column strengths. A total of 192 numerical data is presented in this study. The aluminum CHS tubes of normal strength material (T5) and high strength material (T6) using three different nominal concrete cylinder strengths of 40, 70 and 100 MPa were investigated. The nominal outer diameter-to-thickness (D/t) ratio of the sections ranged from 10 to 160. The test and numerical results of the concrete-filled aluminum CHS columns were compared with the design strengths to evaluate the reliability of the design rules in the American and Australian/New Zealand specifications for aluminum and concrete structures. Furthermore, the composite column design equations are proposed in this study. The proposed design equations consider the benefits of composite action between the aluminum CHS tube and the concrete infill. It is shown that the proposed design equations accurately predicted the strengths of the concrete-filled aluminum CHS columns.

ABSTRACT: The influence of roof on the natural frequencies and the modes of fixed roof, ground supported, liquid storage tanks is presented in this paper. Attention is given to partially filled tanks with the same heights of 12.19 m and the aspect ratios (H/R) of 2, 1.52, and 1.33. The bottom of tanks is considered to be anchored to the foundation. The effect of the roof, along with the liquid height, on dynamic properties is investigated. For this purpose, each tank is modeled in 4 liquid levels, equal to 1.80, 4.80, 8.50, and 10.90 m and in two various roof conditions: with roof (WR) and open top (OT). The finite element package ANSYS is used to model the tank–liquid systems. Tank roof and wall are meshed by shell elements and the liquid is modeled using fluid finite elements. The fluid–structure interaction is taken into account by coupling the nodes at the interface of the fluid and the shell in the radial direction. Results of ambient vibration tests are used to verify the numerical procedure in which good agreement is observed between the numerical and the experimental modal parameters. It is found that the influence of roof on natural frequencies of axial and vertical modes is negligible whereas its effect on the natural frequencies of circumferential modes is significant. It is also concluded that at low liquid levels, equal to 1.80 and 4.80 m, the tank roof does affect the axial modes of the tallest and medium height tanks while, at all of the considered liquid heights and aspect ratios, the tank roof affects the circumferential mode shapes; this confirms the idea that the roof does restrain the tank top against radial deformations.

ABSTRACT: Cold-formed steel sections are often used as wall studs or floor joists; such sections often include web holes for ease of installation of the services. Cold-formed steel design codes, however, do not consider the effect of such web holes. In this paper, a combination of experimental tests and non-linear elasto-plastic finite element analyses are used to investigate the effect of such holes on web crippling under interior-two-flange (ITF) loading conditions; the cases of both flange fastened and flange unfastened are considered. A good agreement between the experimental tests and finite element analyses was obtained. The finite element model was then used for the purposes of a parametric study on the effect of different sizes and position of holes in the web. It was demonstrated that the main factors influencing the web crippling strength are the ratio of the hole depth to the depth of the web, and the ratio of the distance from the edge of the bearing to the flat depth of web. Design recommendations in the form of web crippling strength reduction factors are proposed, that are conservative to both the experimental and finite element results.

ABSTRACT: Over the years the finite strip method (FSM) has proved to be an invaluable tool in the study of buckling modes in thin-walled structural members. This paper presents a formulation of the FSM, which is able
to predict the buckling stresses of initially perfectly straight thin-walled inelastic members under uniform compression. Plasticity is accounted for by means of plastic flow equations. Previous short-comings of plastic flow theory with respect to the modeling of buckling problems are overcome by deriving an expression for the inelastic shear stiffness from second order considerations.

Dragan D. Milasinovic (University of Novi Sad, Faculty of Civil Engineering Subotica, Kozaračka 2a, 24000 Subotica, Serbia), “Harmonic coupled finite strip method applied on buckling-mode interaction analysis of composite thin-walled wide-flange columns”, Thin-Walled Structures, Vol. 50, pp 95-105, January 2012
DOI: 10.1016/j.tws.2011.08.011

ABSTRACT: This paper presents an investigation of bifurcation buckling, buckling-mode interaction and post-buckling equilibrium of composite thin-walled wide-flange columns. The non-linear harmonic coupled finite strip method is used. As far as linear analysis is concerned, it takes advantage of the orthogonality properties of harmonic functions in the stiffness matrices formulation. However, in the case of geometric non-linear analysis all harmonics are coupled. In thin-walled sections the finite strips include the local and global buckling modes. When critical local and global stresses are close, new bifurcations appear due to buckling-mode interaction and failure stresses may be lower than both predictions. In this work, the existence of buckling-mode interaction is verified in H-section columns made of fiber reinforced plastic using the viscoelastic rheological–dynamical modulus and non-linear harmonic coupled finite strip method. Numerical examples showing the theoretical considerations are presented and agree with the experimental data.

ABSTRACT: For thin-walled beams, the classic theory for flexural and torsional analysis of open and closed cross-sections can be generalized by including distortional displacements. In a companion paper it is shown that using a novel semi-discretization process, it is possible to determine specific distortional displacement fields which decouple the reduced order differential equations. In this process the cross section is discretized into finite cross-section elements, and the natural distortional modes as well as the related axial variations are found as solutions to the established coupled fourth order homogeneous differential equations of GBT. In this paper the non-homogeneous distortional differential equations of GBT are formulated using this novel semi-discretization process. Transforming these non-homogeneous distortional differential equations into the natural eigenmode space by using the distortional modal matrix found for the homogeneous system, we get the uncoupled set of differential equations including the distributed loads. This uncoupling is very important in GBT, since the shear stiffness contribution from St. Venant torsional shear stress as well as “Bredt's shear flow” cannot be neglected nor approximated by the combination of axial stiffness and transverse stiffness, especially for closed cross sections. The full analytical solutions of these linear non-homogeneous differential equations are given, including four illustrative examples, which illustrate the strength of this novel approach to GBT. This new approach is a considerable theoretical achievement, since it without approximation gives the full analytical solution for a given discretization of the cross section including distributed loading. The boundary conditions considered in the examples of this paper are restricted to built in ends, which are needed for future displacement formulation of an exact first-order distortional beam element.
Thamarajah Anapayan and Mahen Mahendran (Faculty of Built Environment and Engineering, Queensland University of Technology, Brisbane, QLD 4000, Australia), “Improved design rules for hollow flange sections subject to lateral distortional buckling”, Thin-Walled Structures, Vol. 50, pp 128-140, January 2012 DOI: 10.1016/j.tws.2011.09.004

ABSTRACT: The LiteSteel Beam (LSB) is a new hollow flange section with a unique geometry consisting of torsionally rigid rectangular hollow flanges and a relatively slender web. It is subjected to lateral distortional buckling when used as flexural members, which reduces its member moment capacity. An investigation into the flexural behaviour of LSBs using experiments and numerical analyses led to the development of new design rules for LSBs subject to lateral distortional buckling. However, the comparison of moment capacity results with the new design rules showed that they were conservative for some LSB sections while slightly unconservative for others due to the effects of section geometry. It is also unknown whether these design rules are applicable to other hollow flange sections such as hollow flange beams (HFB). This paper presents the details of a study into the lateral distortional buckling behaviour of hollow flange sections such as LSBs, HFBs and their variations. A geometrical parameter defined as the ratio of flange torsional rigidity to the major axis flexural rigidity of the web ($GJ/El_{web}$) was found to be a critical parameter in evaluating the lateral distortional buckling behaviour and moment capacities of hollow flange sections. New design rules were therefore developed using a member slenderness parameter modified by $K$, where $K$ is a function of $GJ/El_{web}$. The new design rules based on the modified slenderness parameter were found to be accurate in calculating the moment capacities of not only LSBs and HFBs, but also other types of Hollow Flange Sections.

ABSTRACT: This paper presents a development of the finite strip method based on the shallow shell theory of Marguerre. Most of existing semi-analytical finite strips are based on the plate theories of Kirchhoff and of Mindlin. As it is showed in the paper, the plate theories can be considered as the particular cases of the shallow shell theory. Numerical results show the efficiency of the finite strip based on the shallow shell theory in the buckling analysis of prismatic structures which have curved corners.

ABSTRACT: Cracking damage in a stiffened panel is likely to have a deleterious effect on its ultimate strength and collapse characteristics. The present study examines this problem for a crack with different configurations and increasing length inserted in a stiffened plate. The cracks are positioned normal to the direction of the prescribed axial compression and crack propagation is not considered. A key feature of this work is the role of crack closure on the structural response. The ultimate strength reduction and collapse response are reported for stiffened plates of varying aspect ratio. Finally, an FE modeling approach is presented, which has the potential to extend this investigation to multi-bay panels at a reasonable computational cost.

Fathollah Taheri-Behrooz, Ramadan A. Esmaeel and Farid Taheri (Department of Civil and Resource Engineering, Dalhousie University, 1360 Barrington Street, Halifax, Nova Scotia, B3J 1Z1, Halifax, NS,
ABSTRACT: Perforated and slotted tubes are widely used as liners in oil and gas industry to facilitate the collection of products from reservoirs, and prevent sand migration to wellbore, which in return could cause product contamination and affect functionality of the pumps. The objective of this research is to establish the critical axial load of perforated E-glass/epoxy tubes using numerical and experimental methods. Firstly, in an experimental attempt, a total of six sets of composite tubes (three sets with perforations and three sets of intact (non perforated) tubes), having two different thicknesses and diameters, were fabricated and tested under axial compression. The reduction in the critical load and axial stiffness of the composite tubes was investigated experimentally. Secondly, a comprehensive numerical investigation was carried out, using the finite element method (FEM), to simulate the instability response of the intact and perforated composite tubes under compressive axial loading. The effect of various parameters such as the tube diameter, size, number of perforation and wall thickness were investigated in the current research. Good correlation is obtained between the experimental and numerical results. According to the results, the intact and perforated tubes showed similar instability mode shapes under the axial loading. However, the critical load and global stiffness of the perforated tubes were considerably reduced.

ABSTRACT: In this study, the bending characteristics of thin-walled (D/t=30) tubular beams with fixed supports are systematically investigated for different beam lengths and diameters. Bending behavior of the beam is simulated using the finite element method, in which elasto–plastic material, large-deformation and contact are included. Stress distribution is monitored by FE analyses during bending simulation. Also, load carrying and energy absorption capacities of the tubular beams having different geometrical combinations are compared with each other. The results of finite element (FE) analyses indicate that the deformation characteristics and load carrying capacities of the beam strongly depend on the diameter. From the load–displacement curve, three distinct regions were observed and the associated deformation characteristics were identified. There is a noticeable correlation between the energy absorption and transition displacements for the ranges of geometric parameters covered in this study. It is concluded that the presented simulation results can provide significant contribution to the design of side-door impact beams and passive safety research.

ABSTRACT: Cured-in-place plastic pipe linings are widely used in the rehabilitation of deteriorated rigid pipelines. Generally, the thickness of the pipe lining is assumed to be constant for simplification during the previous analysis. However, the thickness of the pipe lining may be a variable due to corrosive liquids or gases in service. This paper develops an analytical solution for the elastic buckling of cylindrical pipe linings with variable thickness subjected to external hydrostatic pressure. In addition to the analytical solution based on the
minimum potential energy theory, a numerical analysis using the finite element method (FEM) is also performed for comparison. The FEM results agree well with the analytical solutions. Both the FEM results and the analytical solutions are discussed and compared with the models presented by other authors. When the thickness of pipe lining is constant, our analytical solutions can be simplified to Glock's typical solutions.

ABSTRACT: The failure mechanism of expanded metal tubes under axial crushing is addressed herein. Experimental results have shown that when collapsing the tubes, the expanded metal cells closes until the plastic moment in all nodes along the mid-section of the tubes is attained exhibiting a plastic collapse mechanism. From this deformed configuration, a simple analytical expression is developed for the ultimate strength of the tube based on a rigid-plastic analysis of a frame-like structure. In addition, the energy absorption capacity of the tubes is also calculated. Theoretical predictions for both strength and energy are in good agreement with experimental results taken from the literature. Thereafter, a numerical study was conducted in order to investigate the validation of the theoretical model depending on the expanded metal cell geometry. It is found that the load-displacement response and failure mechanism of the tubes depend upon the aspect ratio of the expanded metal cell.

Nirosha Dolamune Kankanamge and Mahen Mahendran (Faculty of Built Environment and Engineering, Queensland University of Technology, Brisbane, Australia), “Behaviour and design of cold-formed steel beams subject to lateral-torsional buckling”, Thin-Walled Structures, Vol. 51, pp 25-38, February 2012

DOI: 10.1016/j.tws.2011.10.012

ABSTRACT: Cold-formed steel beams are increasingly used as floor joists and bearers in buildings. Their behaviour and moment capacities are influenced by lateral–torsional buckling when they are not laterally restrained adequately. Past research on lateral–torsional buckling has concentrated on hot-rolled steel beams. Hence a numerical study was undertaken to investigate the lateral–torsional buckling behaviour of simply supported cold-formed steel lipped channel beams subjected to uniform bending. For this purpose a finite element model was developed using ABAQUS and its accuracy was verified using available numerical and experimental results. It was then used in a detailed parametric study to simulate the lateral–torsional buckling behaviour and capacity of cold-formed steel beams under varying conditions. The moment capacity results were compared with the predictions from the current design rules in many cold-formed steel codes and suitable recommendations were made. European design rules were found to be conservative while Australian/New Zealand and North American design rules were unconservative. Hence the moment capacity design equations in these codes were modified in this paper based on the available finite element analysis results. This paper presents the details of the parametric study, recommendations to current design rules and the new design rules proposed in this research for lateral–torsional buckling of cold-formed steel lipped channel beams.

ABSTRACT: Shear wall systems are one of the most commonly used lateral-load resisting systems in high-rise buildings. The composite steel plate shear wall (CSPSW) systems have strong points, such as high bearing capacity, good ductility and energy dissipation capacity, which have been increasingly used as lateral load-resisting system in steel buildings. This paper describes the experimental work related to the tests of steel plate shear wall (SPSW) system and CSPSW system. Two 1/3 scaled specimens were fabricated and tested. The tested shear wall system consisted of concrete-filled circular hollow section (CHS) steel columns, steel beams, and SPSW or CSPSW. The experimental results were summarized and discussed, which showed that both SPSW system and CSPSW system possessed good ductility and energy dissipation capacity. For SPSW system, the primary mechanism for resisting storey shear arising from lateral loads came from the post-buckling inclined tension field that forms for thin-walled steel plate. For CSPSW system, the reinforced-concrete (RC) panels attached on both sides of steel plates were able to ensure the composite action by preventing the overall buckling of steel plate. Compared with SPSW system, the bearing capacity and energy dissipation capacity of CSPSW system increased evidently.

DOI: 10.1016/j.tws.2011.11.002

ABSTRACT: This paper presents distorting buckling solutions for semi-discretized thin-walled columns using the coupled differential equations of a generalized beam theory (GBT). In two related papers recently published by the authors a novel semi-discretization approach to GBT has been presented. The cross section is discretized and analytical solutions are sought for the variation along the beam. With this new approach the general GBT equations for identification of a full set of deformation modes corresponding to both homogeneous and non-homogenous equations are formulated and solved. Thereby giving the (complex) deformation modes of GBT which decouple the state space equations corresponding to the reduced order differential equations. In this paper the developed semi-discretization approach to generalized beam theory (GBT) is extended to include the geometrical stiffness terms, which are needed for column buckling analysis and identification of buckling modes. The extension is based on an initial stress approach by addition of the related potential energy terms. The potential energy of a single deformation mode is formulated based on a discretization of the cross section. Through variations in the potential energy and the introduction of the constraints related to beam theory this leads to a modified set of coupled homogeneous differential equations of GBT with initial stress for identification of distortional displacement modes. In this paper we seek instability solutions using these GBT initial stress equations for simply supported columns with constrained transverse displacements at the end sections and a constant axial initial stress. Based on the known boundary conditions the reduced order differential equations are solved by using the trigonometric solution functions and solving the related eigenvalue problem. This gives the buckling mode shapes and the associated eigenvalues corresponding to the bifurcation load factors. Thus the buckling modes are found directly by the analytical solution of the coupled GBT-equations without modal decomposition. Illustrative examples showing global column buckling, distortional buckling and local buckling are given and it is shown how the novel approach may be used to develop signature curves and elastic buckling curves. In order to assess the accuracy of the method some of the results are compared to results found using the commercial FE program Abaqus as well as the conventional GBT and FSM methods using the software packages GBTUL and CUFSM.

ABSTRACT: Experimental investigations were conducted to evaluate the lateral seismic characteristics of light-weight knee-braced cold-formed steel structures. In all, four full-scale $2.4 \times 2.4 \text{ m}^2$ specimens with different configurations were tested under a standard cyclic loading regime. This paper focuses on the specimens' maximum lateral load capacity and deformation behavior and provides a rational estimate of the seismic response modification factor, $R$, of knee-braced walls. The study also looks at the failure modes of the system and investigates the main factors contributing to the ductile response of CFS walls. That is in order to suggest improvements so that the shear steel walls respond plastically with a significant drift and without any risk of brittle failure, such as connection failure or stud buckling. A discussion on the calculated response factors in comparison to those suggested in the relevant codes of practice is also presented.

“Static analysis of thick laminated shells with different boundary conditions using GDQ”, Thin-Walled Structures, Vol. 51, pp 76-81, February 2012, DOI: 10.1016/j.tws.2011.11.004

ABSTRACT: Equilibrium equations and the associated boundary conditions for doubly curved, relatively deep and thick composite shells are shown. Two First Order Shear Deformation theories (FSDTs) are used. The first one uses plate stiffness parameters for thick shells and the other includes the effect of curvature in the calculation of stiffness parameters. Equilibrium equations are put together with the equations of stress resultants to arrive at a system of seventeen first order differential equations. These equations are solved numerically with the aid of General Differential Quadrature (GDQ) method for isotropic, cross-ply, angle-ply and general lay-up cylindrical shells with six types of different boundary conditions using above mentioned theories. Results obtained using both theories are compared with the available results in literature and those obtained using a three-dimensional (3D) analysis to test the accuracy of the shell theories presented here.

ABSTRACT: In this paper, the collapse behavior of corrugated cross section beams subjected to three-point bending is studied by using the finite element method (FEM). In order to estimate the energy absorption characteristics of the beam, it is essential to estimate the relation between load and deflection in the process of the beam collapse after the peak load. It is found that in the collapse process of the beam the load is decreased by flattening of the cross section of the beam, and that the flattened shape can be quantitatively expressed in terms of the curvature radius of the plane of the top and bottom of the cross section. Based on the energy balance that external work is equated to the flattening deformation energy of the cross section, a new method is proposed for predicting the relation between load and deflection. The validity of the presented method is verified through a comparison with numerical results of FEM analysis under various conditions.

ABSTRACT: This paper presents three methodologies to predict the load carrying capacity of cold formed steel rack columns via nonlinear finite element analysis (FEA). The column lengths are chosen in the range where the main failure is due to distortional buckling. It is demonstrated that for this range, to derive an accurate prediction of the ultimate load is more complex than for lengths where the main failure is local or global. The nonlinear analysis is carried out introducing an initial geometric imperfection on the upright. The three methodologies presented here allow for different imperfection shapes. The first one uses the critical mode shape (the first buckling mode). The second corresponds to an iterative methodology in which the shape that leads to the lowest ultimate load is used. These two first methodologies use exclusively the finite element method (FEM). The third one combines the finite element analysis with the generalised beam theory (GBT) in order to determine the modal participation of the FEM buckling mode and generate a particular combined geometric imperfection. To validate the predicted loads, the results of the three methodologies are compared with values obtained in experimental tests.

ABSTRACT: In this paper, we proposed a strategy to improve energy absorption efficiency of thin-walled columns by introducing extra non-convex corners in the cross section. Several profiles of non-convex multi-corner thin-walled columns obtained through this strategy are presented and their energy absorption capacities under axial crush are investigated analytically and numerically. Explicit formulations for predicting the mean crushing force of non-convex multi-corner thin-walled columns are derived based on the theory of Super Folding Element method, and the predicting results of these formulations have good agreement with the numerical simulation performed by explicit non-linear finite element method. The comparisons of the non-convex columns with square column show that the non-convex multi-corner thin-walled columns have higher energy absorption capacity.

ABSTRACT: This paper presents the formulation and validation of a geometrically and physically ($J_2$ plasticity) non-linear Generalised Beam Theory formulation, intended to calculate accurate non-linear elastoplastic equilibrium paths of thin-walled metal bars and associated collapse loads. This formulation extends previous work (Gonçalves and Camotim, 2011) [1] by including the geometrically non-linear effects. The plate-like bending strains are assumed to be small (as in all GBT formulations), but the membrane strains are calculated exactly. Both stress-based and stress resultant-based GBT approaches are developed and implemented in a 3-node beam finite element. The stress-based formulation is generally more accurate, but the
stress resultant-based formulation makes it possible to avoid numeric integration in the through-thickness direction of the walls. In order to show the potential of the proposed formulation and resulting finite element, several numerical results are presented and discussed. For validation purposes, these results are compared with those obtained with standard 2D-solid and shell finite element analyses.

ABSTRACT: The quasi-static axial buckling response of super-elastic NiTi thin-walled cylindrical shells has been investigated. The results show that the main buckling pattern is the non-axisymmetric mode with various circumferential patterns depending on the geometry of a specimen. The specific energy is strongly related to the geometry and the buckling mode of a specimen. The austenite–martenite phase transition is concentrated in the buckling area to form so-called phase transition hinges. The buckling behavior of a specimen is significantly related to the phase transition and phase transition hinges. After unloading a NiTi specimen can recover to its initial shape, which differs from an elastic–plastic specimen.

ABSTRACT: This paper presents an analytical solution of skin wrinkling for sandwich polymer matrix composite panels in a combined thermal–mechanical condition. The thermal gradient in the transverse direction is induced by one-sided fire exposure, and the mechanical load is the in-plane compression. Due to low thermal conductivities of polymer matrix composites, the thermal gradient exists for a long period of time. The material properties of polymer matrix composites are degraded as temperature rises. These behaviors induce mechanical properties' gradients along the transverse direction. The general solution for the wrinkling load in the thermal–mechanical loading condition is investigated. The solution is characterized in terms of two non-dimensional parameters that represent material properties and dimensional lengths of the skin and the core. The wrinkling load is presented for fairly complete ranges of the two non-dimensional parameters. The wrinkling load is also derived from Winkler model for non-homogeneous materials. An example of thermal-mechanical simulation to design the wrinkling load-bearing capacity of a panel exposed to fire is given.

ABSTRACT: An analytical approach was considered to study the buckling and the behavior of an inflatable orthotropic beam subjected to uniform compression loads under different boundary conditions. In order to assess the stability of inflatable structures, it is necessary to evaluate the critical load of the inflatable components in their pressurized configurations. First, a 3D inflatable orthotropic beam model based on the Timoshenko's kinematics was briefly introduced: the nonlinearities (finite rotation, follower forces) were included in this model. The nonlinear equilibrium equations were derived from the total Lagrangian form of the virtual work principle: the linearized equations were then obtained. By solving these linearized equations, an analytical expression of the critical buckling load was obtained. This critical buckling load was investigated through several load cases with several boundary conditions. The discrepancy due to the orthotropic character between the present model and the isotropic models found in the literature was evaluated, as well as the influence of the inflation pressure and the fabric mechanical properties on the value of critical load. The buckling mode shapes were also determined. To check the limit of validity of the results, the wrinkling load was also presented in every case.

Jia-Hui Zhang and Ben Young (Department of Civil Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong), “Compression tests of cold-formed steel I-shaped open sections with edge and web stiffeners”, Thin-Walled Structures, Vol. 52, pp 1-11, March 2012, DOI: 10.1016/j.tws.2011.11.006

ABSTRACT: A series of column tests on cold-formed steel I-shaped open sections with edge and web stiffeners has been conducted. The test specimens were firstly brake-pressed from high strength zinc-coated steel sheets and then two of the same members were connected back-to-back by self-tapping screws to form an I-shaped section with edge and web stiffeners. The members had the nominal thicknesses of 0.48, 1.0 and 1.2 mm. The column length of the test specimens varied from 300 to 3200 mm with an increment of approximately 600 mm. The column specimens were compressed between fixed ends. Tensile coupon tests were also conducted to obtain the material properties at both flat and corner portions of the sections. Initial local and overall geometric imperfections were measured. The columns were failed by local, distortional, flexural buckling and the interaction of these buckling modes. The failure modes and ultimate strengths of the column specimens were presented. The direct strength method in the North American Specification and the Australian/New Zealand Standard was used to calculate the design strengths of the I-shaped open section columns. The appropriateness of the direct strength method for I-shaped open sections with edge and web stiffeners was evaluated. In addition, the reliability of the direct strength method for the I-shaped open sections was evaluated using reliability analysis. It is shown that the direct strength method can be used for cold-formed steel I-shaped open sections with edge and web stiffeners.

ABSTRACT: A welded built-up square tube is made by flare welding 4 thin steel plates, which are bent to form L-shape. When it is used for a CFST column, the ribs placed at the center of concrete and steel tube width prevent local buckling and the tube confines concrete to improve its structural load capacity. In this study to introduce how to build welded built-up square columns and to evaluate the structural capacities of welded built-
up square steel tubes and CFST columns, 15 full-size specimens were fabricated for structural test with various types of steel tubes (welded built-up square tube and generic steel tube), width–thickness ratio ($B/t=50$, 58 and 67) and concrete strength ($f_c=10$ MPa and 40 MPa) to verify sectional efficiency and structural superiority inherent in welded built-up square columns.

ABSTRACT: The behaviour of thin steel plates fall into three general classes, unstiffened (no edge-stiffener), stiffened (adequate sized edge-stiffener) and partially stiffened (inadequate sized edge-stiffener). When used in cold-formed steel sections they may elastically buckle when subjected to either uniform compression or stress gradient. There are thus six possible combinations of element class and loading condition. All except the class of partially stiffened elements under stress gradient has been investigated experimentally, and design equations developed. This paper presents experiments of edge-stiffened plates under stress gradient, where the edge-stiffener size was increased from zero to a size sufficient to create a stiffened element. Edge-stiffener types investigated are simple lips and complex lips. Design solutions for partially stiffened elements under stress gradient using the effective width concept are presented. A generalised effective width design model is developed to account for all classes of elements under any loading condition.

ABSTRACT: Tubular structures play an important role in energy absorbing components and structural members requiring high strength-to-weight ratio. The theory of buckling of circular, square and rectangular tubes is relatively well established in the literature. The study of buckling of triangular tubes, however, has received much less attention. In this paper, an analytical solution for the elastic buckling of isosceles triangular tubes was obtained by considering the buckling characteristics of individual walls of the triangular tube with appropriate edge conditions. The results from this analytical solution were compared with previously published work in the literature and finite element simulations. The comparison revealed good agreement between these results.

ABSTRACT: This paper discusses the nonlinear analysis of normal and high strength cellular steel beams under combined buckling modes. A nonlinear 3-D finite element model has been developed, which accounted for the initial geometric imperfection, residual stresses and material nonlinearities of flange and web portions of cellular steel beams. The nonlinear finite element model was verified against tests on cellular steel beams having different lengths, different cross-sections, different loading conditions and different failure modes. Failure loads, load–mid-span deflection relationships and failure modes of cellular steel beams were predicted
from the finite element analysis. An extensive parametric study involving one hundred and twenty cellular steel beams was performed using the verified finite element model to study the effects of the change in cross-section geometries, beam length and steel strength on the strength and buckling behaviour of cellular steel beams. The results of the parametric study has shown that cellular steel beams failing due to combined web distortional and web-post buckling modes exhibited a considerable decrease in the failure loads. It is also shown that the use of high strength steel offers a considerable increase in the failure loads of less slender cellular steel beams. The failure loads predicted from the finite element model were compared with that predicted from Australian Standards for steel beams under lateral torsional buckling. It is shown that the Specification predictions are generally conservative for normal strength cellular steel beams failing by lateral torsional buckling, unconservative for cellular steel beams failing by combined web distortional and web-post buckling and quite conservative for high strength cellular steel beams failing by lateral torsional buckling.

ABSTRACT: This paper reports the results of a numerical investigation aimed at providing fresh insight on the mechanics underlying the buckling and (mostly) post-buckling behaviour of short-to-intermediate equal-leg thin-walled angle steel columns exhibiting fixed and pinned (but with the secondary warping prevented) end supports. Although most of the numerical results presented and discussed were obtained through Abaqus shell finite element analyses, the paper also includes some GBT-based critical stresses and buckling mode shapes, whose interpretation help clarify the distinction between local and global buckling. The shell finite element results displayed consist of (i) elastic post-buckling equilibrium paths and (ii) curves and diagrams providing the evolution, along a given path, of the column deformed configurations and normal stress distributions.

ABSTRACT: This paper presents computational modeling and results of steel storage tanks under heat induced by an adjacent fire. In this research, modeling is restricted to the structural behavior of the tank, with emphasis on thermal buckling of the shell. Two tanks that buckled under a huge fire in Bayamón, Puerto Rico in 2009, are investigated in detail: a small tank with a self-supported conical roof, and a large tank in which the conical roof is supported by a set of rafters and columns. For a tank that is empty, the results show that a relatively low temperature is enough to produce static buckling of the shell. In pre-buckling states, the cylindrical shell has thermal expansion; at the critical state the displacements reverse and inwards displacements are observed at advanced post-buckling states. Parametric studies are performed to understand the influence of the shell thickness, the level of fluid stored in the tank, the area affected by fire in the circumferential direction, and the temperature gradient through the thickness. The buckling modes are compared with real deflection of tanks that were affected by fire.
ABSTRACT: This work presents a consistent geometrically exact finite element formulation of the thin-walled anisotropic beam theory. The present formulation is thought to address problems of composite beams with nonlinear behavior. The constitutive formulation is based on the relations of composite laminates and thus the cross sectional stiffness matrix is obtained analytically. The variational formulation is written in terms of generalized strains, which are parametrized with the director field and its derivatives. The generalized strains and generalized beam forces are obtained by introducing a transformation that maps generalized components into physical components. A consistent tangent stiffness matrix is obtained by parametrizing the finite rotations with the total rotation vector; its derivation is greatly simplified by obtaining the derivatives of the director field via interpolation of nodal triads. Several numerical examples are presented to show the accuracy of the formulation and also its frame invariance and path independence.

ABSTRACT: In the paper an alternative for horizontal cylindrical tank is presented. The proposed solution has the form of a barrelled tank in which the classical cylindrical shell is replaced by the barrelled one. The geometry of this shape is described. The buckling behaviour of the horizontal barrelled shell filled with liquid is analysed. The liquid level and the negative internal pressure which appear during emptying of the tank are also taken into consideration. On the basis of numerical analyses number of plots as well as analytical formulae are elaborated as a tool for design of barrelled tank with respect of stability criterion. Analyses are made on three families of barrelled shells of different capacities. In each family the capacity and length are constant. Advantages of barrelled tanks in comparison with cylindrical one are discussed.

ABSTRACT: This work deals with the buckling behavior of large scale oil tanks with a conical roof subjected to harmonic settlement. Firstly, the buckling behavior and the critical harmonic settlement of the tank with the conical roof for different wave numbers are analyzed. The results show that buckling occurs on the roof when the wave number is small, while it changes to the shell when the wave number is large. Also, for the original tank, the critical harmonic settlement decreases greatly for a small wave number, while the critical harmonic settlement decreases slightly for large wave numbers. Then, the parametric studies are conducted including the height-to-radius ratio, the radius-to-thickness ratio, the slope and the thickness of the conical roof. For the height-to-radius ratio, when the wave number is small, the critical harmonic settlement depends not only on the h/r ratio but also on the wave number. However, when the wave number is large, the critical harmonic settlement versus h/r ratio is monotonically increasing. For the radius-to-thickness ratio, for a small wave number, the critical harmonic settlement is not only related to the r/t ratio, but to the wave number as well.
However, for large wave numbers, the critical harmonic settlement versus $r/t$ ratio is monotonically decreasing. For the slope of the conical roof, when the wave number is small, in general, the critical harmonic settlement increases with the slope. However, when the wave number is large, the critical harmonic settlement is almost independent on the slope. For the thickness of the conical roof, for a small wave number, the critical harmonic settlement increases with the thickness of the conical roof. However, for large wave numbers, the critical harmonic settlement is almost independent on the thickness of the conical roof.

ABSTRACT: Dynamic pulse buckling of a single curvature composite shell under external pressure was examined using Lagrange's equation of motion and the Budiansky–Roth criterion. The predicted transient shell response compared very well with results from ABAQUS Implicit, and the predicted buckling loads also agreed with experiments on steel arches. Load duration determined whether the buckling was impulsive, dynamic or quasi-dynamic. Thicker composite shells were more likely to fail by first-ply failure rather than buckling. It was shown that the composite lay-up could be adjusted to increase the buckling resistance of the shell.

ABSTRACT: Critical elastic buckling load of uniformly compressed isotropic plates perforated in equilateral triangular patterns was investigated using FEM. Stiffened and unstiffened square and rectangular elements with wide ranges of hole diameter-to-spacing ratio and plate slenderness were studied. The effect of perforations on the critical elastic buckling load was determined. Design formulas for predicting critical elastic buckling stress based on reduction coefficient approach and equivalent thickness approach were developed using multiple nonlinear regression analysis of FEM results. The obtained critical elastic buckling stress reductions and developed formulas were verified by comparison with results available in literature and with an extensive database of FEM results.

ABSTRACT: In this paper, finite element (FE) studies for LDSS (Lean Duplex Stainless Steel) hollow columns with square, L-, T-, and +-shaped cross sections (i.e., SHC, LHC, THC and +HC respectively) are presented using ABAQUS, to gain an understanding of the cross sectional shape effects. The LDSS hollow columns having equal material cross-sectional areas with thickness varying from 5 m to 20 mm were subjected to uniform axial compression. Short/Stocky columns with lengths ($\sim$1800 mm) of about three times the outer width of square were considered for the analyses. Based on the analyses, it has been found that for all the NRHCs (i.e., LHC, THC and +HC) considered, a nearly linear variation of $P_u$ with section thicknesses has been
observed, although the increase for SHC was relatively slower in thinner sections ($t<12.5$ mm). The % increase in $P_u$ with 300% increase in $t$ (from 5 m to 20 mm) has been found to be $\sim 1273\%$, $1252\%$, $1041\%$ and $679\%$, respectively, for square, L-, T-, and +-shaped sections. The gain in $P_u$ for LHC, THC and +HC sections as compared (expressed as $P_u/P_{u_{sq}}$) to SHC are in the range $120\%–150\%$, $130\%–170\%$, $140\%–230\%$, respectively. Ductility at ultimate load has been observed to be $\sim 0.1–0.6\%$ for SHC, LHC and THC (all thicknesses), and +HC ($t\leq10$ mm).

ABSTRACT: This paper presents an assessment of the influence of structural imperfections, namely, the residual stresses, on the ultimate load capacity of steel plate girders when subjected to patch loading. The basis of the research is a thorough comparison between numerical and experimental results as well as the recommendations for FE-modeling suggested by EN1993-1-5 (Annex C). A systematic exploit of a properly validated numerical model has been used in this study. Several residual stress patterns found in the literature have been implemented in numerical simulations of four different tests on girders subjected to patch loading. On such a basis, an appraisal of the influence of the structural imperfections on the ultimate load capacity of girders subjected to patch loading is presented.

ABSTRACT: Nonlinear free vibration analysis of prestressed circular cylindrical shells placed on Winkler/Pasternak foundation is investigated in the present paper. The nonlinearity is considered due to large deflections. Simultaneous effects of prestressed condition and elastic foundation on natural frequencies of the shells under various boundary conditions are examined extensively in this study. The nonlinear Sanders–Koiter shell theory is employed in order to derive strain–displacement relationships. The nonlinear classical Love's thin shell theory is also applied in some specific cases due to contrast the results. Beam modal functions are used to approximate spatial displacement field. The governing equations in linear state are solved by the Rayleigh–Ritz procedure. Perturbation methods are used to find the relationship between vibration amplitude and frequency in nonlinear state. Prestress state includes the effects of internal hydrostatic pressure and initial uniaxial tension. Results are compared with published theoretical and experimental data for some specific cases.

ABSTRACT: An approximate and simple method for rectangular orthotropic plates, loaded biaxially along two mutually perpendicular directions is presented. The theory is based on the energy method and it is free from difficult calculations such as those encountered when large deflection theory is used. Effects of initial imperfections are taken into account. The number and lengths of half-waves are assumed to be the same in the
post-buckling stage as at incipient buckling. The finite buckled shape in the post-buckling stage is taken to be the same as that during incipient buckling. The Von Mises yield criterion is employed to determine the upper bound solution of the plate. Interaction curves for square plates subjected to longitudinal and transverse stresses, applicable to three different boundary conditions, four edges simply supported or four edges clamped or two opposite edges clamped with the other two edges simply supported, are presented in a non-dimensional form. Results for plates having different values of plate slenderness \((b/t)\) and flexural rigidity ratios, \(D_2/D_1\), are given.

ABSTRACT: Using the conventional cold-formed shapes in built-up assemblies (composed members, trusses, etc.) has allowed designers of light-steel framing to widen the applications of cold-formed steel (CFS) to structures of larger scale. Built-up elements, fastened by bolts, screws or welds are usually symmetrical, more stable and of higher capacity. However, they are not addressed in the various design codes for CFS structures. Additional flexibility is caused by slippage between the constituents of a composed member, especially if bolts are used as interconnectors and hole clearances are provided to ensure the ease of assembly. The paper presents experimental studies on the behaviour of double-Z built-up members (bolted). First, twelve members are tested in weak-axis bending, to evaluate the stiffness of the member for the axis of symmetry. Second, the overall behaviour is analysed in eight compression tests on slender members. The goal is to determine the actual failure mode and overall buckling capacity of these members.

ABSTRACT: This paper presents experiments and theoretical analysis of 16 steel I-section beams strengthened using externally bonded CFRP under quasi-static large deformation 3-point bending. The main parameters examined in this paper were the section and member slenderness and the location of the CFRP plates. The member slenderness examined in this paper was in the range of \(L_e/r_p=40–92\). The section slenderness examined in this paper was in the range of \(b/t_f=6.25–16.67\). The CFRP plates were added either to the tension flange or both compression and tension flanges or even to the whole section including the web. An expression for the yield and plastic moments of the composite section were obtained by means of an equivalent thickness approach for the web and flange. The newly obtained strength results were compared against the present design rules in steel specifications. The CFRP increased the strength by up to 32% for compression and tension flange strengthening whereas the strength increased only by 15% for tension flange strengthening. The per cent increase in strength for short specimens was mostly affected by the section slenderness where the maximum gain was obtained for the semi-compact section. Plastic mechanism analysis was performed to predict the collapse curves. Good agreement was found between the theoretical and experimental post buckling load–deflection curves.
Shahin Nayyeri Amiri and Hayder A. Rasheed (Department of Civil Engineering, Kansas State University, Manhattan, KS 66506, USA), “Plastic buckling of thin hemispherical shell subjected to concentrated load at the apex”, Thin-Walled Structures Volume 53, April 2012, Pages 72–82, DOI: 10.1016/j.tws.2011.11.009

ABSTRACT: This study presents the analytical, numerical, and experimental results of thin hemispherical metal shells into the plastic buckling range illustrating the importance of geometry changes on the buckling load. The hemispherical shell is rigidly supported around the base circumference against horizontal and vertical translation and the load is vertically applied by a rigid cylindrical boss at the apex. Kinematics stages of initial buckling and subsequent propagation of plastic deformation for rigid-perfectly plastic shells are formulated on the basis of Drucker–Shield’s limited interaction yield condition. The effect of the radius of the boss, used to apply the loading, on the initial and subsequent collapse load is studied. In the numerical model, the material is assumed to be isotropic and linear elastic perfectly plastic without strain hardening obeying the Tresca or Von Mises yield criterion. Both axisymmetric and 3D models are implemented in the numerical work to verify the presence of non-symmetric deformation modes in the case of thin shells. In the end, the results of the analytical solution are compared and verified with the numerical results using ABAQUS software and experimental findings. Good agreement is observed between the load–deflection curves obtained using three different approaches. A secondary bifurcation point is detected in thin shells in which the deformation degenerates from symmetric to non-symmetric behavior. The bifurcation point depends on the (R/t0) ratio and the material parameters.

ABSTRACT: This paper examined the potential of the lightweight bamboo–steel composite slab as a structural member. Six slab specimens were tested to study the flexural behavior of the composite slabs, which were composed of cold-formed thin-walled steel channel and bamboo plywood sheathings. Three types of connections to fabricate the composite slabs were investigated, which are simple adhesive connection, self-tapping screw enhanced connection, and stability improved connection with bamboo laths glued on the both sides of cold-formed steel channel. Results indicated that the specimens fabricated using the stability improved connection showed a remarkable increase in stiffness, capacity and stability, compared with the other two connections. The bamboo–steel composite slabs have the potential to replace concrete or wood slabs in low buildings.

ABSTRACT: High strength concrete filled steel tube (HSCFT) members have found wide applications. However, there are few reports on the test and model of their creep. This paper investigates the creep of axially loaded HSCFT columns by testing eight specimens for 380 day. A creep model, considering the state of triaxial stress and autogenous shrinkage of the high strength concrete core, has been proposed and validated against the test data. Parametric analysis demonstrates that there exists an obvious difference in the creep between HSCFT
columns and normal strength concrete filled steel tube columns, additionally, concrete composition influences the creep of HSCFT columns considerably.

“Steel square hollow sections subjected to transverse blast loads”, Thin-Walled Structures, Vol. 53, pp 109-122, April 2012, DOI: 10.1016/j.tws.2012.01.007

ABSTRACT: Thin-walled steel hollow sections are used extensively in the construction, offshore, mining and security industries. Such members subjected to blast loads are of interest due to increased security demands and the occurrence of accidental or intentional explosive events. This paper reports an experimental and analytical investigation of steel square hollow sections subjected to transverse blast load, applied with explosive uniformly distributed along the length of the member. Three different section sizes were tested over three different lengths, and the members were fully clamped at their ends. The explosive loads were sufficient in magnitude to cause plastic deformation of the cross-section (local deformation), plastic flexural deformation of the overall member (global deformation), and tensile tearing at the supports. The energy dissipated in the local deformation is determined using rigid-plastic analysis and yield line mechanisms of the deformed cross-sections. The total input energy minus the energy dissipated in local deformation is assumed to be expended in flexural deformation. Analytical solutions using the energy consumed in flexural deformation are shown to produce bounded solutions of the transverse plastic deformation of the members. Finally, a semi-empirical solution is suggested that can be used to aid in design.

“A design rule for web crippling of cold-formed steel lipped channel beams based on nonlinear FEA”, Thin-Walled Structures, Vol. 53, pp 123-130, April 2012, DOI: 10.1016/j.tws.2012.01.003

ABSTRACT: This paper presents the details of a research study conducted with the aim of developing an alternative design rule to predict the web crippling strength of cold-formed steel lipped channel beams. Current empirical web crippling design rules are perceived to be only accurate for the type of sections and the section dimensions that have been tested. A large number of experiments are often necessary to validate these design rules for a wider range of section types and dimensions, and these experiments are often expensive and impractical. Hence, a design rule which is based on a theoretical or numerical model has been attempted through this work. Four series of tests, replicating the four web crippling loading conditions namely: Interior-One-Flange (IOF), Interior-Two-Flange (ITF), End-One-Flange (EOF) and End-Two-Flange (ETF), were performed to predict the ultimate strength of one hundred and eight specimens. The test specimens were manufactured to include three distinct corner radii and two different web heights, and the specimens were tested using three different lengths of load bearing plates. Two additional loading scenarios which could arise due to the loading flange restraint namely—fixed-flange and free-flange were also examined. Finite element models were developed to numerically simulate the tests performed in the experimental investigations. Load-deformation curves were obtained from both the tests and FE models, and the FE models were validated using
the test results. The validation showed a close agreement of FE results with the test results which provided the confidence of using the FE model for a parametric study beyond the limits of the experiments. Based on the results of the parametric study, a design rule was developed which is much more flexible to adapt for new types of sections and ranges of dimensions.

ABSTRACT: This paper presents experimental tests conducted to investigate the local buckling behavior of thin-walled tubular polygon steel columns. The experimental program consists of six stub columns with three different cross-sections, octagonal (eight-sided), dodecagonal (twelve-sided) and hexdecagonal (sixteen-sided), tested under concentric compression. For each cross-section, two values of the plate slenderness ratio (plate width-to-thickness ratio) are considered. Accurate measurements of geometrical imperfections are taken prior to the test. The experimental results show that the local buckling mode of failure depends on the type of the cross-section. Moreover, the plate slenderness ratio is the main factor controlling the local buckling capacity. Design equations provided in the ASCE 48-05, the EC3 and Migita and Fukumoto to predict the local buckling capacity of tubular polygons are evaluated against experimental results of 22 polygons tested under concentric compression available in the literature. Based on drawbacks observed in the design equations, the Loov’s equation developed on basis of the ultimate stress concept is adjusted with new fitting parameters to fit for tubular polygon columns. The accuracy of the new equation is evaluated through a comparison with the experimental results.

ABSTRACT: This paper studies the behavior of very slender thin-walled concrete filled steel tubular (CFST) columns under axial compression. A finite element analysis (FEA) was developed to carry out the behavior of compressive columns. Initial out-of-straightness imperfection was discussed. Generally good agreement was obtained between the predicted and measured results. The FEA model was then used to perform mechanism analysis on very slender circular CFST columns. Parametric studies were carried out and the ultimate strengths from tested results and design codes were compared and discussed. The reliability analysis method was used to calibrate the existing design formulas given in DBJ/T13-51-2010, ANSI/AISC 360-05 and Eurocode 4.

ABSTRACT: The crush behavior of polycrystalline metallic square tubes under quasi-static axial loading condition is investigated through a mesoscale crystal plasticity model embedded in an explicit finite element simulation code as a concurrent multiscale model. The boundary value problem is defined at the local continuum scale whereas the material behavior is modeled at the mesoscale through crystal plasticity defined in a representative volume element. The anisotropic behavior of the tubes emerges from the texture induced by the large plastic deformations created during the manufacturing process. In this work, this effect is modeled by considering the texture generated by deforming a single element model with an embedded polycrystalline aggregate of face center cubic (FCC) crystals under basic loading paths, including uniaxial tension, uniaxial compression, and simple shear. This initial texture is then used at each integration point in the explicit crush simulations of a square tube model made of an FCC aluminum alloy. As energy absorption is dominated by the plastic collapse mechanisms at the corner elements, the influence of the initial texture and its evolution during crush are found to be significant.

Ashkan Shahbazian and Yong Chang Wang (School of Mechanical, Aerospace and Civil Engineering, The University of Manchester, Pariser Building, Sackville Street, Manchester M13 9PL, United Kingdom), “Direct strength method for calculating distortional buckling capacity of cold-formed thin-walled steel columns with uniform and non-uniform elevated temperatures”, Thin-Walled Structures, Vol. 53, pp 188-199, April 2012 DOI: 10.1016/j.tws.2012.01.006

ABSTRACT: This paper assesses the applicability of the Direct Strength Method (DSM) to calculating the distortional buckling strength of cold-formed thin-walled (CF-TW) steel members with uniform and non-uniform elevated temperature distributions in the cross-section. The assessment was carried out by checking the DSM calculation results with numerical simulation results using the general finite element software ABAQUS which was further validated against ambient and uniform elevated temperature tests on short lipped channel sections, in addition to the author's previous validation studies for thin-walled steel columns with non-uniform temperature distributions. The validated numerical model has been used to generate an extensive database (453) of numerical results of load carrying capacity of CF-TW members with different uniform and non-uniform temperature distributions in the cross-sections, under different boundary and loading conditions and with different dimensions and lengths. It is concluded that the existing DSM distortional buckling curve for ambient temperature application is also applicable for columns with uniform temperature distributions in the cross-section, but is un-conservative for columns with non-uniform temperature distributions in the cross-section. This paper proposes a modification to the distortional buckling curve to enable DSM to deal with distortional buckling in columns with non-uniform temperature distributions.

ABSTRACT: An analytical investigation of the buckling/wrinkling behavior of GFRP webs in cell-core sandwiches subjected to combined in-plane shear and bending stresses is conducted. Web–core panels are modeled as long orthotropic plates stabilized by a relatively thick layer of elastic foam. The boundary condition
of the plate is defined according to the interaction between the webs and face sheets in the presence of the core material by applying a series of numerical analyses using the three-dimensional finite element modeling. Two approaches are adopted to predict the wrinkling behavior. The first is to predict the buckling/wrinkling of webs subjected to combined shear and bending loads using a mixed-mode interaction formula. In the second approach, the wrinkling behavior of web–core panels is treated as a biaxial compression–tension local buckling problem. The developed approaches are applied to predict the wrinkling loads of thin-walled webs in GFRP cell-core sandwich beams designed for the GFRP cell-core sandwich roof of the Novartis Campus Main Gate Building constructed in Switzerland.

Jianghong Xue (Department of Mechanics and Civil Engineering, Jinan University, Guangzhou, Guangdong 510632, China), “Local buckling in infinitely, long cylindrical shells subjected to uniform external pressure”, Thin-Walled Structures, Vol. 53, pp 211-216, April 2013, DOI: 10.1016/j.tws.2012.01.008
ABSTRACT: This paper presents a unique approach to analyze the buckling of an infinitely long cylindrical shell subjected to the external pressure. Buckling is considered to occur locally in the shell, spreading over a certain length along the longitudinal axis of the shell. A plausible function of the flexural displacement is created according to Timoshenko's ring solution of the transverse collapse mode. The governing equations based on Donnell–МУШТАРИ's shell theory are solved using Ritz method and the equilibrium conditions are educed. Numerical computations are performed for cases when shell thickness/radius ratios are 0.1, 0.05 and 0.03. In general, the pressure decreases sharply with a very slight increase of the normalized radial deflection just at the beginning of the initiation, then falls quite slowly till the two opposite points on the inner surface of the shell contact each other. It is found that the buckling pressure of the shell converges to the critical value given by Donnell–МУШТАРИ's shell theory and the span of the buckling mode in the longitudinal axis of the shell is independent of material properties. Solutions given in this paper can be used to address the problem of steady-state buckle propagation in the shells.

ABSTRACT: This paper proposes a new automotive box-beam crash absorber design with sinusoidal patterns embedded on the beam surfaces. Six different types of surface patterns were initially proposed and a total of 43 samples were simulated using the commercial pre-processor HyperCrash™ and the commercial explicit FEM solver RADIOSS™. The aim of the study is to improve energy absorption properties of the beams by controlling the wavelength of progressive buckle formations and obtaining denser collapse formations. It was found that the relief patterns could be used effectively to change the buckling modes and reduce the buckle wavelength. A maximum of 42 percent increase in the amount of total energy absorbed and an increase in the energy efficiency factor from 1.08 to 1.54 was observed moving from the reference model to the best design so far. This research may possibly pave new avenues in crash absorber design.

ABSTRACT: This paper presents an improved finite element approach in which a node-based strain smoothing is merged into shear-locking-free triangular plate elements. The formulation uses only linear approximations and its implementation into finite element programs is quite simple and efficient. The method is then applied for static, free vibration and mechanical/thermal buckling problems of functionally graded material (FGM) plates. In the FGM plates, the material properties are assumed to vary across the thickness direction by a simple power rule of the volume fractions of the constituents. The behavior of FGM plates under mechanical and thermal loads is numerically analyzed in detail through a list of benchmark problems. The numerical results show high reliability and accuracy of the present method compared with other published solutions in the literature.

ABSTRACT: This work deals with the structural behaviour and ultimate strength of fixed-ended cold-formed steel lipped channel columns experiencing local–distortional–global buckling mode interaction, due to the closeness between the critical buckling stresses associated with these three buckling mode types. After briefly addressing the column specimen geometry selection and showing a few numerical elastic post-buckling results, the paper reports the results of an experimental investigation involving a set of 12 columns with several cross-section dimensions and yield stresses, which is aimed at (i) providing experimental evidence of the occurrence of the triple mode interaction under consideration and (ii) quantifying its effect on the column deformed configuration evolution and failure load erosion (drop). Various aspects concerning the test set-up and procedure are described in some detail before presenting and discussing the obtained column experimental results, which basically consist of (i) measured cross-section dimensions, lengths and initial displacements (geometrical imperfections), (ii) stress–strain curves and yield stresses determined from tensile coupon tests, (iii) recorded non-linear equilibrium paths (applied load vs. various relevant displacements) and ultimate strength values, and (iv) observed deformed configurations and collapse mechanisms.

DOI: 10.1016/j.tws.2012.01.016

ABSTRACT: The SAFESA procedure is an idealisation error control process developed for linear static finite element (FE) analysis. This paper investigates the application of this process to non-linear problems. The post-buckled collapse of a stiffened panel in compression is used as the case study. The main part of the paper presents the critical analysis of important modelling assumptions, including the material model, boundary conditions and geometrical imperfections. Several potential error sources are identified and then investigated using the non-linear FE code ABAQUS. The outcome of the analysis is an improved FE model and a quantification of the idealisation error.
Farhad Khalili and Hossein Showkati (Civil Engineering Department, Urmia University, Urmia, Iran), “T-ring stiffened cone cylinder intersection under internal pressure”, Thin-Walled Structures, Vol. 54, pp 54-64, May 2012, DOI: 10.1016/j.tws.2012.01.015

ABSTRACT: Cone–cylinder junctions are vastly used in the industries such as oil refineries and aeronautics. They can be seen in pressure vessels and piping such as tanks' roofs and pipes' reducers. When cone–cylinder junctions are subjected to the internal pressure, compression stresses are established near the joining point of the cone to cylinder and make the junction susceptible to non-symmetric buckling failure or axisymmetric failure. As it is practical to increase the shell wall thickness locally near the point of intersection, sometimes it is more convenient to attach a ring-beam exactly to the point of intersection. Only limited work has been done on the T-ring stiffened cone–cylinder junctions under internal pressure. In this study, experimental behavior along with numerical analysis of T-ring stiffened cone–cylinder intersection under internal pressure has been dealt and experimental results such as buckling mode and load are presented here and compared with numerical results. It can be seen that by wise consideration and manipulated use of material properties and geometric imperfections in nonlinear analysis, buckling mode and load resulted from non-linear analysis are compatible with that of experimental results. Two classes of non-linear analyses have been carried out and compared with each other, then it was inferred that even though pattern of geometrical imperfection is effective in determination of buckling modes, but in these kinds of structures it is not necessarily used for the analysis of buckling loads. Finally experimental results were compared with design proposals. It is shown that these proposals can conservatively predict the failure loads.

ABSTRACT: Thin-walled tubes are a kind of popular design for the energy absorbing devices. However, when they are subjected to axial loading, there exists a large undesirable initial peak force, followed by fluctuation in the forcedisplacement curve. In this paper, the origami patterns are introduced to thin-walled tubes to minimize the initial peak and the subsequent fluctuations. Tubes of square, hexagonal and octagonal cross-sections with origami patterns are investigated by finite element analysis. Numerical results show that compared with the conventional tube, the patterned tubes exhibit a lower initial peak force and more uniform crushing load. The critical states are obtained under which the crushing mode follows the initial origami pattern. The parametric study shows the relationship between the pre-folding angle and the initial peak force as well as the mean crushing force for the tubes with different cross-sections. A prototype of the patterned tube is constructed and tested, showing much lower initial peak force and a smooth crushing process which agrees with the numerical results.

Yuner Huang and Ben Young (Department of Civil Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong, China), “Material properties of cold-formed lean duplex stainless steel sections”, Thin-Walled Structures, Vol. 54, pp 72-81, May 2012, DOI: 10.1016/j.tws.2012.02.003

ABSTRACT: This paper presents the behaviour of cold-formed lean duplex stainless steel for six different sections, among which two are square hollow sections and four are rectangular hollow sections. The test specimens were cold-rolled from flat strips of lean duplex stainless steel. The material properties of high strength cold-formed lean duplex stainless steel square and rectangular hollow sections were determined. Tensile coupons in the flat portions and corners of each section were tested. Hence, the Young's moduli, 0.2% proof stresses, 1.0% proof stresses, tensile strengths, elongation at fracture and the Ramberg–Osgood parameter
of lean duplex material for each section were measured. The material properties of the complete cross-sections in the cold-worked state were also obtained from stub column tests. The initial local geometric imperfections of the six sections were measured, and the profiles of the local imperfections along cross-section were plotted for each section. Residual stresses were measured for section 150×50×2.5 using the method of sectioning. The membrane and bending residual stress distributions in the cross-section were obtained and plotted. Furthermore, finite element model of stub columns was developed and compared well with the test results. The stub column test strengths were also compared with the design strengths predicted by the American Specification, Australian/New Zealand Standard and European Code for stainless steel structures. Generally, the three specifications conservatively predicted the column strengths. The European Code provides the most conservative prediction.

ABSTRACT: This paper describes the finite element method using ABAQUS to model the axial compressive behaviour of inclined, tapered and straight–tapered–straight (STS) concrete filled steel tubular stub (CFST) columns with square hollow sections. The accuracy of the numerical model was verified by comparing the numerical predictions with experimental study of the 200×200×3.75 RHS filled with C60 concrete with inclined angle of 0–9° and tapered angle of 0–4°. The results show that the compressive behaviours, load vs. strain relationship and failure mode predicted by the numerical simulations were agreeable with experimental results. After the validation, a parametric study was performed with 3 typical steel hollow sections (200×200×3.75 RHS, 300×300×6.3 RHS and 400×400×8.0 RHS) and extended the inclined angle and tapered angle to 0–15° and 0–12° respectively. The parametric study highlights some of the behaviour observed in test and extends the application range. In addition, reduction factor for calculating the axial capacity of this form of CFST columns are proposed.

Mohammad Reza Haidarali and David A. Nethercot (Civil and Environmental Engineering Department, Imperial College London SW7 2AZ, United Kingdom), “Local and distortional buckling of cold-formed steel beams with both edge and intermediate stiffeners in their compression flanges”, Thin-Walled Structures, Vol. 54, pp 106-112, May 2012, DOI: 10.1016/j.tws.2012.02.013
ABSTRACT: The true buckling behaviour of cold-formed steel beams with both edge and intermediate stiffeners in their compression flanges has been predicted with the aid of advanced numerical modelling. A series of nonlinear finite element analyses has been carried out to investigate the flexural behaviour of cold-formed Z sections with both edge and intermediate stiffeners in their flanges, when the failure is controlled by local and/or distortional buckling. The effect of the size and position of intermediate stiffeners as well as the effect of the edge stiffener/intermediate stiffener interaction on the buckling behaviour and ultimate strength of these sections has been studied. The knowledge gained from FE analyses was used to check the accuracy of the Eurocode design rules in predicting the ultimate strengths for these sections.
Young Bong Kwon and Gun Ho Seo (Department of Civil and Environmental Engineering, Yeungnam University, Gyongsan, Korea), “Prediction of the flexural strengths of welded H-sections with local buckling”, Thin-Walled Structures, Vol. 54, pp 126-139, May 2012, DOI: 10.1016/j.tws.2012.02.005

ABSTRACT: This paper describes the flexural strength of welded sections based on a series of flexural tests performed on H-sections fabricated from steel plates of thickness 6.0 mm with nominal yield stress of 315.0 MPa. Thin-walled flexural members undergo local, lateral-torsional or their interactive buckling according to the section geometries and lateral boundary conditions. Flexural members with the flanges or the web of large width-to-thickness ratios may undergo local buckling before lateral-torsional buckling and their interaction before the final collapse of the section. The local buckling has a negative effect on the flexural strength based on the lateral-torsional buckling. This phenomenon should be considered in the estimation of the nominal flexural strength of thin-walled flexural members. Welded H-section beams composed of the flanges and the web with various width-to-thickness ratios were tested to failure. The initial imperfections in local and lateral buckling mode, and residual stresses were included in the FE analyses. Simple design flexural strength formulas for the direct strength method (DSM) were proposed based on the test and FE results of welded sections to account for interaction between local and lateral-torsional buckling. The design strength curves were compared with the AISC specifications (2005), Eurocode3 (2003) and test results. The adequacy of the strength curve for the DSM was confirmed. A set of conclusions on the flexural strength and structural behavior of thin-walled welded H-sections was drawn from the experimental studies.

ABSTRACT: This paper presents an original method based on the Generalised Beam Theory (GBT) capable to decompose the elastic buckling modes from a shell finite element analysis (FEA) of an isotropic thin-walled member, into pure buckling modes of global, distorsional or local nature. The main novelty lies in using only the GBT cross-sectional deformation modes instead of member base mode shapes. The contribution of each pure buckling mode can be calculated, allowing a better understanding of the member post-buckling behaviour and strength reserve. Following the GBT classical assumptions, the membrane shear strains and transverse extensions are neglected. The modal participations obtained from FEA are in good agreement with the values calculated via classical GBT approach.

ABSTRACT: The objective of this work is to analyze the initial and post-collapse plate deflections based on measurement records of the experiments of three corroded box girders subjected to pure vertical bending loading inducing a compressive stress on deck. The effect of initial imperfections and corrosion degradation on the final post-collapse deformation shape has been investigated and a relationship between different loading responses, shape of initial imperfections and plate slenderness has been derived. Analyzing initial imperfections, plate slenderness and final post-collapse deformations, a slenderness criterion has been established to predict the post-collapse deformation shape.

ABSTRACT: The effect of geometric imperfections on the buckling capacity of thin cylindrical shells subjected to uniform external pressure is investigated in this paper. Geometric surveys were conducted on small-scale thin cylinders in order to measure geometric imperfections of the shell surface. These imperfections were then modelled in the FE analysis and a geometrically nonlinear static analysis was carried out. The cylinders are tested to collapse in the laboratory and the results are compared to the results of the FE analysis. Both collapse pressure and postbuckling mode shape are accurately predicted by the FE analysis.

DOI: 10.1016/j.tws.2012.02.006

ABSTRACT: The ultimate strength of five narrow stiffened panels tested with two stiffeners under axial compression until collapse and beyond is determined by finite element analysis, and is compared with experimental results. Models with two half bays plus one full bays in the longitudinal direction are used in the finite element analysis. The material properties used in the finite element analysis have been evaluated by tensile tests. The initial geometrical imperfections also affect significantly the collapse behavior of the stiffened panels. Hence, the initial imperfections of the stiffened plates were measured before the experiment. The results of the FE analysis with measured and with equivalent initial imperfections are compared and conclusions are derived about the possible bias of the results when the initial imperfections are not measured.

ABSTRACT: To complement previous experimental studies on the performance of unprotected Elliptical Hollow Section (EHS) steel columns, under the hydrocarbon fire curve, a numerical analysis has been performed and outlined in this paper. A three-dimensional Finite Element Method (FEM) model has been developed and calibrated against 12 experiments, comprising of six unrestrained and six axially restrained EHS columns of two slenderness, $\lambda_z=40.1$ and $\lambda_z=50.8$. The EHS temperature profiles and axial displacements, measured under three different loading levels, ($\alpha_L=0.3, 0.45$ and 0.6) were utilised in the calibration process. The mechanical and thermal properties for carbon steel at elevated temperatures, detailed in the Eurocode standard EC3 Part 1–2, design of steel structures [1] have been applied. Axial displacement charts illustrate that a close agreement between the FEM model and the experiment results was achieved, while highlighting how critical the thermal expansion coefficient and geometric imperfection was during the calibration process. Ultimately, the paper will detail appropriate recommendations for the thermal analysis of unfilled Elliptical Hollow Section steel columns, of steel grade S355J2H, and provide the platform for comprehensive parametric fire investigations to commence.

ABSTRACT: Initial sizing procedures for aircraft stiffened panels that include the influence of welding fabrication residual process effects are missing. Herein, experimental and Finite Element analyses are coupled to generate knowledge to formulate an accurate and computationally efficient sizing procedure which will enable designers to routinely consider panel fabrication, via welding, accounting for the complex distortions and stresses induced by this manufacturing process. Validating experimental results demonstrate the need to consider welding induced material property degradation, residual stresses and distortions, as these can reduce static strength performance. However, results from fuselage and wing trade-studies, using the validated sizing procedure, establish that these potential reductions in strength performance may be overcome through local geometric tailoring during initial sizing, negating any weight penalty for the majority of design scenarios.

ABSTRACT: This paper presents a numerical and analytical study of the behavior of thin-walled plates connected by multiple bolts under shear. A validated finite element model has been used to perform a comprehensive set of parametric studies to investigate the effects of different design parameters on the connected plate behavior, including initial stiffness, ultimate resistance and maximum deformation at the ultimate resistance. The design parameters include edge and end distances, bolt spacing, number of bolts along and perpendicular to the loading direction and elongation limit of steel. It has been found that the existing methods for calculating the stiffness and ultimate resistance are directly applicable. The main focus of this paper is the maximum plate deformation at the ultimate plate resistance. Based on the parametric study results, it has been found that strain distributions around the bolt holes for different failure modes, as proposed by the authors for plate connected by a single bolt, are still applicable. However, it is necessary to modify the plate dimension ranges within which the different strain distributions apply to recognize the difference in failure modes for plates with different bolt arrangements.

ABSTRACT: In this paper global buckling (i.e., flexural, pure torsional, or flexural–torsional buckling) of thin-walled columns is discussed. The considered problem is the most basic one: the column is simply supported and subjected to a uniform concentric compressive force. The column's cross-section is an arbitrary open thin-walled cross-section. For the critical forces of this problem classical analytical solutions are known. In the presented research alternative formulae are derived on the basis of modeling the member as a set of flat plane elements (or strips). As it is found, the derivations can be carried out in various ways, among which eight
options are considered. The resulted critical force formulae are briefly discussed in this paper. Extensive numerical studies are also completed; these studies are summarized in a companion paper.

M.M. Alinia, Ghazaleh Soltanieh and Mozhdeh Amani (Department of Civil Engineering, Amirkabir University of Technology, 424 Hafez Avenue, Tehran 15875-4413, Iran), “Inelastic buckling behavior of stocky plates under interactive shear and in-plane bending”, Thin-Walled Structures, Vol. 55, pp 76-84, June 2012
DOI: 10.1016/j.tws.2012.03.007
ABSTRACT: Inelastic buckling and postbuckling behavior of stocky plates under combined shear and in-plane bending stresses are investigated and compared to slender plates. Aluminum and steel plates having various slenderness ratios are modeled and analyzed by means of (i) numerical nonlinear finite element method and (ii) theoretical p-Ritz energy method; and both results are compared to the classic interaction equation. It is observed that whereas in slender plates, elastic buckling occurs prior to the material's proportional limit load, stocky plates buckle in an inelastic way within the post-yield stage. In contrast to slender plates with considerable postbuckling reserves, the buckling of stocky plates is immediately followed by softening. In addition, it is shown that the classic interaction equation overestimates buckling loads; and therefore, a modified equation that can safely be applied to both stocky and slender plates is proposed.

Gongyao Gu, Yong Xia and Qing Zhou (State Key Laboratory of Automotive Safety and Energy, Tsinghua University, Beijing 100084, PR China), “On the fracture possibility of thin-walled tubes under axial crushing”, Thin-Walled Structures, Vol. 55, pp 85-95, June 2012, DOI: 10.1016/j.tws.2012.03.005
ABSTRACT: Thin-walled tubes are widely used as energy absorption components in vehicle crashworthiness design where axial crushing is one of the most typical loading conditions. Lightweight materials such as high-strength steel, aluminum and magnesium have been applied for thin-walled tubes for weight reduction. Meanwhile, most of these lightweight materials are more brittle and easily fractured than traditional steel. Distribution and history of stress triaxiality and equivalent strain in the thin-walled tubes under axial crushing have been analyzed in this article with finite element simulation, as these two parameters of stress and strain states are commonly used for constructing fracture locus of materials. It is observed that both stress triaxiality and equivalent strain are transferring along the tube length like waves. Analysis results show that fracture is more likely to take place on the edge than the other positions of square thin-walled tubes. For identical axial crushing stroke, there is little difference of stress and strain states inside the square thin-walled tubes with initial impact velocity varying from 6 m/s to 24 m/s. Influence of geometrical parameters on the stress and strain states have also been analyzed, including the shape of cross-section corner, the wall thickness and the shape of cross-section, respectively. Analysis results in this article may offer references for design of thin-walled tubes and the necessary experimental characterization of mechanical properties for lightweight materials.

ABSTRACT: Small-deflection theory is used along with FE models to compute the equivalent elasticity parameters of sandwich structures. Eigenfrequency and eigenmode analyses, comparing the equivalent 2-D continua with full 3-D models, are utilized to determine how continuous connections and in-vacuo assumptions are influenced as real-world discontinuities and gas- or foam-filled cavities are included. It is found that discrete
connections between structural elements reduce stiffnesses and eigenfrequencies of the net structure substantially. The presence of gas or foam in the core cavities is observed to increase the overall damping of the dynamic panel response while also amplifying certain panel resonances.

ABSTRACT: Concrete filled double skin steel tubular (CFDST) columns have some advantages when compared to conventional concrete filled steel tubular (CFST) columns, such as lighter self-weight and better cyclic performance. CFDST columns have the potential to be used in structures such as bridges, high-rise buildings, viaducts and electricity transmission towers. The inner and outer steel tubes will be subjected to preloads from upper structures and wet filled concrete. The initial stresses and extra deformations on steel tubes caused by these preloads would affect the capacity of the CFDST members. This paper thus discusses the behaviour of axially loaded CFDST columns with preload either on the outer tube alone or on both tubes. A general purpose finite element analysis (FEA) model is developed to predict the behaviour of CFDST columns with the steel tubes subjected to preload. The FEA model is verified using test results of CFDST columns without preload and those of CFST columns with preload. The influences of preload ratio, slenderness ratio, hollow ratio and material strength on axial strength are discussed. Finally, formulas are proposed for calculating the ultimate strength of CFDST columns with preload on steel tubes.

Amin Mohebkhah and Behrouz Chengeni (Structural Engineering Division, Faculty of Civil and Architectural Engineering, University of Malayer, Malayer, Iran), “Local-global interactive buckling of built-up I-beam sections”, Thin-Walled Structures, Vol. 56, pp 33-37, July 2012, DOI: 10.1016/j.tws.2012.03.018
ABSTRACT: According to the Specification for structural steel buildings (AISC-LRFD 360-10), the nominal flexural capacity of I-beam sections having compact webs and noncompact or slender flanges can be estimated as the lower value obtained for the limit states of lateral-torsional buckling (LTB) and compression flange local buckling (FLB). The main assumption behind the approach is that there is no interaction between LTB and FLB limit states and they can be considered as two independent phenomena. In this paper a three dimensional finite-element model using ABAQUS is developed for the inelastic nonlinear analysis of I-beams having noncompact or slender flanges. The model is used to investigate the applicability of the AISC-LRFD approach in estimating the moment capacity of locally buckled steel built-up I-beams with various flange slendernesses. It was found that as the distance between the global and local buckling capacities becomes larger, there would be an interaction between the FLB and LTB limit states; indicating a considerable post-local-buckling capacity for such cases.

ABSTRACT: The results of 82 web crippling tests are presented, with 20 tests conducted on channel sections without web openings and 62 tests conducted on channel sections with web openings. The tests consider both end-two-flange and interior-two-flange loading conditions. In the case of the tests with web openings, the hole was located directly under the concentrated load. The concentrated load was applied through bearing plates; the effect of different bearing lengths is investigated. In addition, the cases of both flanges fastened and unfastened to the support is considered. A non-linear elasto-plastic finite element model is described, and the results compared against the laboratory test results; a good agreement was obtained in terms of both strength and failure modes.

ABSTRACT: An experimental study was undertaken to investigate the behaviour of 24 concrete-filled steel tube (CFST) columns, loaded concentrically in compression to failure. Variables in the tests include the length, diameter, strength of the steel tubes and the strength of the concrete. The large slenderness ratio caused all composite columns in Series 1 to fail by overall flexural buckling. Although overall flexural buckling was also experienced in the composite columns of Series 2 tests, the stockier columns failed by crushing of the concrete and yielding of the steel tube. A comparison of the experimental results with the loads predicted by the South African code (SANS 10162-1) and Eurocode 4 (EC4) shows that the codes are conservative by 8.4% and 13.6%, respectively, for Series 1 tests, and 10.5 and 20.2%, respectively, for Series 2 tests. A plot of the compressive load versus the vertical deflection shows the composite columns to be fairly ductile.

Jose Aguilera, Amr Shaat and Amir Fam (Department of Civil Engineering, Queen's University, Kingston, ON, Canada), “Strengthening T-joints of rectangular hollow steel sections against web buckling under brace axial compression using through-wall bolts”, Thin-Walled Structures, Vol. 56, pp 71-78, July 2012 DOI: 10.1016/j.tws.2012.03.013
ABSTRACT: The effectiveness of through-wall bolts is examined for strengthening T-joints of rectangular hollow steel sections. This is accomplished by controlling the web outward buckling of the chord under the brace axial load. The study examined the effect of the number and pattern of bolts, as well as the web height-to-wall thickness \((h/t)\) ratio of the chord, on strengthening effectiveness. Rectangular 203\(\times\)76\(\times\)(3.09, 4.5, and 5.92) mm chord members were tested. The number of 8 mm diameter steel bolts varied from a single bolt to 15 bolts of various distributions. Holes were first drilled in the vertical walls of the chord member, and then bolts were inserted through one wall and anchored at the other wall. The joint strength increased by 29% for chords with \((h/t)\) of 65. As \((h/t)\) ratio reduced to 45 and 35, the gains were only 6.2% and 3.1%, respectively. The number and distribution of bolts had little effect on their effectiveness.

ABSTRACT: A parametric study of cold-formed steel sections with web openings subjected to web crippling was undertaken using finite element analysis, to investigate the effects of web holes and cross-section sizes on the web crippling strengths of channel sections subjected to web crippling under both interior-two-flange (ITF) and end-two-flange (ETF) loading conditions. In both loading conditions, the hole was centred beneath the bearing plate. It was demonstrated that the main factors influencing the web crippling strength are the ratio of the hole depth to the flat depth of the web, and the ratio of the length of bearing plates to the flat depth of the web. In this paper, design recommendations in the form of web crippling strength reduction factors are proposed, that are conservative to both the experimental and finite element results.

ABSTRACT: In this paper, an extended numerical investigation is conducted to study the shear behavior of transversely stiffened hollow tubular flange plate girders (HTFPGs) using ABAQUS software. A comparison between the HTFPGs and plate girders with flat flange plates (IPGs) is first made considering the elastic-buckling and the post-buckling strength. The results indicated that the realistic support condition at the juncture of the web and flanges of HTFPGs is nearly fixed. The study is then extended to examine hybrid HTFPGs (HHTFPGs). The main goal of this extension was to examine the validity of the current EN 1993-1-5 provisions regarding both the shear resistance and the behavior trend of such hybrid girders. The validity of the other international design codes such as the AASHTO, AISC and BS 5950 were also checked. The results of the finite element (FE) models confirmed that using HHTFPGs provides economy as their strength could be utilised efficiently. In addition, it was found that the strengths obtained with EN 1993-1-5 provisions do reproduce suitably the trends obtained numerically, but their design equations were found to be extremely conservative. Moreover, the shear strength recently proposed for homogenous HTFPGs seemed to be slightly conservative for the case of HHTFPGs. Therefore, it was modified herein by taking the relative effect of the actual flange yield strength into account. This shear strength currently modified is found to represent the actual behavior of these girders better than the original and recently proposed EN 1993-1-5 shear strengths. Several remarks regarding the selection of optimum dimensions for the HTFPGs are also presented.

ABSTRACT: This paper investigates the moment modification factors of an I-girder with trapezoidal web corrugations under moment gradient and various end restraint conditions. The moment modification factors are obtained by using the finite element method with beam elements and new general formulas of cross-section properties as well as a new warping constant of the I-girder with trapezoidal web corrugations. The theoretical results of moment modification factors are successfully verified by comparing them with the results from the commercial finite element software using shell elements. A series of finite element analyses with different
corrugation profiles and lengths are investigated. From the results, it is found that the present design of moment modification factor formulas cannot satisfactorily predict the buckling capacities of the I-girder with trapezoidal web corrugations under unequal end moments with various end restraint conditions. For the purpose of design, the closed-form expressions for the moment modification factors are proposed and successfully verified.

ABSTRACT: The initial depression of shell skins is usually created through various panel processes such as rolling or welding. It is important to create some basic design regulations associated with the existing codes. A longitudinal imperfection caused by the continuous welding of a panel's edge to form a cone is the most important case in this context. The present paper discusses 14 laboratory specimens in 2 groups, labeled Shallow Conical Caps (SCC) and Deep Conical Caps (DCC), loaded under uniform hydrostatic pressure. The samples were modified to include either 1 or 2 line imperfections with amplitudes of 1t, 2t and 3t in depth (t the thickness of conical shell). The results presented here are in general agreement with international codes as well as theories concerning initial and overall buckling and collapse.

ABSTRACT: Energy absorption characteristics of regular polygonal columns and rhombic columns under quasi-static axial compression are investigated by using an INSTRON materials testing machine. The influence of central angle on deformation mode and mean crushing force of angle elements is studied. Numerical investigations are also carried out to study the crush resistance of polygonal columns and angle elements under quasi-static and dynamic axial compression. The numerical predicted crushing force and deformation mode of the polygonal columns are found to be in good agreement with the experimental results. In addition, based on the experiment observations, some discussion about the deformation mechanism of energy absorption is presented.

ABSTRACT: Recently, tapered concrete-filled double skin steel tubular (CFDST) columns have been applied in electricity transmission towers in China. However, there is still lack of information on the behaviour of such kind of members. This paper thus carried out the investigation on axially loaded tapered CFDST stub columns. The parameters included the tapered angle and the sectional profile. A finite element analysis (FEA) model was developed to predict the behaviour of the tapered member as well. The results showed that the steel tubes and the sandwiched concrete could work together well despite the tapered angle. The failure mode of the tapered
CFDST stub column was similar to that of the straight one, and the failure occurred near the smallest section. The confinement effect of the tapered member was discussed by using the stress analysis. Finally, formulas were suggested for the calculation on the ultimate strength of the tapered CFDST stub column.

ABSTRACT: Various types of composite members have been developed to utilize the combined advantages of existing reinforced concrete and steel structures, and to actively improve ductility and serviceability of structural members. One of them is the hybrid-type steel beam, in which the prestressing method is applied to a steel beam. Introducing prestress to the existing I-shaped steel beam, however, results in a very low prestress efficiency due to the large axial stiffness of the section. On the other hand, if corrugated webs are used, the prestress introduced to the main flexural-resistant elements—the upper and lower flanges—gets larger due to the accordion effect, so that it is very advantageous not only in terms of serviceability, but also of achieving the improved flexural strength. Most previous studies on steel members with corrugated webs, however, have focused on the shear buckling strength of the corrugated webs, and few studies have been conducted on the accordion effect of the corrugated webbed beam to which prestress is introduced. Therefore, this research proposed two rational and theoretical models to quantitatively estimate the accordion effect, which is induced by the introduction of prestress to corrugated webbed steel beams, and performed experiments on two steel beams with corrugated webs and one with typical wide flange section. The experimental results showed that the prestressing efficiency of steel beams with corrugated webs increased more significantly than that of the steel beam with a typical web, and it is verified that the proposed methods are very simple and provide good agreements with the experimental results.

ABSTRACT: Thin cylindrical shells are the most prevalent and important structural component of vessels across the process industries. Such structures are prone to accidental buckling due to inadvertently induced vacuum. Minor deviations in the nominal geometry of the shell can affect the apparent initial buckling load. One common deviation is that the radius of the vessel is not constant but rather varies randomly with location on the shell. This paper presents extensive experimental data permitting a full statistical characterisation of defects of this nature. The data was obtained from detailed measurements of 39 replicate test vessels at the laboratory scale. Both amplitude and frequency content of this type of imperfection is quantified. Furthermore a methodology whereby the variation in radius is characterised as a two dimensional random field is outlined. An algorithm to generate realisations of this field is developed and the output is shown to be consistent with the measured results.

ABSTRACT: Square concrete-filled steel tubes (CFSTs) are gaining increasing usage in modern construction practice, offering improved mechanical properties and increased material efficiency compared with the individual steel and core concrete components. However, the cross-section slenderness of the encasing steel is, although more inflexible than a comparable hollow steel tube, restrained due to local buckling. A number of innovative kinds of reinforcement stiffeners have been put forward particularly for the square CFSTs with slender sections of encasing steel. To investigate the mechanical effect of the reinforcement stiffeners and compare them with traditional ones in practice, four square CFSTs welded with various reinforcement stiffeners and one reference CFST have been tested, and are presented in this paper. The mechanical behaviors such as the resistance, ductility and failure modes investigated during the test were also studied in the theoretical research, which was carried out to predict and further summarize the comprehensive properties of the specimens. A numerical analysis program was written and verified with related scholars’ experimental data, and extensive parametric analysis was conducted to investigate the influencing parameters on mechanical properties. Design recommendation for the cross-section strength has been put forward based on the test results and previous research.

ABSTRACT: The structural behaviour of elliptical hollow sections has been examined in previous studies under several loading conditions, including pure compression, pure bending and combined uniaxial bending and compression. This paper examines the elastic buckling response of elliptical hollow sections under any linearly varying in-plane loading conditions, including the most general case of combined compression and biaxial bending. An analytical method to predict the elastic buckling stress has been derived and validated against finite element results. The predictive model first identifies the location of the initiation of local buckling based on the applied stress distribution and the section geometry. The critical radius of curvature corresponding to this point is then introduced into the classical formula for predicting the elastic local buckling stress of a circular shell. The obtained analytical results are compared with results generated by means of finite element analysis. The comparisons between the analytical and numerical predictions of elastic buckling stress reveal disparities of less than 2.5% for thin shells and, following an approximate allowance for the influence of shear, less than 7.5% for thick shells.

ABSTRACT: The aim of the present paper is to investigate the effects of pitting corrosion on the ultimate capacity of mild steel rectangular plates under biaxial compression, extending earlier results of uniaxially loaded plates. A series of non-linear FEM analysis of plates with partial depth corrosion pits are carried out, changing geometrical attributes of both pits and plates, i.e., the radius, depth and location of pits and the slenderness of plates. Simulation results show that volume loss dominates the degradation of the compressive capacity of pitted mild steel plates as well as loading ratio. Plate slenderness has considerable effect on biaxial interaction curve shape. A regression analysis of FEM results is conducted leading to a closed form formula able to predict the remaining strength of pitting corroded plates, where both volume loss and plate slenderness are taken into account. The proposed formula will facilitate a quick estimation of the remaining strength of pitting corroded plates during lifetime ship design phase which is relevant to maintenance decision-making of aging ship structures and components.

ABSTRACT: Aluminium tubular structural members may experience web crippling failure due to localise concentrated loads or reactions. This paper presents a test programme on strengthening of high strength aluminium tubular structural members using externally bonded carbon fibre-reinforced polymer (CFRP). A series of tests on CFRP strengthened aluminium square and rectangular hollow sections subjected to web crippling is presented. The web crippling tests were conducted under four loading conditions of End-Two-Flange, Interior-Two-Flange, End-One-Flange and Interior-One-Flange. A total of 48 web crippling tests was conducted in this study. The investigation was mainly focussed on the effects of web slenderness of aluminium tubular sections on CFRP strengthening against web crippling. The tests were performed on eight different sizes of square and rectangular hollow sections which covered a wide range of web slenderness (flat portion of web depth-to-thickness) ratio from 6.2 to 62.2. The test specimens were fabricated by extrusion from 6061-T6 heat-treated aluminium alloys. Material properties of the aluminium sections were obtained from tensile coupon tests. Most of the strengthened specimens were failed by debonding of CFRP plate from the aluminium tubes. Three main failure modes were observed in the tests, namely the adhesion, combination of adhesion and cohesion, and interlaminar failure of CFRP plate. The failure loads, failure modes and the load-web deformation behaviour of the aluminium sections are also presented. It was found that the web crippling capacity of aluminium sections are significantly increased due to CFRP strengthening, especially for those sections with large value of web slenderness ratio.

DOI: 10.1016/j.tws.2012.05.001

ABSTRACT: In this paper, strengthening effects of stiffeners on regular and arbitrarily stiffened plates are discussed in terms of the ultimate strength limit (USL) obtained through full nonlinear transient analysis. This study starts from the investigation of strengthening effects of regular stiffened plates which are subjected to uniaxial stress and then arbitrarily stiffened plates that are subjected to biaxial stress. The optimal height,
number, and arrangement of the stiffener that provide the best strengthening effect are revealed and it is also found that the strengthening effects of an arbitrarily oriented stiffener (or oblique stiffener) can be decoupled to two perpendicular regular stiffeners which are located in appropriate positions. Nonlinear buckling analyses were performed on the arbitrarily stiffened plates with one and two arbitrarily oriented stiffeners to verify this finding. The outcome of this paper can be further extended and applied to develop simplified semi-analytical models for buckling strength analysis of constructional plates.

A. Alavi Nia, Kh. Fallah Nejad, H. Badnava and H.R. Farhoudi (Mechanical Engineering Department, Bu-Ali Sina University, Hamedan, Iran), “Effects of buckling initiators on mechanical behavior of thin-walled square tubes subjected to oblique loading”, Thin-Walled Structures, Vol. 59, pp 87-96, October 2012
DOI: 10.1016/j.tws.2012.03.002
ABSTRACT: Thin-walled structures usually collapse in Eulerian buckling mode under oblique loads. Energy absorption capacity and crush force efficiency of the structure in this type of collapse are low. Collapse initiators are used to improve these properties. In this research, effect of collapse initiators on energy absorption characteristics of square tubes under oblique quasi-static loads is investigated both experimentally and numerically. Initiators are in the form of cuttings on the tube corners. Results show that collapse initiators in most of the specimens change deformation mode from general buckling to progressive buckling and decrease considerably the peak load; therefore increase crush force efficiency. Furthermore, effect of location and number of initiators is studied. There is good agreement between the numerical results and data from experiments.

C.G. Wang (1,2), Z.Y. Du (1,2) and H.F. Tan (1,2) (1) Center for Composite Materials, Harbin Institute of Technology, Harbin 150080, China (2) National Key Laboratory of Science and Technology on Advanced Composites in Special Environments, Harbin Institute of Technology, Harbin 150080, China “Initial wrinkling and its evolution of membrane inflated cone in bending”, Thin-Walled Structures, Vol. 59, pp 97-102, October 2012, DOI: 10.1016/j.tws.2012.05.007
ABSTRACT: The concept of the wrinkling factor is firstly presented to obtain the wrinkling condition. An extremum method is then proposed to predict the critical wrinkling load and the initial wrinkling location by searching the maximum of the wrinkling factor. Here the critical wrinkling load is defined as the ratio of the wrinkling moment versus the initial wrinkling location, which is different from previous definition. The nondimensional analyses show that the critical wrinkling load and the initial wrinkling location are both closely related to the taper ratio of the inflated cone. The critical taper ratio is 1.5 which corresponds to the highest load-carrying efficiency of the inflated cone in bending. The wrinkled region is finally predicted to deeply understand the wrinkling evolution in the bended membrane inflated cone. A series of wrinkling experiments on the inflated cone in bending are performed to verify the accuracy and the validation of the proposed method. The good agreements between the tests and the predictions give confidence to use the extremum method for wrinkling analysis of the inflated load-carrying structures.

Chang Qi, Shu Yang and Fangliang Dong, “Crushing analysis and multiobjective crashworthiness optimization of tapered square tubes under oblique impact loading”, Thin-Walled Structures, pp 103-119, October 2012
DOI: 10.1016/j.tws.2012.05.008
ABSTRACT: In this paper, a class of axisymmetric thin-walled square (ATS) tubes with two types of
geometries (straight and tapered) and two kinds of cross-sections (single-cell and multi-cell) are considered as energy absorbing components under oblique impact loading. The crash behavior of the four types of ATS tubes, namely single-cell straight (SCS), single-cell tapered (SCT), multi-cell straight (MCS) and multi-cell tapered (MCT), are first investigated by nonlinear finite element analysis through LS-DYNA. It is found that the MCT tube has the best crashworthiness performance under oblique impact regarding both specific energy absorption (SEA) and peak crushing force (PCF). Sampling designs of the MCT tube are created based on a four-level full factorial design of experiments (DoE) method. Parametric studies are performed using the DoE results to investigate the influences of the geometric parameters on the crash performance of such MCT tubes under oblique impact loading. In addition, multiobjective optimization design (MOD) of the MCT tube is performed by adopting multiobjective particle swarm optimization (MOPSO) algorithm to achieve maximum SEA capacity and minimum PCF with and without considering load angle uncertainty effect. During the MOD process, accurate surrogate models, more specifically, response surface (RS) models of SEA and PCF of the MCT tubes are established to reduce the computational cost of crash simulations by finite element method. It is found that the optimal designs of the MCT tubes are different under different load angles. It is also found that the weighting factors for different load angles are critical in the MOD of the MCT tubes with load angle uncertainty.

ABSTRACT: The post-buckling path for cylindrical shells under external pressure and twisting moment is unstable. The effect of stabilization in most cases is obtained by changing geometry of the structure. In this paper an alternative concept is applied, namely stabilization of the unstable post-buckling path is achieved by application of additional axial loads imposed to the ends of the structure without changing its shape and sizes. Three types of stabilizing forces were investigated: active forces applied to the structure or passive ones or combinations of both. Calculations were performed using ANSYS 11.0 code for elastic shells under different combinations of loadings.

ABSTRACT: Modern aircraft wings are thin-walled structures composed of ribs, spars and stiffened panels, where the top skin is subject to compressive forces in flight that can cause buckling instability. If these panels are machined from a single billet of metal then the initial buckling performance can be significantly improved by increasing the fillet radius along the line junction between the stiffener webs and skin. Typically thin-walled structures are usually modelled with two dimensional elements. To model the stiffened panel with fillets three dimensional elements are required. For the stiffened panel selected for the analysis the paper shows that the three dimensional model shows a substantial increase in skin initiated buckling if the fillet is taken account of. A 5 mm radius leads to an increase of 34% increase in local buckling load performance for a skin portion of breath to thickness ratio of 100. The associated overall buckling load increases by 1.8%. The mass penalty for a 5 mm radius is 5.1%. To avoid local and overall buckling interaction an accurate measure of both buckling loads is very important and may have impact for designers. The three dimensional models with no fillets show
very good agreement with the two dimensional models.

ABSTRACT: For the cylindrical reticulated mega-structure, two types of cable-strut arrangements are presented. The basic static properties of the pretensioned reticulated mega-structures with different types of cable-strut arrangements are compared and the optimal one is then selected. The elastic static property and stability of the structure with the optimal cable-strut arrangement is comprehensively analyzed. And the indexes including the decrease in structural displacement, reduction in horizontal support reactions, uniformity of distribution of member forces, and the improvement of structural stability are compared with those of the corresponding non-pretensioned reticulated mega-structure. Also, the effect of values and distribution of the cable pretensions on structural stability is studied, and the influence of half-span loading on structural stability
is investigated. Results indicate that the static properties and stability of the structure can be most effectively improved for adoption of the crossover arrangement of the cables and struts according to the buckling shape of the non-pretensioned structure. Additionally, the ultimate load-carrying capacity of the structure with small ratio of rise to span can be more effectively improved when the pretension of the cables set in the mid-span is larger than that of the cables set on both sides of the structure.

M. Nithyadharan and V. Kalyanaraman (Department of Civil Engineering, IIT Madras, Chennai-600036, India), “Behaviour of cold-formed steel shear wall panels under monotonic and reversed cycled loading”, Thin-Walled Structures, Vol. 60, pp 12-23, November 2012, DOI: 10.1016/j.tws.2012.05.017

ABSTRACT: This paper presents the results of an experimental study on the behaviour and strength of the cold-formed steel shear wall panel (CFSSWP) with calcium silicate board as sheathing, when subjected to monotonically increasing and reversed cyclic in-plane shear deformation. These specimens were specifically designed to reach the strength as governed by the strength of the screw connection between the board and the CFS framing and avoid all other modes of failure, ahead of this. The main objectives of the experimental study are (a) to study the influence of board thicknesses and the distance of the screws from the nearest free edge of the board on the wall panel behaviour and strength; (b) to study the behaviour of different wall board configurations normally used in construction practice (c) to develop the values of the important parameters that determine the load-deformation behaviour of the wall panels under in-plane shear and (d) to determine the different limit states in the failure of the screws connecting the board and the CFS framing in such CFSSWP. In addition, a simplified design equation is proposed to evaluate the ultimate shear strength of CFSSWP based on the strength of the screw connection obtained from a sub assemblage shear strength test.

V. Jandaghi Shahi and J. Marzbanrad (School of Automotive Engineering, Iran University of Science and Technology, Tehran, Iran), “Analytical and experimental studies on quasi-static axial crush behavior of thin-walled tailor-made aluminum tubes”, Thin-Walled Structures, Vol. 60, pp 24-37, November 2012 DOI: 10.1016/j.tws.2012.05.015

ABSTRACT: In this paper, the crush behavior of segmented circular tubes, made of aluminum alloy 6061 and subjected to quasi-static axial loading, has been analytically and experimentally investigated. Crush behavior of these tubes was modeled by integrating available analytical models and superposition principle. In the certain overall length of segmented circular tubes, effects of changing the wall thickness and length of each segment on the energy absorption characteristics have been evaluated. One successful approach toward obtaining lightweight energy absorbers with high energy absorption capacity is the use of thin-walled Tailor-Made Tubes (TMTs). In these tubes, the thickness and mechanical properties of the wall vary along the length of the tube. Applying these tubes; crush force can be controlled by changing the length and thickness of each tube segment, improving the performance of energy absorbing systems. Results of this research showed that Tailor-made tubes have higher energy absorption capacity at identical crush lengths, and they can absorb more energy per unit weight compared to simple tubes with constant wall thickness and mechanical properties. Moreover, for the same specific energy absorption, the TMTs exhibit a considerable reduction in the magnitude of the mean and initial maximum crush forces. With the use of TMTs, the maximum crush force shifts to the end of the crush range, reducing the exerted deceleration on occupants and equipments. Comparing mean crush force and specific energy absorption obtained by analytical and experimental approaches, it was observed that combining current analytical models with superposition principle can prepare a set of analytical formulations to predict TMTs crush characteristics within an acceptable proximity.

ABSTRACT: This paper focuses on the buckling of cylindrical shells under axial compression with small arbitrary thickness variations in the axial direction. General asymptotic formula of the buckling load, which is in terms of the thickness variation parameter $\varepsilon$ up to arbitrary order, is first derived by the perturbation expansion. Then effects led by three patterns of thickness variations on the buckling of axially compressed cylindrical shells, which are axisymmetric modal, local and stepwise variable, are, respectively investigated. Buckling loads of thin shells with axisymmetric modal thickness variation obtained from general analyses coincide with the Koiter's results. Particularly, an analytical study on the buckling of cylindrical shells with stepwise variable thickness is carried out, because these thin-walled structures are widely used in actual engineering. In addition to the analytic investigation, numerical analyses and comparisons are also performed.

ABSTRACT: The geometric non-linear analysis of imperfect composite laminates is presented based on the concept of the Semi-Energy finite strip method (FSM). The initial out-of-plane imperfection is assumed to be of the sinusoidal shape in the longitudinal direction, and of different shapes in the transverse direction. The validity and numerical efficiency of the developed semi-energy FSM is investigated by comparing the results with those obtained from a fairly conventional and well exploited finite strip technique, namely the Full-Energy FSM as well as the evaluated results from ANSYS.

ABSTRACT: The use of the finite element method (FEM) for the design of composed, thin-walled, structural steel members is considered. The bolted double-Z frame member is an interesting and economical engineering solution, already used in practice [1]. However, the European recommendations for the design of steel structures do not consider built-up members from cold-formed steel profiles. Finite element analysis is used to capture the various buckling effects that shape the response of slender thin-walled members. From the finite element model, the importance of initial imperfections and stiffness of connections is identified. The experimentally validated model predictions show that a non-linear finite element analysis can predict the member behaviour, in terms of failure mode and ultimate load, yield line pattern, overall stiffness and local strain in the cold-formed profiles. To obtain a good prediction, overall and localised initial imperfections should be considered and included in the analysis.

ABSTRACT: For the coupled static and dynamic buckling of thin walled beam subjected to various forces, such as axial force, uniform bending moment, and bending moment due to concentrated and distributed lateral forces, the spline finite element method is employed to obtain the dynamic stiffness matrix. Second order effects of the axial force and moment are considered. A doubly symmetric cantilever beam with uniform cross-section is investigated. Extensive static and dynamic interaction diagrams are plotted. The effects of warping rigidity, torsional rigidity, axial tension and compression on moment buckling, moment on axial buckling compression, higher buckling modes are discussed in detail. The spline finite element method is proved to be very efficient for the present problem and many interaction diagrams can be plotted easily. Some new results are presented. The methodology is based on finite element formulation and therefore it can be easily extended to analyze structural frames.

ABSTRACT: In case of hot-rolled or extruded profiles, the fillet corner shaping of the flange-to-web connection may highly increase the transverse load resistance. Real test illustrates the proneness of compact aluminium profiles to web crippling and the influence of the curved corner. Numerical model is developed and validated by the real test. Invoking non-linear numerical analysis, parametric study on simply supported girders subjected to interaction of transverse load and bending confirms the beneficial influence of the curved corners. Based on the results the author proposes a modification in the Eurocode formulation. The simulation results prove the validity of the proposed method.

Salvatore S. Ligaro and Riccardo Barsotti (Department of Civil Engineering, University of Pisa, Largo L. Lazzarino 1, 56126 Pisa, Italy), “Shear deformations in inflated cylindrical beams: An old model revisited”, Thin-Walled Structures, Vol. 60, pp 137-144, November 2012, DOI: 10.1016/j.tws.2012.07.004
ABSTRACT: The paper considers the effects of shear deformations on the load-displacement response of pressurized thin-walled circular-cylindrical beams subjected to lateral loads. A classical structural model, able to account for the inability of the wall's constituent material to withstand compressive stresses, is used to model the nonlinear behavior of partially wrinkled beams under simultaneous bending and shear. Particular attention is devoted to accurate determination of the shear stiffness within the wrinkled zones of the beam. The system of nonlinear equations governing the equilibrium of the inflated beams after the onset of the post-critical stage is amenable to numerical solution via standard incremental-iterative algorithms, as long as the wrinkling of the cross sections is small or moderate. Application of the proposed model to some well-documented problems drawn from the literature serves to illustrate the proposed algorithm's potential.
ABSTRACT: Recently worldwide cold formed steel buildings are recognized as viable alternatives to reinforced concrete buildings especially in seismic areas. This is because they are lightweight (easy to handle), fast constructed, energy efficient (green houses), economical, dimensionally stable and they do not need skilled worker. Under vertical loading the design principles of these buildings are well established and codified, however, under lateral loadings such as wind and earthquake loads efficiently design is needed. In this paper a new sheathing technique uses shotcreted ribbed steel sheets is proposed to improve the stability and increase the lateral load carrying capacities of the CFS walls in order to withstand earthquake and wind loads safely. The idea is to sheath the outer side of CFS structure external walls with thin ribbed steel sheets, then shotcreted the sheets with cement or gypsum mortars. To test the concept full size wall specimens were prepared in the laboratory and tested under monotonic vertical and lateral loads. Some of the specimens were sheathed with the traditional fiber cement boards or gypsum boards with mat reinforcement, while the others were sheathed with the proposed technique. Test results indicates that the lateral load carrying capacities of the walls sheathed with the proposed technique increases by about two times compared with the walls sheathed with traditional boards. And under ultimate loads they fail in local failure modes rather than overall buckling failure modes which commonly occur in the walls sheathed with traditional boards.

ABSTRACT: The current study assesses the enhancement in the buckling capacity of steel plates through bonding glass fibre reinforced polymer (GFRP) plates. Despite their low modulus of elasticity, GFRP plates are relatively thick and, therefore, can be efficient in magnifying the buckling capacity of the retrofitted steel plates. In this application, a heavy duty adhesive system that was tested in a previous experimental programme is employed to bond the steel and the GFRP plates. The current study is conducted numerically using a nonlinear shell element model to simulate the steel and GFRP plates and a special contact element to simulate the flexibility of the adhesive medium. The failure modes in the adhesive and the GFRP plates, based on real strength values, as well as the instability of the entire system are considered. A buckling magnification factor relating the capacity of the retrofitted system to the capacity of the corresponding bare steel plate is evaluated. The study considers two types of boundary conditions as well as two types of in-plane compatibility between the steel and GFRP plates. The effect of geometric imperfection is also studied. Both elastic and inelastic stability analyses are considered in this investigation.

Zhangming Wu, Paul M. Weaver, Gangadharan Raju and Byung Chul Kim, “Buckling analysis and optimisation of variable angle tow composite plates”, Thin-Walled Structures, Vol. 60, pp 163-172, November
ABSTRACT: Variable angle tow (VAT) placed composite laminates, where the fibre orientations continuously varying over the plane of each ply, generally exhibit variable stiffness properties. The stiffness tailoring of VAT plates through the design of fibre orientation distributions can substantially improve the buckling resistance, which is mainly due to the benign, non-uniform, in-plane load redistribution. In this work, a new mathematical definition is proposed to represent the general variation of fibre-orientation in the VAT plate. In this definition, the coefficients of polynomials are directly equal to the designed fibre angles at pre-selected control points. A Rayleigh-Ritz approach is used to determine the prebuckling loads distributions and critical buckling load of VAT plates. It provides a more efficient means to evaluate the buckling load of VAT laminates, compared with other numerical solutions. Subsequently, preliminary optimisation of VAT plates for maximum buckling load is done using the proposed definition of non-linear variation of fibre angles. Results obtained for simply supported square VAT plates are compared with optimal results reported in the literature. Finally, long VAT plates with one free edge and others simply supported are studied to demonstrate the viability of the proposed modelling strategy.

ABSTRACT: This paper presents the optimisation of cold-formed steel open columns using the recently developed self-shape optimisation method that aims to discover new profile shapes. The strength of the cold-formed steel sections is calculated using the Direct Strength Method, and the rules developed in the present work to automatically determine the local and distortional elastic buckling stresses from the Finite Strip and constrained Finite Strip Methods are discussed. The rules are verified against conventional and optimum sections yielded in this research, and found to accurately predict the elastic buckling stresses. The optimisation method is applied to singly-symmetric (mono-symmetric) cold-formed steel columns, and the operators behind the method for the special case of singly-symmetric open profiles are introduced in this paper. “Optimum” cross-sections for simply supported columns, 1.2 mm thick, free to warp and subjected to a compressive axial load of 75 kN are presented for column lengths ranging from 1000 to 2500 mm. Results show that the optimum cross-sections are found in a relatively low number of generations, and typically shape to non-conventional “bean”, “oval” or rounded “Σ” sections. The algorithm optimises for distortional and global buckling, therefore likely subjecting the cross-sections to buckling interaction. A manual attempt to redraw the “optimum” cross-sections to include limitations of current manufacturing processes is made. Future developments of the method for practical applications are also discussed.

DOI: 10.1016/j.tws.2012.06.012

ABSTRACT: In this paper, the planar nonlinear dynamics of an axially accelerating beam in the subcritical speed regime is examined theoretically, via two different numerical techniques, employing a large enough number of modes in order to investigate modal interactions. The equation of motion is discretized via the Galerkin method which results in a set of coupled nonlinear ordinary differential equations (NODEs) with time-
dependent coefficients. The set of NODEs is solved by means of the pseudo-arclength continuation technique and some of the results are tested and verified via direct time integration of the NODEs. The analyses include the system tuned to a three-to-one internal resonance, as well as for the case where it is not. Results are illustrated through frequency–response diagrams, time traces, phase–plane portraits, and fast Fourier transforms (FFTs).

ABSTRACT: For economical benefits, optimisation of mass-produced structural steel products has been widely researched. The objective is to minimise the quantity of material used without sacrificing the strength and practicality of the structural members. Current research focuses on optimising the main dimensions of conventional cross-sectional shapes but rarely considers discovering new optimum shapes. This paper introduces the concepts of a new optimisation method that enables the cross-section to self-shape to an optimum by using the evolution and adaptation benefits of Genetic Algorithm (GA). The feasibility and the accuracy of the method are verified by implementing it to optimise the section capacity of thin-walled profiles. Specifically, the profiles are optimised against simple parameters, for which analytical solutions are known, namely the optimisation of doubly-symmetric closed profiles. Results show that the cross-section accurately self-shapes to its optimum in a low number of generations. Factors influencing the convergence are presented in this paper. The method is extended to optimisation of cold-formed steel open section columns in the companion paper.

ABSTRACT: In the present work buckling stresses of prismatic flat and stiffened shell structures are derived within the framework of the Kantorovich approach, making reference to both Von Karman and Koiter–Sanders theories, the latter exploiting the Green–Lagrange strain tensor which is needed if the expected buckling modes involve comparable in-plane and out-of-plane displacements. Additionally, in order to highlight the contribution of each nonlinear term of the Koiter–Sanders model, two further intermediate choices are also considered, namely an enhanced Von Karman model and a spurious model which collects selected terms from different theoretical approaches, generally adopted in literature with the aim of simplifying the numerical analyses. The obtained results show how in buckling problems where the weight of in-plane displacements cannot be neglected the Von Karman model tends to overestimate the critical load, while the three considered alternative models result substantially equivalent, at least from the practical standpoint.

“Some thoughts on a surprising result concerning the lateral-torsional buckling of monosymmetric I-section beams”, Thin-Walled Structures, Vol. 60, pp 216-221, November 2012, DOI: 10.1016/j.tws.2012.06.015

ABSTRACT: This technical note addresses a surprising result concerning the lateral-torsional buckling of monosymmetric I-section beams: amongst all bending moment diagrams caused by any combination of applied end moments and transverse loads acting at the shear centre, the lowest critical moment does not necessarily correspond to uniform bending, which is at odds with the “intuitive expectation” of most engineers that such bending moment distribution is the most unfavourable with respect to lateral-torsional buckling. It is shown, by means of several illustrative examples, that this may not be the case for I-section beams with unequal flanges (monosymmetric cross-section – symmetry with respect to the minor axis). Moreover, the critical inspection of the terms (i) associated with the cross-section monosymmetry and (ii) appearing in the beam potential energy expression and differential equilibrium equation provides the mechanical/mathematical explanation for this surprising behavioural feature.

Feng Fan, Jiachuan Yan and Zhenggang Cao (School of Civil Engineering, Harbin Institute of Technology, Harbin 150090, China), “Elasto-plastic stability of single-layer reticulated domes with initial curvature of members”, Thin-Walled Structures, Vol. 60, pp 239-246, November 2012, DOI: 10.1016/j.tws.2012.01.012

ABSTRACT: Initial curvature of members is an inevitable geometrical imperfection for reticulated domes. To investigate the stability of single-layer domes with initial curvature of members, the multi-beam method was presented to simulate the initial curvature of members, and two modeling methods were adopted to introduce the initial curvature of members for reticulated domes by means of ANSYS. First, the random imperfection mode method was introduced according to the randomness of initial curvature of members. The example of a Kiewitt-8 dome was used to explain the method and investigate the influence of angle and amplitude random variables on the stability of reticulated domes. Second, the modified consistent imperfection mode method was obtained, which was an efficient method to evaluate the lowest buckling load of the structure with initial curvature of members. Based on this method, the Kiewitt-6 and Kiewitt-8 single-layer reticulated domes were taken as examples to analyze the stability of structures with initial curvature of members, and the influences of initial curvature of members on the ideal structure and the structure with nodes deviation were obtained quantitatively. The results show that, for the ideal structure and the structure with nodes deviation, initial curvature of members can decrease the buckling load of the structure obviously. Initial curvature of members can change the buckling mode and plasticity development of the structure. The influence of initial curvature of members on the elasto-plastic stability of single-layer reticulated domes cannot be neglected.

ABSTRACT: This work aims at contributing towards understanding the structural response and predicting the ultimate strength of cold-formed steel lipped channel columns affected by local–distortional–global (LDG)
interaction. Initially, the most relevant aspects concerning the buckling and elastic–plastic post-buckling behaviours of fixed-ended lipped channel columns with nearly coincident local, distortional and global (flexural–torsional) buckling loads are briefly addressed. Then, the paper (i) summarises the most important test results obtained in a recently reported experimental investigation carried out at the Federal University of Rio de Janeiro, (ii) addresses their numerical simulation by means of Abaqus shell finite element analyses (SFEA) and (iii) presents the outcome of a fairly extensive numerical parametric study performed to obtain ultimate strength data concerning fixed-ended lipped channel columns experiencing LDG interaction. Finally, the ultimate strength “data bank” gathered, consisting of 12 experimental and 134 values, are used as the starting point to assess the performance (accuracy and safety) of design approaches, based on the currently available Direct Strength Method (DSM) strength curves and intended to estimate the failure loads of cold-formed steel lipped channel columns affected by the triple mode interaction under consideration.

J. Loughlan, N. Yidris, K. Jones, “The failure of thin-walled lipped channel compression members due to coupled local-distortional interactions and material yielding”, Thin-Walled Structures, Vol. 61, pp 14-21, DOI: 10.1016/j.tws.2012.03.025
ABSTRACT: This paper details appropriate finite element modelling strategies and procedures for the determination of the coupled local-distortional interactive response of thin-walled lipped channel sections. The modelling procedures are able to describe the complete loading history of the compression members from the onset of local buckling through post-local buckling behaviour leading to local-distortional interaction including material yielding and yield propagation to ultimate conditions and then to elasto-plastic unloading. The numerical simulations take due account of the influence of geometrical imperfections on the compressive ultimate failures of the sections and the results from the finite element models are shown to agree favourably with the ultimate loads and failure mechanisms from experimental tests on steel lipped channel sections exhibiting local-distortional interaction.

Cao Hung Pham, Gregory J. Hancock, “Elastic buckling of cold-formed channel sections in shear”, Thin-Walled Structures, Vol. 61, pp 22-26 DOI: 10.1016/j.tws.2012.05.004
ABSTRACT: The paper studies and provides solutions to the elastic buckling of whole channel sections including flanges and lips where the sections are loaded in pure shear parallel with the web. The elastic buckling analyses of thin-walled channel sections in pure shear have been implemented by means of the Spline Finite Strip Method (SFSM) to determine the elastic buckling loads (Vcr) of the sections. The shear buckling coefficients (kv) of the web for design of a section are back-calculated from the shear buckling loads. The main variables are the flange widths, member lengths and lip sizes. The boundary conditions at two end sections are simply supported. The results of the analyses plotted in the format of interaction charts are given as design guidelines for designers to predict the elastic buckling shear coefficient (kv) without using the Spline Finite Strip Method (SFSM) software. Typical buckling modes at different flange widths, member lengths and lip sizes are also included in this paper. The modes include local web and flange buckling, section distortional buckling and section twisting.

ABSTRACT: This paper presents and illustrates a GBT formulation to analyse the elastic localized web buckling of thin-walled steel beams under concentrated loads. The theme of localised web buckling is first introduced by describing the parameters that most influence the buckling behaviour of slender plates subjected to edge loads. After that, a GBT formulation to analyse the elastic localized web buckling of thin-walled steel beams under concentrated loads is presented: the GBT equations are derived and the determination of deformation modes is briefly addressed. Then, two illustrative examples are shown and validated by comparison with shell finite element results: (i) cold-formed steel plain channel beams with web crippling configurations and (ii) welded steel I-section beams with patch loading configurations. It is found that both pre-buckling longitudinal normal ($\sigma_{xx0}$) and shear ($\tau_{xs0}$) stresses have to be included in the buckling analyses of cold-formed steel beams with External One Flange (EOF) and Internal One Flange (IOF) configurations as well as welded steel beams with Patch Loading Test (PLT) configuration. Furthermore, the pre-buckling transverse normal ($\sigma_{ss0}$) stresses have to be included in the buckling analysis of cold-formed steel beams with External Two Flange (ETF) and Internal Two Flange (ITF) configurations as well as welded steel beams with Opposite Patch Loading Test (OPLT) configuration. In beams with EOF, IOF, PLT configurations, the GBT pre-buckling analysis should consider global and shear modes while the GBT buckling analysis may only consider local modes. In beams with ETF, ITF, OPLT configurations, the GBT pre-buckling analysis should consider transverse extension modes while the GBT buckling analysis may only consider local modes.

ABSTRACT: The decomposition of buckling modes of thin-walled members subjected to axial stresses is a topic of great practical interest which can be achieved using the generalised beam theory (GBT) or the constrained finite strip method (cFSM). However, the latter is not general enough to study prismatic members with arbitrary cross-sections and the objective of this paper is to extend the cFSM to allow the buckling modes decomposition for prismatic members with branches and/or closed parts. To define the combined GD buckling mode, two assumptions are used: (i) cylindrical plate bending and (ii) negligible in-plane transverse/shear strains. The corresponding constraint matrix, $R_{GD}$, is derived in a simple and general way. The methodology used to separate the global and distortional modes is similar to that used in the original cFSM while the derivation of the constraint matrix for local modes remains identical. Some examples are considered and the pure buckling curves are compared to the conventional FSM results. The conclusion is that the new cFSM has successfully computed the GD and the L modes of these sections.

ABSTRACT: A recently developed inelastic large displacement isoparametric spline finite strip method was used to investigate the inelastic stress distributions, load transfers and failure modes for a range of hole shapes, sizes and spacings. While such study is available for elastic material behaviour, the influence of yielding on the load transfers in and failure modes of perforated plates and sections is not well understood. This study considers perforated simply supported plates under compression and perforated C-section columns in compression failing by local buckling. Several inelastic material models were included in the study, including elastic perfectly-plastic and linear hardening models, and a model with nonlinear yielding and isotropic hardening. Comparisons are made with elastic analyses and conclusions are drawn about the influence of yielding and strain hardening
on the stress distributions, load transfers and failure modes of typical thin-walled metallic plates and structural sections.

Miquel Casafont, Magdalena Pastor, Jordi Bonada, Francesc Roure, Teoman Peköz, “Linear buckling analysis of perforated steel storage rack columns with the finite strip method”, Thin-Walled Structures, Vol. 61, 71-85, DOI: 10.1016/j.tws.2012.07.010

ABSTRACT: An investigation on the use of the Finite Strip Method (FSM) to calculate elastic buckling loads of perforated cold formed storage rack columns is presented. Nowadays, this calculation can be accurately performed by means of the Finite Element Method (FEM), because the effect of perforations can be explicitly considered in the analysis. However, the FSM is preferred in cold-formed steel design since it is implemented in much convenient and easy to use software. The problem with FSM is that holes cannot be easily modeled. In this paper, the concept of the reduced thickness of the perforated strip is applied to take into account their effect. A formulation is presented for the reduced thickness that has been calibrated with loads obtained in eigen-buckling FEM analyses. Its accuracy has been verified carrying out analyses on real rack columns with different end conditions.

ABSTRACT: This paper is the first part of a study devoted to interactive buckling of steel pallet racks compression members, carried out at the CEMSIG Research Centre http://cemsig.ct.upt.ro from “Politehnica” University of Timisoara; this part summarizes the experimental program 1 and 2. Upright members of two different cross-sections, with and without perforations, were tested according to the guidelines of European design code for pallet rack systems EN15512 [3], in order to determine the ultimate strength for specimens of length corresponding to local buckling, i.e. stub columns, and of length equal to the distance between two subsequent nodes of an upright frame, i.e. upright members. The last set of tests was devoted, mainly, to the observation of distortional buckling of upright members. However, depending on the cross-section dimensions, the length between two subsequent nodes can be often larger than distortional critical length. In such cases the test results correspond rather to the distortional–global interaction, than to pure distortion. Consequently, additional specimens having the length calibrated to correspond to distortional buckling and to interactive distortional-overall buckling range, respectively, were tested. Material tests and imperfection measurements were also performed.

ABSTRACT: Based on the results of experimental tests, presented in the first part of this paper, Part 1 — Experimental Investigations [1], and using the ECBL (Erosion of Critical Bifurcation Load) approach, in this second part the influence of imperfections on the erosion of critical bifurcation load in the coupling point, both for brut and perforated sections, subjected to uniform compression, is investigated using numerical analysis. A numerical sensitivity analysis is performed on the purpose to identify the most significant imperfections. The “theoretical” compression capacity of the tested members is calculated considering the significant imperfections and compared with the experimental results. The calibrated Finite Element (FE) model and the ECBL approach
are used to determine the buckling curves for studied sections. At the end, a numerical procedure is proposed in order to obtain the buckling curves for such a type of sections.

ABSTRACT: As more metallic alloys are introduced in engineering structures, the demand for the proper utilisation of their nonlinear stress–strain relationship is increasing. This paper discusses the inelastic buckling of members from such materials with a special focus on ferritic stainless steels. Here we introduce an alternative approach for the overall stability of members that considers material nonlinearity, namely the strain hardening parameter \( n \). The suitability of the new model is verified by regression analysis in comparison with the commonly used standard calculations. The analysis results show that the present approach could be applied successfully in flexural, flexural–torsional and lateral–torsional buckling.

Maria Kotelko, Radoslaw J. Mania, “Quasi-static and dynamic axial crushing of TWCF open-section members”, Thin-Walled Structures, Vol. 61, pp 115-120, DOI: 10.1016/j.tws.2012.03.026
ABSTRACT: The paper presents the results of theoretical and experimental investigations into an influence of strain rate (loading velocity) upon the structural behaviour of TWCF members, namely top hat section and plain channel section columns subjected to uniaxial uniform compression. Theoretical analysis was performed using the FE method and the analytical solution based on the plastic yield-line analysis. In both cases the plastic strain rate was taken into account. Experimental static and quasi-static tests were conducted with different loading velocities up to 600 mm/min. Results of numerical calculations together with tests results are shown in load-shortening diagrams. Failure patterns are also presented. Some conclusions concerning the influence of strain-rate upon the ultimate load and post-failure path of examined members are derived.

ABSTRACT: In this paper the bending-shear interaction of slender plates is studied. Six large tests were performed on longitudinally and transversally stiffened girders in the range of high bending moment and shear force. In longitudinal direction the web was stiffened with a trapezoidal stiffener positioned at the mid web depth for two girders and in the compression zone for the other four girders. The test procedure and test results are presented in details from the point of global behaviour and web buckling. The girders were divided in three groups; within each group one of the parameters was varied. Furthermore, a numerical model built in the general-purpose code ABAQUS is presented and verified against test results regarding initial stiffness, resistance and failure mode. In the last part of this paper the maximum load and the design resistance according to EN 1993-1-5 are compared and discussed. The design resistance was calculated with both options, according to the effective width method and the reduced stress method.

ABSTRACT: Due to its advantages corrugated steel plates are widely used in various applications. Engineers realized a potential application field in bridges, especially in composite bridges. When such a bridge is
incrementally launched, the girder is subjected to combined action of bending moment, shear and transverse forces, resulting in a complex stress field and interacting instability phenomena. The current paper focuses on the experimental and numerical investigation of the structural behaviour of the girders with corrugated webs under all of the above mentioned actions. 12 large scale test specimens are investigated under combined patch load and bending moment. Based on the experimental investigations a numerical model is developed and the structural behaviour of the girders with corrugated web is analysed under the complex loading situation due to combined bending moment, shear force and patch loading.

Tian Gao, Cristopher D. Moen, “Predicting rotational restraint provided to wall girts and roof purlins by through-fastened metal panels”, Thin-Walled Structures, Vol. 61, pp 145-153, DOI: 10.1016/j.tws.2012.06.005
ABSTRACT: This paper introduces mechanics-based expressions for predicting the rotational restraint provided by through-fastened metal panels to Z- and C-section girts or purlins. The analytical prediction equations include the effect of local panel deformation at a screw, and girt or purlin flange bending at a through-fastened connection. Finite element parameter studies are performed to quantify the local fastener pull-out stiffness for a common panel profile, and flange bending stiffness is determined with a cantilever beam model. Rotational restraint experiments are conducted to validate the prediction equations. The through-fastened connection stiffness is simulated in a finite strip elastic buckling analysis with a rotational spring to demonstrate how system effects can be included in design.

ABSTRACT: The paper is devoted to the analytical, numerical and experimental studies of the global and local buckling–wrinkling of the face sheets of sandwich beams and sandwich circular plates. A mathematical model of displacements, which includes a shear effect, is presented. The governing differential equations of sandwich plates are derived. The equations are analytically solved and the critical loads are obtained. Finite element models of the plates are formulated and the critical loads and buckling modes are calculated. Moreover, experimental investigations are carried out for the family of sandwich beam-plates. The values of the critical load obtained by the analytical, numerical (FEM), and experimental methods are compared.

ABSTRACT: Metal cylindrical storage structures of significant size, such as silos and vertical-axis tanks, are almost always constructed from many short cylindrical shells of different thickness as the stress resultants on the wall progressively increase towards the base. The resulting increases in thickness are always made in step changes using metal sheets of uniform thickness because of the availability of such source materials. The result is a shell with a stepped wall with multiple discrete steps in thickness. Such shells are very susceptible to buckling under external pressure when empty or partially filled, but the buckling mode may involve only part of the shell height due to the changes in shell thickness. These changes must therefore be accounted for within the design process. A new method of determining the critical buckling resistance of such shells was recently developed, and although it has been shown to be valid, the methodology for its application in practical design has not been set out or shown. This paper therefore briefly describes the new method and demonstrates the
manner in which it can be used to produce rapid, safe assessments of cylindrical shells with a wide range of patterns of wall thickness changes. The results are then suitable for direct introduction into such documents as the European standard on metal shells [1] and the ECCS Recommendations [2].

ABSTRACT: Modern procedures for the design of shell structures against buckling have their basis in analytical studies of axisymmetric shell geometries under the very simple load cases of uniform compression, external pressure and torsion. Studies of more complex but realistic stress states were based on prebuckling analyses using either membrane theory or linear bending theory because even these involved considerable mathematical complexity. As a result, only limited conclusions for practical design could be drawn and the effects of geometric nonlinearity could not be assessed. With recent advances in computing power and nonlinear finite element programs, it is now possible to undertake nonlinear analyses of complex load patterns that would have been very difficult to do only a decade or so ago. A number of practical load cases lead to a strip of pressure down one meridian, of which the best known ones are probably wind on tanks, eccentric discharge in silos, local thermal differentials, and partial fluid filling of a cylinder. This paper explores some of the rather unexpected stress patterns and modes of buckling that are predicted to develop in thin-walled cylindrical shells under such unsymmetrical strips of normal pressure. The results of a parametric study are presented to show the influence of the circumferential spread of the pressure strip on the structural behaviour. It is shown that the structural response to such loads may be very different, depending on whether the load acts inward or outward, and whether geometric nonlinearity and geometric imperfections are also included in the assessment.

ABSTRACT: In terms of the buckling problem related to elastic cylindrical shells under axial compression, experimental results have shown that after primary buckling, secondary buckling occurs accompanied by successive reductions in the number of circumferential waves at every path jumping. In this paper, we traced
this successive buckling of the elastic cylindrical shells using the latest general-purpose finite element technology with a static stabilizing method. The study accomplished a fully automatic and seamless simulation of successive path jumping in the deep post-buckling region and showed good agreement with Yamaki’s experimental results and Esslinger’s high-speed photography.

Carlos F. Estrada, Luis A. Godoy, Fernando G. Flores, “Buckling of vertical sandwich cylinders embedded in soil”, Thin-Walled Structures, Vol. 61, pp 188-195, DOI: 10.1016/j.tws.2012.05.010

ABSTRACT: Composite or sandwich materials have been used in the construction of pipelines for some time, but not for the construction of inspection cameras, which are buried vertical cylinders that connect the pipeline with the ground. This paper explores the buckling and post-buckling behavior of vertical sandwich shells under lateral pressure, considering typical dimensions of inspection cameras employed in the industry. The analysis is carried out using a finite element model including geometric nonlinearity, in which the shell and the soil are represented together with the contact zone between them. Parametric studies are reported to account for the influence of shell slenderness, imperfection amplitude and soil elasticity. Results are also compared with those obtained for a circular ring under similar lateral constraints. The results show that for a shell in rigid soil the critical loads are higher than in the case of elastic soil, but the sensitivity with respect to imperfections in the geometry is also high. Cylinders in an elastic soil, on the other hand, tend to have lower buckling loads and moderate imperfection sensitivity. Finally, a ring model leads to good approximations to buckling loads but does not adequately represent the post-buckling behavior of a shell in this problem.

ABSTRACT: Hybrid FRP-concrete-steel double-skin tubular columns (hybrid DSTCs) are a new form of hybrid columns which consists of a layer of concrete sandwiched between an inner steel tube and an outer FRP tube. While a large amount of research has been conducted on the monotonic behavior of this novel form of columns, only a limited amount of work has been conducted on their behavior under cyclic loading. This paper presents the first ever study on the behavior of circular hybrid DSTCs under cyclic axial compression. Results from a series of stub column tests, where the hybrid DSTCs were subjected to cyclic axial compression, are first presented and discussed. The test results show that hybrid DSTCs are very ductile under cyclic axial compression, with the envelope axial load-strain curve being almost the same as the axial load-strain curve of a corresponding DSTC under monotonic compression. It is also shown that repeated unloading/reloading cycles have a cumulative effect on the permanent strain and the stress deterioration of the confined concrete in hybrid DSTCs. The experimental stress–strain curves of the confined concrete in hybrid DSTCs are then compared with predictions from two existing models: (1) a monotonic stress–strain model for the confined concrete in hybrid DSTCs; and (2) a cyclic stress–strain model for the concrete in FRP-confined solid columns. The comparison suggests that the combined use of the two models can give reasonably accurate predictions of the test results.

Lincy Pyl, Luc Schueremans, Willem Dierckx, Iveta Georgieva, “Fire safety analysis of a 3D frame structure based on a full-scale fire test”, Thin-Walled Structures, Vol. 61, pp 204-212, DOI: 10.1016/j.tws.2012.03.023

ABSTRACT: The topic of this paper is the fire safety analysis of 3D frame structures such as industrial halls. Cold-formed thin plated elements are used as structural components. The building, which is submitted to a full-
scale fire test, is introduced. A blind prediction analysis is performed using the finite element model SAFIR. The thermal response of the structural elements under both a standard fire and a natural fire corresponding to a fire load density of 625 MJ/m² and an opening factor 0.009 m^{1/2} is predicted. As expected, the temperature of the cold-formed sections follows more or less the gas temperature in the fire compartment due to the thin plates. The results of the predicted mechanical response are presented, giving a resistance of 27 min (standard fire) and 54 min (natural fire). The model is validated based on the results of the full-scale fire test, demonstrating a fire resistance of 62 min. Comparison with a simple 2.5D model is made and proved to provide results sufficiently accurate to make it applicable for daily design practice.

Niroscha Dolamune Kankanamge, Mahen Mahendran, “Behaviour and design of cold-formed steel beams subject to lateral-torsional buckling at elevated temperatures”, Thin-Walled Structures, Vol. 61, pp 213-228, DOI: 10.1016/j.tws.2012.05.009

ABSTRACT: Cold-formed steel beams are increasingly used as floor joists and bearers in buildings and often their behaviour and moment capacities are influenced by lateral–torsional buckling. With increasing usage of cold-formed steel beams their fire safety design has become an important issue. Fire design rules are commonly based on past research on hot-rolled steel beams. Hence a detailed parametric study was undertaken using validated finite element models to investigate the lateral–torsional buckling behaviour of simply supported cold-formed steel lipped channel beams subjected to uniform bending at uniform elevated temperatures. The moment capacity results were compared with the predictions from the available ambient temperature and fire design rules and suitable recommendations were made. European fire design rules were found to be over-conservative while the ambient temperature design rules could not be used based on single buckling curve. Hence a new design method was proposed that includes the important non-linear stress–strain characteristics observed for cold-formed steels at elevated temperatures. Comparison with numerical moment capacities demonstrated the accuracy of the new design method. This paper presents the details of the parametric study, comparisons with current design rules and the new design rules proposed in this research for lateral–torsional buckling of cold-formed steel lipped channel beams at elevated temperatures.

Wei Lu, Zhongcheng Ma, Pentti Mäkeläinen, Jyri Outinen, “Behaviour of shear connectors in cold-formed steel sheeting at ambient and elevated temperatures”, Thin-Walled Structures, Vol. 61, pp 229-238, DOI: 10.1016/j.tws.2012.04.008

ABSTRACT: Cold-formed profiled steel roof sheeting can be directly connected to the top chord of a steel truss through powder-actuated shot nails or self-tapping screws. The lap shear behaviours of both shot nailed and screwed connections are studied in this paper using both testing and FE analysis at ambient and elevated temperatures. The studies for screwed connections show four components of loading capacity, including bearing force between thin sheet and screw shank, frictional force between washer and thin sheet, frictional force between thin sheet and thick plate, and the bearing force by the tilting of thin sheet are identified and quantified. The studies for shot nailed connections show strong interactions among washer, shot nail, thin sheet and supporting plate. The protuberance feature developed during the nail driving process, which causes material in thick plate flowing upward, has a significant positive contribution to the loading capacity of the connection.

ABSTRACT: An experimental program of nine steel deck roof diaphragm specimens was carried out to assess their seismic characteristics. The dynamically loaded diaphragms were able to develop the shear strength but not the shear stiffness values calculated using current diaphragm design methods. Furthermore, the shear stiffness decreased with increasing excitation amplitude. Diaphragm ductility decreased with the use of thicker deck panels and when the deck was oriented parallel to the loading direction. Most of the damaged diaphragms could be repaired to recuperate their original strength. A seismic retrofit scheme was effective in increasing the shear strength and stiffness of an arc-spot weld/ button-punch diaphragm.

Luigi Fiorino, Ornella Iuorio, Vincenzo Macillo, Raffaele Landolfo, “Performance-based design of sheathed CFS buildings in seismic area”, Thin-Walled Structures, Vol. 61, pp 248-257, DOI: 10.1016/j.tws.2012.03.022
ABSTRACT: The widely recognized structural performance provided by cold-formed steel (CFS) systems together with high levels of prefabrication, safety, durability and sustainability are spreading the CFS construction systems all over the world. At the same time, the actual lack in European seismic design codes requires the development of specific design procedures for the application in seismic area. The seismic behaviour of CFS structures is characterized by the lateral response of shear walls. In particular, when the sheathing-design methodology is adopted, then the seismic behaviour is strongly influenced by the nonlinear response of sheathing-to-frame connections. In this paper a performance-based design methodology for the seismic design of sheathed CFS walls is proposed. The presented methodology is based on the results of an extensive parametric nonlinear dynamic study carried out on one story buildings by means of incremental dynamic analysis. Moreover, a multistep design procedure that allows all the main structural components to be defined in three steps is developed. In particular, a nonlinear dynamic (ND) nomograph for the assessment of the external screw spacing is presented in this work in order provide a new tool that upgrade the design procedure under investigation by the Authors in the last years. Finally the application of the proposed design methodology is verified through a case study.

ABSTRACT: The main aspects of theory, design, codification and application of 3D aluminium structures are examined, by emphasising the peculiar differences with steel, by referring to real cases. The main applications in the field of geodetic domes represent a challenging example of 3D aluminium structures. The theoretical and experimental results were used for setting-up Part 1.5 “Shell Structures” of Eurocode 9.

Mahmoud R. Maheri and A. Abdollahi (Shiraz University, Iran), “The effects of long term uniform corrosion on the buckling of ground based steel tanks under seismic loading”, Thin-Walled Structures, Vol. 62, pp 1-9, January 2013, DOI: 10.1016/j.tws.2012.06.004
ABSTRACT: Material degradation due to corrosion significantly alters the seismic response of ground-based cylindrical steel storage tanks. A numerical study is conducted to investigate the effects of internal shell corrosion on the dynamic buckling of three cone roof ground-based, steel cylindrical tanks with height to diameter ratios \((H/D)\) of 0.40, 0.63 and 0.95, subjected to horizontal seismic base excitations. Internal corrosion is considered as a time dependent uniform thinning of the wall at the upper and the lower parts of the tank being in contact with, respectively, atmospheric oxygen and acid gases and residual water. Detailed numerical models
of the tank–liquid systems at different stages of corrosion degradation are subjected to two representing accelerograms and for each model the critical peak ground acceleration (PGA) for dynamic buckling of the shell and its associated mode of failure are evaluated. It is found that in all three tanks, the critical PGA is markedly reduced with thinning of the shell, irrespective of the type of ground input. The buckling mode of failure of the tanks also changed from an elastic diamond-shaped failure at the top of the shell to an elasto-plastic elephant foot type failure near the base, after 10 years for the shorter tanks ($H/D=0.4$ and 0.63) and after 15 years for the tallest tank. The effects of uniform corrosion degradation on the critical buckling load of the tanks were found to be such that after 20 years of thinning due to corrosion, the static loading alone was responsible for the elephant foot buckling of the shell.

ABSTRACT: To study the collapse mode and energy absorption of triangular tubes, quasi-static axial compression experiments were carried out. Deformation curves and collapse modes were revealed by the experiments. Based on various combinations of the two basic folding elements, four potential collapse modes were proposed and compared to predict the mean crushing force of the tube theoretically. Numerical simulations were applied to suggest a fitted formula of the mean crushing force. Both the analytical and numerical predictions were compared with the experiments to build an effective method to predict the mean crushing force of the triangular tube.

ABSTRACT: Corrugated steel plates have several advantages such as high resistance for shear without stiffeners, minimization of welding process, and high fatigue resistance. To take advantage of these benefits, several researchers have attempted to use corrugated steel plate as a web for I-girders. The flexural–torsional buckling is the major design aspect of such I-girders. However, the flexural–torsional buckling of the I-girder with corrugated steel webs still needs to be investigated especially for a real loading condition such as non-uniform bending. This paper investigated the flexural–torsional buckling strength of an I-girder with corrugated steel webs under linear moment gradient by using finite element analysis. From the results, it was found that the buckling behavior of the I-girder with corrugated steel webs differed depending on the number of periods of the
corrugation. Also, a simple equation for the moment gradient correction factor for the I-girder with corrugated steel webs was suggested. The inelastic flexural–torsional buckling strength of the I-girder with corrugated steel webs was then discussed based on current design equations for ordinary I-girders and inelastic finite element analysis considering initial imperfection and residual stresses.

ABSTRACT: Semi-analytical elastic methods for stiffened plate analysis are computationally very efficient. In addition to eigenvalue analysis, such methods may also offer a viable approach for the prediction of ultimate strength limits (USLs) of the plates when combined with appropriate strength criteria. In this paper, existing strength criteria are discussed, and extended criteria proposed for plates with various stiffener arrangements and boundary conditions such as full out-of-plane supports along all edges or plates with a free or partially stiffened edge. The extended criteria reflect in a simplified manner the effect of redistribution of stresses due to the formation of local plastic regions at stiffeners, supporting edges and in the plate interior. The equilibrium path is traced using large deflection theory and the Rayleigh–Ritz approach on an incremental form. The approach is able to account for the reserve strength of slender plates in the postbuckling region. With the considered criteria included, good agreement is obtained with results from fully nonlinear finite element analyses for different support conditions and for a variety of plate and stiffener dimensions.

ABSTRACT: The elaborated method of eigenfunction expansion in elliptic coordinates is employed to obtain an exact time-domain series solution, involving products of angular and radial Mathieu functions, for the forced flexural vibrations of a thin elastic plate of elliptical planform. The plate is supported by a constant moduli two-parameter foundation, while elastically restrained against translation and rotation at its edge, and subjected to the combined action of uniform in-plane static edge forces and general arbitrary time-dependent transverse loads with arbitrary initial conditions. Numerical calculations are carried out for the displacement response of clamped or simply supported elliptical plates of selected aspect ratios in various practical loading configurations (i.e., an impulsive point load, a point force in circular motion, a uniformly distributed harmonic load, and a blast load), with or without an elastic foundation, while taking the effects of initial tension or compression below the buckling load into consideration. Limiting cases are considered and good agreements with available results as well as with the computations made by using a commercial finite element package are obtained.

analytical calculation of the plastic collapse load of thin pressure vessels with strain hardening and large deformation”, Thin-Walled Structures, Vol. 62, pp 46-52, January 2013, DOI: 10.1016/j.tws.2012.08.001

ABSTRACT: The paper investigates the assessment of the capacity loading in terms of internal limit pressure of thin metallic vessels such as thin tubes and thin spheres. This assessment is dealt with, taking into consideration large deformations of the geometry as well as the most common rules for strain hardening modeling such as isotropic, kinematic or isotropic and kinematic combined. Analytical solutions are established for predicting plastic limit pressure evolution together with hardening variables.

ABSTRACT: A type of cylindrical multi-cell column is proposed to improve energy absorption performance, which is inspired by the phenomenon that the circular tube is more efficient than the square tube in energy absorption. This type of structure shows high performance in energy absorption for its considerable number of corners on the cross section and the angles between neighbor flanges are in the optimal range as well as some more efficient cylindrical shells have been adopted. Numerical examples illustrate that cylindrical multi-cell column is more efficient than square column and square multi-cell column in energy absorption. In addition, a parametric study considering the effects of geometrical parameters on the structural crashworthiness has been carried out. And it is found that wall thickness, the number of cells alone the radial and circumferential directions have a distinct effect on the energy absorption.

ABSTRACT: The present paper deals with the experimental and computational study of collapse of the metallic shells having combined tube–cone geometry subjected to axial compression between two parallel plates. The aim is to study the influence of the shell thickness and cone angle on its mode of deformation. Shells were having top one third length as tube and remaining bottom two third length as truncated cone having semi-apical angle about 23°. The other geometrical dimensions were almost same. Shells were tested in an INSTRON universal testing machine, to identify their modes of collapse and associated energy absorption capacity. In experiments it was found that the collapse process of all shells was initiated by development of an axisymmetric fold followed by a plastic zone of increasing length. An axisymmetric Finite Element computational model of collapse process is presented and analysed, using a non-linear FE code FORGE2 [13]. Six noded triangular elements were used to descretize the domain. The material of the shells was idealised as rigid visco-plastic. Experimental and computed results of the deformed shapes and their corresponding load-compression and energy–compression curves were compared to validate the computational model. Typical computed variations of nodal velocity distribution, equivalent strain rate, equivalent strain, hoop stress and principal stress are presented to help in predicting the mode of collapse. On the basis of the experiments and computed results development of the axisymmetric mode of collapse has been presented, analysed and discussed. Further the
A computational model is used to simulate the mode of collapse of specimens having lower semi-apical angles between 19° and 23° of the conical portion. It was found that the mode of collapse of combined geometry specimens mainly governed by the semi-apical angle of the truncated cone portion.

ABSTRACT: In this paper, a theoretical and numerical model based on the power series method is investigated for the lateral buckling stability of tapered thin-walled beams with arbitrary cross sections and boundary conditions. Total potential energy is derived for an elastic behavior from strain energy and work of the applied loads. The effects of the initial stresses and load eccentricities are also considered in the study. The lateral-torsional equilibrium equations and the associated boundary conditions are obtained from the stationary condition. In presence of tapering, all stiffness coefficients are not constant. The power series approximation is then used to solve the fourth-order differential equations of tapered thin-walled beam with variable geometric parameters having generalized end conditions. Displacement components and cross section properties are expanded in terms of power series of a known degree. The lateral buckling loads are determined by solving the eigenvalue problem of the obtained algebraic system. Several numerical examples of tapered thin-walled beams are presented to investigate the accuracy and the efficiency of the method. The obtained results are compared with finite element solutions using Ansys software and other available numerical or analytical approaches. It is observed that suggested method can be applied to stability of beams with constant cross sections as well as tapered beams.

ABSTRACT: Uni-lateral buckling behavior of cylindrical panels on tensionless elastic foundation under axial compression is investigated through Rayleigh–Ritz method. Derivation of the equations is based on Kirchhoff–Love’s hypotheses. All the contributed researches on the uni-lateral buckling problem are limited to plates. Buckling curves are produced that indicate relationships between buckling load and geometrical parameters. It is concluded that increasing the surface of panel does not necessarily lead to an increase in the contact region between panel and foundation. Influences of geometrical parameters and foundation on the uni-lateral buckling behavior are examined. The results for flat panel are validated with available data.

ABSTRACT: In this study, the buckling analysis of homogeneous and non-homogeneous orthotropic, thin walled truncated conical shells under axial load and in large deformation has been investigated. First, the
governing relations are derived using the large deformation theory with von Karman–Donnell-type of kinematic non-linearity. Then modified Donnell type stability and compatibility equations of non-homogeneous orthotropic thin-walled truncated conical shells in large deformation are obtained and solved analytically. Finally, influences of the non-homogeneity, orthotropy and the variation of the shell geometry on the non-linear axial buckling load are investigated. Comparing the results of this study with those in the literature validates the present analysis.

ABSTRACT: Due to the increased consumption of thin-walled structural elements there has been increasing focus and need for more detailed calculations as well as development of new approaches. In this paper a thin-walled beam element including distortion of the cross section is formulated. The formulation is based on a generalized beam theory (GBT), in which the classic Vlasov beam theory for analysis of open and closed thin-walled cross sections is generalized by including distortional displacements. The beam element formulation utilizes a semi-discretization approach in which the cross section is discretized into wall elements and the analytical solutions of the related GBT beam equations are used as displacement functions in the axial direction. Thus the beam element contains the semi-analytical solutions. In three related papers the authors have recently presented the semi-discretization approach and the analytical solution of the beam equations of GBT. In this approach a full set of deformation modes corresponding to the homogeneous GBT equations are found. The deformation modes of which some are complex decouple the state space equations corresponding to the reduced order differential equations of GBT and allow the determination of the analytical solutions. Solutions of the non-homogeneous GBT differential equations and the distortional buckling equations have also been found and analyzed. Thus, these related papers are not dealing with an element but dealing with analytical solutions to the coupled differential equations. To handle arbitrary boundary conditions as well as the possibility of adding concentrated loads as nodal loads the formulation of a beam element is needed. This paper presents the formulation of such a generalized one-dimensional semi-discretized thin-walled beam element including distortional contributions. It should be noticed that we are only dealing with a basic generalized beam theory and not an extended finite element formulation of an approximate beam element, which allows the addition of special (transverse extension and shear lag) modes. Illustrative examples showing the validity and the accuracy of the developed distortional semi-discretized thin-walled beam element are given and it is shown how the novel approach provides accurate results making it a good alternative to the traditional and time consuming FE calculations.

ABSTRACT: A model of deformation of a metal hollow section beam under a uniform blast loading is developed in order to reveal the characteristic features of deformation and energy absorption of hollow section beams under such loading. It is established that as a typical structural component a hollow section distinguishes itself from its solid counterpart with two characteristic features of the response. First, a considerably larger kinetic energy is generated in the hollow section beam as the impulsive load is imparted on the upper flange of the beam having a significantly lower mass than the member. Second, a considerable proportion of the blast energy can be absorbed by the local collapse of the section. A two-phase analytical model is proposed. In the first phase, the local collapse of the thin-walled cross-section is determined by using an upper bound approach; and in the subsequent second phase, the global bending of the beam with the distorted section is analyzed by taking into account the effect of axial force. It is demonstrated that mass distribution in the hollow section is an important factor in determining the energy partitioning between the local deformation phase and global bending of the hollow beam. Reasonable agreement is obtained with the experimental data published in the literature [Jama HH, Nurick GN, Bambach MR, Grzebieta RH, Zhao XL, Steel square hollow sections subjected to transverse blast loads, Thin-Walled Structures 2012;53:109–122].

ABSTRACT: Cold-formed stainless steel tubular structural members which may experience web crippling failure due to localised concentrated loads or reactions are investigated. A series of tests on fibre-reinforced polymer (FRP) strengthening of cold-formed stainless steel tubular structural members subjected to End-Two-Flange and Interior-Two-Flange loading conditions is presented. The strengthening only applied to a localise area of the members under concentrated load. A total of 58 web crippling tests were conducted. The investigation mainly focused on the effects of different surface treatment, different adhesive, and FRP for strengthening of stainless steel tubular sections against web crippling. The behaviour of stainless steel members strengthened by different widths of FRP plate against web crippling has been also investigated in this study. The test specimens consisted of ferritic stainless steel EN 1.4003 square and rectangular hollow sections. Two different surface treatments were considered. Furthermore, six different adhesives and six different FRPs were also considered in this study. The properties of adhesive and FRP as well as the bonding between the FRP and stainless steel tube have significant influence on the effectiveness of the strengthening. Most of the strengthened specimens were failed by debonding of FRP plates form the stainless steel tubes. Six different failure modes were observed in the tests, namely the adhesion, cohesion, combination of adhesion and cohesion, interlaminar failure of FRP plate, FRP delaminating failure and web crippling failure. The failure loads, failure modes, and the load-web deformation behaviour of the ferritic stainless steel sections are presented in this study. It was found that the web crippling capacity of ferritic stainless steel tubular sections may increase up to 51% using FRP strengthening.

ABSTRACT: The objective of this paper is to explore the potential strength and serviceability implications of metallic foams, specifically steel foam, utilized as a thin-walled channel structural member. A typical advantage sought in the selection of a thin-walled member is minimal weight. However, the stability of the thin walls and the related limit states constrains the extent to which weight minimization may be utilized. As a material, steel foam (literally creating air voids in the steel microstructure) offers the potential to provide increased plate stiffness for a given weight and thus create even lighter thin-walled members and structures. In this work analytical material relationships are used to explore the structural potential for steel foam. First, the local buckling and yielding of an isolated steel foam plate is explored. Second, the local, distortional, and global buckling of a prototypical cold-formed steel channel using steel foam is examined. Finally, the strength and governing limit state of the channel as a function of relative density (i.e., the degree to which the material is foamed) is explored. The results show the key tradeoff made when foaming–stiffness per weight is increased, including stiffness related to member buckling modes; however, yield strength per weight decreases. Depending on the slenderness (in local, distortional, and global modes) of the member this tradeoff can be beneficial or detrimental.

ABSTRACT: This paper presents the development and illustrates the application of a beam finite element based on the generalised beam theory (GBT) and intended to analyse the local, distortional and global post-buckling behaviour of thin-walled steel frames. After briefly reviewing the main concepts and procedures required to obtain the GBT system of non-linear equilibrium equations, the paper describes the steps involved in the numerical implementation (incremental-iterative strategy) of a non-linear beam finite element that incorporates the influence of the frame joint behaviour. Next, one uses evidence gathered from shell finite element simulations to establish kinematic constraint conditions ensuring displacement compatibility at frame joints connecting two non-aligned plain/lipped channel members. Finally, the application and capabilities of the proposed GBT-based beam finite element formulation are illustrated by presenting and discussing numerical results concerning the post-buckling behaviour of two “L-shaped” frames and a symmetric portal frame. For validation purposes, most GBT-based results are compared with values yielded by beam and shell finite element analyses carried out in the code ANSYS.

ABSTRACT: The nonlinear behaviour of fibre reinforced (FR) concrete-filled stainless steel tubular columns is discussed in this paper. A nonlinear 3-D finite element model was developed for the analysis of the composite columns. The pin-ended axially loaded composite columns had different lengths, which varied from stub to long columns. The nonlinear material properties of the composite column’s components comprising stainless steel
tube and FR concrete were incorporated in the model. The effect of FR concrete confinement and interface between the stainless steel tube and FR concrete infill was also considered allowing the bond behaviour to be modelled. In addition, the measured initial overall (out-of-straightness) geometric imperfection was carefully incorporated in the model. The finite element model has been validated against tests recently conducted by the author on FR concrete-filled stainless steel tubular columns. The composite column strengths, load–axial strain relationships and failure modes were predicted from the finite element analysis and compared well against that measured experimentally. Furthermore, the variables that influence the composite column behaviour and strength comprising different lengths, external diameter-to-plate thickness \((D/t)\) ratios and FR concrete strengths were investigated in a parametric study. The parametric study has shown that the increase in column strengths owing to the increase in concrete strength is more significant for the columns having \(L/D\) ratios less than 6 as well as for the columns having \(D/t\) ratios less than 50. The composite column strengths obtained from the finite element analysis were compared with the design strengths calculated using Eurocode 4 for composite columns. It is shown that the EC4, in most cases, accurately predicted the design strength for axially loaded FR concrete filled stainless steel tubular columns.

ABSTRACT: A new framework, EBF3PanelOpt, is being developed for design and optimization of complex, multifunctional, aircraft structural concepts like pressurized non-circular fuselage structures to be used in hybrid wing/body vehicles that are subjected to complex structural loading cases. This tool can be used to integrate materials and structural concepts to exploit emerging additive manufacturing processes that offer the ability to efficiently fabricate complex structural configurations. Commercial software packages, MD-Patran (geometry modeling and mesh generation), MD-Nastran (Finite Element Analysis), are integrated in the EBF3PanelOpt framework using Python programming environment to design stiffened panels with curvilinear stiffeners. Typically, these panels experience multiple loading conditions during the operations of these vehicles. EBF3PanelOpt has the capability to optimize flat/curved multi-sided panels with straight/curved edges having curvilinear, blade-type stiffeners under multiple loading conditions. The mass of the panel is minimized subjected to constraints on buckling, von Mises stress, and crippling or local failure of the stiffener using global optimization techniques or gradient based optimization techniques. The panel/stiffener geometry is parametrized using design variables that include variables for orientation and shape of the stiffeners, the thicknesses and height of the stiffeners, and the plate thickness. The plate can have uniform thickness or non-uniform thicknesses for the pockets created by the stiffeners. During optimization, constraints can be applied for each of the loading conditions by aggregating all the responses using Kreisselmeir–Steinhauser criteria or using worst response amongst all the responses or applying all the constraints. Initially, the flat rectangular panel is optimized for the single load-case to study the effectiveness of the panel thickness option. Then, the optimization of flat rectangular and cylindrical panels is carried out for three sample load cases of practical interest. This paper discusses the advantages and disadvantages of the proposed constraints' application.

ABSTRACT: This work addresses the buckling behavior of the open top tanks subjected to harmonic settlement. First of all, the buckling behavior and the critical harmonic settlement of an open top tank for various wave numbers are investigated. The results present that buckling occurs on the upper shell for a small wave number, while it changes to other places of the shell for large wave numbers. Also, with the wave number increasing, the buckling point is closer to the base of the shell. Besides, for the original tank, the critical harmonic settlement decreases greatly when the wave number is small, while the critical harmonic settlement decreases slightly when the wave number is large. Then, the parametric studies for the buckling behavior of the open top tank are conducted, composed of the height-to-radius \((h/r)\) ratio and the radius-to-thickness \((r/t)\) ratio. Regarding the \(h/r\) ratio, for a certain wave number, the critical harmonic settlement versus the \(h/r\) ratio is monotonically decreasing. Also, with the wave number increasing, the critical harmonic settlement decreases more and more slightly. Regarding the \(r/t\) ratio, for a certain wave number, the critical harmonic settlement versus the \(r/t\) ratio is monotonically decreasing. Moreover, with the increasing wave number, the critical harmonic settlement decreases more and more slightly. Finally, the buckling results of the open top tank are compared with that of the conical roof tank. The results illustrate that the open top tank can hold a larger harmonic settlement than the conical roof tank for no restraint from the roof for a small wave number. However, for large wave numbers, there is a small difference in settlement sustaining capacity for open top tanks and conical roof tanks.

ABSTRACT: A series of bending tests of thin-walled concrete-filled steel tubes (CFST) were presented in this study. A total of 4 specimens were tested, two square specimens and two rectangular specimens, with width to wall thickness ratio ranging from 50 to 100. The load–displacement curves, failure mode and ultimate capacity of test specimens were obtained. An analytical model was developed for the thin-walled CFSTs subjected to bending. Material properties of confined concrete, corner strength enhancement of cold-formed steel sections, residual stresses and plate local buckling were considered in the developed model. The proposed model was able to predict the behavior and strengths of test specimens with reasonable accuracy. In addition, the suitability of current AISC standard, Eurocode 4 and Han's model for thin-walled CFSTs subjected to bending was also evaluated.

“In-plane ultimate compressive strengths of HPS deck panel system stiffened with U-shaped ribs”, Thin-Walled Structures, Vol., 63, pp 70–81, February 2013, DOI: 10.1016/j.tws.2012.10.001

ABSTRACT: The ultimate compressive strengths of deck plates stiffened longitudinally by U-shaped stiffeners have been investigated by the nonlinear finite element analysis (FEA). A total of 112 hypothetical models with various combinations of slenderness parameters for the deck plates and column slenderness parameters for the stiffeners were modeled and analyzed. Both conventional and high performance steels were considered in models following elasto-plastic strain hardening constitutive relationships. Initial geometric imperfections and residual stresses were also incorporated in the FEA. Numerical results from FEA have been compared to
compressive strengths from Eurocode 3 EN 1993-1-5, FHWA-TS-80–205, and other available formulas. Based on analysis results, new unified strength predictor equations have been developed for the stiffened plate systems with conventional steel and/or high performance steel (HPS). It has been found that use of Eurocode 3 EN 1993-1-5 and FHWA-TS-80–205 may lead to highly conservative design when large column slenderness parameters are encountered. The proposed equations have simple forms yet provide accurate strength predictions resulting in more economic design.

ABSTRACT: Free vibration analysis of laminated composite skew hypar shells are presented using a $C_0$ finite element (FE) formulation based on higher order shear deformation theory (HSDT). Effect of cross curvature is included in the formulation. The $C_0$ finite element formulation has been done quite efficiently to overcome the problem of $C_1$ continuity associated with the HSDT. The isoparametric FE used in the present model consists of nine nodes with seven nodal unknowns per node. Since there are no results available in the literature based on HSDT on the problem of free vibration of laminated composite skew hypar shells, present results are validated with the results available for laminated composite hypar shells without skew angle and with the results available for laminated composite skew plates. New results are presented by varying geometry, boundary conditions, ply orientations and skew angles.

ABSTRACT: This paper presents a finite element (FE) study on fixed-ended LDSS slender hollow columns with square (SHC), and non-rectangular hollow columns (NRHCs) viz., L- (LHC), T- (THC), and +- (+HC) shaped cross-sections subjected to pure axial compression using Abaqus software. SHC columns with thicknesses of 5.25 mm and 2.0 mm, which lie in Class 3 (stocky) and Class 4 (slender) sections, respectively, as per EN 1993-1-4 were considered in the study as referral sections. Variations in buckling strength with changes in the cross-sectional shapes were studied by considering NRHCs having equal material cross-sectional areas (or equal material consumption) as that of SHCs over a range of column lengths. The FE results of SHC and NRHCs were then compared with the design strengths predicted by the EN1993-1-4 and ASCE 8-02 specifications. Good agreements between the FE strengths and codal predictions have been observed, except for the ASCE 8-02 prediction of LHC where it over predicts the FE strengths. At both the slenderness regime (i.e., low and high slenderness values) of Class 3 sections and high slenderness regime of Class 4, all the sections exhibit similar structural capacities. Cross-sectional shape is found to become increasingly significant with decreasing member slenderness in Class 4 sections. In Class 3 sections, compared to SHC there is a nearly linear variation in strength (increased for +HC, similar behavior for THC and decreased for LHC) up to $\lambda^-$ about 2.0, then it stabilizes out. After, $\lambda^-$ about 2.0, $P_u$ for +HC showed about 30% higher; THC showed similar strength; and LHC showed about 20% lower than the corresponding value for SHC, indicating that +HC has an improved ultimate strength for all the ranges of $\lambda^-$. The strength enhancement as compared to that of SHC are about 10%, 50%, and 90% higher for LHC, THC, and +HC, respectively, for Class 4 sections. Based on the
reliability analyses it is recommended that both the codes can be adopted for all the design of fixed-ended LDSS columns except for LHC, wherein a suitable modification may be employed after systematic studies.

**ABSTRACT:** The nonlinear buckling and post-buckling behavior of functionally graded stiffened thin circular cylindrical shells subjected to external pressure are investigated by the analytical approach in this paper. The shells are reinforced by eccentrically rings and stringers attached to the inside and material properties of shell and stiffeners are assumed to be continuously graded in the thickness direction. Fundamental relations, equilibrium equations are derived based on the smeared stiffeners technique and the classical shell theory with the geometrical nonlinearity in von Karman sense. Approximate three-terms solution of deflection is more correctly chosen and explicit expression to finding critical load and post-buckling pressure-deflection curves are given by using the Galerkin's method. The numerical results show the effectiveness of stiffeners in enhancing the stability of shells.

**ABSTRACT:** A concrete-filled stainless steel–carbon steel tubular (CFSCT) column is introduced as a new form of composite member in this paper, which is believed to achieve higher corrosion resistance, higher bearing capacity and lower cost by combination the advantages of stainless steel and concrete filled steel tube (CFST) structure. A series of compression test was carried out on this newly proposed composite column. A modified stress–strain model for concrete core was proposed and then three-dimensional nonlinear finite-element (FE) models were established and verified with the experimental results. Close agreement was achieved between the test and numerical results in terms of load–deformation responses. A parametric study, including tube thickness, diameter and yield strength of carbon steel tube was also conducted to give a clear insight on the performance such composite columns.

**ABSTRACT:** Reinforced concrete (RC) shear-dominant walls can fail suddenly at lower ductility levels, which can lead to catastrophic damage. Accurate modeling of shear-dominant RC walls is therefore essential. In this paper, fiber beam elements, which are proven to be computationally very efficient, were developed to model the
behavior of thin-walled RC shear walls. Concrete and steel were considered as separate materials, and are combined at the section level to describe the behavior of the reinforced concrete member. Concrete was modeled as an orthotropic material in which the principal directions of total stresses were assumed to coincide with the principal directions of total strains, thus changing the directions continuously during the loading. The constitutive model follows the Softened Membrane Model (SMM) in which the compressive strength of concrete is reduced as a function of the lateral strain. The model was subsequently used to conduct a series of numerical studies to evaluate the effect of several parameters affecting the nonlinear behavior of the shear dominated wall. These parameters include the aspect ratio, the transverse reinforcement ratio, the axial force, and the concrete compressive strength. These studies resulted in several important conclusions regarding the global and local behavior of wall systems.

ABSTRACT: In deep and ultra-deep waters the diameter of trunk lines coupled with the hydrostatic pressure tends to lead to failure of the pipeline by external collapse. This failure mode is an instability phenomenon that is governed by the geometry of the pipeline and its material properties and takes place through a subtle combination of its properties. As such the exact limiting collapse pressure is very difficult to determine and twenty years of studies seem to have not managed to clarify entirely the matter. In the present paper the elastic-plastic collapse of test rings from UOE formed pipes under external uniform pressure is analysed both from an analytical and a computational viewpoint and the significance of the actual shape of the out of roundness and of the material inhomogeneity is examined in details. The work has been motivated by a number of accurate experimental tests recently performed on rings cut from UOE pipes and it is found that the material inhomogeneity can affect the collapse modes and produce an occasionally unforeseen reduction in the carrying capacity of the rings prompting a swing between the underlying collapsing modes. Importantly, it is shown that this behaviour can turn quite difficult to follow numerically, also by means of robust strategies such as Riks and improved arc-length. The features of the problem can help to give reason of some apparently anomalous experimental results.

“Finite element investigation of the influence of material properties on the crushing characteristics of in-plane loaded composite sandwich panels”, Thin-Walled Structures, Vol. 63, pp 163-174, February 2013
DOI: 10.1016/j.tws.2012.09.011

ABSTRACT: In the present paper, the explicit finite element code LS-DYNA3D was used to investigate the influence of selected material properties in the crash energy absorption characteristics of composite sandwich panels subjected to in-plane compressive loading. The first step in this investigation was to simulate as accurate as possible representative tests corresponding to the collapse modes that occurred in a series of static edgewise compression tests performed in the National Technical University of Athens (NTUA) using various types of composite sandwich panels. These sandwich panels were candidate materials for use in the new type of composite front-end bumper of a transportation vehicle. Subsequent to the precise reproduction of the collapse
modes, a step-by-step approach was followed in order to examine the influence of selected faceplate and foam core material properties on the crash energy absorption characteristics of the in-plane loaded sandwich panels. More specifically, several series of finite element models were created, by altering the value of only one material parameter per time of the initial FEA models used for the simulation of the sandwich panels collapse modes. The results from the processing of these series of FEA models were used to create figures that graphically depict the influence of the material properties on the energy characteristics. Moreover, the simulation results were analysed in order to express by means of simple linear or polynomial functions the dependence of the crash energy absorption characteristics on the sandwich material parameters. The findings of this series of investigations were recorded aiming to be used as reference to the design of composite sandwich panels in various crashworthiness applications.

ABSTRACT: Cold-formed steel structural members play a great role in modern steel structures due to their high strength and light weight. The behavior and strength of battened column members composed of slender angle sections are mainly governed by local buckling of angle legs or torsional buckling of the angle between batten plates. Moreover, local buckling depends on the interaction between the width–thickness ratio of angle leg, overall slenderness ratio of angle between batten plates and overall slenderness of column. Theoretical study has been carried out by a nonlinear material and geometrical finite element model. Numerous cases of slender battened column sections having different width–thickness angle leg ratios, overall slenderness ratios between batten plates and overall slenderness ratios are chosen in this study. Complete ultimate strength curves are drawn and different failure modes are studied by taking different member lengths, which produce local or torsional buckling of single angles between batten plates or overall buckling of the member. Empirical equations for the effect of shear deformation factor and the ultimate axial load capacities of members formed of battened slender angle sections are proposed. Strengths of axially loaded battened members predicted using finite element as well as the proposed empirical equations is compared with the design strengths obtained using North American and European codes. It is concluded that the design strengths predicted by North American and European codes are generally conservative, and these design rules have been shown to be reliable using reliability analysis.

“Strengthening of steel members in compression by mortar-filled FRP tubes”, Thin-Walled Structures, Vol. 64, pp 1-12, March 2013, DOI: 10.1016/j.tws.2012.11.001

ABSTRACT: A strengthening approach to improve the buckling resistance of steel members in compression is introduced in this paper, where a mortar-filled FRP tube is sleeved outside the steel member and wrapped with
FRP fabrics at the ends of the tube. Through axial compression tests on 18 specimens with bi-axial symmetrical cross-section, the load–strain development and failure modes were obtained and improved load bearing capacity and ductility were evidenced. The effects of the cross-section of core steel, slenderness and FRP fabric layers wrapped at the ends of specimens were investigated. It was found that, after strengthening, the failure modes changed from steel yielding at the mid-height of the steel member due to global buckling to local damage at the steel end. As a result, the load bearing capacity increased by 44–215% and ductility increased by up to 877%. The segmentation model was developed for strengthened specimens, by which the calculated load bearing capacity agrees well with the experimental result.

ABSTRACT: The dimpling process is a novel cold-roll forming process that can enhance the steel material and structural performance by plastically deforming the material surface prior to the section forming operation [1]. Owing to the complex and interrelated nonlinear changes in contact, geometry and material properties that occur in the process and section forming, there have been no existing methods to simulate the process and resultant dimpled products and validate through physical measurements. This paper describes a numerical modelling approach and results into the mechanical properties and structural behaviour of cold-formed dimpled steel. A series of mechanical tests including tensile, plate bending and column compression tests on cold-formed plain and dimpled steel material were conducted for evaluation of numerical results. A finite element approach to practically simulate the dimpling process and experimental tests was presented. True stress–strain data obtained from tests were incorporated into nonlinear simulations of dimpled steel sheets and sections. The simulation of the dimpling process revealed that during the process, various levels of plastic strain are developed throughout the thickness of the steel sheet; this could correlate to the increase in the strength of the dimpled steel as observed in experimental tests and simulations. The simulation of the mechanical tests of dimpled specimens predicted similar results to the experiments, in terms of mechanical properties and structural behaviour. Since the finite element approach was able to successfully represent mechanical properties and structural behaviour of dimpled steel, it can be a powerful method in analysis and design of dimpled steel material and completed sections.

“Buckling analysis of stiffened plates subjected to non-uniform biaxial compressive loads using conventional and super finite elements”, Thin-Walled Structures, Vol. 64, pp 41-49, March 2013
DOI: 10.1016/j.tws.2012.12.004

ABSTRACT: This paper presents the buckling analysis of stiffened plates, using both conventional and super finite element methods. Mindlin plate and Timoshenko beam theories are utilized so as to formulate the plate and stiffeners, respectively. The arbitrary oriented stiffeners can be positioned anywhere within the plate element and are not limited to be placed on nodal lines. Therefore, any configuration of plate and stiffeners can be modeled. Furthermore, extensive boundary conditions as well as general in-plane loading conditions can be
considered using the proposed method. As the applied in-plane loads are not uniform, the buckling load is evaluated in two steps. First, the elasticity problem is solved to determine the stress distribution in prebuckling stage. Applying the principle of minimum potential energy, based on derived stress distribution, yields to the buckling equation of stiffened plates. Numerical examples are proposed to study the accuracy and efficiency of the developed super elements. Effects of various combinations of biaxial loads along with different boundary conditions on buckling characteristics of stiffened panels are also investigated.

ABSTRACT: Cylindrical ground supported steel tanks are traditionally applied to store water and inflammable liquids due to their simple structural design, very good behavior under hydrostatic loads, low cost and easy construction. Despite these advantages, thin-walled steel tanks are sensitive to seismic loading. The aim of this work is the simplified, fast and direct optimum seismic design of these special structures, avoiding complicated computational methods such as the finite element or the boundary element methods. This objective is achieved using software developed in-house, where the optimum seismic design is achieved satisfying the stability of these structures under extreme seismic design loads according to the Eurocode 8 or the Greek seismic regulation provisions. The proposed method provides with the most economical dimensions for the tank and its foundation, for a predefined, design liquid volume. The proposed method can be considered as a basis for determining minimum cost seismic design of thin-walled steel tanks that satisfy the structural and stability requirements.

Xiushu Qu, Zhihua Chen and Guojun Sun (Structural Engineering, School of Civil Engineering, Tianjin University, Tianjin 300072, PR China), “Experimental study of rectangular CFST columns subjected to eccentric loading”, Thin-Walled Structures, Vol. 64, pp 83-93, March 2013, DOI: 10.1016/j.tws.2012.12.006
ABSTRACT: To study the behavior of rectangular CFST columns subjected to eccentric loading, a total of 17 rectangular CFST columns uniaxial and biaxial bending tests were carried out. Concrete compressive strength, steel strength, cross-sectional proportion and eccentricity were selected as the variables to be investigated. The relationship between the load and the lateral displacement at the mid-height of the columns in the directions of both the strong and weak axes and the relationships of load versus end shortening for each specimen were duly recorded. The influences of the constraining factor and eccentric ratio in relation to the strength and ductility indexes of the specimens were investigated. Moreover, in order to achieve the ultimate bearing capacity of the relative rectangular hollow sections with a load of the same eccentricity, the rectangular hollow section models were established by means of the FEM. The concrete contribution ratio necessary for the rectangular CFST columns to be able to resist the eccentric loading was obtained also through comparison of the simulated results and the test data. Finally, based on the definitions and conclusions obtained for the design strength of rectangular CFST columns relying on the “Technical specification for design of steel structure dwelling houses in Tianjin” code (DB 29-57-2003), a factor \( \beta \) was proposed to enhance the steel strength in order to take into account the concrete contribution to the resistance. The modified equation can subsequently provide improved understanding and a more accurate predictive ability or value.
ABSTRACT: Conventionally a pipeline resting on a prop tends to buckle upward under thermal loads, which is called upheaval pipeline buckling. To analyze the phenomenon, most previous studies have modeled the pipeline as a long heavy beam resting on a rigid seabed. However, the seabed may be very soft and uneven; consequently, the pipeline may penetrate into the seabed under thermal compressive forces and change its buckling mode. This study is concerned with the effect of seabed resistance on upheaval buckling of pipelines with prop imperfection. We find that the seabed resistance exerts a remarkable influence on the phenomenon of upheaval pipeline buckling.

ABSTRACT: This paper presents an energy-consistent beam theory and uses it to show the order deficiency, shear locking, and other problems of shear-deformable beam theories. The order of spatial differentiation of both Timoshenko's first-order shear-deformable beam theory and the Euler–Bernoulli beam theory is four, but Timoshenko's theory can account for shear deformation but the other cannot. However, Timoshenko's beam theory is shown to be order-deficient by two, and this order deficiency causes the shear locking problem in finite-element analysis of thin beams. Moreover, the use of one shear correction factor alone cannot fully account for the influence of shear warping on the total strain energy of composite beams. The Cosserat rod theory with Green–Lagrange strains is often used to model highly flexible beams because it can account for geometric nonlinearity and first-order shear deformation. Unfortunately, the use of first-order shear theory makes it order-deficient and is prone to shear locking problems. Moreover, it requires the use of three Rodrigues parameters or four Euler parameters for modeling large rotations, but these math-based variables may experience soft singularity (due to discontinuous spatial derivatives) and artificial strains. Furthermore, the use of Green–Lagrange strains to account for geometric nonlinearity is well known to be problematic. It is also shown that shearing- and bending-induced displacements are relative quantities and they cannot be used as nodal degrees of freedom in finite-element analysis.

ABSTRACT: The load-carrying behavior of cylindrical thin-walled shell structures under load pressure is strongly dependent on the nature and magnitude of the imperfections invariably caused by various manufacturing/welding processes. Weld-induced geometric imperfections have been reported to have especially detrimental effects on the buckling resistance of shells under uniform external pressure. Buckling and post buckling capacity of the shells depend considerably on the cross-sectional form and depth of the geometric imperfections. It also relies on the $H/R$ and $R/t$ ratios ($H$=height, $R$=radius, and $t$=thickness of a cylindrical shell). In the present study, we manufactured and tested a series of specimens having 4 $t$ and 8 $t$ magnitudes of
imperfections with different ratios of $H/R$ and $R/t$. The results of testing under different codes are compared. This study shows considerable reduction in the buckling resistance of the shells.

DOI: 10.1016/j.tws.2013.01.002
ABSTRACT: The paper presents an analysis of the optimal design of cold-formed beams with generalized open shapes under pure bending, uniformly distributed loads, concentrated loads and axial loads with constant bending moment. The optimization problem includes the cross section area as the first objective function and the deflection of a beam as the second one. The geometric parameters of cross sections are selected as design variables. The set of constraints includes global stability condition, selected forms of local stability conditions, strength condition and technological and constructional requirements in a form of geometric relations. The strength and stability conditions are formulated and analytically solved using mathematical equations. The optimization problem is formulated and solved with help of the Pareto concept of optimality. The numerical procedure, based on the Messac normalized constraint method, include discrete, continuous and discrete-continuous sets of design variables. Results of the numerical analysis for different loads of beams with monosymmetrical cross section shapes are presented in tables.

“Effect of offset web holes on web crippling strength of cold-formed steel channel sections under end-two-flange loading condition”, Thin-Walled Structures, Vol. 65, pp 34-48, April 2013,
DOI: 10.1016/j.tws.2012.12.003
ABSTRACT: A combination of experiments and non-linear finite element analyses are used to investigate the effect of offset web holes on the web crippling strength of cold-formed steel channel sections under the end-two-flange (ETF) loading condition; the cases of both flanges fastened and unfastened to the support are considered. The web holes are located at the mid-depth of the sections, with a horizontal clear distance of the web holes to the near edge of the bearing plate. Finite element analysis results are compared against the laboratory test results; good agreement was obtained in terms of both strength and failure modes. A parametric study was then undertaken to investigate both the effect of the position of holes in the web and the cross-section sizes on the web crippling strength of the channel sections. It was demonstrated that the main factors influencing the web crippling strength are the ratio of the hole depth to the depth of the web, and the ratio of the distance from the edge of the bearing to the flat depth of the web. Design recommendations in the form of web crippling strength reduction factors are proposed in this study.

M.F. Hassanein, O.F. Kharoob and A.M El Hadidy (Department of Structural Engineering, Faculty of Engineering, Tanta University, Tanta, Egypt), “Lateral-torsional buckling of hollow tubular flange plate girders with slender stiffened webs”, Thin-Walled Structures, Vol. 65, pp 49-61, April 2013
DOI: 10.1016/j.tws.2013.01.006
ABSTRACT: This paper is concerned with the assessment of the lateral–torsional buckling (LTB) of hollow tubular flange plate girders (HTFPGs) with slender stiffened webs. Using the general purpose finite element package ABAQUS, 3-D finite element (FE) models for simply supported HTFPGs subjected to uniform bending are built. First, a preliminary analysis is conducted to compare the HTFPGs with their equivalent I-section plate girders with flat flanges (IPGs). The results indicate that the HTFPGs display larger load-carrying capacities and stiffnesses compared to IPGs especially in the elastic LTB range. In addition, it is found that the inelastic LTB dominates the failure mode for higher spans of HTFPGs compared to equivalent IPGs. Consequently, a parametric study for the HTFPGs is carried out considering two key parameters; namely the radius of gyration of the compression–flange and the section modulus. The results showed that using HTFPGs with less slender webs (i.e. with shorter webs) for medium-to-long spans optimizes the girders by reducing their weight. Additionally, to save the fabrication costs via reducing the weld lengths, it is more significant to increase the hollow tubular flange depth. It is as well found that the AISC and EC3 provide highly conservative predictions for the HTFPGs under bending. A modified AISC design method is, therefore, suggested to predict the flexural strength of the HTFPGs. The results predicted by the proposed method show better agreement with the FE strengths than the values predicted by the AISC and EC3.

ABSTRACT: The purpose of this work is to investigate the effect of top stiffening rings of open top tanks on the critical harmonic settlement. First, the buckling behavior of a tank with a top stiffening ring is provided and the results are compared with that of the model with no stiffening ring. The results show that the critical harmonic settlement for the tank with a top stiffening ring is lower than that for the tank with no top stiffening ring. Moreover, the top stiffening ring plays a significant role on the critical harmonic settlement when the wave number is small, but plays a minor role on that when the wave number is large. Then, the imperfection sensitivity analysis is conducted to identify whether the top stiffening ring can decrease the sensitivity of imperfection. Meanwhile, the worst imperfection form for tanks subjected to harmonic settlement is reported. The results present that the weld depression has the most adverse effect on the settlement carrying capacity of tanks. Moreover, it is indicated that the top stiffening ring cannot always decrease the sensitivity of the imperfection. The sensitivity plots are related to harmonic wave numbers, as well as imperfection forms. Finally, the effect of top stiffening rings with different structure parameters on the critical harmonic settlement is reported, including the length and the thickness of the top stiffening ring. For the length of the top stiffening ring, the critical harmonic settlement versus the wave number decreases more and more slightly with the increasing length of the top stiffening ring. For the thickness of the top stiffening ring, the critical harmonic settlement versus the wave number decreases more and more mildly with the thickness of the top stiffening ring on the increase.

Shanmuganathan Gunalan, Prakash Kolarkar and Mahen Mahendran (School of Civil Engineering and Built Environment, Science and Engineering Faculty, Queensland University of Technology), “Experimental study of load bearing cold-formed steel wall systems under fire conditions”, Thin-Walled Structures, Vol. 65, pp 72-92, April 2013, DOI: 10.1016/j.tws.2013.01.005
ABSTRACT: Light Gauge Steel Framing (LSF) walls made of cold-formed and thin-walled steel lipped channel studs with plasterboard linings on both sides are commonly used in commercial, industrial and residential buildings. However, there is limited data about their structural and thermal performance under fire
conditions while past research showed contradicting results about the benefits of using cavity insulation. A new composite wall panel was recently proposed to improve the fire resistance rating of LSF walls, where an insulation layer was used externally between the plasterboards on both sides of the wall frame instead of using it in the cavity. In this research 11 full scale tests were conducted on conventional load bearing steel stud walls with and without cavity insulation, and the new composite panel system to study their thermal and structural performance under standard fire conditions. These tests showed that the use of cavity insulation led to inferior fire performance of walls, and provided supporting research data. They demonstrated that the use of insulation externally in a composite panel enhanced the thermal and structural performance of LSF walls and increased their fire resistance rating. This paper presents the details of the LSF wall tests and the thermal and structural performance data and fire resistance rating of load-bearing wall assemblies lined with varying plasterboard-insulation configurations under two different load ratios. Fire test results including the time–temperature and deflection profiles are presented along with the failure times and modes.

Iman Dayyani, Masih Moore and Alireza Shahidi (Department of Mechanical Engineering, Isfahan University of Technology, Isfahan 84156-83111, Iran), “Unilateral buckling of point-restrained triangular plates”, Thin-Walled Structures, Vol. 66, pp 1-8, May 2013, DOI: 10.1016/j.tws.2013.01.007

ABSTRACT: In this paper the unilateral buckling behavior of point restrained triangular plates is studied. Firstly, the energy functional of a general triangular plate with elastic foundation is calculated. The Rayleigh–Ritz method for investigating the local buckling of unilaterally restrained triangular plates is applied. The displacement functions and restraining medium are modeled as polynomials and tensionless foundation respectively. The results are obtained for different boundary conditions, aspect ratios and various in-plane compressive and shear loadings. Confirming the validity of this investigation, convergence and comparison studies are undertaken. The comparisons show the efficiency and accuracy of the presented method.

ABSTRACT: The collapse of thin-walled tubes under axial and oblique loading is frequently encountered in real crash events. The windowing and multi-cell methods are effective in improving tubes' energy absorbing performance. In this paper, a comparative study on the performance of windowed and multi-cell square tubes of the same weight under axial and oblique loading is conducted numerically. The results show that the multi-cell tube can achieve higher mean crushing force than the windowed tube but the windowed tube has lower initial peak force. The effectiveness of both methods reduces as the load angle increases. Moreover, the multi-cell and windowed tubes may have worse performance than the conventional tube if the former two collapse in global bending and the later in axial mode.

ABSTRACT: Thin-walled tubes made from metals or fibre–resin composites have been used widely as energy absorbers in structural crashworthiness applications. A relatively recent advent of composite energy absorbers are externally fibre-reinforced metal tubes, where fibres are bonded to the metal tube surface. Such composites take advantage of the favourable characteristics of each material, being the stable, ductile plastic collapse mechanism of the metal and the high strength to weight ratio of the fibre–resin composite. While several recent experimental and analytical studies have highlighted the substantial improvements in performance fibre strengthening provides, the potential use of such members as structural components in vehicles has yet to be explored. This paper presents a numerical study of the application of fibre strengthened steel tubes to the frontal crush tubes of two different passenger vehicles under frontal collisions. Substantial improvements in vehicle crash performance are demonstrated, as is the potential for vehicle light-weighting. Such components have the potential to contribute to improvements in fuel efficiency and emissions reductions in future passenger vehicle fleets.

ABSTRACT: An analytical method is proposed to determine the dynamic response of 3-D rectangular fluid containers with four flexible walls, subjected to seismic ground motion. By applying Rayleigh–Ritz method using the vibration modes of flexible plates, fluid–structure interaction effects on the dynamic responses of fluid containers are considered. A mechanical model, which takes into account the deformability of the tank wall, is developed. The maximum seismic loading of the base at the tank and a section immediately above it can be predicted by this model. Accordingly, a 2-D simplified model is proposed to evaluate pressure distribution on the flexible tank wall.

ABSTRACT: To simplify the waste concrete recycling process, the authors have proposed several new kinds of structural members containing demolished concrete with a distinctly larger size than conventional recycled aggregates. Previous researches and applications have preliminarily verified the suitability of these new environment-friendly structural members. The objective of the presented research is to provide new test data to study the seismic performance and to evaluate the strength and ductility of the thin-walled circular steel tubular column filled with demolished concrete blocks (DCBs) and fresh concrete (FC). Fifteen specimens, including 10 columns filled with DCBs and FC and 5 reference columns filled with FC alone, were tested under combined constant axial compression and reversed cyclic lateral loadings. Test variables are: replacement ratio of DCBs, thickness of steel tube, and axial load ratio. Based on the concept of combined strength of new and old concrete in steel tube, some design codes are employed to predict the lateral strength of the specimens. Research findings
indicate that: (1) the seismic performance of thin-walled circular steel tubular columns filled with DCBs and FC is similar to that of the reference columns filled with FC alone; (2) the lateral strength of the columns filled with DCBs and FC is slightly lower than that of the reference columns filled with FC alone; and (3) even though the diameter-to-thickness ratio is only 168, the ultimate drift ratio of such a specimen filled with DCBs and FC with an axial load ratio of 0.4 can reach 4%, showing good deformation capacity.

You-Fu Yang and Guo-Liang Ma (State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, Dalian 116024, China), “Experimental behaviour of recycled aggregate concrete filled stainless steel tube stub columns and beams”, Thin-Walled Structures, Vol. 66, pp 62-75, May 2013 DOI: 10.1016/j.tws.2013.01.017

ABSTRACT: The behaviour of recycled aggregate concrete (RAC) filled stainless steel tube (RACFSST) stub columns and beams under short-term loadings was experimentally studied, and a total of 28 specimens, including 14 stub columns and 14 beams, were tested. The experimental investigations were carried out on circular and square specimens with recycled aggregate replacement ratio of 0, 25%, 50% and 75%, and both recycled coarse aggregate (RCA) and recycled fine aggregate (RFA) were adopted in the tests. The main objectives of these tests were threefold: first, to describe a series of tests on new composite stub columns and beams; second, to investigate the effect of cross-section type and recycled aggregate replacement ratio on the compressive and flexural behaviour of RACFSST specimens; and finally, to evaluate the accuracy of the calculated bearing capacity, bending moment capacity and section flexural stiffness of the RACFSST specimens by using the design formulae in six codes related to the design of concrete filled carbon steel tube. The experimental results showed that the RACFSST stub columns and beams under short-term loadings had the stable load versus deformation responses and the good deformation-resistant ability, and the performance of core RAC was generally enhanced due to the confinement of the outer stainless steel tube.

Jian-guo Nie, Yu-hang Wang and Jian-sheng Fan (Key Laboratory of Civil Engineering Safety and Durability of China Education Ministry, Department of Civil Engineering, Tsinghua University, Beijing 100084, China), “Experimental research on concrete filled steel tube columns under combined compression-bending-torsion cyclic load”, Thin-Walled Structures, Vol. 67, pp 1-14, June 2013, DOI: 10.1016/j.tws.2013.01.013

ABSTRACT: Based on the force–displacement mixed control quasi-static test on eight CFST columns subjected to combined compression, bending and torsion cyclic load, the mechanical behavior of CFST columns with various section types, bending moment to torsion moment ratios and axial load levels was studied. The test results showed that the hysteretic curves of CFST columns under combined compression, flexure and torsion are plump due to the good seismic behavior and the ductility was also good. But for rectangular CFST columns with high bending moment to torsion moment ratio, the strength degradation was observed due to the local buckling of the steel plate at the bottom. The torsion capacity of CFST columns would be reduced by the bending moment. The plane section assumption of axial strain of CFST columns could be satisfied. The shear strain of the steel tube has good linear relationship with the rotation angle of the section when CFST columns subjected to combined compression, flexure and torsion. Based on the test results and literatures available, the mechanism of CFST columns was qualitatively analyzed.

ABSTRACT: In low speed collisions, insurance cost is a factor which is taken into account as a design criterion to reduce structure damage and fixing cost. In this study, it is focused on the applied permanent damages of vehicle frontal door caused by pole impacts. In the side impact, the side door beam is responsible to absorb the most possible kinetic energy. Two significant parameters including material and geometry of a side door beam are discussed here to reduce permanent damage of the door. To study the effect of material as the first phase, six different sheets of material have been concerned to investigate the rigidity of the structure. For the second phase, geometry modification of the side door beam has been performed via creating new CAD-reinforcing ribs. Consequently, the strength in elasto-plastic mode, maximum deflection and plastic strain of the equipped system representing the permanent damage is obtained in order to achieve lower losses.

Hasan Gedikli (Karadeniz Technical University, Department of Mechanical Engineering, Trabzon 61080, Turkey), “Crashworthiness optimization of foam-filled tailor-welded tube using coupled finite element and smooth particle hydrodynamics method”, Thin-Walled Structures, Vol. 67, pp 34-48, June 2013

DOI: 10.1016/j.tws.2013.01.020

ABSTRACT: This paper has presented the optimal design for empty and foam-filled tailor welded tubes (TWTs). Specific energy absorption, peak force and crushing force efficiency (CFE) were used to determine energy absorbing capacity in empty and foam-filled tubes using both finite element and smooth particle hydrodynamics methods. Numerical results showed that SEA and peak force increased with increasing thickness of upper part and foam density while peak forces were significantly low in TWTs made from different materials. Moreover, CFE decreased with increasing thickness of upper part and with decreasing welding location whereas CFE slightly increased with increasing foam density.

Ming Song and ShiRong Ge (Institute of Rescue Technology and Equipment, School of Mechanical and Electrical Engineering, China University of Mining & Technology, Xuzhou 221116, China), “Dynamic response of composite shell under axial explosion impact load in tunnel”, Thin-Walled Structures, Vol. 67, pp 49-62, June 2013, DOI: 10.1016/j.tws.2013.02.009

ABSTRACT: This paper presents a study on the dynamic response of a capsule-shaped composite metallic shell under axial explosion impact load in a tunnel. The composite shell, which consists of a cylindrical shell and a semi-spherical shell on both ends, is analyzed by experimentation and simulation. The three-dimensional finite element models of the shell and tunnel were established using DYTRAN®, and the simulation and experiment results are highly consistent. The spread trend of shock wave around the shell is analyzed, thus the stress distribution and deformation trend on the composite shell given different shell thicknesses and fixed mode is obtained.

ABSTRACT: In this paper, the nonlinear vibrations of functionally graded (FGM) circular cylindrical shells are analysed. The Sanders–Koiter theory is applied to model the nonlinear dynamics of the system in the case of finite amplitude of vibration. The shell deformation is described in terms of longitudinal, circumferential and radial displacement fields. Simply supported, clamped and free boundary conditions are considered. The
displacement fields are expanded by means of a double mixed series based on Chebyshev orthogonal polynomials for the longitudinal variable and harmonic functions for the circumferential variable. Both driven and companion modes are considered; this allows the travelling-wave response of the shell to be modelled. The model is validated in the linear field by means of data retrieved from the pertinent literature. Numerical analyses are carried out in order to characterise the nonlinear response when the shell is subjected to a harmonic external load; a convergence analysis is carried out by considering a variety of axisymmetric and asymmetric modes. The present study is focused on determining the nonlinear character of the shell dynamics as the geometry (thickness, radius, length) and material properties (constituent volume fractions and configurations of the constituent materials) vary.

M.P. Kulatunga and M. Macdonald (School of Engineering & Built Environment, Glasgow Caledonian University, Cowcaddens Road, Glasgow, Glasgow G4 0BA, UK), “Investigation of cold-formed steel structural members with perforations of different arrangements subjected to compression loading”, Thin-Walled Structures, Vol. 67. Pp 78-87, June 2013, DOI: 10.1016/j.tws.2013.02.014

ABSTRACT: An investigation of cold-formed steel sections subjected to compression loading was undertaken using Finite Element Analysis to study the effects of perforation positions on the load capacity of column members of lipped channel cross-section. For this purpose, a finite element model was developed using ANSYS and its accuracy was verified using experimental and theoretical results. The study showed that the ultimate load of the lipped channels under compression varied greatly with the perforation position. Comparisons of the finite element results and the test results are also made with existing design specifications, and conclusions are drawn on the basis of the comparisons.

ABSTRACT: A new formulation of the Generalized Beam Theory (GBT) that coherently accounts for shear deformation is presented in this paper. In particular, a modified formulation of the kinematics early proposed by Silvestre and Camotim for shear deformable GBT is devised. The new formulation, which preserves the general format of the original GBT for flexural modes, introduces the shear deformation along the wall thickness direction besides that along the wall midline, so guaranteeing a coherent matching between bending and shear strain components of the beam. According to the new kinematics, a reviewed form of the cross-section analysis procedure is devised, based on a unique modal decomposition for both flexural and shear modes. Much attention is posed on the mechanical interpretation of the deformation parameters in the modal space. It is shown that, in the modal space, it is possible to clearly distinguish bending deflections from deflections due to shearing strains, and to recover classical beam degrees of freedom and standard beam theories as special cases. The effectiveness of the proposed approach is illustrated on two typical benchmark problems.

Sherif Saleh Safar (Cairo University, Giza 11835, Cairo, Egypt), “Shear strength of end web panels”, Thin-Walled Structures, Vol. 67, pp 101-109, June 2013, DOI: 10.1016/j.tws.2013.02.003

ABSTRACT: In most classical theories for post-buckled web panels under shear, it was assumed that tension-field action was anchored by flanges and adjacent web panels. Such an assumption led to the conclusion that post-buckling strength can only develop in intermediate web panels. Accordingly, the AISC specifications do not account for post-buckling strength in end web panels. In this paper, more than sixty full-scale plate girders
were modelled and analyzed by the finite element method to assess the shear strength of end web panels. An objective of this nonlinear large deflection numerical study was to clarify the effect of geometric properties of end web panels on their shear strength in the elastic and inelastic buckling ranges. Numerical results were verified by comparison to classical web buckling theory and experimental results published in literature. Unlike most post-buckling theories, it was shown that end web panels possessed post-buckling strength where diagonal tension stresses were equilibrated by compressive stresses in end-bearing stiffeners and portions of the web stiffened by flanges and stiffeners. Numerical results were used to establish new design rules for shear strength of end web panels including tension field action.

ABSTRACT: Inflatable tubes must be pressurized before they are able to resist to external loadings. While there are many studies dedicated to the behavior of inflated tubes under bending or twisting, few results are available on the inflating stage when the beam is only submitted to the internal pressure. In this paper, an exact solution is proposed for a cylindrical tube made of an orthotropic membrane, with the orthotropy axes parallel to the circumferential and longitudinal directions of the cylinder, and undergoing finite deformations under internal pressure. The solution of the problem amounts to solving a cubic equation and analytical relations are given for the inflated geometry as well as the resultant stresses in the membrane. Numerical results are shown to compare very well with those obtained from a finite element code.

Bin Cheng, Jianlei Wang and Chun Li (Department of Civil Engineering, Shanghai Jiao Tong University, Shanghai, China), “Compression tests and numerical analysis of perforated plates containing slotted holes in steel pylons”, Thin-Walled Structures, Vol. 67, pp 129-143, June 2013, DOI: 10.1016/j.tws.2013.02.005

ABSTRACT: This paper presents experimental and numerical studies on the compression behaviors of perforated plates in steel pylons. Each rectangular plate considered has a centrically located slotted hole and is simply supported on four edges in the out-of-plane direction. In a experimental study, 15 specimens, i.e., four non-perforated plates and 11 perforated plates, are tested under uniaxial compression by the use of a self-balanced loading device. The elastic strain distribution, out-of-plane deformation, failure pattern, and ultimate strength are observed in the compression test. In the numerical analysis, finite element models are developed to predict the stress concentration factor and the ultimate strength of plates with various dimensions. The results of the finite element analyses are validated by the experimental data. The influences of non-dimensional parameters including plate slenderness ratio, plate aspect ratio, hole width/plate width as well as hole aspect ratio on the concerned predictions are illustrated on the basis of numerous parametric studies. The results of the studies indicate that slotted perforations make significant alterations in the compression behaviors of perforated plates, and those alterations vary with non-dimensional parameters of plates, holes or between them.

ABSTRACT: Alternative structural layouts for wind turbine blades are investigated with the aim of improving their design, minimizing weight and reducing the cost of wind energy. New concepts were identified using topology optimization techniques on a 45 m wind turbine blade. Additionally, non-dimensional structural shape factors were developed for non-symmetric sections under biaxial bending to evaluate structural concepts in terms of ability to maximize stiffness and minimize stress. The topology optimization evolves a structure which transforms along the length of the blade, changing from a design with spar caps at the maximum thickness and a trailing edge mass, to a design with offset spar caps toward the tip. The shape factors indicate that the trailing edge reinforcement and the offset spar cap topology are both more efficient at maximizing stiffness and minimizing stress. In summary, an alternative structural layout for a wind turbine blade has been found and structural shape factors have been developed, which can quantitatively assess the structural efficiency under asymmetric bending.

ABSTRACT: The steel plate shear wall system has been used in a number of buildings as an innovative lateral force resistance system. Stiffened steel plate shear walls possess greater stability and energy absorption during dynamic loading, such as during seismic loading, when compared with unstiffened steel plate shear walls. Openings, however, often exist in the steel plate shear walls due to various functional requirements of the structure. These openings may negatively impact the overall capacity of the shear wall, necessitating additional stiffening. Therefore, an experimental research program was instituted to investigate the seismic behavior of stiffened steel plate shear walls, with and without openings. Strength, stiffness, ductility and energy absorption were evaluated based on the results of reversed cyclic loading tests on three specimens. Two of the test walls had openings, while one wall was constructed without any openings. The test program results showed that stiffened steel plate shear walls exhibit satisfactory seismic behavior, and, as expected, the strength and stiffness characteristics of the walls were reduced in walls with openings. In addition to the test program, an analytical study utilizing a beam–shell mixed Finite Element (FE) model of a single-story wall panel with boundary columns is made to determine the critical factors influencing the shear strength reduction of stiffened wall panels with the opening. Furthermore, extensive numerical calculation and parametric analysis are conducted to derive a simplified formula for the determination of the shear strength reduction coefficient. In addition, complex elasto–plastic FE models of the three specimens are developed to investigate in detail the lateral force resistance behavior of stiffened steel plate shear walls. Good agreement is observed between the experimental and numerical results. Finally, a design method for calculating the lateral resistance capacity, based on the test program and the FE model analysis, is recommended to be used for the routine design practice of stiffened steel plate shear walls.

ABSTRACT: This work reports the results of a numerical investigation on the influence of the cross-section geometry and end support conditions on the post-buckling behaviour and Direct Strength Method (DSM) design of cold-formed steel columns buckling and failing in distortional modes. The columns analysed exhibit (i) four end support conditions, (ii) different cross-section shapes, dimensions and lengths, and (iii) several yield stresses. These features were carefully selected in order to ensure, as much as possible, that all columns (i) buckle and fail in “pure” distortional modes and (ii) cover a wide (distortional) slenderness range. The post-buckling equilibrium paths and ultimate loads presented and discussed were obtained through Ansys elastic and elastic-plastic shell finite element analyses. Moreover, the ultimate strength data acquired are used to show that, regardless of the column geometry, the current DSM distortional design curve is not able to predict adequately (safely and accurately) the ultimate loads of columns with other than fixed end supports. The paper also includes a preliminary assessment/proposal of the modifications that must be included into this DSM design curve in order to overcome the above limitation.

Ehab Ellobody (Department of Structural Engineering, Faculty of Engineering, Tanta University, Tanta, Egypt), “A consistent nonlinear approach for analyzing steel, cold-formed steel, stainless steel and composite columns at ambient and fire conditions”, Thin-Walled Structures, Vol. 68, pp 1-17, July 2013
DOI: 10.1016/j.tws.2013.02.016

ABSTRACT: This paper presents a consistent nonlinear 3-D finite element approach, adopted by the author over the last ten years, for analysing steel, cold-formed steel, stainless steel and composite columns at ambient and fire conditions. The main parameters affecting the finite element approach, which has accounted for the nonlinear material properties of the column cross-sections at ambient and elevated temperatures, initial local and overall geometric imperfections and residual stresses, are highlighted in this paper. The finite element approach could be easily extended to study columns constructed from other materials or built-up using different sections. This paper also presents up-to-date review for previously published experimental and numerical investigations highlighting the stability of the aforementioned columns at ambient and elevated temperatures. In addition, the paper highlights the design rules specified in current codes of practice for the columns. Furthermore, this paper presents, as examples, comparisons of finite element analysis results, previously reported by the author, with design values calculated using of current codes of practice. In overall, the paper aims to stress the fact that consistent, robust and efficient nonlinear 3-D finite element models could improve and assess the accuracy of design rules specified in current codes of practice at ambient and elevated temperatures. Also, better understanding of the structural performance of the columns in the cold condition is essential to analyse the column behaviour under severe fire conditions.

ABSTRACT: This study presents the effect of various geometrical parameters of circular single perforation on the critical/ultimate buckling load of a circular lean duplex stainless steel (LDSS) stub column loaded axially using finite element (FE) software, Abaqus. The effect of eccentricity (distance between the perforation centre and edge of column), hole diameter and column thickness are studied on the critical buckling load capacity. The decrease of buckling load when perforation size \((d/D)\) is increased from 0.02 to 0.20 is found to be 13.9%, 13.5%, 12.0%, 10.1%, 8%, respectively, for perforation eccentricities \((e/L)\) of 0.5, 0.4, 0.3, 0.2 and 0.1, indicating maximum reduction of buckling load when the perforation is located at mid-height (or \(e/L=0.5\)). For
lower values of \( d/D \) (say 0.02), there is no significant effect of perforation on the buckling load for all values of eccentricities considered. With 72% increase in thickness (from \( t=2.75 \)), the buckling load is found to increase by 5.0%, 4.2%, 3.2%, 1.2%, 0.3%, 0% for \( d/D=0.20, 0.12, 0.10, 0.08, 0.04, 0.02 \), respectively, with the rate of increase higher for higher \( d/D \) ratios.

A. Alavi Nia and M. Parsapour (Mechanical Engineering Department, Bu-Ali Sina University, Hamedan, Iran), “An investigation on the energy absorption characteristics of multi-cell square tubes”, Thin-Walled Structures, Vol. 68, pp 26-34, July 2013, DOI: 10.1016/j.tws.2013.01.010
ABSTRACT: Due to increasing applications of thin-walled structures, especially as energy absorber, considerable researches have been made about them. In this paper, firstly, behavior of simple and multi-cell square tubes with equal cells is studied analytically, experimentally and numerically. Then, it is shown that for 3×3 square tubes with unequal cells, adding the partitions at corners increases energy absorption capacity of the tubes. Furthermore, the Zhang’s formula for prediction of mean crushing load (MCL) is revised to inclusion of unequal cells square tubes; then, analytical and numerical results are validated with experiments. Finally, it is shown that the energy absorption capacity of the proposed new multi-cell square section is about 227% greater than that of simple section.

Qijie Ma and Peijun Wang (Civil Engineering Department, Shandong University, Jinan, Shandong Province 250061, China), “Simplified stability design method for the stiffened plate with slotted holes under uniform compression”, Thin-Walled Structures, Vol. 68, pp 35-41, July 2013, DOI: 10.1016/j.tws.2013.02.017
ABSTRACT: The elastic buckling and nonlinear post-local buckling behavior of a stiffened plate with slot holes is different to that of a solid plate. As results of systematic parameter studies, design equations for calculating the elastic buckling stress of a solid plate is modified for design a stiffened plate with slot holes. Numerical simulation shows that in the post-local buckling phase, the slots cause the membrane stress redistribution and help the non-slotted region developing into a much higher stress state, which may lead to the increase in the load bearing capacity of the slotted plate. Through studying the longitudinal stress distribution along the plate width, the effective width design equation for the solid plate is also modified to account for effects of the slots. Comparisons of the effective width factor obtained from the proposed equations, previous research results and the numerical simulation show that they agree well with each other.

ABSTRACT: Current stainless steel design standards are based on elastic, perfectly plastic material behaviour providing consistency with carbon steel design expressions, but often leading to overly conservative results, particularly in the case of stocky elements. More economic design rules in accordance with the actual material response of stainless steel, which shows a rounded stress–strain curve with significant strain hardening, are required. Hence, the continuous strength method (CSM) was developed. The CSM replaces the concept of cross-section classification with a cross-section deformation capacity and replaces the assumed elastic, perfectly plastic material model with one that allows for strain hardening. This paper summarises the evolution of the method and describes its recent simplified form, which is now suitable for code inclusion. Comparison of the predicted capacities with over 140 collected test results shows that the CSM offers improved accuracy and reduced scatter relative to the current design methods. The reliability of the approach has been demonstrated by
statistical analyses and the CSM is currently under consideration for inclusion in European and North American design standards for stainless steel structures.

“Full-range analysis on square CFST stub columns and beams under loading and chloride corrosion”, Thin-Walled Structures, Vol. 68, pp 50-64, July 2013, DOI: 10.1016/j.tws.2013.03.003
ABSTRACT: This paper presents a finite element analysis (FEA) on concrete filled steel tubular (CFST) members with square sections under both loading and chloride corrosion, the established FEA model was verified by the experimental results presented in the companion paper (Han et al., 2012) [1]. The FEA model was then used to perform mechanism analysis on the CFST stub columns and beams subjected to both loading and chloride corrosion. Full-range analysis on the load versus deformation relations was carried out. Finally, simplified methods for calculating the strength of CFST stub column and beam under long-term loading and corrosion were illustrated based on the parameter analysis.

ABSTRACT: This paper presents finite element simulations of the crash behavior and the energy absorption characteristics of thin S-shaped longitudinal members with variable cross-sections made of different materials to investigate the design of optimized energy-absorbing members. Numerical studies are carried out by simulation via the explicit finite element code LS-DYNA [1] to determine the desired variables for the design of energy-absorbing members. The specific energy absorption (SEA), the weight of the members and the peak force responses during the frontal impact are the main measurements of the S-shaped members' performance. Several types of inner stiffening members are also investigated to determine the influence of the additional stiffness on the crash behavior.

ABSTRACT: Filament winding and twice co-curing processes were applied to make advanced carbon fiber reinforced composite (CFRC) sandwich cylinder with lattice cores. Split metallic moulds were designed and adopted for easy demoulding after winding the lattice core. The cylinders were designed with a small tapering to assure tight contact between the lattice core and the inner skin. To avoid local failure at the end of the
cylinder, flange structures were placed continuously from the fibers of skins and lattices. Axial compression was carried out to reveal the mechanical behaviors of the fabricated sandwich cylinder. The experiment shows that the advanced making technology shows the promise of lattice sandwich cylinder (LSC) avoiding instability, local buckling, local cracking and debonding.

DOI: 10.1016/j.tws.2013.02.013
ABSTRACT: A hypothesis that when subject to biaxial stress, the strengthening effects of arbitrarily oriented stiffener can be approximated by those of regularly oriented stiffener is proved through several simulations and comparisons. It is also found that in an arbitrarily stiffened plate with multiple stiffeners, the orientation of the stiffeners does not apparently affect the plate's strength limit. Based on this find, any arbitrarily stiffened plate can be simplified as regularly stiffened plate, therefore can be analyzed through simplified semi-analytical models during buckling strength analysis. The proved hypothesis can also be explained from an existing analytical model for the arbitrarily oriented stiffener. Engineering simulation software ANSYS is used for modeling and analysis involved in this study.
ABSTRACT: Engineers are increasingly expected to consider dynamic loads in the design of structures due to increased security demands and as a result of accidental or intentional impact or explosive events, for example in the construction, infrastructure, offshore, mining, protective and security industries. Metal hollow section tubular columns are used extensively in such applications, however currently no blast design procedures exist for such sections. Recent experimental studies have shown that such sections often sustain substantial local deformations and/or collapse of the cross-section, in addition to global (overall) transverse displacement of the member, when subjected to transverse blast load. These studies investigated a limited range of boundary conditions and blast environments due to the limitations of laboratory testing. The present paper validates numerical models of these experiments, and then extends the numerical models to consider a broad range of geometric properties, boundary conditions and blast conditions typical to axial compression members. The numerical results are used to develop generalised design methods for metal hollow section columns subjected to transverse blast loads. The design model is unified with a recently developed model for tubular columns subjected to transverse impact, providing a generalised solution for the design of metal tubular columns for dynamic loads. Accounting for the development of local deformation of the cross-section is shown to be especially important in the blast design of such members.

ABSTRACT: An L frame made up by beam and column having channel cross sections, has been analyzed in a previous work by two of the authors [14]. Depending on the aspect ratio and the joint configuration, it has been proved that the structure can exhibit two simultaneous buckling modes. Here using the asymptotic theory of elastic bifurcation that takes into account mode interaction, the initial slope of the bifurcated paths has been determined. Three cases of joint configurations, which are the more common used in welded connections, have been considered. For each case three admissible bifurcated paths have been found. Two of them show a slope having the same order of magnitude of the ones found in the absence of mode interaction while the remaining exhibits a slope largely steepest. Selecting, for each joint case, the bifurcated path with the higher slope and between them the smallest one, it is found that it is associated to the path which bifurcates at the higher critical load. This means that the stiffer structure is also the less imperfection sensitive. Finally for each one of the cases studied, the effect of initial imperfection has been considered and the real load carrying capacity of the frames has been determined. Finally some results have been compared with those obtained using the FE code ABAQUS.

“Experimental and theoretical investigation on torsional behavior of CFRP strengthened square hollow steel section”, Thin-Walled Structures, Vol. 68, pp 135-140, July 2013, DOI: 10.1016/j.tws.2013.03.008
ABSTRACT: Carbon fibre reinforced polymer (CFRP) has been used to strengthen steel members in bending and compression. There is a lack of understanding on behaviour of CFRP strengthened steel beams subject to torsion. This paper presents an experimental study on the behaviour of CFRP strengthened square hollow section (SHS) beams in pure torsion. A set of tests on CFRP strengthened steel specimens under torsion was carried out in which several different strengthening configurations were used. CFRP sheet wrapping consisted of different configurations including vertical, spiral, and reverse-spiral wrapping were used. The results showed that using CFRP could improve the elastic and plastic torsional strength of CFRP strengthened steel beam specimens. The number of layers of CFRP and the strengthening configurations were important factors for the improvement. Based on the measured values of the torsional moment at yielding and at ultimate, the corresponding twists, the torsional behavioural curves and the failure modes of the strengthened beam specimens, useful concluding remarks are presented.

ABSTRACT: This paper describes a series of compression tests performed on welded rectangular hollow section (RHS) columns fabricated from 6.0-mm-thick steel plates with a nominal yield stress of 315 MPa. The ultimate strength and performance of the welded RHS compression members undergoing a nonlinear interaction between local buckling and overall buckling were investigated experimentally and theoretically. The compression test results indicated that the interaction between local buckling and overall buckling had a significant negative effect on the ultimate strength of the welded RHS columns. Design strength formulae for the direct strength method (DSM) for the welded RHS columns were proposed based on the compression test results. The study results confirmed that DSM based on the American Institute of Steel Construction (AISC) or Eurocode 3 (EC3) column curves can properly predict the ultimate strength of welded RHS columns when local buckling and overall buckling occur simultaneously or nearly simultaneously.

ABSTRACT: Multi-cell metal columns were found to be much more efficient in energy absorption than single-cell columns under axial compression. However, the experimental investigations and theoretical analyses of them are relatively few. In this paper, the quasi-static axial compression tests are carried out for multi-cell columns with different sections. The significant advantage of multi-cell sections over single cell in energy absorption efficiency is investigated and validated. Numerical simulations are also conducted to simulate the compression tests and the numerical results show a very good agreement with experiment. Theoretical analyses based on constitutive element method are proposed to predict the crush resistance of multi-cell columns and the theoretical predictions compare very well with the experimental and numerical results.

response of rectangular and square stiffened plates supported on two opposite edges”, Thin-Walled Structures, Vol. 68, pp 164-182, July 2013, DOI: 10.1016/j.tws.2013.03.007

ABSTRACT: Experimental drop weight impact tests have been performed to examine the dynamic response of small-scale stiffened plates struck laterally by a mass with a spherical indenter. The laboratory results are compared with numerical simulations. The plates stiffened with a flat bar or L profile are supported at two opposite edges and impacted at different velocities and locations along the span. The impact scenarios could represent incidents in marine structures, such as load actions due to dropped objects on decks. The experiments are conducted using a fully instrumented impact testing machine. The obtained force–displacement responses show a good agreement with the simulations performed by the LS-DYNA finite element solver. The finite element model includes defining the experimental boundary conditions so as to simulate small axial displacements of the specimen at the supports. This representation can be used to analyze the structural crashworthiness of similar marine structures under collision scenarios. The strain hardening of the material is defined using experimental data of quasi-static tension tests and the strain rate sensitivity is evaluated using standard coefficients of the Cowper–Symonds constitutive model. The results show that the plastic response of the specimens is highly sensitive to the amount of restraint provided at the supports. Furthermore, it is found that in most of the specimens the contribution of the stiffeners to the impact response is insignificant, since the ends of the stiffener are free at the unsupported edges and the specimens experience small axial displacements at the supports.

ABSTRACT: A numerical study on the elastic buckling behaviour of simply supported cylindrically curved panels, with longitudinal edges unconstrained and loaded edges constrained, including the influence of curvature, aspect ratio and loading type (from pure compression to full in-plane bending) is presented in this paper. Subsequently, an extension of rules for internal plated members’ critical stress calculation from EN 1993-1-5 is proposed that takes into account the effect of curvature. The proposed approach, based on the numerical results, gives a safe but accurate estimate (lower bound) for the elastic critical stress.

“Theoretical model and investigation of concrete filled stub columns under axial force-torsion combined action”, Thin-Walled Structures, Vol. 69, pp 1-9, August 2013, DOI: 10.1016/j.tws.2013.03.005

ABSTRACT: Concrete filled steel tube (CFST) columns are currently being widely used in the construction of modern buildings and bridges. In practice, the torsion effect will be often created in CFST columns when the horizontal earthquake happened. Based on geometrical, material constitutive and equilibrium equations, a theoretical model called laminated tubes model for analyzing the mechanical behavior of CFST columns under axial force–torsion combined action was proposed. The confined effect provided by the steel tube and the compression softening effect of the concrete could be considered in the proposed concrete material model. Based on the theoretical model, the non-linear analysis program was developed for obtaining the entire loading
history of CFST columns under axial force–torsion combined action. The predicted results have good agreement with test results. The torsion behavior of CFST columns was detailed discussed based on the theoretical model, and the simplified formulae for practical design are also proposed based on regression methods.

M.F. Hassanein and O.F. Kharoob (Department of Structural Engineering, Faculty of Engineering, Tanta University, Tanta, Egypt), “Flexural strength of hollow tubular flange plate girders with slender stiffened webs under mid-span concentrated load”, Thin-Walled Structures, Vol. 69, pp 18-28, August 2013
DOI: 10.1016/j.tws.2013.03.016

ABSTRACT: A three-dimensional elastic finite element (FE) model, considering merely the geometric nonlinearity, is used in the first part of this paper to study the overall buckling resistance of hollow tubular flange plate girders (HTFPGs). Modeling is conducted using the general-purpose FE software package ABAQUS under mid-span concentrated loads. The developed model consists of the type and number of elements that allows capturing the different possible buckling mode patterns including local, interactive and lateral-torsional buckling. Finite element results revealed that, unlike the case of conventional beams with solid webs, the moment-gradient factor $C_b$ is significantly influenced by the girder geometry and slenderness. Hence, an equation representing the $C_b$ factor for the case of HTFPGs with slender stiffened webs is proposed. The paper extends to investigate the nonlinear flexural strengths of such girders. The results are compared to the AISC predictions. The original AISC predictions are found to be highly conservative using the code recommended $C_b$ value as well as the current proposed value. However, the suggested AISC strength (found in Hassanein et al., 2013 [1]) using $C_b=1.35$ is found to be the best among other values but it suffers from the discontinuity in the flexural strength-unbraced length relationship. Accordingly, a line representing the middle part of this relationship is currently assumed. Comparisons with FE results indicate that the currently proposed AISC method can fairly predict the flexural strength of the HTFPGs with slender stiffened webs.

DOI: 10.1016/j.tws.2013.03.015

ABSTRACT: Cold-formed stainless steel members are widely used due to their high corrosion resistance and high resistance-to-weight ratio but their susceptibility to buckle implies that instability phenomena such as web crippling, where the web locally buckles due to concentrated transverse forces, must be considered. On the other hand, the emergent ferritic stainless steel has very low nickel content and therefore, they are cheaper and relatively price stable compared to austenitics and duplex. Their promising future has aimed to develop efficient design guidance and as a result, a new unified web crippling resistance expression based on numerical simulations and thereafter validated with experimental results has been proposed.

ABSTRACT: Two kinds of tubular structures were axially compressed under impact condition, where type-A structure consisted of hat shaped part and flat plate and type-B consisted of two similar hat parts. They were constructed with adhesive. Sheet materials were A1050 and A5052. The crush strength was greater in type-B. Separation of bonded flange was almost suppressed in A1050 type-A and -B structures, though it was highly visible for A5052 structure, especially in type-A. Predicted deformation behavior with separation behavior of the bonded flange by finite element method well agreed with the corresponding experimental result.

Chih-Pong Wu, Yen-Cheng Chen and Shu-Ting Peng (Department of Civil Engineering, National Cheng Kung University, Tainan 70101, Taiwan, ROC), “Buckling analysis of functionally graded material circular hollow cylinders under combined axial compression and external pressure”, Thin-Walled Structures, Vol. 69, pp 54-66, August 2013, DOI: 10.1016/j.tws.2013.04.002

ABSTRACT: The unified formulations of finite cylindrical layer methods (FCLMs) based on the Reissner mixed variational theorem (RMVT) and the principle of virtual displacements (PVD) are developed for the three-dimensional (3D) linear buckling analysis of simply-supported, multilayered functionally graded material (FGM) circular hollow cylinders and laminated composite ones under combined axial compression and external pressure. In this work, the material properties of the FGM layer are assumed to obey the power-law distributions of the volume fraction of the constituents through the thickness coordinate, and full kinematic nonlinearity is also considered. The accuracy and convergence of the RMVT- and PVD-based FCLMs are assessed by comparing their solutions with both the exact 3D and accurate two-dimensional (2D) solutions available in the literature. A parametric study for variations of the lowest critical load parameters with the material-property gradient index, the load intensity, and the orthotropic, length-to-radius, and radius-to-thickness ratios is carried out.

ABSTRACT: A design method for continuous profiled decking based on post-elastic moment re-distribution is presented. This method is based on that permitted in EN 1993-1-3: Eurocode 3, and in this paper, its application to highly stiffened composite deck profiles is explored. The new aspect is the way in which the residual negative bending moment is established at high rotations using a non-linear moment–rotation stiffness relationship. Tests on three modern deck profiles of 80 mm depths are presented. It was found that the degree of redistribution of negative moment can be high, and so the stiffness coefficient used for deflection calculations should also reflect the degree of redistribution of moment that occurs at the serviceability limit state.

ABSTRACT: The deformed geometry often is the most important information for applications of highly flexible plates/shells, and a geometrically exact shell theory should be displacement-based in order to directly
and exactly describe any greatly deformed geometry. The main challenges of modeling a shell undergoing large deformation are how to describe its deformed reference plane and its differential element's large rotations and how to derive objective strains in terms of global displacements and rotations that contain both elastic straining and rigid-body movement. This paper presents a truly geometrically exact displacement-based shell theory without singularity problems. The theory fully accounts for geometric nonlinearities, all possible initial curvatures, and extensionality by using Jaumann strains and stresses, exact coordinate transformation, and orthogonal virtual rotations. Moreover, transverse shear deformations are accounted for by using a high-order shear deformation theory. The derived fully nonlinear strain–displacement relations enable geometrically exact forward analysis (obtaining the deformed geometry under a set of known loads) and inverse analysis (obtaining the required loads for a desired deformed geometry). Several numerical examples are used to demonstrate the accuracy and capabilities of the geometrically exact shell theory. Moreover, different theoretical and numerical problems of other geometrically nonlinear shell theories are shown to be mainly caused by the use of Mindlin plate theory to account for transverse shears, Green–Lagrange strains to account for geometric nonlinearities, and/or Euler and Rodrigues parameters to model large rotations.

ABSTRACT: This study presents detailed and rigorous numerical analysis for a parametric series of unstiffened aluminium plates typical of those used in lightweight ships and equivalent thin walled stiffened structures. The study is undertaken with a nonlinear finite element analysis procedure using ABAQUS. The strength behaviour of the plates under a progressively increasing longitudinal in-plane load are shown to be affected by a number of parameters including the alloy, geometric imperfection shape, heat affected zone distribution, level of heat softening and residual stress distribution. The comparative influences of these various factors, some of which are specific to welded aluminium structure, are explored to determine which must be accounted for in the development of a parametric series of design curves.

Kojiro Uenaka (Department of Civil Engineering, Kobe City College of Technology, Gakuenhigashimachi 8-3, Nishi, Kobe 6512194, Japan), “Concrete filled double skin circular tubular beams with large diameter-to-thickness ratio under shear”, Thin-Walled Structures, Vol. 70, pp 33-38, September 2013
DOI: 10.1016/j.tws.2013.04.009
ABSTRACT: Concrete filled double skin circular tubular (CFDST) members consist of double concentric circular steel tubes with concrete sandwiched between them. Having hollow cross-section, CFDST members are lighter than ordinary concrete filled steel tubular (CFT) members, which have solid cross-sections. Therefore, by alleviating seismic force against the foundation during earthquake, CFDST members can be effectively applied to seismic resistant structures such as a high raise bridge pier. The present study aims to investigate shear characteristics of deep CFDST beams experimentally through an asymmetric static four-point loading test. Two main parameters were selected, namely, the diameter-to-thickness and the inner-to-outer diameter ratios. The results showed that the shear resistance of CFDST gradually decreased as inner-to-outer diameter ratio increased. Methods to predict the shear resistance of deep CFDST beams are also provided. Additionally, stress histories of both tubes are discussed based upon their elasto-plastic stress behavior under plane stress condition.

ABSTRACT: Gap between the steel tube and concrete core can be considered as a kind of initial concrete imperfection in concrete-filled steel tubular (CFST) structures. This paper performs a nonlinear analysis of CFST stub columns with a circumferential gap or spherical-cap gap under axial compression. A nonlinear finite element model is developed, where the nonlinear material behaviour and the effect of gap on the interface behaviour of the concrete and steel tube are included. Close agreement is achieved between the test and calculated results in terms of load-deformation response and ultimate strength. In light of the numerical results, the behaviour of CFST columns with a circumferential gap or spherical-cap gap is analysed. Parametric studies are then carried out to investigate the influence of different parameters on the ultimate strength of CFST stub columns with gaps. Finally, the maximum limit of the gap ratio is proposed for CFST stub columns with circumferential gaps, and a simplified formula is proposed to estimate the effect of spherical-cap gap on the ultimate strength of CFST stub columns as well.

Yang Zhao, Xiang Lei, Zhen Wang and Qing-shuai Cao (Space Structures Research Center, Zhejiang University, Hangzhou 310058, China), “Buckling behavior of floating-roof steel tanks under measured differential settlement”, Thin-Walled Structures, Vol. 70, pp 70-80, September 2013
DOI: 10.1016/j.tws.2013.04.015
ABSTRACT: Large vertical cylindrical steel tanks constructed on soft foundations may bring forth various types of settlement, which is well known as the uniform settlement, the planar tilt and the differential settlement. Measured settlements of steel tanks in several practical projects are first summarized according to the in-site surveying data, and two kinds of settlement patterns are clearly defined, which are referred to as the global differential settlement and the localized differential settlement. Two practical floating-roof steel tanks are taken as the illustrative examples of large steel tanks, which are marked TK-2020 with the height-to-radius ratio of 0.35 as the representatives of large volume tanks and TK-2090 with the height-to-radius ratio of 0.7 as representatives of smaller volume tanks in this paper. Buckling behaviors of the two illustrative tanks under the global and localized differential settlement are investigated using the general-purpose finite element computer package ABAQUS by means of the geometrical nonlinearity algorithm. It is shown that for tanks under global differential settlement, local buckling occurs first at the eave wind girder, followed by a stable post-buckling behavior, so that the local buckling of the wind girder can be taken as the serviceability limit state and the post-buckling strength can be utilized in structural design of tanks. Moreover, the behavior of tanks under localized differential settlement is related to the degree of localization. The buckling behavior in the case of a large circumferential central angle for localized settlement is similar to that under global differential settlement, while the effect of the localized settlement with a relatively small central angle is more obvious than that of the global differential settlement, and the snap-through buckling induced by localized settlement would govern the design.

M.F. Hassanein and O.F. Kharoob (Department of Structural Engineering, Faculty of Engineering, Tanta University, Tanta, Egypt), “Shear capacity of stiffened plate girders with compression tubular flanges and slender webs”, Thin-Walled Structures, Vol. 70, pp 81-92, September 2013, DOI: 10.1016/j.tws.2013.04.013
ABSTRACT: In this paper, finite element (FE) investigation is conducted to study the shear behaviour of compression hollow tubular flange plate girders (CHTFPGs) using ABAQUS software. The compression and tension flanges are formed from tubular and flat plate, respectively. First, a comparison is made between the CHTFPGs and plate girders with flat flanges (IPGs). This comparison indicated that CHTFPGs provide higher strengths and consequently provide weight savings compared to IPGs. A parametric study is, then, carried out on simply supported CHTFPGs regarding the span length, the flange dimensions, and the thickness and the aspect ratio of the web. From this study, the key parameters affecting the behaviour and the strength of CHTFPGs are discussed. The shear strengths of the CHTFPGs are determined from the current FE models and then compared to the unfactored design strengths computed according to Eurocode 3. It is found that the predictions following the European specifications are conservative compared to the FE strengths. The FE strengths are also compared with the strength recently proposed by the current authors for girders with upper and lower tubular flanges (HTFPGs). The comparison indicates that the later strength is unconservative compared with the FE strengths. Accordingly, a design method is suggested to calculate the nominal shear strengths of the CHTFPGs based on their FE strengths and the strength results of additionally generated equivalent plate girders with upper and lower flat flanges (IPGs). The suggested design method is found to give more accurate predictions for the shear strengths of the CHTFPGs.

Hossein Khalilpasha and Faris Albermani (School of Civil Engineering, The University of Queensland, Australia), “Hyperbaric chamber test of subsea pipelines”, Thin-Walled Structures, Vol. 71, pp 1-6, October 2013, DOI: 10.1016/j.tws.2013.05.001

ABSTRACT: An experimental study of buckle propagation in subsea pipelines is presented in this paper. The experimental protocol consists of two types of experiments; hyperbaric chamber and ring squash tests. Intact and dented steel and aluminium pipes with different diameter-to-thickness ratio are used in these tests. The experimental results are presented and compared with available analytical and empirical solutions. The sensitivity of buckle initiation to initial geometric imperfection is evaluated. The evolution of hoop and longitudinal strain during buckle propagation is presented to show the extent of plastic deformations.

“Design of thin wall structures for energy absorption applications: Enhancement of crashworthiness due to axial and oblique impact forces”, Thin-Walled Structures, Vol. 71, pp 7-17, October 2013
DOI: 10.1016/j.tws.2013.04.003

ABSTRACT: This paper describes a computationally aided design process of a thin wall structure subject to dynamic compression in both axial and oblique directions. Several different cross sectional shapes of thin walled structures subjected to direct and oblique loads were compared initially to obtain the cross section that fulfills the performance criteria. The selection was based on multi-criteria decision making (MCDM) process. The performance parameters used are the absorbed crash energy, crush force efficiency, ease of manufacture and cost. Once the cross section was selected, the design was further enhanced for better crash performances by investigating the effect of foam filling, increasing the wall thickness and by introducing a trigger mechanism.
The outcome of the design process was very encouraging as the new design was able to improve the crash performance by an average of 10%.

ABSTRACT: An exact dynamic stiffness element based on higher order shear deformation theory and extensive use of symbolic algebra is developed for the first time to carry out a buckling analysis of composite plate assemblies. The principle of minimum potential energy is applied to derive the governing differential equations and natural boundary conditions. Then by imposing the geometric boundary conditions in algebraic form the dynamic stiffness matrix, which includes contributions from both stiffness and initial pre-stress terms, is developed. The Wittrick–Williams algorithm is used as solution technique to compute the critical buckling loads and mode shapes for a range of laminated composite plates including stiffened plates. The effects of significant parameters such as thickness-to-length ratio, orthotropy ratio, number of layers, lay-up and stacking sequence and boundary conditions on the critical buckling loads and mode shapes are investigated. The accuracy of the method is demonstrated by comparing results whenever possible with those available in the literature.

Iman Shamim and Colin A. Rogers (Department of Civil Engineering & Applied Mechanics, McGill University, Macdonald Engineering Building, 817 Sherbrooke Street, Montreal, QC, Canada H3A 0C3), “Steel sheathed/CFS framed shear walls under dynamic loading: Numerical modeling and calibration”, Thin-Walled Structures, Vol. 71, pp 57-71, October 2013, DOI: 10.1016/j.tws.2013.05.007

ABSTRACT: This paper describes the numerical modelling using OpenSees of shear walls constructed of cold-formed steel (CFS) framing and flat steel sheathing. The first phase comprised non-linear models calibrated using existing reversed cyclic shear wall test data. The second phase involved more advanced models calibrated using data from dynamic shake table tests of single- and double-storey shear walls and additional ancillary component testing. These advanced models were able to accurately reproduce the shear strength and displacement time history and hysteretic response of the dynamically tested shear walls. The use of a building model that incorporates the second phase wall models is demonstrated for the evaluation of representative CFS framed structures using non-linear time history dynamic analyses.

DOI: 10.1016/j.tws.2013.05.004

ABSTRACT: Buckling of thin-walled sections in pure shear has been recently investigated using the Semi-Analytical Finite Strip Method (SAFSM) to develop the “signature curve” for sections in shear. The method assumes that the buckle is part of an infinitely long section unrestrained against distortion at its ends. For sections restrained at finite lengths by transverse stiffeners or other similar constraints, the Spline Finite Strip Method (SFSM) has been used to determine the elastic buckling loads in pure shear. These loads are higher than those from the SAFSM due to the constraints. The SFSM requires considerable computation to achieve the buckling loads due to the large numbers of degrees of freedom of the system. In the 1980s, Anderson and
Williams developed a shear buckling analysis for sections in shear where the ends are simply supported based on the exact finite strip method. The current paper further develops the SAFSM buckling theory of Y.K. Cheung for sections in pure shear accounting for simply supported ends using the methodology of Anderson and Williams. The theory is applied to the buckling of plates of increasing length and channel sections in pure shear also for increasing length. The method requires increasing numbers of series terms as the sections become longer. Convergence studies with strip subdivision and number of series terms is provided in the paper.

Abolfazi Darvizeh, Mansour Darvizeh, Reza Ansari and Ata Meshkinzar (Department of Mechanical Engineering, University of Guilan, P.O. Box 3756, Rasht, Iran), “Effect of low density, low strength polyurethane foam on the energy absorption characteristics of circumferentially grooved thick-walled circular tubes”, Thin-Walled Structures, Vol. 71, pp 81-90, October 2013, DOI: 10.1016/j.tws.2013.04.014
ABSTRACT: In this paper, analytical and experimental investigations are performed on the energy absorption characteristics of circumferentially grooved thick-walled circular tubes filled with low density and very low strength polyurethane foam typical of cushioning material. Thick-walled grooved tubes filled with low density foam are prepared for experiments. The results are also compared with the ones for the geometrically identical empty tubes. Employing the Taguchi method for designing the geometrical parameters of the specimens leads to a suitable range of groove length-to-wall thickness ratios to be covered. Based on the concept of energy dissipation through the circumferential plastic hinges during the successive folding of the specimens, an analytical approach is proposed. In addition, the amount of energy dissipated due to the interaction between tube metal and foam material is expressed by a conventional semi-empirical equation. A new constant, \( C_{av},Cav \), for low strength foam material is found by fitting the experimental data. The modified analytical model is in reasonable agreement with the experiments. This may indicate the validity of the proposed analytical model. The obtained results show that grooved thick-walled tubes filled with low strength foams can offer favorable energy absorption capacity and stability. Euler buckling is prevented due to the grooves and specific energy absorption is increased approximately twice that of the empty tubes. Structural effectiveness is increased nearly two times that of the empty tubes.

Tarek Sharaf and Amir Fam (Department of Civil Engineering, Queen’s University, Kingston, ON, Canada), “Analysis of large scale cladding sandwich panels composed of GFRP skins and ribs and polyurethane foam core”, Thin-Walled Structures, Vol. 71, pp 91-101, October 2013, DOI: 10.1016/j.tws.2013.05.006
ABSTRACT: This paper addresses the numerical modeling of lightweight sandwich panels intended for cladding of buildings. The proposed sandwich panels are composed of woven glass fiber reinforced polymer (GFRP) skins and ribs and soft polyurethane foam core, which provides excellent insulation. The panels are designed to resist wind loading. A robust 3D FE model was developed for the large scale panels (9145×2440×78 mm\(^3\)) tested under transverse loading. The model accounts for material nonlinearities; most pronounced in the soft polyurethane core and in the [0/90] GFRP ribs under shear, as well as geometric nonlinearities in the form of a reduction in panel thickness due to the soft core. The model captures both stability and material failure modes, essentially skin wrinkling and crushing in compression. It was then successfully validated using experimental results. Failure of the tension skin never occurred in this type of panels as compression skin wrinkling and crushing consistently governed. The cladding panel was shown to satisfy design code requirements in terms of strength and stiffness.
ABSTRACT: The buckling behavior of quadrilateral laminated thin-to-moderately thick plates composed of perfectly bonded carbon nanotube reinforced composite (CNTRC) layers is studied. The stability equations are derived using the adjacent equilibrium (Trefitz) buckling criterion and based on the first-order shear deformation theory (FSDT) of plates. Four different profiles of the single walled carbon nanotubes (SWCNTs) distribution through the thickness of layers are considered, which include their uniform distribution (UD), functionally graded (FG) symmetric and asymmetric distributions. The stability equations subjected to arbitrary boundary conditions are discretized by employing a mapping-differential quadrature technique. The formulation and method of solution are validated by showing their fast rate of convergence and performing comparison studies with the available results in the open literature wherever possible. In addition, analytical solution for the simply supported symmetric laminated rectangular plate with CNTRC layers is derived and excellent agreement of the numeric results with the analytical solution is exhibited. Then, the effects of volume fraction of carbon nanotubes (CNTs), geometrical shape parameters, thickness-to-length ratio, different kinds of CNTs distribution along the layers thickness and boundary conditions on the critical buckling load of the quadrilateral laminated plates are investigated.

ABSTRACT: The paper concerns the load capacity analysis of thermally loaded multilayered plates and shells. The multilayered body is treated as an equivalent single layer whose kinematics is consistent with the first-order shear deformation theory. The authors focus on the thermo-elastic stability problem of the thin-walled structures. The equilibrium paths are traced with the use of Riks–Wempner–Ramm algorithm. By making use of the Tsai–Wu hypothesis the material's strength examination is included in the study. The considered problems are resolved with the authors' program. The presented results confirm that proposed model can be very effective in the stability analysis of multilayered panels.

ABSTRACT: Expanded metal tubes have a great potential for energy absorbing applications. A study on the energy absorption capacity of axially compressed expanded metal tubes is conducted herein; the investigation is performed through nonlinear finite element analyses. At first, the numerical models are validated with experimental results, thereafter a parametric study is carried out in order to investigate the effects of the length-to-diameter ratio, on both the peak forces and the energy absorption capacity of the tubes. The numerical results are also compared with those obtained using a mechanical model found in the literature. Finally, it is found that peak loads and energy absorption capacity depends on the number of expanded metal cells in the cross-section. The results also show that, concentrical expanded tubes could be an effective mean to enhance energy absorption capacity.

“Experimental investigation of channel-section composite profiles’ behavior with various sequences of plies subjected to static compression”, Thin-Walled Structures, Vol. 71, pp 147-154, October 2013
DOI: 10.1016/j.tws.2013.07.008

ABSTRACT: This paper deals with the buckling of thin-walled channel-section composite columns subjected to static compression. It was assumed that the columns were supported with articulated joints at both ends. For experimental testing, three series of specimens were manufactured with autoclaving technique. The specimens had identical dimensions but differed about ply sequence. The Hexcel's HexPly M12 carbon-epoxy prepreg was used in order to fabricate the channel-section profiles. During the stand tests minimal critical forces of the real structure and the corresponding buckling modes were determined with an application of electrical strain gauges. In addition, post-critical equilibrium paths for small overloads—150% of the critical load for the ideal structure—were determined. The experimental results were compared to the ones obtained numerically with the finite element method (FEM).

“Experimental and numerical analysis on the structural behaviour of cold-formed steel beams”, Thin-Walled Structures, Vol. 72, pp 1-13, November 2013, DOI: 10.1016/j.tws.2013.06.008

ABSTRACT: A research study on the structural behaviour of cold formed steel beams with C-, I-, R- and 2R-shaped cross-sections at ambient temperature is presented, based on the results of a large programme of experimental tests and numerical simulations. Firstly, several four-point bending tests were carried out in order to assess mainly the failure loads and failure modes of the beams. Secondly, a suitable finite element model was developed to compare with the experimental results, and finally, a parametric study was undertaken in order to investigate the influence of the thickness, height and length of the beams on its structural behaviour.

ABSTRACT: Carbon fiber reinforced polymer (CFRP) composites are considered to have high performance and potential for use in strengthening, retrofitting and for the rehabilitation of structural sections. In this paper, design procedures are proposed for the axial load capacity of cold formed steel lipped channel columns strengthened with carbon fiber reinforced polymer (CFRP). For the purpose of validation, the results are based on the proposed design equation from the North American specification for the design of cold-formed steel structural members (AISI-2007) and Euro code for cold-formed members and sheeting (EC3-EN1993-1-3:2006) are compared against the experimental test data. The test results showed that the capacity of the columns are close to the theoretical values predicted by the AISI-2007 and EC 3 provisions. Some tested specimens showed reduced capacity and premature failure due to peeling and debonding of the CFRP from the
Rahman Seifi and Ali Reza Kabiri (Faculty of Engineering, Bu-Ali Sina University, Hamedan, Iran), “Lateral load effects on buckling of cracked plates under tensile loading”, Thin-Walled Structures, Vol. 72, pp 37-47, November 2013, DOI: 10.1016/j.tws.2013.06.010
ABSTRACT: Fractured thin plates may be buckled locally due to applying the tensile loads in certain conditions. Sometimes the buckling mode can occur before fracturing or collapsing. Lateral loads can affect the buckling loads and modes. In thin cracked plates, compressive stress region near the crack or defect can be changed due to the lateral loads, so critical local buckling loads can be increased or decreased. Experimental and numerical study of the buckling load of plates with central crack under axial tensile loading is done. Effects of lateral load and constraint, relative crack length and its direction are investigated.

“Numerical buckling analysis of an inflatable beam made of orthotropic technical textiles”, Thin-Walled Structures, Vol. 72, pp 61-75, November 2013, DOI: 10.1016/j.tws.2013.06.014
ABSTRACT: This paper is devoted to the linear eigen and nonlinear buckling analysis of an inflatable beam made of orthotropic technical textiles. The method of analysis is based on a 3D Timoshenko beam model with a homogeneous orthotropic woven fabric. The finite element model established here involves a three-noded Timoshenko beam element with $C^0$-type continuity for the transverse displacement and quadratic shape functions for the bending rotation and the axial displacement. In the linear buckling analysis, a mesh convergence test on the beam critical load was carried out by solving the linearized eigenvalue problem. The stiffness matrix in this case is generally assumed not to be a function of displacements, while in the nonlinear buckling problem, the tangent stiffness matrix includes the effect of changing the geometry as well as the effect of the stress stiffening. The nonlinear finite element solutions were investigated by using the straightforward Newton iteration with the adaptive load stepping for tracing the load–deflection response of the beam. To assess the effect of geometric nonlinearities and the inflation pressure on the stability behavior of inflatable beam: a simply supported beam was studied. The influence of the beam aspect ratios on the buckling load coefficient was also pointed out. To check the validity and the soundness of the results, a 3D thin-shell finite element model was used for comparison. For a further validation, the results were also compared with those from experiments at low inflation pressures.

“Exploring the constancy of the global buckling load after a critical geometric imperfection level in thin-walled
ABSTRACT: Some of the knock-down factors applied in design of rocket launcher structures are based on design recommendations which rely on lower-bound curves from experimental data. The best known example is the NASA guideline SP 8007, published in 1965 and revised in 1968, which is applied for cylindrical structures in the space industry. This guideline is based on test data, computational methods and resources from the 1930–1960’s. At that time the application of less empirical methods for the design of actual cylindrical shells could not count with the current computational power, and the available methods led to quite large discrepancies between experiments and test observations. Significant improvement on the available analyses approaches and manufacturing techniques since 1960’s have not been taken into account in design processes using the NASA SP-8007, and many authors have recognized that for the current standards this guideline is leading to conservative structures. Another aspect for attention regarding application of the NASA SP-8007 for composite shells is that it does not consider the laminate stacking sequence. Moreover, physical observations regarding how does the imperfection sensitivity of unstiffened cylindrical shells change with the presence of an induced geometric imperfection have also suggested that the current applied design rules are too conservative. This conservativeness is confirmed by many tests carried out recently. This study presents an overview of the problem and a detailed description of the physical observations regarding the buckling mechanism of the thin shells under consideration. It is discussed how these observations can be used for less conservative, laminate dependent, knock-down factors accounting for geometric imperfections. The single perturbation load approach is studied in detail and a physically based definition for the minimum perturbation load ($P_1$) is given, paving the way for the development of semi-analytical methods to calculate this minimum perturbation load.

DOI: 10.1016/j.tws.2013.06.009
ABSTRACT: Through a programme of experiments, numerical modelling and parametric studies, the implications of allowing for strain-hardening in the design of laterally restrained steel beams is investigated with particular emphasis on the performance of the bracing elements. A total of twelve tests were performed on simply supported beams considering two basic scenarios: discrete rigid restraints and discrete elastic restraints of varying stiffness. In the latter case, the forces developed in the restraints were measured and compared to the design forces specified in EN 1993-1-1 (2005). Two different restraint spacings were considered in the tests to give non-dimensional lateral torsional slenderness values of 0.3 and 0.4 for the unrestrained lengths. In all tests, bending resistances in excess of the plastic moment capacity were observed, but for the considered restraint spacings, the resistances often fell short of that predicted by the deformation-based continuous strength method (CSM), which allows for strain-hardening. It was concluded that closer restraint spacing may be required to harness significant benefit from strain-hardening and to develop the full CSM bending resistance, though the forces generated in the restraints were within current code requirements.

ABSTRACT: This paper is concerned with an approximate method to predict the bending behaviour and ultimate strength of partially connected composite plate girders. Based on curvature compatibility, analytical
solution incorporating post-buckling effect in the webs and different degree of shear connection is presented herein. Slender girders with centrally placed square or circular web openings of various proportions are considered in the analysis. The obtained results are verified against the corresponding ones using the established finite element method. A satisfactory correlation between the findings establishes the accuracy of the proposed method to a certain extent. Results are presented in the form of ultimate strength and load-deflection response for girders with variations in shear connection stiffness.

“Buckle interaction in deep subsea pipelines”, Thin-Walled Structures, Vol. 72, pp 113-120, November 2013
DOI: 10.1016/j.tws.2013.07.003
ABSTRACT: The paper investigates the interaction between propagation buckling and upheaval or lateral buckling in deep subsea pipelines. The upheaval and lateral buckling are two possible global buckling modes in long pipelines while the propagation buckling is a local mode that can quickly propagate and damage a long segment of a pipeline in deep water. A numerical study is conducted to simulate buckle interaction in deep subsea pipelines. The interaction produces a significant reduction in the buckle design capacity of the pipeline. This is further exasperated due to the inherent imperfection sensitivity of the problem.

Ingrit Lillemae, Heikki Remes and Jani Romanoff (Aalto University, School of Engineering, Department of Applied Mechanics, P.O. BOX 15300, FIN-00076 Aalto, Finland), “Influence of initial distortion on the structural stress in 3 mm thick stiffened panels”, Thin-Walled Structures, Vol. 73, pp 121-127, November 2013
DOI: 10.1016/j.tws.2013.07.001
ABSTRACT: This paper investigates the effect of initial distortion on the structural stress in 3 mm thick stiffened panels. The influence of initial distortion shape as well as magnitude is studied under axial tension and compression using geometrically non-linear finite element analysis. Different levels of structures are analyzed starting from the plate strips to an actual panel in order to understand how the structural response of thin initially distorted panel builds up. This way the difference between having initial distortion in one or two directions as well as the effect of boundary conditions becomes visible. The results reveal high non-linearity in the behavior of plate strip models and relatively linear behavior of actual plates and panel models in typical fatigue relevant ranges. This is due to support that the actual structures get from having initial distortion in two directions and from surrounding structures. In case of panels the most important effect on structural stresses near the transverse butt weld is the shape of the initial distortion. The second important is the magnitude of initial distortion and significantly less relevant is the straightening effect, i.e. decrease in structural to nominal stress ratio under loading.

DOI: 10.1016/j.tws.2013.06.020
ABSTRACT: Based on the bending stiffness of socket joints obtained through experiments, the finite element models of single-layer elliptical paraboloid latticed shells with the semi-rigid socket joints are established. Parametric analysis of the latticed shells is carried out using ANSYS. The parameters considered are bending
stiffness, ratio of rise to span, rotation-stiffness, ball size, asymmetric load distribution, tube section, support conditions and initial imperfections. The effects of the different parameters on the critical loads of the shells are thereby identified. Both geometric and material nonlinearity are considered during the analysis. Finally, formulae are derived for the calculation of critical loads of the shells under symmetric and asymmetric loading conditions. This will be useful for the design and application of single-layer latticed shells with semi-rigid joints.

“Finite element model based on coupled refined high-order global-local theory for static analysis of electromechanical embedded shear-mode piezoelectric sandwich composite beams with various widths”, Thin-Walled Structures, Vol. 72, pp 139-163, November 2013, DOI: 10.1016/j.tws.2013.06.001

ABSTRACT: In this study, a new theory for the accurate simulation of the shear-mode behaviour of thin or thick piezoelectric sandwich composite beams is developed. The effects of transverse normal stress and transverse flexibility of layers are considered in the development of the proposed formulation. In order to increase the computational accuracy, all kinematic and stress continuity conditions are satisfied at layer interfaces. Moreover, for the first time, both the electrically induced strain components and the transverse flexibility are taken into account in the proposed formulation. Despite the fact that the number of unknown mechanical parameters in this theory is only one degree higher than the first order shear deformation theory, the accuracy is surprisingly more pronounced for the thicker beams.

ABSTRACT: Glass fiber reinforced polymer (GFRP) pultruded profiles are being increasingly used in civil engineering applications. Although they offer several advantages over traditional materials, such as high strength, lightness and non-corrodibility, GFRP profiles present low elasticity and shear moduli, which together with their slender walls makes them very prone to buckling phenomena. Several previous studies addressed the global and local buckling behavior of GFRP pultruded members under concentric loading. However, little attention has been given to the effect of small eccentricities, which may arise from material geometrical imperfections or construction errors. This paper presents results of experimental and numerical investigations about the structural behavior of GFRP pultruded columns subjected to small eccentric loading about the major (strong) axis. To accomplish such goal, three series of 1.50 m long GFRP I-section (120×60×6 mm) columns were tested in compression applied with the three following eccentricity/height of the cross-section ratios: e/h=0.00, 0.15 and 0.30. It was found that such small eccentricities are of major importance for the behavior of GFRP pultruded columns. Although the initial axial stiffness of eccentrically loaded columns was similar to that of concentrically loaded ones, for increasing loads the stiffness considerably decreased due to bowing and second-order P–δ effects. Furthermore, results show that the load capacity of columns subjected to loads applied within the kern boundaries is reduced up to 40% at an approximately linear trend. Results obtained from
the experimental campaign were compared with analytical predictions and numerical simulations using (i) the finite element method (FEM) and (ii) the generalized beam theory (GBT). In general, a very good agreement was obtained between experimental data and analytical and numerical results.

ABSTRACT: This work presents a state-of-the-art report of the most recent developments concerning formulations, numerical implementations and applications of Generalised Beam Theory (GBT) to analyse the structural response of thin-walled steel members and frames. After a brief overview of the cross-section analysis, one addresses new findings dealing with the use of GBT to assess the (i) first-order behaviour of steel-concrete composite bridge decks, (ii) buckling and post-buckling behaviour of members and frames with arbitrary loading and support conditions, (iii) vibration behaviour of load-free and loaded open-section members and (iv) dynamic behaviour of members subjected to periodic and moving loads. In order to illustrate the unique features and show the potential of the GBT approach, several numerical results are presented and discussed. For validation purposes, most of these results are compared with values yielded by shell finite element analyses, performed in the codes ADINA, ABAQUS and ANSYS.

References listed at the end of the paper:

DOI: 10.1016/j.tws.2013.07.004
ABSTRACT: This paper presents the main steps and procedures involved in the development of a Generalised Beam Theory (GBT) formulation to perform dynamic analyses of thin-walled members subjected to initial perturbations or acting loads. It combines (i) the GBT modal discretisation of the cross-section deformation with (ii) the commonly adopted vibration mode superposition approach – this combination leads to an original “doubly modal” representation of the displacement field, which (i) provides deep insight into the mechanics involved in the dynamic response under consideration and, moreover, (ii) makes it possible to obtain accurate results with surprisingly low degree of freedom numbers. The application and potential of the formulation is illustrated by presenting and discussing numerical results concerning the dynamic responses of cold-formed steel lipped channel beam in several situations, namely (i) the damped oscillations following the release from a deformed configuration, (ii) the action of uniformly distributed loads with periodic (sinusoidal and square-wave) and impulsive (rectangular) time variations, and (iii) the effect of a point load moving along the span with constant speed. For validation purposes, the GBT-based results are compared with values yielded by Ansys shell finite element analyses – the total number of degrees of freedom involved in the GBT analyses was significantly lower.

Batra (Department of Engineering Science and Mechanics, Virginia Polytechnic Institute and State University, MC 0219 Blacksburg, VA 24061, USA), “Transient hydroelastic analysis of sandwich beams subjected to slamming in water”, Thin-Walled Structures, Vol. 72, pp 206-216, November 2013
DOI: 10.1016/j.tws.2013.06.002
ABSTRACT: This work deals with the transient hydroelastic analysis of a sandwich beam which represents a boat hull. The beam is subjected to slamming pressure while it enters into water with constant vertically downward velocity. A coupled hydroelastic finite element model is developed using higher order shear and normal deformation theories for the faces and the core of the beam and the velocity potential theory for the fluid. Transient responses of the beam for transverse deflection and stresses are studied. Dynamic failure analysis has been carried out to investigate the initiation and cause of the failure of the beam due to slamming load.

“GBT-based assessment of the buckling behavior of cold-formed steel purlins restrained by sheeting”, Thin-Walled Structures, Vol. 72, pp 217-229, November 2013, DOI: 10.1016/j.tws.2013.06.005
ABSTRACT: This paper presents and discusses the results of a GBT-based numerical investigation concerning the local, distortional and global buckling behaviour of lipped channel and zed-section cold-formed steel purlins restrained by steel sheeting and subjected to an uplift loading. Strengthened (lapped) joints, commonly employed at internal supports to preclude the occurrence of local/distortional buckling phenomena, are also investigated and an illustrative application of the use of GBT to determine strengthening lengths is also presented. The sheeting restraint is modelled by means of elastic translational and rotational springs, located at the purlin upper flange, and the joint strengthening is modelled by doubling the cross-section wall thickness. For validation, the GBT-based results are compared with values yielded by Ansys shell finite element analyses.
Shanmuganathan Gunalan and Mahen Mahendran (School of Civil Engineering and Built Environment Science and Engineering Faculty, Queensland University of Technology, Brisbane QLD 4000, Australia), “Improved design rules for fixed ended cold-formed steel columns subject to flexural-torsional buckling”, Thin-Walled Structures, Vol. 73, pp 1-17, December 2013, DOI: 10.1016/j.tws.2013.06.013
ABSTRACT: This paper has presented the details of an investigation into the flexural and flexural–fl buckling behaviour of cold-formed structural steel columns with pinned and fixed ends. Current design rules for the member capacities of cold-formed steel columns are based on the same non-dimensional strength curve for both fixed and pinned-ended columns. This research has reviewed the accuracy of the current design rules in AS/NZS 4600 and the North American Specification in determining the member capacities of cold-formed steel columns using the results from detailed finite element analyses and an experimental study of lipped channel columns. It was found that the current Australian and American design rules accurately predicted the member capacities of pin ended lipped channel columns undergoing flexural and flexural torsional buckling. However, for fixed ended columns with warping fixity undergoing flexural–torsional buckling, it was found that the current design rules significantly underestimated the column capacities as they disregard the beneficial effect of warping fixity. This paper has therefore proposed improved design rules and verified their accuracy using finite element analysis and test results of cold-formed lipped channel columns made of three cross-sections and five different steel grades and thicknesses.

ABSTRACT: An arch often has elastic end restraints provided by the connected structures or elastic foundations. When the arch is subjected to an in-plane central concentrated load, the load produces combined non-uniform axial compressive and bending actions with complicated distributions along the arch length and these actions are significantly influenced by the stiffness of the end restraints. These combined axial compressive and bending actions increase with an increase of external loads and may reach the values, at which the arch suddenly deflects laterally and twists out of the plane of loading, and fails in a lateral–torsional buckling mode. Little research of the lateral–torsional buckling of such arches has been reported in the open literature. This paper derives the analytical solution for the elastic lateral–torsional buckling load of pin-ended circular arches with a thin-walled section and having in-plane elastic rotational end restraints under a central concentrated load, using the principle of stationary potential energy in conjunction with the Rayleigh–Ritz method. The analytical solution agrees with independent finite element results very well, which indicates that the analytical solution can provide accurate predictions for the lateral–torsional buckling loads of arches having in-plane rotational end restraints. The effects of the stiffness of rotational end restraints on the lateral–torsional buckling resistance of arches are investigated. It is found that the change of the stiffness of rotational end restraints has significant effects on the lateral–torsional buckling resistance of arches.

ABSTRACT: In this paper in-plane (membrane) shear deformations in thin-walled members are discussed. Unlike many earlier works on the effect of shear deformations, the actual work is based on shell model rather than beam model. Thus, the presented work has no intention to develop a new shear-deformable beam theory, by adding some assumed shear deformations to classical beam degrees of freedom, but the actual research considers the thin-walled member as a set of connected flat plates, the displacement field of which is determined by nodal displacements and shape functions. The goal here is to make a full and meaningful modal decomposition within the given displacement field, i.e., to determine sub-fields within the general displacement field so that deformations within the sub-fields would correspond to some desired buckling or deformation modes. The presented work is therefore the direct extension of constraint finite strip method (cFSM), however, this time having a special focus on the shear modes. Though the presented shear modes are initiated by cFSM, and the presentation utilizes the terminology of cFSM, it is to highlight here that the proposed modal decomposition of in-plane shear deformations is not limited to buckling analysis or to the finite strip method. Indeed, the proposed shear space decomposition can be used in any case when the analysed member is thin-walled, built up from flat plates, is modelled by shell-type elements, and the member is prismatic. Since the flexural behaviour of the plates is assumed to follow Kirchhoff thin plate theory, no out-of-plane shear is considered.

ABSTRACT: The elaborate finite element model of Kiewitt-8 single-layer reticulated dome with span of 40 m subjected to eccentric blast loading was established and all the process from the detonation of the explosive charge to the demolition of reticulated dome structure was reproduced. The blast performance of reticulated dome was numerically studied and two approaches to improve the blast resistant capacity of reticulated dome were discussed. Response types of reticulated dome under eccentric blast loadings were defined. Partially reinforcement of reticulated dome is found to be an effective and economical way to improve its blast resistant capacity compared with fully reinforced reticulated dome. The pre-designed openings on the wall to release blast loading were studied, which provided some guidance on the blast resistant design of such structures.

ABSTRACT: An experimental–numerical investigation of the ballistic impact of 7.62×51 mm soft-core ball 9.5 g projectiles on aluminium tubes is presented in this paper. The tubes are made of Al-6061-T6 and simulate actual components of a helicopter tail rotor drive shaft. Several tests have been carried out: a real gun has been used to produce ordnance velocities and a dedicated support frame has been built to perform impact tests with an angle of obliquity (in order to reproduce the most critical damage on the component that is subjected to torsional service load). Initial and residual velocity of the bullets, shape and dimensions of the damage, and the residual stresses on the components, have been measured. Numerical models of the impact have been developed with the commercial Finite Element code ABAQUS/Explicit. The Johnson–Cook (JC) constitutive model and the Bao–Wierzbicki (BW) ductile fracture criterion have been calibrated for Al-6061-T6 and have been used for
the analyses. The effect of the bullet type on the damage has been investigated; therefore the ball bullet has been fully modelled (core and jacket) to highlight the effect and danger of this type of soft core bullet in case of impact against aluminium thin structures. Numerical models are in good agreement with the experimental results; more specifically they show a satisfactory capability to reproduce the residual velocity of the bullets and the failure mode, as well as the residual stress fields on the tubes near the damaged zone.

ABSTRACT: The finite element simulation of structures subjected to post-buckling still faces computational limits, especially for large stiffened structures. Several solving strategies have already been proposed in response to this issue. Among them are the adaptive model reduction solving techniques which demonstrated their ability to drastically reduce the number of unknowns as well as to control the approximation error of solving non-linear problems like post-buckling. The challenges regarding these techniques are the computation of a reduced basis at lower cost, the use of an efficient adaptive procedure and the limitation of the number of call to the adaptive procedure. This paper proposes a Post-Buckling Adaptive Model Reduction (PBAMR) strategy, which requires only two initial Ritz vectors without compromising the accuracy of the simulation. This solving method is tested in the case of shear of a stiffened panel.

ABSTRACT: Adding complex sinusoidal patterns on wall surfaces has been recently suggested in literature as an effective innovation for improving energy dissipation of thin walled box beams during axial collapses. This paper studies the energy absorption efficiency and performance of patterned beams under pure bending. A numerical investigation is carried out using commercially available Marc Mentat solver and the investigation is also verified using existing analytical models. Five different types of patterns are tested. The result of adding patterns on individual and combination of walls and the effect of progressive triggering proposed previously in literature on the maximum bending moment of the beam is also studied. Results indicate that the beams with sinusoidal patterns are significantly better in energy absorption in deep bending collapse; an increase of about 53.49% at 0.6 rad is noted in the optimal case. The pattern types which had higher energy absorption in axial impact reflect the same trend in bending collapses. This research may further endorse the viability of using sinusoidal patterned beams in mainstream practical applications.

ABSTRACT: Trapezoidal sheeting of thin-walled steel is applied frequently for roofing and cladding. As such, it is loaded by a concentrated load (at the support) and a bending moment. A recently developed model to predict the sheeting’s failure behaviour leaves the question open whether mode jumping (the phenomenon where a plate dynamically changes its buckling mode during an increasing load) should be taken into account in the model. This article presents the analytical and finite element modelling of square and long plates, which, depending on the boundary conditions, may represent the compressed flange of trapezoidal sheeting. The analytical modelling is based on the combination of several displacement functions and using the principle of minimal potential energy. Hereafter the stability of each part of the resulting equilibrium curves is determined. A spin-off of the analytical model is an analytical expression for a current curve-fitted based prediction formula for the post/pre-buckling stiffness ratio by Rhodes. Furthermore, the accuracy range of a solution by Williams and Walker for the far-post buckling behaviour can be confirmed. The finite element modelling has been carried out by implicit dynamic, and explicit (dynamic) simulations. Both for the load levels and the buckling mode sequences, the analytical and finite element models give equivalent results. It is concluded that for the specific boundary conditions that represent the situation of a compressed flange for trapezoidal sheeting, it is very likely that mode jumping will not occur.

ABSTRACT: This paper is focused on the lateral-torsional buckling of cracked or weakened elastic beams. The crack is modelled with a generalised elastic connection law, whose equivalent stiffness parameters can be derived from fracture mechanics considerations. The same type of generalised spring model can be used for beams with semi-rigid connections, typically in the fields of steel and timber engineering. As the basis for the present investigation, we consider a strip beam with fork end supports and exhibiting a single vertical edge crack, subjected to uniform bending in the plane of greatest flexural rigidity. We adopt both direct and variational approaches. In the former, conducted within the framework of the Kirchhoff–Clebsch theory, the effect of prebuckling curvature is taken into consideration. This effect is subsequently neglected in the variationally based analyses. First, the three-dimensional elastic connection law adopted is a direct extension of the planar case, which leads to a paradoxical conclusion: the critical moment is not affected by the presence of the crack, regardless of its location. It is shown that the above paradox is due to the non-conservative nature of the connection model adopted (in the sense that the connection law cannot be derived from a potential). Simple alternatives to this cracked-section constitutive law are proposed, based on conservative moment-rotation laws (quasi-tangential and semi-tangential) and consistent variational arguments. Only one of the proposed alternatives leads to a critical moment that depends on both the torsional and flexural stiffnesses of the spring modelling the cracked cross-section. The analyses are always conducted analytically, yielding closed-form characteristic equations for the buckling moments.
Poolanganthan Keerthan and Mahen Mahendran (Science and Engineering Faculty, Queensland University of Technology, Brisbane, QLD 4000, Australia), “Experimental studies of the shear behaviour and strength of lipped channel beams with web openings”, Thin-Walled Structures, Vol. 73, pp 131-144, December 2013
DOI: 10.1016/j.tws.2013.06.018

ABSTRACT: Cold-formed steel members are increasingly used as primary structural elements in the building industries around the world due to the availability of thin and high strength steels and advanced cold-forming technologies. Cold-formed lipped channel beams (LCB) are commonly used as flexural members such as floor joists and bearers. However, their shear capacities are determined based on conservative design rules. Current practice in flooring systems is to include openings in the web element of floor joists or bearers so that building services can be located within them. Shear behaviour of LCBs with web openings is more complicated while their shear strengths are considerably reduced by the presence of web openings. However, limited research has been undertaken on the shear behaviour and strength of LCBs with web openings. Hence a detailed experimental study involving 40 shear tests was undertaken to investigate the shear behaviour and strength of LCBs with web openings. Simply supported test specimens of LCBs with aspect ratios of 1.0 and 1.5 were loaded at mid-span until failure. This paper presents the details of this experimental study and the results of their shear capacities and behavioural characteristics. Experimental results showed that the current design rules in cold-formed steel structures design codes are very conservative for the shear design of LCBs with web openings. Improved design equations have been proposed for the shear strength of LCBs with web openings based on the experimental results from this study.

“Improved fire resistant performance of load bearing cold-formed steel interior and exterior wall systems”, Thin-Walled Structures, Vol. 73, pp 145-157, December 2013, DOI: 10.1016/j.tws.2013.07.017

ABSTRACT: In order to improve the fire performance of load-bearing CFS wall systems for applications in mid-rise buildings, different panels and external insulation were examined in this paper. Experiments on six full-scale CFS wall specimens were performed in which the insulation material of aluminum silicate wool was located outside the CFS frame and sandwiched between two layers of boards on the fire side instead of being placed in the cavity. Five types of panels were involved in the experiments, including gypsum plasterboard, bolivian magnesium board, oriented standard boards (OSB), autoclaved lightweight concrete (ALC) boards and rock wool boards. The results showed a noticeable reduction of heat transfer to the surface of steel stud and a considerable improvement of fire performance of CFS walls by using aluminum silicate wool as external insulation. For CFS walls with aluminum silicate wool as external insulation on fire side, gypsum plasterboard as face layer and bolivian magnesium board as base layer on both sides, different load ratios may result in different failure modes, and the fire resistant time can be more than 150 min when the load ratio was less than 0.65. It was also demonstrated that the fire performance of CFS wall systems lined with bolivian magnesium board or ALC boards were superior to those lined with gypsum plasterboard and OSB. Therefore, bolivian magnesium board may be recommended to replace gypsum plasterboards as the base layer and ALC board may be used to replace OSB as exterior wall panels of CFS wall systems for applications in mid-rise buildings.

ABSTRACT: This paper presents a study of the failure behaviour of column-supported silos with flexible engaged steel columns, based on finite element analyses. For a wide range of silo and column geometries, the influence of all geometrical parameters to the failure behaviour will be demonstrated. An important finding is that the height over which the column is attached to the silo initially has a positive influence to the failure behaviour and the failure load, but proves to be disadvantageous from a certain critical height.

ABSTRACT: This paper investigated the bending strength of girth-welded stainless steel circular hollow sections by numerical method. At first, finite element simulation of girth welding process was carried out to obtain the weld-induced residual stresses and deformations employing sequentially coupled three-dimensional thermo-mechanical finite element formulation. Then, nonlinear finite element analysis in which the moment versus end-rotation response, the ultimate moment resistance and the failure mode of the girth-welded circular hollow sections under pure bending were explored incorporating the residual stresses and depressions along with the initial global geometric imperfections was performed. Feasibility of adopting the current codified provisions (Eurocode 3) for stainless steel circular hollow sections in bending as the cross-section slenderness limit for girth-welded stainless steel circular hollow section flexural members was also examined. Results showed that the flexural behavior of girth-welded stainless steel circular hollow sections always involves local buckling near the girth weld on the compression side, which significantly affects the moment versus end-rotation behavior. Moreover, the results demonstrated that the Class 3 slenderness limit of 280ε^2 from Eurocode 3 for stainless steel circular hollow sections in flexure may be applied to girth-welded stainless steel circular hollow sections subjected to bending.

ABSTRACT: This paper presents a novel energy absorption structure known as the origami beam. It is made from a shallow curved thin-walled beam of square cross section whose surface is pre-folded according to an origami pattern. Numerical simulation of the quasi-static lateral collapse of the origami beam shows that two new collapse modes, referred to as the longitudinal folding mode and the mixed mode both of which feature
large magnitude of plastic deformation along the entire beam, can be triggered in the beam, leading to higher energy absorption and lower peak force than those of conventional ones.

ABSTRACT: Buckling and postbuckling behavior of metal plates is governed by their slenderness parameter. Using nonlinear finite element simulations, unstiffened mild carbon steel, stainless steel and aluminum plates under the action of axial compression are first classified into slender, moderate and stocky plates. Then the effects of initial imperfection amplitude on each plate type and material is studied via sensitivity analyses. The results show that the transition from slender to stocky plates, regardless of material type, occurs at the slenderness parameter of 2. Empirical equations for evaluating the buckling and postbuckling capacities of imperfect plates are drawn out. It is observed that the increase of imperfection amplitude decreases the buckling load of slender plates, but their postbuckling reserves and ultimate capacities are unaffected. In contrast, the ultimate strength of stocky plates is highly affected by initial imperfections.

Yuner Huang and Ben Young (Department of Civil Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong, China), “Experimental and numerical investigation of cold-formed lean duplex stainless steel flexural members”, Thin-Walled Structures, Vol. 73, pp 216-228, December 2013 DOI: 10.1016/j.tws.2013.07.019
ABSTRACT: Experimental and numerical investigation of cold-formed lean duplex stainless steel flexural members is presented in this paper. The test specimens were cold-rolled from flat plates of lean duplex stainless steel with the nominal 0.2% proof stress of 450 MPa. Specimens of square and rectangular hollow sections subjected to both major and minor axes bending were tested. A finite element model has been created and verified against the test results using the material properties obtained from coupon tests. It is shown that the model can accurately predict the behaviour of lean duplex stainless steel flexural members. An extensive parametric study was carried out using the verified finite element model. The test and numerical results as well as the available data on lean duplex beams are compared with design strengths predicted by various existing design rules, such as the American Specification, Australian/New Zealand Standard, European Code and direct strength method for cold-formed stainless steel. Reliability analysis was performed to evaluate the reliability of the design rules. It is shown that these current design rules provide conservative predictions to the design strengths of lean duplex stainless steel flexural members. In this study, modified design rules on the American Specification, Australian/New Zealand Standard, European Code and direct strength method are proposed, which are shown to improve the accuracy of these design rules in a reliable manner.

Zuxing Pan, Yuansheng Cheng and Jun Liu (School of Naval Architecture and Ocean Engineering, Huazhong University of Science and Technology, Wuhan 430074, PR China), “A semi-analytical analysis of the elastic buckling of cracked thin plates under axial compression using actual non-uniform stress distribution”, Thin-Walled Structures, Vol. 73, pp 229-241, December 2013, DOI: 10.1016/j.tws.2013.08.007
ABSTRACT: An improved hybrid semi-analytical method for calculating elastic buckling load of a thin plate with a central straight through-thickness crack subject to axial compression is proposed. In the study, the actual non-uniform in-plane stress distribution is firstly conducted by using Muskhelishvili’s complex variable formulation in conjunction with boundary collocation method. A deflection shape function, satisfying not only
the outer boundary conditions but also the inner boundary conditions of the crack edges, is obtained by using domain decomposition method. Finally the buckling load of a cracked plate using Raleigh–Ritz energy method is calculated based on the actual in-plane stress distribution and the reasonable deflection shape function obtained. The effects of crack length, plate's aspect ratio are studied for thin plates with different boundary conditions. Results obtained from the proposed method are in good agreement with the existing numerical results and experimental ones. It is finally shown that the proposed method, based on a correct non-uniform in-plane stress distribution, is more accurate than the few existing analytical methods based on a uniform in-plane stress distribution.

Zhanming Qin, Yizhe Feng and Guiping Zhao (State Key Lab for Strength and Vibration of Mechanical Structures, School of Aerospace, Xi’an Jiaotong University, No. 28 West Xianning Rd, Xi’an 710049, PR China), “Modal interactions of a geometrically nonlinear sandwich beam with transversely compressible core”, Thin-Walled Structures, Vol. 73, pp 242-251, December 2013, DOI: 10.1016/j.tws.2013.07.014
ABSTRACT: Modal interactions of a geometrically nonlinear sandwich beam with transversely compressible core in the presence of combination internal resonance are investigated. At first, a geometrically nonlinear, {2,1}-order theory is used to derived the equations of motion and the compatible boundary conditions of the beam. Then, Galerkin's weighted residual method and the multiscale approach are used to address the governing system. Next, modal interactions in the presence of combination internal resonance and subjected to primary-resonance excitation are investigated. Finally, the commercial code ABAQUS is used to validate the theoretical results we have obtained.

ABSTRACT: Lean duplex stainless steel (EN 1.4162) has recently gained significant attention for its higher structural performance, similar corrosion resistance and lower cost compared to the austenitic steel. This paper presents the nonlinear finite element (FE) analysis, behaviour and design of circular lean duplex stainless steel–concrete–carbon steel double skin tubular (CFDST) short columns under compression. The finite element (FE) model for CFDST short columns is developed and validated by comparisons with experimental results available in the literature. The FE model is used to investigate the fundamental behaviour of axially loaded CFDST short columns with various parameters. The results show that the ultimate axial strength of CFDST short columns increases significantly with increasing the concrete compressive strength or with decreasing the hollow ratio. However, increasing the ratio of inner-to-outer thickness or increasing the yield strength of the inner carbon steel tube leads to insignificant increase in the ultimate axial strength of the short column. The accuracy of the design models given in ACI code and by Han et al. (2011) and of the modified continuous strength method (CSM) for CFDST short columns is examined against the FE and experimental results. It is demonstrated that the ACI code and Han et al. model provide conservative strength predictions of CFDST short columns, with a relatively high margin of safety. The ultimate axial strengths of CFDST short columns predicted by the CSM are unconservative. A new design model is proposed and shown to be a reliable predictor of the ultimate axial strength of CFDST short columns under axial loading.

ABSTRACT: Compressive tests of the CFT stub columns with artificial notches in the steel tubes were conducted in this paper to investigate the effects of the material imperfections of steel tubes on mechanical performances of the CFT stub columns. The load–displacement responses, column strength and confining effects were discussed in detail. A parametric study, including the notch length, notch orientation, concrete strength and steel ratio, was also conducted. The results indicated that the notched CFT specimens had quite different failure modes from the intact CFT specimens. A notched CFT specimen might fail by cracking of the steel tube or closing of the notch, which was determined by the notch orientation. The results also showed that the notched CFT specimens had lower mechanical performance than those intact CFT specimens because the notch steel tube could not offer sufficient confining effect on the concrete core inside it. Based on the experimental results, an empirical equation for predicting the column strength of a notched CFT column was proposed.

“Reduced numerical model to investigate the dynamic behaviour of honeycombs under mixed shear–compression loading”, Thin-Walled Structures, Vol. 73, pp 290-301, December 2013
DOI: 10.1016/j.tws.2013.08.016

ABSTRACT: Cellular materials such as aluminium honeycombs combine lightweight with an efficient crash energy absorption capability. They have a major role in a wide range of transport applications to reduce gas emission by the design of lighter structures but remaining safe in accident case. Many investigations on the honeycomb behaviour have been performed, under uni-axial compression loading and more recently under mixed shear–compression loading. The influence of the in-plane orientation has not been however considered. The objective is to develop a reduced numerical model able to investigate, with a reduced cost of calculations, the dynamic behaviour of honeycomb under mixed shear–compression loading and taking into account of the in-plane orientation angle. Reduced model based on the periodicity procedure is developed and its validity range is evaluated. The numerical results show that in terms of pressure–crush curve and collapse mechanisms, the reduced model is consistent with a complete FE model composed of 39 cells with a CPU-time gain efficiency about 97.17%. The reduced model is valid from a loading angle $\psi=0^\circ,\psi=0^\circ$ to a loading angle $\psi_{\text{limit}}$ contained between $\psi=30^\circ,\psi=30^\circ$ and $\psi=45^\circ,\psi=45^\circ$. The reduced model allows investigating in depth the influence of the in-plane orientation and the loading angles on the crush behaviour with minimum time calculations in accord with the validity range.

ABSTRACT: In this study, the shear buckling behavior and shear failure mode of a locally corroded web were examined using nonlinear FE analysis, depending on the corroded web and web boundary conditions. Longitudinally corroded web panels and triangularly corroded webs were considered for quantitatively evaluating the shear buckling behaviors of the corroded web panel. For the longitudinally corroded web panels, the shear buckling strengths were only slightly reduced by about 9–16% depending on the corroded web conditions and web boundary conditions. Their diagonal tension field widened and became distorted with the pronounced shear-bent shape of the corroded web. In particular, in a web-flange separated boundary case, it is out-of-plane displacement and deformation exhibited different shear buckling modes, i.e., a diagonal tension field in its upper part and a large triangular lateral displacement in its lower part. On the other hand, the triangularly corroded web panels had only slight effect on the shear buckling resistance of the corroded web because this corroded model does not affect the diagonal tension field of web panel.

ABSTRACT: The nonlinear rotational behaviour of bolted joints in the cold-formed steel purlin system is normally approximated to a linear theoretical model. Based on the experimental and numerical results, this paper employs a new method to obtain the nonlinear flexural rigidity of the sleeved connections for deflection analysis. Two equations are proposed to predict the moment resistance and the effective flexural rigidity ratio respectively, for the sleeved modified Z connections with different configurations. The nonlinear load-deflection behaviour of sleeved connections can then be predicted using these equations.

ABSTRACT: The influence of inner and outer reinforcements on the bending performance of a thin walled aluminum tube was investigated. Polymeric materials (PA6, PP) and glass/carbon fiber reinforced epoxy were considered to form the composite beam for the inner and outer reinforcement, respectively. The experimental results indicated that the outer reinforcement with a [0°/90°] fiber orientation layout increased the collapse load by a factor of 4.5 and 5.3. In the hybrid composite beam (HCB), load carrying capacity (LCC) increased a maximum of 14 times. Load carrying capacity of HCB is 2.5 times higher than the steel tube that is used in automotive industry.

Yang Zhao, Qing-shuai Cao and Liang Su (Space Structures Research Center, Zhejiang University, Hangzhou 310058, China), “Buckling design of large circular steel silos subject to wind pressure”, Thin-Walled Structures, Vol. 73, pp 337-349, December 2013, DOI: 10.1016/j.tws.2013.08.015
ABSTRACT: Large steel silos are typical kinds of thin-walled structure which are widely used for storing huge quantities of granular solids in industry and agriculture. In the present analyses, buckling design of large steel silo subject to wind pressure is demonstrated in accordance with Eurocode (EN1990, 1991, 1993) and the proposed combinational Load Case WE (wind and empty silo) and WF (wind and full silo). The finite element model is established by using the commercial general purpose computer package ANSYS. Five types of buckling analyses are carried out for the geometrically perfect and imperfect models with and without the consideration of the material plasticity, which are designated as LBA, GNA, GMNA, GNIA, and GMNIA in EN 1993 Part 1–6. The geometrical imperfections are known to have a large impact on the buckling behavior of steel silo structure, in which the magnitude and distribution of the weld depression during construction process is adopted to account for fabrication quality. The buckling behavior of a reference silo with a diameter of 40 m and an aspect ratio of 0.9 is first investigated, which shows that the buckling behaviors from Load Case WE and WF are much different. The material nonlinearity shows little influence on buckling resistance in Load Case WE, while the buckling resistance and buckling mode is much sensitive to weld imperfection. In Load Case WF, both material nonlinearity and geometrical nonlinearity effect is strong and detrimental to buckling behavior of steel silos, resulting in decrease of buckling resistance. The buckling deformation corresponding to the critical point in Load Case WE is governed by the circumferential compression which is generated in the windward region of the shells localized at the top part of silo wall. The buckling mode in Load Case WF takes the form of the well-known elephant-foot deformation at the bottom part of the shell wall, which is induced by the meridional compressive stress. It is also indicated from the parametric analyses that the buckling resistance of steel silo is closely correlative with the loading conditions involving the wind velocity, the patch load, and the geometrical parameters including the aspect ratio, the radius-to-thickness ratio, the type of wall thickness, and the wall openings.

M.R. Bambach (Transport and Road Safety (TARS), Faculty of Science, Old Main Building (K15), University of New South Wales, Sydney, NSW 2052, Australia), “Fibre composite strengthening of thin steel passenger vehicle roof structures”, Thin-Walled Structures, Vol. 74, pp 1-11, January 2014, DOI: 10.1016/j.tws.2013.09.018

ABSTRACT: There is an increasing pressure on vehicle manufacturers internationally to increase the strength of vehicle roofs, in response to the ongoing morbidity and mortality related to vehicle rollover crashes. Several countries are mandating increased roof strengths for future vehicle fleets, and this is occurring at the same time as increased regulations to reduce vehicle emissions. Thus light weight strengthening solutions are required to increase roof strengths while minimising structural mass. This paper presents the novel approach of strengthening vehicle roof structure components by bonding carbon fibres to the steel surface. Such fibre strengthening systems have been shown to provide substantial increases in force and energy resistance for steel tubes under both axial crushing and pure bending. The strengthening potential is assessed with a numerical study of two different passenger vehicles subjected to various roof crush test protocols. Numerical models of fibre composite strengthening systems are validated against experiments, then applied to numerical models of the vehicles. Substantial improvements in the roof strength, and correspondingly the vehicles' roof strength to weight ratio, are demonstrated with the fibre strengthening technique. Comparisons are made with models of strengthening the roof structure components by adding steel rather than fibre composite, and the implications with regards to vehicle light-weighting are discussed. It is shown that fibre composite strengthening of vehicle roof structures has the potential to contribute to higher roof strengths and/or light-weighting in future vehicle fleets.

ABSTRACT: This paper aims to investigate the crushing behaviors of tailor-welded blank (TWB) thin-walled structures. A series of TWB high-strength steel (HSS) square tubes with different weld line locations is used to perform the crushing tests for evaluating the effects of different TWB parameters, such as weld line locations and material combinations, on crushing characteristics. These TWB specimens are fabricated through the laser welding process to ensure sufficiently narrow weld line. In the study, the center edge of TWB square specimens is not welded so that such special TWB structures have open cross section. The crushing test results exhibit excellent repeatability. The collapse modes and force–displacement relationships are compared with each other. It is found that the crushing behaviors of different material combinations are fairly significant for a given weld line location. Such key crushing characteristics as specific energy absorption (SEA), average crush force ($F_{avg}$), peak force ($F_{max}$) are also evaluated for understanding crashworthiness of these TWB structures. The experimental results provide us with some insightful guidance to crashworthiness design of TWB thin-walled HSS structures.

ABSTRACT: This research is concentrated on the structural strength and behavior of cold-formed steel wall frame sheathed with calcium silicate board under shear load. Test specimens with two different thicknesses of sheathing were assembled, 9 mm and 12 mm, with one-side or two-side of attachment. Monotonic shear and cyclic loading tests are conducted on wall specimens utilizing two C sections connected back-to-back to be as chord studs and calcium silicate board sheathing on the exterior. Based on the test results, detailed discussions on the strength, stiffness, energy absorption, ductility ratio, and failure mode of cold-formed steel wall specimens are given. It is noted that the failure mostly occurred at the bottom track of wall specimens due to the large deformation or tearing failure of track. The wall strength is not affected by the change of sheathing's thickness significantly, but wall frames attached with two-side calcium silicate board sheathing provide higher resisting strength and stiffness than those attached with one-side sheathing. In this study, test results are also used to compare with the previous study that single chord stud was used in the assembly of wall frame. In addition, the suggested response modification factor of the wall sheathed with calcium silicate board is proposed for design purpose.

ABSTRACT: A partially encased composite I-girder with flat or corrugated web has been proposed to improve the structural performance of continuous composite girder under hogging moment. The flexural behavior of such structure under two points symmetric loading has been experimentally and analytically investigated. Static flexural loading tests showed that the partially encased girder improved bending strength in comparison to steel I-girder, as local buckling of steel flange was restricted by encased concrete. Especially for the corrugated web girder, the ultimate bending strength was improved about 20%, and the ductility also increased about 3 times. In addition, the limitation of width-to-thickness ratios for steel and concrete-encased composite I-girders with corrugated web were suggested to prevent premature failure due to local buckling of compressive flange. Moreover, the analytical methods of flexural strength under service and ultimate state for partially encased composite girder were proposed and verified with experimental results. It was found that the analytical bending strengths agreed well with the experimental ones at both service and ultimate state, which means the proposed analytical equations can be applied in predicting flexural strength accurately for such encased composite girder with flat or corrugated web.

ABSTRACT: A linear model for beams with compact or thin-walled sections and heterogeneous anisotropic materials is presented. It is obtained by means of a Ritz–Galerkin approximation using independent descriptions of the stress and displacement fields. These are evaluated by a preliminary semi-analytic solution based on a finite element description of the cross section. A coherent definition of the deformations and stresses is obtained which includes both the generalized Saint Venànt solution for generic materials and some significant additional effects, due to out-of-plane warping and section distortions. The so-built 1-D model maintains the richness of the 3-D solution using a small number of variables.

ABSTRACT: The great majority of the studies in this area emphasise further the structural behaviour of cold-formed steel members by means of analytical approximation and purely numerical methods. In addition, they generally only take into account the structural behaviour of members with just one profile. On the contrary, this paper reports a series of flexural tests under fire conditions focused on cold-formed galvanised steel beams consisting on compound cold-formed steel profiles which are often used in floors and roofs of warehouses and industrial buildings. The main objective of this research was to assess the failure modes, the critical temperature and the critical time of the studied beams. Other important goals of this research work were also to investigate the influence of the cross-sections, the axial restraint to the thermal elongation of the beam and the rotational
stiffness of the beam supports. Finally, the results showed above all that the critical temperature of a cold-formed steel beam might be strongly affected by the axial restraint to the thermal elongation of the beam.

ABSTRACT: This paper proposes a new approach for the evaluation of the conventional modes, i.e. rigid, distortional, local and Bredt shear-modes, to be used in the framework of the Generalised Beam Theory (GBT) for the analysis of thin-walled members. The new method identifies a set of conventional modes in a single step cross-sectional analysis and for any type of cross-section, i.e. open, closed and partially-closed ones. The algorithm differs from that of the classical GBT, which requires a two-step evaluation procedure, consisting of an initial choice of the vector basis and its successive orthogonalization. The method is based on a definition of a new quadratic functional, whose steady condition leads to an eigenvalue problem, and directly generates the sought orthogonal basis, here found using a finite-element approach. The accuracy of the proposed method is validated by means of two numerical examples, one dealing with a lipped C-section and one with a partially-closed profile. It is shown that the conventional modes derived with the proposed approach are identical to those determined with the classical two-step procedure, thus limiting the computational effort required in their identification.

ABSTRACT: In this paper, a procedure for a posteriori reconstruction of three-dimensional stresses in the finite element analysis of beams modelled within the framework of the Generalized Beam Theory is presented. The reconstruction is based on the enforcement of the pointwise three-dimensional equilibrium equations over the beam, interpreted as an assembly of thick plates, and on the use of the Recovery by Compatibility in Patches procedure. No corrections to meet the equilibrium boundary conditions on bottom/top wall faces are needed. Numerical results show that the proposed approach allows to effectively recover local stress profiles which match those of three-dimensional solid finite element models.

ABSTRACT: Energy must dissipate during a collision to prevent damage and injury. To reduce loss from collision, energy absorbers are used that dissipate energy upon deformation and folding to prevent damage to critical parts of a structure. In this paper, simple and multi-cell thin-walled tubes made from aluminum with triangular, square, hexagonal and octagonal sections were subjected to quasi-static loading. The experimental results were then compared with numerical simulations. The results showed that the energy absorption capacity
of multi-cell sections is greater than for that of simple sections. Also, hexagonal and octagonal sections in a multi-cell configuration absorbed the greatest amounts of energy per unit of mass.

ABSTRACT: An experimental investigation of square concrete-filled thin-walled steel tube under local bearing forces is described, and the loads are applied by a steel bearing member (BM). A total of 20 specimens, including 12 concrete-filled steel tubular (CFST) members, 4 reference hollow structural section (HSS) members and 4 reference plain concrete (PC) members, were tested. The parameters considered in the tests included (1) type of BM: solid and hollow; (2) width ratio between BM and compression member: from 0.36 to 0.73; (3) wall thickness of the steel tube of the compression member: 2.6 mm and 3.7 mm, and (4) angle between BM and the compression member: 45° and 90°. It is found that, while being subjected to local bearing forces, square CFST has a higher bearing capacity and a better deformation-resistant ability, and the performance of a CFST member is better than that of the superposition of HSS and PC members. The calculated bearing capacities of square CFST under local bearing forces using the simplified design method in CIDECT design guide [9] and Feng and Young [12] are evaluated by comparison with the experimental results.

ABSTRACT: The mechanical behaviour of welded structures can be significantly affected by the effects of the employed joining process. The main goal of this work is to assess the influence of the longitudinal residual stresses on the overall compressive performance of aluminium friction stir welded plates. Longitudinal residual stress distribution was measured by means of the contour method and introduced as initial condition into a finite element model of the compressed assembly. Also, the sensitivity of the plates to the magnitude of the initial geometrical imperfections was analysed. It can be inferred that both factors influence the plate's mechanical behaviour.

DOI: 10.1016/j.tws.2013.09.023
ABSTRACT: Free vibration of a plate-cavity system is analytically studied in this paper. For this purpose, a rectangular enclosure composed of one flexible and five rigid walls are taken into account. The flexible wall is modeled by the Von-Karman plate theory and the Galerkin method is employed to derive interior acoustic pressure and subsequent equations of motion. Harmonic balance approach, variational iteration method (VIM) and direct integration method are employed to determine nonlinear natural frequencies of the coupled system. A
parametric study is then carried out and effects of different parameters on the value of frequency ratio are studied.

ABSTRACT: A long, thin, inextensible cylindrical tube made of Hollomon's power-law material acted upon by a uniform normal pressure is considered. The nonlinear boundary value problem that governs the equilibrium states of such a tube is formulated as a differential system of equations. Perturbation solutions are obtained for the cases of small pressure values in the neighborhood of the critical buckling pressures. Numerical solutions based on a special initial value problem Matlab solver, Newton's and shooting methods are obtained. The results show that a high strength material tube deforms similarly to an elastic material tube for values of strain hardening exponent.

ABSTRACT: The fact that the buckling load of cylindrical shells depends on imperfections raised the idea of applying probabilistic design methods for these structures. Whether a probabilistically motivated design load may be regarded as a representative for a type of shell depends, among others, on the samples that build the data basis for the probabilistic methodology. In the current paper a methodology is presented that takes into account the samples size within a fast probabilistic design. The method presented leads to a lower design load, as the sample size decreases. The methodology is applied to a set of 33 beer cans, which have been measured and tested at the Delft University of Technology. The 33 cans are subdivided into groups which are then analyzed probabilistically in order to observe how the probabilistically motivated design load varies for different samples sizes. The results indicate that the method presented provides a useful tool for designers to ensure that a small data basis does not yield an unsafe probabilistic design.

ABSTRACT: The design of steel sheathed cold-formed steel (CFS) framed shear walls is not addressed in Canadian design standards. A program of displacement based loading tests was carried out on single-storey shear walls of various configurations to investigate their performance and to establish a comprehensive database of information. The walls, which were subjected to lateral loading and combined lateral plus gravity loading, differed in sheathing thickness, screw fastener detailing, framing thickness, aspect ratio and framing reinforcement. The performance under loading was directly related to the sheathing connection pattern;
however, when the framing elements were not blocked tension field forces resulted in significant damage to the chord studs. Details of the test program and general results are presented in this paper.

ABSTRACT: In this paper, a novel layerwise theory based on first order shear deformation theory has been developed to evaluate the buckling load of delaminated composite plates with through-the-width and rectangular embedded delaminations. The Rayleigh–Ritz method has been adopted and displacement fields are obtained by incorporating polynomial series. Besides, contact constraints are imposed to the delaminated area using penalty method in order to prevent unacceptable penetration. The present layerwise theory provides a more realistic description of the kinematics of composite laminates when compared to equivalent single layer theories. This method is capable of predicting buckling response of thick delaminated composite plates.

DOI: 10.1016/j.tws.2013.09.009

ABSTRACT: In the present paper, two independent functions of displacements along the z axis direction, i.e., the total lateral displacement w and the bending deflection φ, have been introduced within the first order shear deformation plate theory FSDT. The differential equations of motion and boundary conditions have been derived from Hamilton's principle employing the classical Mindlin approach. Modified conditions of two adjacent component plate interactions have been formulated. A plate model of the plate structure has been adopted to describe all possible buckling modes. The obtained equations are approximate since the shear locking is not ignored but the boundary layer effect is neglected. A method of the modal solution to the buckling problem within Koiter's asymptotic theory has been used. The calculations have been conducted for a few beam-columns of various shapes of cross-sections. The obtained results that account for transverse shear deformation have been compared to the results attained for the classical thin plate theory.

ABSTRACT: Following recent investigations on the decomposition of elastic buckling modes into combinations of structurally meaningful deformation modes, this work presents a novel extension of the above procedure to elastic–plastic collapse mechanisms and highlights the relevant role that this concept may play in
the mechanical knowledge/interpretation of thin-walled member failures. In order to achieve the sought decomposition, a code based on a Generalised Beam Theory (GBT) formulation developed to perform first-order elastic–plastic analyses of thin-walled members is employed. Five illustrative examples are presented and discussed, and the results displayed, namely load-deflection curves, deformed configurations and stress contours, are validated through the comparison with values provided by shell finite element analyses. The most relevant modal results addressed consist of (i) load-deflection curves determined on the basis of pre-selected deformation mode sets, (ii) modal participation diagrams and (iii) modal amplitude functions. These results make it easy to characterise and interpret the mechanics associated with the thin-walled member elastic–plastic failures (as well as with the various loading stages), which may be of great importance in the improvement/development of existing/new design methods (e.g., yield-line theory, direct strength method).

ABSTRACT: Shells are thin-walled structures whose stability and performance is governed by geometrical buckling. The buckling stability of shell structures has been investigated through numerous analytical and experimental studies. In an experimental investigation, it is quite important to determine the accurate buckling load of the structure as the critical load is usually masked by failure owing to large deformations as well as the effects of initial imperfections. On this basis, the main objective of this study is to evaluate the applicability of the Southwell, Massey, Modified, and Meck plotting methods in predicting the accurate critical buckling loads of conical shell structures with various geometrical properties. To this end, the buckling loads of several test specimens are determined through application of the aforementioned plotting methods as well as consideration of the test data for strain and displacement deformation variables, and compared with numerical and analytical predictions. Based on the findings of this study, agreement between the extrapolated and numerical as well as analytical results for buckling loads of the considered conical shell specimens is quite satisfactory, which is in turn indicative of applicability of the extrapolation techniques in experimental determination of buckling loads of shell structures. The applicability of extrapolation techniques in predicting the critical buckling load of conical shell structures is demonstrated. Southwell, Massey, and Modified Plots are successfully applied on strain and displacement data and reliable predictions are obtained for the critical buckling loads. The proportionality between strain and displacement deformation variables is demonstrated. The critical buckling loads of conical shells are satisfactorily predicted through application of Meck Plot method on strain and displacement data.

“Crashworthiness optimization design for foam-filled multi-cell thin-walled structures”, Thin-Walled 
Structures, Vol. 75, pp 8-17, February 2014

ABSTRACT: Foam-filled thin-walled structure and multi-cell thin-walled structure both have recently gained 
attentions for their excellent energy absorption capacity. As an integrator of the above two kinds of thin-walled 
structures, foam-filled multi-cell thin-walled structure (FMTS) may have extremely excellent energy absorption 
capacity. This paper firstly investigates the energy absorption characteristics of FMTSs by nonlinear finite 
element analysis through LS-DYNA. Based on the numerical results, it can be found that the FMTS with nine 
cells has the most excellent crashworthiness characteristics in our considered cases. Thus, the FMTSs with cell 
number n=9 are then optimized by adopting a multi-objective particle swarm optimization (MOPSO) algorithm 
to achieve maximum specific energy absorption (SEA) capacity and minimum peak crushing force (PCF). 
During the process of multi-objective optimization design (MOD), four kinds of commonly used metamodels, 
namely polynomial response surface (PRS), radial basis function (RBF), Kriging (KRG) and support vector 
regression (SVR) for SEA and PCF, are established to reduce the computational cost of crash simulations by 
the finite element method. In order to choose the best metamodel for optimization, the accuracies of these four 
kinds of metamodels are compared by employing the error evaluation indicators of the relative error (RE) and 
the root mean square error (RMSE). The optimal design of FMTSs with nine cells is an extremely excellent 
energy absorber and can be used in the future vehicle body.

“Improving strength, stiffness and ductility of CFDST columns by external confinement”, Thin-Walled
ABSTRACT: Concrete-filled double-skin tubular (CFDST) column is one of the most efficient forms of column construction in which the steel tubes provides both axial strength and confining pressure to enhance the strength and ductility of the in-filled concrete. Compared with confined reinforced concrete columns, CFDST columns had stronger and more uniform confining pressure provided to the in-filled concrete by the steel tubes, which reduces the steel congestion problem for better concrete placing quality. However, a major shortcoming of the CFDST columns is the imperfect interface bonding that occurred at the elastic stage that reduces the elastic strength and stiffness of columns. To improve the situation, it is proposed in this study to use external steel rings to restrict the dilation of outer steel tube of CFDST columns. For verification, a series of uni-axial compression test was performed on some CFDST columns with external steel rings. From the results, it was found that the elastic strength, elastic stiffness and ductility were enhanced by installing the steel rings as external confinement. Lastly, a theoretical model for predicting the axial strength of confined CFDST columns has been developed.

ABSTRACT: A rotational resistant stiffness of the zed-purlins connection with sandwich panels is investigated. A simple finite element method model of the connection is proposed. The numerical analysis of the model performed by ABAQUS software, in physically linear and geometrically nonlinear ranges, leads to the rotational resistant stiffness sought. The numerical solution obtained is verified experimentally. Two variants of distribution of screws connecting the purlin with the sandwich panel are taken into investigation. A good agreement of both, theoretical and experimental, results should be noticed. Conclusion related to possible application in design practice is formulated.

ABSTRACT: A new cold-formed steel corrugated shear wall seismic force resisting system has been recently
developed by Tipping Mar and Associates of Berkeley, California. The seismic performance quantification of buildings with the system requires non-linear dynamic analysis, where the shear wall – to reduce calculation demands – is modeled by cyclic strut element. The paper presents the model development and calibration to test results. In lack of monotonic test results, monotonic backbone curve is estimated by non-linear static analysis. Cyclic deterioration parameters are determined by genetic algorithm optimization method. Standard model that is applicable to the various shear wall configurations is developed.

ABSTRACT: Critical loads were determined experimentally from the condition of the local buckling of thin-walled bars with Z-section subjected to warping torsion. The experimental investigations were carried out using simply supported models, loaded with a concentrated torsional moment at the mid-span. A method of determining the so-called “local ordered deflection interval” was developed. In this interval, the modeled deflection of the component plates (walls) of a thin-walled bar with random wall geometrical imperfections is compliant with the local buckling mode. The “local ordered deflection interval” makes it possible to adjust the known experimental methods so that they could be used to determine critical torsional loads and local critical bimoments. Experimental investigations showed the occurrence of two local critical bimoments in bars with Z-section. The bimoments are different in their absolute values, depending on the sense (sign) of the torsional load. Experimentally determined critical loads were compared with theoretical results.

ABSTRACT: State-of-the-art studies of the crushing of composite tubes reveal different factors affecting their crushworthiness. Of those factors, the geometrical property of the tube is of great interest. In the current study, four different categories of tube cross-sectional geometrical properties were tested under a quasi-static crushing scenario to investigate the best cross-section in terms of the crushing load and the energy-absorption capacities. A woven GFRP consisting of eight layers was used to manufacture the tubes. The results showed that reinforcing the circular tube with radial GFRP webs could improve both the load-carrying capacity and the specific energy-absorption capability. The stability of the crushing process is of great interest in automotive applications. It was found that introducing the geometrical reinforcement inside the tubes could have a positive effect on the stability of the crushing during the loading, the average crush load, and the crush-load efficiency.

ABSTRACT: A generalized Ritz based approach that accounts for pre-buckling bending deformations as well as geometric non-linearity to find the buckling load for thin cylindrical shells under uniform axial compression is proposed. The approach accommodates within a unified framework, based on a shell and spring restraint system, the entire range of boundary conditions: ranging from free boundaries to compliant boundaries. The classical kinematic boundary conditions are recovered as limiting cases. The method involves choice of a single trial function that is invariant with respect to boundary conditions. The proposed approach is validated using existing analytical results, where available, and numerical solutions, otherwise.

ABSTRACT: Results of a theoretical analysis of the local buckling in thin-walled bars with open cross-section subjected to warping torsion are presented. The local critical bimoment, which generates local buckling of a thin-walled bar and constitutes the limit of the applicability of the classical Vlasov theory, is defined. A method of determining local critical bimoment on the basis of critical warping stress is developed. It is shown that there are two different local critical bimoments with regard to absolute value for bars with an unsymmetrical cross-section depending on the sense of torsion load (sign of bimoment). However, for bars with bisymmetrical and monosymmetrical sections, the determined absolute values of local critical bimoments are equal to each other, irrespective of the sense of torsional load. Critical warping stresses, local critical bimoments and local buckling modes for selected cases of thin-walled bars with open cross-section are determined.

ABSTRACT: Finite Element simulations and mechanical tests are undertaken to assess the impact of weld joint location on stiffened panel static strength. An upper wing cover panel, with a manufacturing process of welding multiple near-net-shape multi-stiffener extrusions with a final net-shape machining phase is investigated. The 7000 series aluminium alloy extrusions and skin bay longitudinal friction stir butt welds are examined. Geometric imperfections exhibit the greatest influence on panel collapse, thus for static strength design the selection of weld joint location should minimise imperfection generation. Moreover the analysis demonstrates limited impact on panel collapse strength when an optimised welding process is employed.

ABSTRACT: Because the deformed beam geometry often is the most important information for applications of highly flexible beams, a geometrically exact beam theory needs to be displacement-based in order to directly and exactly describe any greatly deformed geometry. Main challenges in geometrically exact beam modeling
are how to describe a beam's large reference-line deformation and cross-sectional rotations without singularity and how to derive objective directional strains in terms of global displacements and rotations that contain elastic deformation and rigid-body movement. By comparing with a geometrically exact displacement-based beam theory this paper shows that theoretical and numerical problems of other geometrically nonlinear beam theories are mainly caused by: (1) use of independent variables to account for bending-shear rotations, (2) use of problematic energy-based Green–Lagrange strains in order to have objective strain measures, and/or (3) use of strain-based formulations in order not to use problematic Green–Lagrange strains. The theoretical problems include inconsistent governing equations from energy- and momentum-based formulations, inexistence of material property matrices for the chosen strain and stress measures, and non-directional stresses. The numerical problems include shear locking in finite-element analysis, the need of internal nodes and hence more degrees of freedom in finite-element modeling, singularity of mathematics-based rotational variables, deformed geometry being obtained by approximate post-processing numerical integration, and difficult to match secondary (force) variables with deformed conditions.

ABSTRACT: This paper presents an equation for the effective tangent moduli for steel axial members of hot-rolled I-shaped section subjected to various residual stress distributions. Because of the existence of residual stresses, the cross section yields gradually even when the member is subjected to uniform axial stresses. In the elasto-plastic stage, the structural response can be easily traced using rational tangent modulus of the member. In this study, the equations for rational tangent moduli for hot-rolled I-shaped steel members in the elasto-plastic stage were derived based on the general principle of force-equilibrium. For practical purpose, the equations for the tangent modulus were presented for conventional patterns of the residual stress distribution of hot-rolled I-shaped steel members. Through a series of material nonlinear analyses for steel axial members modeled by shell elements, the derived equations were numerically verified, and the presented equations were compared with the CRC tangent modulus equation, the most frequently used equation so far. The comparative study shows that the presented equations are extremely effective for accurately analyzing elasto-plastic behavior of the axially loaded members in a simple manner without using complex shell element models.

ABSTRACT: To complement available design methods, this study develops a practical and economical approach to estimate shear strength of non-composite symmetric and asymmetric cellular beams, based on
failure by local web-post buckling. Influence of geometric web-post parameters on the buckling strength and mechanism, such as section size, opening depth ratio, spacing ratio and tee depth, are investigated with a validated finite element (FE) web-post model. The validation is against 13 cases reported in the literature, and 390 parametric web-post models are analyzed. Tee depth is found to be the key parameter distinguishing failure modes between buckling and Vierendeel bending. The buckling design equation is adopted based on a simple strut model. The observed stress distributions from simulations suggest half the web-post width for the effective strut width and half the length of a line segment tangent to neighboring openings as the strut length. Based on the simulation study, an effective length is proposed to incorporate the effects of restraint due to the tee section and the stress variation around the opening. The strut models of the upper and lower parts of the web-post are separately computed for their buckling shear strength according to BS EN 1993-1-1 and ANSI/AISC 360-10. The shear strength of each part is related to the web-post shear strength through the vertical shear area of the tee section. Accuracy of the proposed model is validated against existing experiments or their FE models. The new design equations facilitate safe and cost-effective design of cellular beams.

Yuner Huang and Ben Young (Department of Civil Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong, China), “Experimental investigation of cold-formed lean duplex stainless steel beam-columns”, Thin-Walled Structures, Vol. 76, pp 105-117, March 2014, DOI: 10.1016/j.tws.2013.11.006
ABSTRACT: This paper describes a test program on cold-formed lean duplex stainless steel members in combined compression and minor axis bending. The test specimens were cold-rolled from flat strips of lean duplex stainless steel grade EN 1.4162. In this study, square and rectangular hollow sections were compressed at different eccentricities, in order to obtain a beam-column interaction curve for each series of tests. Initial overall geometric imperfections of the members were measured prior to testing. The ultimate loads and the failure modes of each specimen were obtained. The observed failure modes include local buckling, flexural buckling and interaction of local and flexural buckling. The test strengths obtained from this study and other available data were compared with the design strengths predicted by the American Specification, Australian/New Zealand Standard and European Code for stainless steel structures. It should be noted that these specifications do not cover the material of lean duplex stainless steel. Therefore, the suitability of the beam-column design rules in these specifications for lean duplex stainless steel is assessed in this study. Generally, these specifications are capable of predicting the beam-column strengths of the lean duplex stainless steel test specimens, and the design rules in the specifications are considered to be reliable. It is observed that the European Code generally provides quite conservative predictions for the beam-column specimens compared to the American Specification and Australian/New Zealand Standard predictions.

ABSTRACT: Nowadays stiffened aluminium panels have been widely used for marine applications such as building high speed vessels. The panels of high speed vessels are subjected to different in plane and out-of-plane loads. One of the most important out-of-plane loads is the impulse caused by bottom slamming. In the present study, the transient large deflection elastic-plastic responses of a number of stiffened aluminium panels subject to slamming impulsive loads are investigated. The impulsive loads are exerted on the finite element models of aluminium panels proposed by Ultimate Strength Committee of ISSC 2003. Several impact conditions are considered to study the influence of several structural factors such as heat affected zone (HAZ)
arrangement, boundary conditions, thickness of plating, number of transverse frames and in-plane fixation. Based on these studies, several design-oriented conclusions are issued. Moreover, this paper outlines the various aspects of the influence of the HAZ presence on the strength of the slam-loaded panels with respect to loading time ratio.

ABSTRACT: This paper aims at finding the optimal folding of open cold formed steel cross sections under compression. Starting with a fixed coil width, a design point in the design space is defined by a vector of turn angles at a set of points along the coil width. Generalized Finite Strip Method (FSM) and Direct Strength Method (DSM) are combined to calculate the nominal compressive strength for a given cross section (a given design with a given set of turn angles). The design space is searched primarily via a stochastic search algorithm, Genetic Algorithm (GA). The near-optimal folding of the cross section is then fine-tuned through a few steps of the gradient descent optimization. To arrive at practical designs the optimization problem is augmented with constraints on the geometrical properties of the cross section. The optimal cross sections are found to have compressive capacities that are higher than the original designs by a factor of more than three in many cases. The shape of the optimal folding is shown to be greatly influenced by the choice of boundary condition. Strategies for identification of instability modes, a necessary first step to using DSM, are also discussed in detail.

Eduardo M.B. Campello and Leonardo B. Lago (Department of Structural and Geotechnical Engineering, Polytechnic School, University of São Paulo, P.O. Box 61548, 05424-970 São Paulo, Brazil), “Effect of higher order constitutive terms on the elastic buckling of thin-walled rods”, Thin-Walled Structures, Vol. 77, pp 8-16, April 2014, DOI: 10.1016/j.tws.2013.11.001
ABSTRACT: In this paper we revisit an elastic constitutive equation proposed in two previous works and extend it in order to include all higher-order terms on the deformations. Our purpose is to assess the influence of these terms on the elastic buckling of thin-walled rods. The resulting material model was incorporated into a geometrically exact rod formulation and implemented into a nonlinear finite element code. By means of simple numerical examples we show that the higher order terms may play a significant role on the values of the buckling loads and on the post-buckling behavior of thin-walled beams and columns.

ABSTRACT: This paper investigates the behavior of steel plate shear walls (SPSWs) with pre-compression from adjacent frame columns which is produced in the construction process. Firstly, some parameters used in analytical finite element models, such as the stiffness of frame beams and columns and the magnitude of the loads are discussed. Then, numbers of numerical examples are analyzed and show that the influence of pre-compression varies with the dimension of SPSWs. Also, the distribution and transferring of axial forces
between frame columns and SPSWs during loading are discussed. Finally, a reduction coefficient of shear-carrying capacity of SPSW due to pre-compression is proposed.

ABSTRACT: This paper presents a non-linear finite element model (FEM) used to predict the behaviour of slender concrete filled steel tubular (CFST) columns with elliptical hollow sections subjected to axial compression. The accuracy of the FEM was validated by comparing the numerical prediction against experimental observation of eighteen elliptical CFST columns which carefully chosen to represent typical sectional sizes and member slenderness. The adaptability to apply the current design rules provided in Eurocode 4 for circular and rectangular CFST columns to elliptical CFST columns were discussed. A parametric study is carried out with various section sizes, lengths and concrete strength in order to cover a wider range of member cross-sections and slenderness which is currently used in practices to examine the important structural behaviour and design parameters, such as column imperfection, non-dimension slenderness and buckling reduction factor, etc. It is concluded that the design rules given in Eurocode 4 for circular and rectangular CFST columns may be adopted to calculate the axial buckling load of elliptical CFST columns although using the imperfection of length/300 specified in the Eurocode 4 might be over-conservative for elliptical CFST columns with lower non-dimensional slenderness.

ABSTRACT: A numerical study on the post-buckling behaviour of simply supported short cylindrically curved panels, with longitudinal edges unconstrained and loaded edges constrained (internal element of a section), including the influence of curvature and loading type (pure compression and in-plane bending) is presented in this paper. Additional relevant parameters are identified and their influence on the ultimate strength of cylindrically curved panels is studied. Numerical results of the ultimate reduction factor from the parametric study are converted into geometry (width) reduction factors by an iterative routine. Subsequently, an extension of rules for internal plated members’ ultimate load calculation from EN 1993-1-5 is proposed based on the effective width concept. It is concluded that (except for stocky panels) the increase in the curvature parameter led to an increase on the cylindrically curved panel’s resistance and that the upper limit proposed by EN 1993-1-5 to the value of the curvature parameter is reasonable. Finally, a statistical study is performed that concludes that the proposed approach provides an accurate estimate of the ultimate load.

ABSTRACT: This paper investigates the local buckling strength of stainless steel beam webs, subjected to a stress gradient. Due to relatively low values of the proportional limit, stainless steels resist loads at stresses beyond the proportional limit. The design of such steels is therefore influenced by its inelastic buckling strength. To determine this strength, plasticity reduction factors are used in local buckling calculations to account for inelastic post-buckling behavior. Steels chosen for this study are AISI Type 304, 410 and Type 3CR12 stainless steels. Dimensions of the sections were selected to promote local buckling, and inhibit other forms of buckling, such as distortional and lateral-torsional buckling. The depth of the web was varied in order to study channels of different slenderness ratio. It was concluded in this investigation that an acceptable prediction of the local buckling strength of stainless steel beam webs may be obtained through the use of the effective width approach, using no plasticity reduction factor.

“A statistical and experimental investigation into the accuracy of capacity reduction factor for cold-formed steel shear walls with steel sheathing”, Thin-Walled Structures, Vol. 77, pp 56-66, April 2014
DOI: 10.1016/j.tws.2013.11.016

ABSTRACT: Buildings constructed of cold-formed steel members are increasingly used in many countries. In recent years, cold-formed steel shear walls with steel sheathing were introduced as lateral force resisting systems. Design provisions of these structures require that the shear strength of shear walls with a height to width aspect ratio \( ({h/w}) \) greater than 2:1 be reduced by the factor \( 2w/h \) for satisfying allowable story drift limit. In this research, the accuracy of the factor is investigated using the results of previous tests and the tests performed by the researcher. Results show that the reduction factor \( (2w/h) \) is conservative. Thus, a relation is proposed for the reduction factor.

Ashkan Shahbazian and Yong Chang Wang (School of Mechanical, Aerospace and Civil Engineering, the University of Manchester, Pariser Building, Sackville Street, Manchester M13 9PL, United Kingdom), “A fire resistance design method for thin-walled steel studs in wall panel constructions exposed to parametric fires”, Thin-Walled Structures, Vol. 77, pp 67-76, April 2014, DOI: 10.1016/j.tws.2013.12.001

ABSTRACT: This paper investigates the applicability of a simple fire resistance design method for axially loaded thin-walled steel studs in wall panel assemblies when exposed to parametric fires from one side. The simple method includes calculations of cross-section temperatures and ultimate load carrying capacities at elevated temperatures. The simplified calculation method for heat transfer in the cross-section is based on dividing the cross-section into a number of segments. The thermal properties of these layers are based on weighted averages of the thermal properties of the components contained within. The structural capacity calculation method is based on the Direct Strength Method. Results from the design method are compared with the results from Finite Element simulations for heat transfer and structural analysis (236 models). The calculation results are in good agreement with the simulation results and the proposed method may be used in performance-based fire engineering design of such construction.

ABSTRACT: To rehabilitate damaged or sub-standard box girders, techniques utilising the lightweight, high strength and corrosion resistance of carbon fibres reinforced polymers (CFRP) composites have been proposed. This paper presents experimental results for two series of CFRP strengthened and rehabilitated model box girders under quasi-static large deformation 3-point bending. The first series represents strengthening 12 undegraded rectangular hollow section (RHS) beams from the manufacturer using externally wrapped CFRP sheets. The second series was for rehabilitation of 41 artificially degraded RHS beams strengthened using externally wrapped sheets or bonded plates. The main parameters examined in this paper were the section type, section and member slenderness and the type and number of the CFRP sheets. The flange and web slenderness examined in this paper was in the range of \( b/t = 20 \) to 66.67 and \( d/t_w = 20 \) to 75. The CFRP sheets were wrapped around the section in the transverse direction with a sufficient overlap. The results show that the combined flexural and bearing strength of the steel box girder can be significantly increased by adhesively bonding CFRP. Expressions for the bearing strength and plastic moment of the composite section were obtained by means of an equivalent thickness approach. The newly derived interaction equations were compared against the present design rules in steel specifications. The average gain in strength due to bonding the CFRP laminate was 65% and 19.9% for the strengthening and rehabilitations series, respectively. The percent increase in strength was mostly affected by the section slenderness where the maximum gain was obtained for the slender section.

ABSTRACT: This paper presents a finite element analysis (FEA) of circular concrete filled steel tubular (CFST) members under local bearing forces applied either perpendicularly to the member or at an angle of 45°. The established FEA modeling was verified by the experimental results that have been published in an international journal. The FEA modeling was then used to perform analysis on the typical failure modes and full-range load-deformation relations of CFST subjected to local bearing forces. Finally, simplified formulae for calculating the strength of CFST under local bearing forces was presented. Practical guidance was also given to avoid premature local buckling of brace member and premature fracture of chord member.

Poologanathan Keerthan, David Hughes and Mahen Mahendran (Science and Engineering Faculty, Queensland University of Technology, Brisbane, QLD 4000, Australia), “Experimental studies of hollow flange channel beams subject to combined bending and shear actions”, Thin-Walled Structures, Vol. 77, pp 120-140, April 2014, DOI: 10.1016/j.tws.2013.12.003

ABSTRACT: This paper presents the details of an experimental study of a cold-formed steel hollow flange channel beam known as LiteSteel beam (LSB) subject to combined bending and shear actions. The LSB sections are produced by a patented manufacturing process involving simultaneous cold-forming and electric resistance welding. Due to the geometry of the LSB, as well as its unique residual stress characteristics and initial geometric imperfections resultant of manufacturing processes, much of the existing research for common
cold-formed steel sections is not directly applicable to LSB. Experimental and numerical studies have been carried out to evaluate the behaviour and design of LSBs subject to pure bending actions and predominant shear actions. To date, however, no investigation has been conducted into the strength of LSB sections under combined bending and shear actions. Combined bending and shear is especially prevalent at the supports of continuous span and cantilever beams, where the interaction of high shear force and bending moment can reduce the capacity of a section to well below that for the same section subject only to pure shear or moment. Hence experimental studies were conducted to assess the combined bending and shear behaviour and strengths of LSBs. Eighteen tests were conducted and the results were compared with current AS/NZS 4600 and AS 4100 design rules. AS/NZS 4600 design rule based on circular interaction equation was shown to grossly underestimate the combined bending and shear capacities of LSBs and hence two lower bound design equations were proposed based on experimental results. Use of these equations will significantly improve the confidence and cost-effectiveness of designing LSBs for combined bending and shear actions.

ABSTRACT: In this paper, a soft-computing based study aimed to estimate the available rotation capacity of cold-formed rectangular and square hollow section (RHS-SHS) steel beams is described and novel mathematical models based on neural network (NN) and genetic expression programming (GEP) are proposed. In order to develop the proposed formulations, a wide experimental database obtained from available studies in the literature has been considered. The data used in the NN and GEP models are arranged in a format of eight input parameters covering both geometrical and mechanical properties such as width, depth and wall thickness of cross section, inside corner radius, yield stress, ratio of modulus of elasticity to hardening modulus, ratio of the strain under initial hardening to yield strain and shear length. The accuracy of the proposed formulations is verified against the experimental data and the rates of efficiency and performance are compared with those provided by analytical semi-empirical formulation developed by some of the Authors in a previous study. The proposed prediction models proved that the NN and GEP methods have strong potential for predicting available rotation capacity of cold-formed RHS-SHS steel beams.

ABSTRACT: This paper focuses on the compressive strength of the concrete-filled double skin steel tubular (CFDST) short columns. Columns with external and internal circular carbon steel tubes are merely considered. First, this paper summarises previously developed formulas for predicting the compressive strength of the CFDST columns, along with the formula recently suggested by Yu et al. (2013) for solid and hollow circular concrete-filled tubular (CFST) columns. The various formulas for predicting compressive strength are then compared with test results. Test results are then organised and evaluated according to the relevant test specimen parameter; the diameter-to-thickness ratio (D/tD/te). It is found that the available tests do not cover the full range of the D/tD/te ratio. Hence, numerical nonlinear simulations, based on the finite element (FE) method
using the software package ABAQUS/Standard, are constructed to compensate for the shortage in the available results. Through comparison with test and FE results, a new design formula is suggested. Such formula is shown to be more accurate than available formulas for estimating the compressive strength of the CFDST short columns. This recommended design model requires relatively less calculation efforts, and provides less scattered predictions than those using the current design rules. At the end, an illustrative example for the calculation of the compressive strength of the CFDST columns using the currently proposed formula is provided.

DOI: 10.1016/j.tws.2013.09.026
ABSTRACT: Forced vibration response of laminated composite and sandwich shell is studied by using a 2D FE (finite element) model based on higher order zigzag theory (HOZT). This is the first finite element implementation of the HOZT to solve the forced vibration problem of shells incorporating all three radii of curvatures including the effect of cross curvature in the formulation using Sanders' approximations. The proposed finite element model satisfies the inter-laminar shear stress continuity at each layer interface in addition to higher order theory features, hence most suitable to model sandwich shells along with composite shells. The $C_0$ finite element formulation has been done to overcome the problem of $C_1$ continuity associated with the HOZT. The present model can also analyze shells with cross curvature like hypar shells besides normal curvature shells like cylindrical, spherical shells etc. The numerical studies show that the present 2D FE model is more accurate than existing FE models based on first and higher order theories for predicting results close to those obtained by 3D elasticity solutions for laminated composite and sandwich shallow shells. Many new results are presented by varying different parameters which should be useful for future research.

ABSTRACT: In this study, the thermal buckling behavior of a circular aluminum plate that results from thermal loading was investigated using a digital image correlation (DIC) technique. The aluminum plate was placed in a titanium ring and the structure was heated from room temperature 25 °C to 160 °C. Due to the differences in the coefficients of thermal expansion (CTEs) between aluminum and titanium, the aluminum plate buckles at a certain temperature. The buckling temperature was determined from the full-field deformation shape and temperature-displacement curve that were obtained using the DIC-based ARAMIS® software. In order to obtain an appropriate full-field deformation, a polarized light filter was used to reduce the out-of-plane displacement error, which is an unavoidable error in the experiment. Using this method, the standard deviation of the $z$ directional displacement was reduced from ±3.14 μm to ±2.70 μm. In addition, the results demonstrated that the measured buckling temperature was close to the theoretical buckling temperature of the circular plate in a simply supported boundary condition. In order to verify the proposed measurement method, a finite element analysis of the structure was performed using the ABAQUS software. The results of the DIC-based measurement and finite element analysis were in good agreement regarding the deformation curve tendency. The buckling temperature from the finite element method (FEM) was slightly larger than that from the
experimental results due to the initial imperfections of the aluminum specimen. These results provide a good method for studying thermal buckling for the design and analysis of engineering structures in diverse fields such as aerospace engineering, oil refineries, and nuclear engineering.

ABSTRACT: The free vibration of inflatable beams was studied using the dynamic stiffness method. A 3D Timoshenko beam with a homogeneous orthotropic woven fabric (OWF) was considered. Using the usual total Lagrangian form of the virtual work principle, the model took the geometric nonlinearities and the inflation pressure follower force effect into account. The nonlinear equilibrium equations were then linearized around the prestressed reference configuration. The exact dynamic stiffness matrix was developed by directly solving the governing differential equations of a 3D loaded inflatable beam in a free vibration. The effects of the inflation pressure, fabric mechanical properties and the boundary conditions on the natural frequencies and mode shapes of the inflatable beams were demonstrated. The proposed model was validated favorably through its comparison with a 3D thin shell finite element model and an isotropic fabric model found in the literature.

ABSTRACT: A fully geometrically nonlinear finite element (FE) model is developed using large rotation shell theory for static analysis of composite and piezoelectric laminated thin-walled structures. The proposed large rotation theory is based on the first-order shear deformation (FOSD) hypothesis. It has six independent kinematic parameters which are expressed by five mechanical nodal degrees of freedom (DOFs). Linear electromechanically coupled constitutive equations with a constant electric field distribution through the thickness of each smart material layer are considered. Eight-node quadrilateral plate/shell elements with five mechanical DOFs per node and one electrical DOF per smart material layer are employed in the FE modeling. The present large rotation FE model is implemented into static analysis of both composite and piezoelectric laminated plates and shells. The equilibrium equation is solved by Newton–Raphson algorithm with system matrices updated in every iteration. The results are compared with those presented in the literature and others calculated by various simplified nonlinear shell theories. They indicate that large rotation theory has to be considered for the calculation of displacements and sensor output voltages of smart structures undergoing large deflections, since other simplified nonlinear theories fail to predict the static response precisely in many cases.
P. Malekzadeh, M.R. Golbahar Haghighi and M. Shojaee (Department of Mechanical Engineering, School of Engineering, Persian Gulf University, Bushehr 7516913798, Iran), “Nonlinear free vibration of skew nanoplates with surface and small scale effects”, Thin-Walled Structures, Vol. 78, pp 48-56, May 2014
DOI: 10.1016/j.tws.2013.10.027

ABSTRACT: The nonlinear free flexural vibration of skew nanoplates is studied by considering the influences of free surface energy and size effect (small scale) simultaneously. The formulations are derived based on classical plate theory (CPT) in conjunction with nonlocal and surface elasticity theories using Hamilton's principle. Green's strain tensor together with von Kármán assumptions is employed to model the geometrical nonlinearity. The free surfaces are modeled as two-dimensional membranes adhering to the underlying bulk material without slipping. The solution algorithm is based on the transformation of the governing differential equation from the physical domain to a rectangular computational one, and discretization of the spatial derivatives by employing the differential quadrature method (DQM) as an efficient and accurate numerical tool. The effect of small scale parameter and surface effect together with the geometrical parameters and boundary conditions on the nonlinear frequency parameters of the skew nanoplates are studied.

ABSTRACT: The axial crushing responses of bonded and brazed multi-layer 1050 H14 trapezoidal aluminum corrugated core (fin) sandwich structures, with and without aluminum interlayer sheets in 0°/0° and 0°/90° core orientations, were both experimentally and numerically investigated at quasi-static and dynamic strain rates. Multi-layering the core layers decreased the buckling stress and increased the densification strain. The experimental and simulation compression stress–strain curves showed reasonable agreements with each other. Two main crushing modes were observed experimentally and numerically: the progressive fin folding and the shearing interlayer aluminum sheets. Both, the simulation and experimental buckling and post-buckling stresses increased when the interlayer sheets were constraint laterally. The multi-layer samples without interlayer sheets in 0°/90° core orientation exhibited higher buckling stresses than the samples in 0°/0° core orientation. The increased buckling stress of 0°/0° oriented core samples without interlayer sheets at high strain rate was attributed to the micro-inertial effects which led to increased bending forces at higher impact velocities.

ABSTRACT: The present study deals with the effects of moist environment on the natural frequencies of vibration of Glass/Epoxy woven fibre composite doubly curved panels with strip delamination using the finite element method (FEM). For modelling the delamination, multipoint constraint algorithm is incorporated in the analysis. The effects of boundary condition, delamination size and shape of panels on natural frequencies of
vibration are investigated in the moisture content range. The frequencies of vibration reduce with increase of moisture in delaminated curved panels. The reductions of frequencies are more prominent for higher degree of moisture concentrations and significantly affected by boundary conditions.

Ahmad Partovi Meran, Tuncer Toprak and Ata Mugan (Faculty of Mechanical Engineering, Istanbul Technical University, 34437 Gumussuyu, Istanbul, Turkey), “Numerical and experimental study of crashworthiness parameters of honeycomb structures”, Thin-Walled Structures, Vol. 78, pp 87-94, May 2014
ABSTRACT: Crashworthiness parameters of aluminum hexagonal honeycomb structures under impact loads are investigated by using finite element methods and conducting experiments. To validate the finite element models, numerical results are compared with experimental measurements and theoretical results reported in literature. In numerical simulations of honeycomb structures, out-of-plane loads are considered while the aluminum foil thickness, cell side size, cell expanding angle, impact velocity and mass are varying, and dynamic behavior and crashworthiness parameters are examined. It is observed that there are good agreements between numerical, experimental and theoretical results. Numerical simulations predict that crashworthiness parameters depend on cell specification and foil thickness of the honeycomb structure and are independent of impact mass and velocity.

ABSTRACT: This paper summarizes results from an experimental program that investigated the cyclic axial behavior and energy dissipation of cold-formed steel C—sections structural framing members. Fully characterized cyclic axial load—deformation response of individual members is necessary to facilitate performance-based design of cold-formed steel building systems. Specimen cross-section dimensions and lengths were selected to isolate specific buckling modes (i.e., local, distortional or global buckling). The cyclic loading protocol was adapted from FEMA 461 with target displacements based on elastic buckling properties. Cyclic response showed large post-buckling deformations, pinching, strength and stiffness degradation. Damage accumulated within one half-wave after buckling. The total hysteretic energy dissipated within the damaged half-wave decreased with increasing cross-section slenderness. More energy dissipation comes at the cost of less cumulative axial deformation before tensile rupture.

ABSTRACT: Vertical cylindrical tanks for fluid and bulk storage are generally with very thin wall so they are very susceptible to buckling under wind loads. One of the main challenges for designers is the scarcity of reliable wind loads on tanks. A particular case of wind loads on tanks may occur when a tank is situated at the corner of a group in tank farm or distribution station, since it is expected to be loaded by different wind pressures compared with those of an isolated tank. In this paper, a large number of wind tunnel tests are conducted to investigate the wind loads on vertical cylindrical open-topped tanks in group, with main focus on
the grouping effect of large cylindrical tanks with a very low aspect ratio. Three types of tank groups are covered in this study: two adjacent tanks including tandem, parallel and staggered configurations, three adjacent tanks in triangular array and four adjacent tanks in square array. The effects of spacing between tanks and wind attack angle on wind pressure distributions of both external and internal wall are investigated, and the difference of wind loads on tanks in a group compared with those on an isolated tank is discussed.

Kojiro Uenaka (Department of Civil Engineering, Kobe City College of Technology, Gakuenhigashimachi 8-3, Nishi, Kobe 6512194, Japan), “Experimental study on concrete filled elliptical/oval steel tubular stub columns under compression”, Thin-Walled Structures, Vol. 78, pp 131-137, May 2014, DOI: 10.1016/j.tws.2014.01.023
ABSTRACT: A concrete filled elliptical/oval steel tubular (CFEST) member consists of elliptical/oval steel tube and in-filled concrete. The CFEST member is a new type of steel–concrete composite member and is part of a family of concrete filled steel tubular members known as CFT. The present study aims to investigate, experimentally, the characteristics of CFEST stub columns under centric loading. The main test parameters selected are diameter-to-thickness and diameters ratios of elliptical/oval steel tube. From the results, local buckling of the elliptical/oval steel tube associated with shear failure of in-filled concrete could be observed. Axial loading capacity decreased as diameter-to-thickness ratio increased. Whereas, those capacities normalized by the summation of the individual strengths, namely the elliptical/oval steel tube and in-filled concrete strengths, are regulated in case the diameter-to-thickness ratio becomes larger. Finally, a method to predict the axial loading capacity induced by confinement effects of the in-filled concrete is proposed.

Anthony Deloge Ariyanayagam and Mahen Mahendran (School of Civil Engineering and Built Environment, Science and Engineering Faculty, Queensland University of Technology, Brisbane, QLD 4000, Australia), “Numerical modeling to load bearing light gauge steel frame wall systems exposed to realistic design fires”, Thin-Walled Structures, Vol. 78, pp 148-170, May 2014, DOI: 10.1016/j.tws.2014.01.003
ABSTRACT: Fire safety has become an important part in structural design due to the ever increasing loss of properties and lives during fires. Conventionally the fire rating of load bearing wall systems made of Light gauge Steel Frames (LSF) is determined using fire tests based on the standard time–temperature curve in ISO834 (ISO 834-1, 1999 [1]). However, modern commercial and residential buildings make use of thermoplastic materials, which mean considerably high fuel loads. Hence a detailed fire research study into the fire performance of LSF walls was undertaken using realistic design fire curves developed based on Eurocode parametric (ENV 1991-1-2, 2002 [2]) and Barnett's BFD (Barnett, 2002 [3]) curves using both full scale fire tests and numerical studies. It included LSF walls without cavity insulation, and the recently developed externally insulated composite panel system. This paper presents the details of finite element models developed to simulate the full scale fire tests of LSF wall panels under realistic design fires. Finite element models of LSF walls exposed to realistic design fires were developed, and analysed under both transient and steady state fire conditions using the measured stud time–temperature curves. Transient state analyses were performed to simulate fire test conditions while steady state analyses were performed to obtain the load ratio versus time and failure temperature curves of LSF walls. Details of the developed finite element models and the results including the axial deformation and lateral deflection versus time curves, and the stud failure modes and times are presented in this paper. Comparison with fire test results demonstrate the ability of developed finite element models to predict the performance and fire resistance ratings of LSF walls under realistic design fires.

ABSTRACT: This paper addresses the nonlinear vibration problem of simply supported functionally graded (FG) cylindrical shells with embedded piezoelectric layers. The governing differential equations of motion of the FG cylindrical shell are derived using the Lagrange equations under the assumption of the Donnell’s nonlinear shallow-shell theory. A semi analytical approach, wherein the displacement fields are expanded by means of a double mixed series based on linear mode shape functions for the longitudinal, circumferential and radial variables, is proposed to characterize the nonlinear response of the cylindrical shell. The large-amplitude response and amplitude frequency curves of the cylindrical shell are obtained by using the proposed approach. Finally, the effects of excitation force and applied voltage on the vibration behavior of the cylindrical shell are investigated.

ABSTRACT: Closed-form equations to determine the local buckling critical stress of typical pultruded fiber reinforced polymer (FRP) sections – angles, I-shaped, channels and rectangular tubes – comprised of orthotropic thin walls subject to concentric compression are developed. Approximate deflected-shape functions addressing boundary conditions and compatibility of rotation between plate elements are chosen for each section having uniform thickness and material properties. The Rayleigh energy method is used to obtain equations for the local buckling critical stress. Results are compared with numerical analyses using the finite strip method (FSM) for isotropic and orthotropic sections with typical ranges of properties. Comparison is also made with the method recommended by current available standards and guidelines.

ABSTRACT: This paper investigates the strength and behaviour of concrete-filled double skin steel tubular (CFDST) slender columns under axial compression. The lean duplex stainless steel material (EN 1.4162) which has recently gained significant attention is considered herein as the external jacket of such columns. Finite element (FE) analyses of several CFDST columns are conducted. Careful consideration is taken in the modelling for the concrete behaviour, for which both of the compressive and the tensile behaviours and the nonlinear behaviour due to cracking are fully considered. The accuracy of the current FE models is ensured through the comparison with the existing columns in literature. A parametric study is then conducted to investigate the behaviour of such columns under different affecting factors; the slenderness ratio, the concrete confinement effect, the hollow ratio, the concrete compressive strength and the thickness ratio. The behavioural differences
between intermediate length and very long CFDST columns are carefully addressed. Analytically obtained ultimate strengths are compared with design strengths calculated by European and American specifications. European design strength is found to give better predictions compared to the American specifications. However, it is shown that both strengths cannot be used in design because they overestimate the ultimate strengths and thereby do not satisfy the safety requirements. Therefore, a modification is suggested to the European design model which is shown to be able to estimate the compressive resistance of the CFDST columns more accurately than other methods.

ABSTRACT: In this study, based on the analytical model of circular plane plate with initial bending curvature under large deflection and conical shells theory, the energy method is proposed and a new analytical solution of the load deformation characteristic of the Belleville springs was obtained. Compared with experimental results, the analytical solution has higher precision than the traditional A-L algorithm solution and the FEA method, and the validity of energy method is verified. On this basis, the deformation energy is studied and the analytical solution is applied to the mono-freedom conservative system consisting of a single Belleville spring and mass. The natural frequency of the conservative system under free vibration is analyzed, followed by the discussion on two factors, the ratio of free height and width, the width of supporting surface, which affect load deformation characteristic of Belleville springs.

“Strength design curves and an effective width formula for cold-formed steel columns with distortional buckling”, Thin-Walled Structures, Vol. 79, pp 62-70, June 2014, DOI: 10.1016/j.tws.2014.02.004
ABSTRACT: Distortional buckling mode of cold-formed steel thin-walled member is an unstable behavior, and in some cases it may govern the load-carrying capacity of the member. The source, evolution and performance of the formulas and test data for the two strength design curves developed by Hancock are studied, for predicting the load-carrying capacity in the distortional mode. A proposed strength design curve based on available test data and Hancock’s strength design curves are then compared with the current design methods, the Direct Strength Method and the Effective Width Method, which are incorporated in the “North American specification for the design of cold-formed steel structural members” (AISI-NAS: 2007), “cold-formed steel structures” (AS/NAS 4600: 2005), and the Chinese “Technical specification for low-rise cold-formed thin-walled steel buildings” (JGJ 227-2011). The results indicate that the current design standards adopted the two strength design curves for the DSM and EWM, but they have some differences at the partial extent. A novel formula is proposed for dealing with this problem. The range of applicability of the proposed strength equation is extended from that in AS/NZS 4600 and is shown to be more accurate than AS/NZS 4600 when compared with that in the NAS S100.
ABSTRACT: The use of thin-walled steel members has significantly increased in the last decades, especially in the field of logistics. Goods and products are frequently stored in pallet racks, i.e., in structural framed systems assembled from components manufactured from cold formed steel coils. The great convenience in using rack systems is, however, counterbalanced by a complex local and global structural behavior, often difficult to predict accurately. Owing to the light weight of the key structural components, rack design requires high engineering competence. A structural failure of these structures may result in a very great economic loss. Several research programs are currently in progress worldwide; their outcomes are expected to contribute significantly to the improvements of design rules. Standards, however, do not seem to cover adequately the modeling phase of the framed systems nor minimum requirements for the finite element (FE) analysis programs to be used for analysis. These two points are fundamental pre-requisites for guaranteeing an adequate safety level in design. A research project aimed at improving the reliability of the design rules for steel storage pallet racks and at developing suitable approaches for preliminary calculations is currently in progress. Main results of a numerical study carried out on typical medium-rise unbraced pallet racks are summarized here with the goal of investigating the key features of the warping influence on the structural frame behavior under monotonic loading; the seismic response of rack is considered in a separate paper.

ABSTRACT: Vertical cylindrical welded steel tanks are typical thin-walled structures which are very susceptible to buckling under wind load. This paper investigates the buckling behavior of open-topped steel tanks under wind load by finite element simulation. The analyses cover six common practical tanks with volumes of $2\times10^3$ m$^3$ to $100\times10^3$ m$^3$ and height-to-diameter ratios $H/D<1$. The linear elastic bifurcation analyses are first carried out to examine the general buckling behavior of tanks under wind load, together with comparison to that of tanks under uniform pressure and windward positive pressure (only loaded by positive wind pressure in the windward region). The results show that for larger tanks in practical engineering, the stability carrying capacity of wind load is relatively lower. It is also indicated that the buckling behavior of tanks under wind load is governed by the windward positive pressure while wind pressure in other region of tank essentially has no influence on the buckling performance. The geometrically nonlinear analyses are then conducted to investigate the more realistic buckling behavior of tanks under wind load. It is found that the buckling behaviors of perfect tanks and imperfect tanks are much different. The weld induced imperfection only has little influence on the wind buckling behavior while the classical buckling mode imperfection has significant influence, leading to a considerable reduction of wind buckling resistance. The influences of thickness reduction of cylindrical wall, liquid stored in the tank and wind girder on the buckling behavior are also examined. It shows that the thickness reduction of cylindrical wall considerably reduces the wind buckling resistance while sufficient liquid stored in the tank and wind girder significantly increase the wind buckling resistance.

ABSTRACT: An experimental study investigating the mechanical response of both empty and aluminum foam filled braided stainless steel tubes subjected to transverse loading is presented in this manuscript. Tube specimens were loaded using a custom built testing machine which operated at a constant velocity of 18.8 mm/s. The braided tubular specimens utilized in this study were round AISI 301 stainless steel tubes with a nominal wire diameter of 0.51 mm, external nominal diameter of 64.5 mm, and length of 330 mm. Four different foam core configurations were tested, with densities ranging from 248 kg/m³ to 493 kg/m³. Additionally, two different core geometries were considered, namely cylindrical and rectangular prism configurations. Both core geometries were constructed from circular and rectangular flat panel sections of larger metallic foam panels. Structural adhesive was used to bond the smaller sections of the foam panels together to generate the cylindrical and rectangular prism cores. Deformation mechanisms of these structures were identified through use of a high speed, high resolution camera. The applied transverse load resulted in significant tensile loads within the braided tube and further resulted in braid diameter reduction as well as crushing and pulverization of the metallic foam core. Failure of the circular foam filled braided tubes was observed to be a combination of foam core separation, foam pulverization, as well as braid tow failure resulting from tensile forces and to a lesser extent bending. Failure of rectangular foam filled braided tubes was generally consistent with the mechanisms associated with the cylindrical cores, with the exception of the foam core separation. Force/displacement behavior was dependent on foam core density prior to tow lockup. Energy absorption levels ranged from 2.37 kJ to 9.13 kJ for the core densities and geometries are considered within this investigation.

ABSTRACT: In bridge construction, the use of stiffened plates for box-girder or steel beams is common day to day practice. The advantages of the stiffening from the economical and mechanical points of view are unanimously recognized. For curved steel panels, however, applications are more recent and the literature on their mechanical behaviour including the influence of stiffeners is therefore limited. Their design with actual finite element software is possible but significantly time-consuming and this reduces the number of parameters which can be investigated to optimise each panel. The present paper is thus dedicated to the development of a preliminary design formula for the determination of the ultimate strength of stiffened cylindrical steel panels. This approximate formula is developed with the help of a design of experiment method which has been adapted from the current statistical knowledge. This method is first presented, and its feasibility as well as its efficiency are illustrated through an application to the reference case of unstiffened curved panels. Then, the case of stiffened curved panels is investigated and a preliminary design formula is developed. The ease of use of this formula for preliminary design is finally illustrated in a cost optimisation problem.

ABSTRACT: Flutter of cantilevered, functionally graded cylindrical shells under an end axial follower force is addressed. The material properties are assumed to be graded along the thickness direction according to a simple power law. Using the Hamilton principle, the governing equations of motion are derived based on the first-order shear deformation theory. The stability analysis is carried out using the extended Galerkin method and minimum flutter loads and corresponding circumferential mode numbers are obtained for different volume fractions, length-to-radius, and thicknesses-to-radius ratios. Two different configurations are considered for the FGM: one in which the metal phase is the outer layer and the ceramic phase is the inner one, and the other vice versa. Results indicate the ranges of major influence due to the volume fraction, and the combined effect of thickness and volume fraction on the flutter load. Also, the optimum and critical power parameters between zero and infinity for which the flutter loads are maximum and minimum are determined.

DOI: 10.1016/j.tws.2014.02.008
ABSTRACT: This paper presents the results of dynamic stability analysis of pre-aged aluminium profiles subjected to dynamic impulse loading. As an example a rectangular compressing pulse is considered. The analysis deals with the open cross-section ‘channel profile’ and its section modifications where the material properties obtained in experimental testing are employed. Instead of static buckling to determine a critical load, usage of a criterion is necessary. Thus the application of dynamic buckling criterion is commented on according to presented results of computations. The influence of material aging on dynamic buckling load level is argued.

ABSTRACT: In composite construction, rectangular hollow steel tubular slender beam-columns are subjected to preloads arising from construction loads and permanent loads of the upper floors before infilling of the wet concrete. The behavior of biaxially loaded thin-walled rectangular concrete-filled steel tubular (CFST) slender beam-columns with preloads on the steel tubes has not been studied experimentally and numerically. In this paper, a fiber element model developed for CFST slender beam-columns with preload effects is briefly described and verified by existing experimental results of uniaxially loaded CFST columns with preload effects. The fiber element model is used to investigate the behavior of biaxially loaded rectangular CFST slender beam-
columns accounting for the effects of preloads and local buckling. Parameters examined include local buckling, preload ratio, loading angle, depth-to-thickness ratio, column slenderness, loading eccentricity and steel yield strength. The results obtained indicate that the preloads on the steel tubes significantly reduce the stiffness and strength of CFST slender beam-columns with a maximum strength reduction of more than 15.8%. Based on the parametric studies, a design model is proposed for axially loaded rectangular CFST columns with preload effects. The fiber element and design models proposed allow for the structural designer to efficiently analyze and design CFST slender beam-columns subjected to preloads from the upper floors of a high-rise composite building during construction.

Young Bong Kwon and In Kyu Jeong (Department of Civil Engineering, Yeungnam University, Gyongsan 712-749, Republic of Korea), “Resistance of rectangular concrete-filled tubular (CFT) sections to the axial load and combined axial compression and bending”, Thin-Walled Structures, Vol. 79, pp 178-186, June 2014 DOI: 10.1016/j.tws.2014.02.019

ABSTRACT: This paper describes the development of the direct strength method (DSM) for concrete-filled tubular (CFT) sections. The axial and flexural strength of CFT sections with local buckling are proposed based on previous test results. Although Eurocode4 does not allow the use of slender steel skins for CFT sections, the limit of the width-to-thickness ratio for the steel skin has recently been extended to slender sections in AISC specifications. A simple formula for the axial and flexural strength of CFT sections for the DSM is proposed to account for the local buckling of a thin steel skin and for the enhanced compressive strength of concrete from the confining effect of the steel skin. The squash load predicted by the proposed formula is compared with test results and those predicted by AISC specifications and Eurocode4. A formula for strength interactions of CFT members under combined compression and flexure is proposed and is compared with test results. The comparison confirmed that the formula for axial and flexural strength and that for strength interactions can conservatively predict the resistance of CFT columns to the axial load and combined compression and bending.

ABSTRACT: Approximate finite strip eigen-buckling solutions are introduced for local, distortional, flexural, and flexural-torsional elastic buckling of a thin-walled metal column with perforation patterns. These methods are developed to support a calculation-based strength prediction approach for steel pallet rack columns employing the American Iron and Steel Institute’s Direct Strength Method, however they are generally posed and could also be useful in structural studies of thin-walled thermal or acoustical members made of steel, aluminum, or other metals. The critical elastic global buckling load including perforations is calculated by reducing the finite strip buckling load of the cross-section without perforations using the weighted average of the net and gross cross-sectional moment of inertia along the length of the member for flexural (Euler) buckling, and for flexural-torsional buckling, using the weighted average of both the torsional warping and St. Venant torsional constants. For local buckling, a Rayleigh–Ritz energy solution leads to a reduced thickness stiffened element equation that simulates the influence of decreased longitudinal and transverse plate bending stiffness caused by perforation patterns. The cross-section with these reduced thicknesses is input into a finite strip analysis program to calculate the critical elastic local buckling load. Local buckling at a perforation is also treated with a net section finite strip analysis. For distortional buckling, a reduced thickness equation is derived for the web of an open cross-section to simulate the reduction in its transverse bending stiffness caused by
perforation patterns. The approximate elastic buckling methods are validated with a database of 1282 thin shell finite element eigen-buckling models considering five common pallet rack cross-sections featuring web perforations that include 36 perforation dimension combinations and twelve perforation spacing combinations.

Yuanqi Li, Yinglei Li, Shukun Wang and Zuyan Shen (Department of Building Engineering, Tongji University, Shanghai 200092, China), “Ultimate load-carrying capacity of cold-formed thin-walled columns with built-up box and I section under axial compression”, Thin-Walled Structures, Vol. 79, pp 202-217, June 2014
DOI: 10.1016/j.tws.2014.02.003
ABSTRACT: The use of cold-formed thin-walled steel structures has increased in recent years, and some built-up section members are motivated and also widely used for their excellent structural behaviors. In this paper, a series of axially-compressed tests on built-up box section members composed of two C-section by self-drilling screws at flanges are conducted. The differences of global, local and distortional buckling behaviors between members with built-up and single sections are investigated at first. Then the effects of installation error and fastener spacing on ultimate load-carrying capacity of built-up members are analyzed. A strength estimation method for built-up members under axial compression is proposed based on the experimental investigation in this paper, as well as some existing experiments, and corresponding numerical analysis studies. Finally, the predicted capacity obtained by using the proposed strength estimation method is compared with experimental results and the nominal axial strength determined according to the AISI provisions, by which the suitability and accuracy of the proposed strength estimation method have been established.

ABSTRACT: This paper formalizes the domain of all and only manufacturable open cold-formed steel (CFS) profiles aimed at improving their strength capability in the development of new products. A Genetic Algorithm is applied over this domain to get a set of best solutions from structural and constructive viewpoints. A basic review is carried out with regard to (i) Shape Grammar, (ii) Finite Strip Method-based elastic buckling analysis, (iii) Direct Strength Method-based structural strength computation and (iv) modified procedure of the Non-dominated Sorting Genetic Algorithm. CFS-manufacturing is defined as a language and its general grammar is presented. This grammar-based model responds to requisites of descriptive power, simplicity of implementation, and customization to specific needs. The CFS grammar has been implemented using scripting languages available in pre-existing CAD and CAE applications. Implementation includes generation, visualization, analysis and improvement capabilities. Results show that innovative shapes with improved strength could be generated from the finite set of allowable manufacturing grammar rules encoded by the grammar.

ABSTRACT: An investigation was carried out into the influence of perforations of various shapes on the buckling behaviour of cold-formed column members of lipped channel cross-section. A finite element analysis using ANSYS, an experimental investigation, and design code predictions using the AISI Specification, British Standards (BS) and EU Standards, are employed to determine the buckling load capacity. An experimental investigation of the buckling behaviour of flat and fixed ended columns is presented, and the findings from this are used to validate finite element results, and compare with design code predictions. The numerical results of load vs. displacement behaviour are shown to be in good agreement with those reported from the tests. It is shown that the ultimate failure load of the lipped channels under compression varies greatly with the presence of perforations.

Tohid Ghanbari Ghazijahani, Hui Jiao and Damien Holloway (School of Engineering, University of Tasmania, Hobart, Australia), “Experimental study on damaged cylindrical shells under compression”, Thin-Walled Structures, Vol. 80, pp 12-21, July 2014, DOI: 10.1016/j.tws.2014.02.029
ABSTRACT: Sensitivity to initial imperfections under compressive loading has been extensively studied in shell structures. However, due to the existence of a wide range of imperfections with various shapes and amplitudes, the real behavior of such structures needs to be further investigated when they face with a damaged area. This study presents an experimental program in which buckling and failure response of damaged shell specimens are analyzed. The results of this study can be generalized for many kinds of cylindrical shells to full scale of applications with similar D/t ratios.

ABSTRACT: An experimental study on stiffened plates subjected to combined action of in-plane load and lateral pressure is described in the paper. Details of the experiments and finite element analyses of the specimens tested are presented along with the results. Measurements of initial imperfection in the specimens have been made and included in the analyses. Results show that lateral load carrying capacity of stiffened plate drops with increase in axial load and vice-versa. It is found that plate slenderness ratio has significant influence on the ultimate load capacity of stiffened plates subjected to both in-plane load and lateral pressure. Increase of plate slenderness ratio results in a decrease of ultimate load capacity of stiffened plate. The accuracy of the finite element modelling is established by comparing the results with the corresponding experimental values.

ABSTRACT: Due to the long stroke and stable reaction force, circular tubes under inversion are always adopted in the design of energy absorbers. Although a few studies were conducted, the existing theoretical predictions on the knuckle radius and the reaction force of the circular tube during its free inversion displayed large discrepancy from the experimental observations. In this paper, currently existing two-dimensional theoretical models of the free inversion tube are carefully reviewed. After realizing the defects of these models, Reddy’s model is improved by adopting the appropriate external work rate and material yield condition, for tubes made of rigid, perfectly plastic material. In order to validate the improved theoretical model, experiments of the free inversion of circular aluminum tubes, and finite element simulations of tubes made of the elastic, perfectly plastic material are all carried out. It is confirmed that compared with the experimental data and the FE simulations, the current model provides more accurate predictions on both the knuckle radius and the steady inversion load for the quasi-static free inversion of circular tubes.

ABSTRACT: This paper presents a study to extend a previously developed theoretical model to predict the crushing behavior of hexagonal multi-cell thin-walled structures, e.g. honeycombs under quasi-static loading. The low speed compressive tests were conducted on three types of aluminum honeycomb panels. Based on the test data and existing theoretical models, a new analytical model was developed to predict its mean crushing strength. Some key parameters in this new model were determined with the finite element (FE) method. Then the predictions based on the new model were compared with the results reported in the published literature. It has been shown that the new model has a similar or better performance compared to its counterparts. Considering its concise expression, the newly developed model can be deemed as a convenient computational tool in engineering practice.

ABSTRACT: In this study, compressive strength, modulus of elasticity and steel tensile coupon tests are performed to determine material properties. Sixteen hollow cold formed steel tubes and 48 concrete filled steel tube specimens are used for axial compression tests. The effects of width/thickness ratio (b/t), the compressive strength of concrete and geometrical shape of cross section parameters on ultimate loads, axial stress, ductility and buckling behavior are investigated. Circular, hexagonal, rectangular and square sections, 18.75, 30.00, 50.00, 100.00 b/t ratio values and 13, 26, 35 MPa concrete compressive strength values are chosen for the experimental procedure. Analytical models of specimens are developed using a finite element program (ABAQUS) and the results are compared. Circular specimens are the most effective samples according to both axial stress and ductility values. The concrete in tubes has experienced considerable amount of deformations
which is not expected from such a brittle material in certain cases. The results provide an innovative perspective on using cold formed steel and concrete together as a composite material.

ABSTRACT: Circular hollow steel sections are normally specified in truss and dome structures to take advantage of their efficiency in compression and the ease in which they can be curved to match the various radii of different domes. However, it is not easy to connect these members together or to other members. In order to connect them together or to other members the ends are sometimes squashed or flattened. Although the process of flattening does not reduce the area of the section, it does reduce the flexural stiffness of the section. The aim of this paper is to study the behaviour of circular hollow members with flattened edges, in compression. Variables in the tests include the diameter, thickness and length of the sections, and number of bolts in the connection. Two failure modes were observed and these are overall flexural buckling (OFB) of the member and excessive deformation of the transition zone (DTZ). The results from these tests are compared with the flexural compressive resistance formula in the South African steel code (SANS10162-1) and the European steel code (EN 1993-1-1), with a view of determining a simple formula for designing such members.

ABSTRACT: A model of the dynamic response of a relatively long circular hollow section beam to a uniform blast modeled as an impulsive loading is developed in order to reveal the characteristic features of deformation and energy absorption of hollow section beams under such loading. A two-phase analytical model is proposed for a circular metallic hollow beam made of a strain-rate insensitive material. Both local and global deformations build up simultaneously during the first phase, and then only global bending occurs during the second phase. Because mainly large plastic deformations develop in the hollow section, the elastic deformations are neglected and a rigid-plastic method of analysis is applied. The responses of circular hollow beams with lengths between 600 and 1000 mm are analyzed for beam radii varying between 50 and 70 mm and wall thicknesses between 1.2 and 1.6 mm. The model predictions are verified by numerical simulations and reasonable agreement is observed with respect to the characteristic displacements and deformed section shape. The energy partitioning during the deformation process is briefly discussed.

“Seismic performance and collapse prevention of concrete-filled thin-walled steel tubular arches”, Thin-Walled Structures, Vol. 80, pp 91-102, July 2014, DOI: 10.1016/j.tws.2014.03.005

ABSTRACT: The primary objective of this paper is to investigate the seismic behaviour of concrete-filled steel tubular (CFST) arches using incremental dynamic analysis (IDA). A nonlinear elastic–plastic finite element model is developed using OpenSees software and is verified with a shaking table test. Single-record IDA studies indicate that a CFST arch undergoes global dynamic instability when subjected to ground motions of increasing intensity levels. During this process, either dynamic elastic buckling or dynamic elastic–plastic buckling may occur. Dynamic strength, which is defined as the capacity for preventing global dynamic instabilities of CFST arches, is determined with a series of multi-record IDA calculations. A lower bound equation that takes into account the effect of slenderness ratio, axial compression ratio, and included angle is proposed for the prediction of the dynamic strength of CFST arches.

“Mechanism investigation of welding induced buckling using inherent deformation method”, Thin-Walled Structures, Vol. 80, pp 113-119, July 2014, DOI: 10.1016/j.tws.2014.03.003

ABSTRACT: Due to the increasing use of thin plates in lightweight welded structure, welding induced buckling may occur in such thin plate welded structure. In this study, welding induced buckling of thin plate welded structure is investigated using the eigenvalue analysis and elastic Finite Element (FE) analysis based on inherent deformation theory, and the mechanism of welding induced buckling is clarified. Bead-on-plate welding is first examined. Measured out-of-plane welding distortion indicates that saddle type buckling is produced after cooling. Eigenvalue analysis shows the computed lowest buckling mode is the saddle type and the corresponding critical force is less than the applied tendon force evaluated by Thermal–Elastic–Plastic (TEP) Finite Element (FE) analysis beforehand. Using elastic Finite Element (FE) analysis in which all components of inherent deformation are used and also considering initial deflection, out-of-plane welding distortion is predicted with high accuracy compared with measurement. It is also concluded that tendon force (longitudinal inherent shrinkage) is the dominant reason of buckling and it determines the buckling mode, and initial deflection and inherent bending are considered to be disturbances which trigger buckling. Later, a thin plate stiffened welded structure with fillet welded joints is examined. Although welding did not induce buckling of plate fields in bending modes in the considered thin plate stiffened welded structure, the whole stiffened welded structure buckles in a twisting mode, while plate panels remain unbuckled. Eigenvalue analysis gives the twisting buckling mode as the lowest buckling mode. However, in stiffened welded structures, not only tendon force (longitudinal inherent shrinkage) but also transverse inherent shrinkage is responsible for buckling. The good agreement between computed and measured out-of-plane welding distortion shows that the elastic Finite Element (FE) analysis using inherent deformation theory is an advantage of the computational approach to predict welding distortion in large-scale and complex welded structure with enough computational accuracy.

ABSTRACT: To date, despite the significant development in the field of structural mechanics, there still remains a paradox in the solutions available for a classical shell buckling problem. The difference in strength between a cylindrical shell under uniform axial compression and that under pure bending is not quite well
investigated. This lack of research is reflected in the wide variations in the elastic bending strength and the slenderness limits given in current international design standards. The discrepancies in the available classical solutions and hence the design rules have initiated the current research. The main aim of this paper is to present a closed-form solution for the elastic buckling strength of unstiffened circular cylinders under pure bending using a new simplified energy approach employing the well-known Ritz method. Two types of analyses are presented for cylinders with large \((D/t>200)\) and medium \((100<D/t<200)\) diameter-to-thickness ratios. A unique testing rig was used to experimentally verify the new theory using a Moiré fringe film. The theoretical results are compared against the available and present test results and the existing classical solutions. The current design rules for thin-cylinders in international steel specifications are also compared, and the newly derived design curve is proposed which was found in a good agreement with the available test results.

“Cold-formed steel lipped and plain angle columns with fixed ends”, Thin-Walled Structures, Vol. 80, pp 142-152, July 2014, DOI: 10.1016/j.tws.2014.03.001

ABSTRACT: The objective of this study is to explore the significant post-buckling reserve in global buckling that has been observed in tests on cold-formed steel angle columns, and to provide design guidance for locally slender cold-formed steel lipped and plain angle columns with fixed end boundary conditions. Global buckling modes are generally regarded to have no post-buckling reserve, and indeed all column design curves, including those used in North America for cold-formed steel columns limit the strength to 0.877\(P_{cre}\) (where \(P_{cre}\) is the global buckling load) or lower. However, tests conducted on cold-formed steel angles by Young (2004,2005) 1 and 2 demonstrate capacities significantly in excess of \(P_{cre}\) – an observation usually reserved for local-plate buckling modes, which due to transverse membrane resistance are known to have significant post-buckling reserve. In this work, specific attention is paid to the impact of end boundary conditions, with emphasis on warping (longitudinal) deformations. Utilizing nonlinear collapse analysis with shell finite element models, and existing testing, alternatives to current design methods are explored. New design procedures are recommended for strength prediction of cold-formed steel angle columns with fixed end boundary conditions.

ABSTRACT: A homogeneous generalized yield criterion (HGYC) expressed by piecewise polynomial is given for angle section. The element bearing ratio (EBR), reference EBR, and uniformity of EBR are defined in term of the HGYC. Then, a HGYC based elastic modulus reduction method for limit analysis of thin-walled structures with angle steel is presented based on the modulus adjustment strategy established on the EBR and the conservation criterion of energy. The method proposed can overcome the disadvantage of the conventional elastic modulus adjustment procedure where the nonhomogeneous generalized yield criterion is employed and the proportional loading condition is not satisfied.
Noureddine Ferhoune (Doctorate at Civil Engineering, University Larbi Ben Mhidi Oum El Bouaghi, Algeria), “Experimental behaviour of cold-formed steel welded tube filled with concrete made of crushed crystallized slag subjected to eccentric load”, Thin-Walled Structures, Vol. 80, pp 159-166, July 2014
DOI: 10.1016/j.tws.2014.02.014
ABSTRACT: This paper presents results of tests conducted on thin welded rectangular steel stubs filled with concrete that gravel was substituted by 10 mm crushed crystallized slag stone. The studied section was made of two cold steel plates with U shape and welded with electric arc to form a steel box section. The cross-section dimensions were: 100×70×2 mm³. the main studied parameters were the stub height (200, 300, 400, 500 mm), the effect of the in filled concrete, the continued weld and the eccentric force. The tests were carried out 28 days after the date of casting. A total of 20 stubs were tested in a 50 tf machine up to failure, 4 stubs subjected to axial load compression and 16 stubs subjected to eccentric load compression along the minor and major rigidity axis. The aim of the study is to provide some evidences that the use of crushed slag could be integrated in the manufacturing of non-conventional concrete. All failure loads were predicted by using the Euro code 4 and the design method proposed by Z. Vrcelj and B. Uy. From test results, it was confirmed that the length of stubs and the eccentric load had a drastic effect on the load carrying capacity. The failure mode of composite stubs was a local buckling mode with all steel sides deformed outwards. The Euro code 4 loads predictions were generally in good agreement compared with experimental loads and on safe side. The loads results of design method proposed by Vrcelj and B. Uy were generally on safe side compared with experimental load except the columns subject to eccentric load with 400 mm and 500 mm height.

Guangjun Gao, Haipeng Dong and Hongqi Tian (Key Laboratory of Traffic Safety on Track of Ministry of Education, Central South University, Changsha 410075, China), “Collision performance of square tubes with diaphragms”, Thin-Walled Structures, Vol. 80, pp 167-177, July 2014, DOI: 10.1016/j.tws.2014.03.007
ABSTRACT: The energy absorption responses of conventional tubes and tubes with diaphragms are analysed here by means of finite element simulation. Numerical results show that tubes with diaphragms exhibit a relatively stable crushing process. The effect of imperfect energy absorption responses is also analysed, including the top shape of tubes and oblique loading. The strain rate affects the dynamic response of tubes with diaphragms. Four prototypes of these tubes were constructed and tested; however, sizeable differences were obtained between experimental results and the results of numerical simulation of the ideal structure in terms of process errors.

DOI: 10.1016/j.tws.2014.03.016
ABSTRACT: The buckling problem of a heterogeneous orthotropic truncated conical shell subjected to an axial load and surrounded by elastic media is analyzed based on the finite deformation theory. Using von-Karman nonlinearity, the governing equations of elastic buckling of heterogeneous orthotropic truncated conical shells surrounded by elastic media are derived. The governing equations are solved using superposition and Galerkin methods and obtained expressions for upper and lower critical axial loads. The influences of elastic foundations, heterogeneity, orthotropy and geometric characteristics on the upper and lower critical loads of conical shells with and without elastic foundations are studied in detail.

ABSTRACT: Analytical approach used for critical load determination is based on Ritz energy technique in which two factors are crucial for the accuracy of results. First factor is deflection function. Herein, double Fourier series are used to represent buckled shape of the plates under arbitrary external loads. The second and the most important factor is adoption of adequate realistic stress distribution within plate prior to buckling. Based on the Baker&Pavlović&Tahan and Pavlović&Liu investigations, exact stress distributions were introduced herein. In that way, with the adequate deflection functions and precise stress distribution, Ritz energy method can produce highly accurate results. Through several examples for the plates with different boundary conditions, for which available literature offers very few analytical solutions, accuracy of the presented analytical approach is proved. Results obtained by analytical approach are reaffirmed by numerical finite-element runs.

ABSTRACT: This paper presents a comprehensive experimental and numerical investigation on the cyclic response of cold-formed steel columns with hollow rectangular sections. The present study examined the columns’ post-buckling strength and rigidity degradation, deformation and failure modes, ductility, and energy dissipation capacity. The cold-formed steel members exhibited stable hysteretic performance up to the point of local buckling with considerable degradation in strength and ductility. The energy dissipation mechanisms from the in-plane plastic behavior and out-of-plane elastic buckling deformation were identified. The influence of the height-to-width ratio and axial-compression ratio on energy-dissipation and failure mode was also investigated.

ABSTRACT: The paper describes the recently ballots Direct Strength Method (DSM) of design for shear of the North American Specification for Cold-Formed Steel Structural Members NAS S100. The method requires the shear buckling load $V_{cr}$ of the complete section to be computed. Shear buckling examples of channel sections in pure shear using both the semi-analytical and spline finite strip buckling analyses are presented. Recent work on the buckling and strength of channel sections in pure shear with rectangular and triangular web stiffeners is also described.

ABSTRACT: Space and aircraft industry demands for reduced development and operating costs. Structural weight reduction by exploitation of structural reserves in composite space and aerospace structures contributes to this aim, however, it requires accurate and experimentally validated stability analysis. Currently, the potential of composite light weight structures, which are prone to buckling, is not fully exploited as appropriate guidelines in the field of aerospace and space applications do not exist. This paper deals with the state-of-the-art advances and challenges related to coupled stability analysis of composite structures which show very complex stability behaviour. Two types of thin-walled light weight structures endangered by buckling will be considered; imperfection tolerant and imperfection sensitive structures. For both groups improved design guidelines for composites structures are still under development. This paper gives a short state-of-the-art and presents proposals for future design guidelines.

ABSTRACT: In the case of an ideal structure, the theoretical equilibrium bifurcation point and the corresponding load, $N_{cr}$, are obtained at the intersection of the pre-critical (primary) force–displacement curve with the post-critical (secondary) curve. For a real structure, affected by a generic imperfection the bifurcation point does not appear anymore and, instead, the equilibrium limit point is the one characterizing the ultimate capacity, $N_u$, of the structure. The difference between $N_{cr}$ and $N_u$ represents the Erosion of the Critical Bifurcation Load (ECBL), due to the imperfections. This model applies in the instability mode interaction. The meaning of mode interaction inherently refers to the erosion of critical bifurcation load in case of interaction of
two (or more) buckling modes associated with the same, or nearly the same, critical load. A well-known example of such a mode interaction is the one resulting from the coupling of local or distortional buckling with overall buckling in the case of thin-walled cold-formed members. Van der Neut [1] stated the erosion due to coupling and imperfection effects is maximum in the local–global coupling point. The ECBL approach extracts its basic principle from this conclusion. This is a review paper of which purpose is to summarize the mode interaction problem and ECBL approach, presenting the last results obtained by the authors.

ABSTRACT: This paper reports the main results of an ongoing numerical investigation aimed at (i) assessing the buckling, post-buckling, strength and collapse behaviour of thin-walled steel structural systems and (ii) developing an efficient direct approach to estimate the ultimate loading of such structural systems, which may fail in complex modes that combine local, distortional and global features. The results currently available, obtained from Generalised Beam Theory and Ansys shell finite element analyses, concern continuous beams and simple frames subjected to various transverse loadings applied at/along the shear centre axis and causing non-uniform bending. The possibility of developing a design approach, based on the application of the existing Direct Strength Method (DSM) strength curves, is explored for the structural systems under consideration. The quality of the corresponding failure loading estimates is assessed through the comparison with the values yielded by shell finite element simulations.

ABSTRACT: The paper presents the case of plastic instability of I-shaped beams where the rotation capacity is a very important characteristic in order to assure the required ductility in plastic or seismic design. The failure of such beams can be due to the local plastic plate buckling of compression flange and local plate buckling of the web in flexural compression, produced in-plane or out-of-plane. In the same time the failure can occur by coupling of these two local buckling modes. In order to study the plastic buckling of beams and to determine the available rotation capacity which is required by the plastic or seismic design, the collapse plastic mechanism theory was developed and a specialized computer program DUCTROT-M was elaborated. The parametrical analysis reveals the paramount importance of the web to thickness ratio and furthermore the sensitivity in out-of-plane buckling of the European hot-rolled sections.

“Behaviour, failure and DSM design of cold-formed steel beams: Influence of the load point of application”, Thin-Walled Structures, Vol. 81, pp 78-88, August 2014, DOI: 10.1016/j.tws.2013.07.007

ABSTRACT: This work presents and discusses the results of an ongoing numerical investigation on the buckling, post-buckling, collapse and design of cold-formed steel beams subjected to non-uniform bending due to transverse loadings acting away from the shear centre (either at the top or bottom flange). These results consist of (i) elastic buckling loads and modes, obtained through analyses based on Generalised Beam Theory (GBT), and (ii) elastic–plastic equilibrium paths and collapse loads, yielded by Ansys geometrically and materially non-linear shell finite element analyses. The numerical ultimate strength values are compared with their estimates provided by the current Direct Strength Method (DSM) strength curves and, on the basis of this comparison, it is possible to assess the merits of the DSM approach to design beams subjected to transverse loadings acting away from the shear centre – moreover, novel features that may improve the performance of this approach are identified.

ABSTRACT: An analytical model that describes the interactive buckling of a thin-walled I-section strut under pure compression based on variational principles is presented. A formulation combining the Rayleigh–Ritz method and continuous displacement functions is used to derive a system of differential and integral equilibrium equations for the structural component. Numerical continuation reveals progressive cellular buckling (or snaking) arising from the nonlinear interaction between the weakly stable global buckling mode and the strongly stable local buckling mode. The resulting behaviour is highly unstable and when the model is extended to include geometric imperfections it compares excellently with some recently published experiments.

ABSTRACT: The elastic Van der Neut column has been a very useful tool to enhance our understanding of local-flexural interaction buckling of columns. In particular, Van der Neut's work has (a) illuminated the basic mechanism behind interaction buckling and (b) demonstrated that local-flexural interaction buckling is a highly imperfection sensitive phenomenon. In this paper, a component of inelastic behaviour is added to the classical Van der Neut column and its influence on the column buckling curve and the imperfection sensitivity is investigated. Numerical calculations are carried out using a finite differences scheme which is first explained in detail. In general, plasticity gives rise to a second ‘plateau’ in the buckling curve, curtailing the column capacity at low column slenderness values. This plateau typically exhibits low to moderate imperfection sensitivity. However, for yield stresses of the order of the local buckling stress of the flanges, both plateaus merge to form an extended zone of very high imperfection sensitivity.

Dieter Ungermann, Sebastian Lubke and Bettina Brune (Dortmund University of Technology, Institute of Steel Construction, August-Schmidt-Street 6, 44227 Dortmund, Germany), “Tests and design approach for plain

ABSTRACT: Thin-walled plain channels are often subjected to coupled local and global flexural buckling. The objective of this paper is to verify and discuss the current design procedure of Eurocode 3 for plain channels in coupled instabilities. This paper deals with experimental investigations on plain channel stub columns subjected to local buckling only and long columns subjected to coupled local-flexural buckling. The test series consists of cold-formed and welded plain channels made of steel grade S355 and S460. Based on this experimental results modifications of the method of effective width (and thickness) as stated by Eurocode 3 Part 1-3 are discussed. Previously developed modified buckling coefficients, which take into account the rigidity of the connection of web and flange, are verified by comparative calculations. Additionally an approach for an approximation of effective stiffness for coupled instabilities is discussed as well.

ABSTRACT: The direct strength method (DSM) has been adopted by the NAS (2004) and AS/NZS 4600 (2005) for the design of cold-formed steel members. The method can be successfully applied to the design of welded and hot-rolled sections. This paper reviews the development of the DSM for welded steel structural members. The design strength formulae for welded section columns and beams for the DSM are provided based on the tests performed on welded H-section, C-section, circular and rectangular hollow section columns fabricated from steel plates whose nominal yield stress is 235 MPa or 315 MPa. The comparison between the design strength of welded sections predicted by the DSM and that estimated by existing specifications is provided. This paper verifies that the DSM which adopts the nominal axial strength and flexural strength in the AISC (2010) or EC3 (2004) can properly predict the ultimate strength of welded section columns and beams.

“The local-overall flexural interaction of fixed-ended plain channel columns and the influence on behaviour of local conditions at the constituent plate ends”, Thin-Walled Structures, Vol. 81, pp 132-137, August 2014 DOI: 10.1016/j.tws.2014.02.028

ABSTRACT: This paper examines the effect of the local support conditions at the ends of the constituent plates of plain channel section columns when subjected to uniformly compressed loading. The buckling and post-buckling interactive response of the columns have been determined through the development of suitable finite element modelling strategies and solution procedures which take due account of the influence of material nonlinearity and geometrical imperfections. Uniformly compressed loading means, of course, fixed conditions at the column ends with respect to global rotations and the ends of the constituent plates of the cross-section can be treated as either locally rotationally constrained or locally rotationally free. These two conditions are shown to lead to quite different characteristic interactive responses of the columns due to amplitude modulation in the buckling mode for the rotationally constrained case.

Enio Mesacasa Jr. (1), Pedro Borges Dinis (2), Dinar Camotim (2) and Maximiliano Malite (1)
ABSTRACT: This paper presents and discusses numerical results, obtained through Ansys shell finite element analyses, dealing with the post-buckling behaviour (mostly elastic, but also elastic–plastic), ultimate strength and failure mode nature of fixed-ended and pin-ended thin-walled equal-leg angle steel columns with coincident critical flexural-torsional and minor-axis flexural buckling loads (i.e., experiencing very strong coupling effects between these two global instability phenomena) – for comparative purposes, columns that are buckling in pure flexural-torsional and flexural modes are also analysed. Since the main aim of the work is to investigate the column imperfection-sensitivity, the analyses concern otherwise identical columns containing initial geometrical imperfections with different shapes and amplitudes, combining the competing critical buckling modes – particular attention is paid to the sign of the minor-axis flexural component. The results reported consist of column (i) elastic equilibrium paths and the corresponding peak loads and deformed configurations and (ii) elastic–plastic collapse loads and mechanisms, making it possible to assess how they are influenced by the initial geometrical imperfections.

Mihai Nedelcu and Hortensiu L. Cucu (Faculty of Civil Engineering, Technical University of Cluj-Napoca, Str. C. Daicoviciu No. 15, 400020 Cluj-Napoca, Romania), “Buckling modes identification from FEA of thin-walled members using only GBT cross-sectional deformation modes”, Thin-Walled Structures, Vol. 81, pp 150-158, August 2014, DOI: 10.1016/j.tws.2013.06.007

ABSTRACT: This paper presents the latest developments of an original method based on Generalized Beam Theory (GBT) capable to identify the fundamental deformation modes of global, distorsional or local nature, in general buckling modes provided by the shell finite element analysis (FEA) of isotropic thin-walled members. This method has the advantage of using only the GBT cross-sectional deformation modes instead of the member base mode shapes. The participation of each fundamental buckling mode can be calculated, allowing an accurate and quantitative evaluation of the coupled instability. There are no restrictions regarding the element cross-sectional shape, loading and quite recently discovered, boundary conditions.

Mihai Nedelcu, Andrei Crisan, Viorel Ungureanu and Dan Dubina, “Analysis of storage rack members by using GBT and Shell FEA”, Proceedings of the ICTWS 2014, 7th International Conference on Thin-Walled Structures, ICTWS2014, Busan, Korea

ABSTRACT: This paper analyses the interactive buckling behaviour of compression members used for steel pallet racks. Recently, the proposed rack members were thoroughly analyzed at CEMSIG Research Centre of “Politehnica” University of Timisoara. Following the guidelines of EN15512, the authors of this study performed experimental and numerical testing on a large number of specimens with lengths carefully chosen in order to capture the lower critical loads related with pure Local, Distortional buckling and also with the interactive Distortional-Global buckling usually met in practice for this type of sections. The aim of the presented paper is to quantify the Local-Distortional-Global (L-D-G) modes participation in the linear buckling shapes, assessing with high precision if the methods used for choosing the members lengths for experimental analyses, are valid. For this reason, an original modal identification method, based on the Generalised Beam Theory (GBT), is applied, providing the pure modes participation in any general buckling shape produced by
shell Finite Element Analysis.

Mihai Nedelcu, Anca Popa, Hortensiu-Liviu Cucu and Nicolae Chira (Faculty of Civil Engineering, Technical University of Cluj-Napoca, Str. C. Daicoviciu No. 15, 400020 Cluj-Napoca, Romania), “Vibration mode decomposition from finite element analysis of thin-walled members with holes”, publisher not listed, June 2016

ABSTRACT: Perforated thin-walled steel members are often used in civil engineering as structural elements for residential buildings and storage racks systems. In this paper the local-plate, distortional and global vibration behavior of perforated thin-walled members subjected to various loading is studied. This investigation is carried out by means of a very recently developed method based on the Generalised Beam Theory capable to decompose the general vibration/buckling modes provided by the shell finite element analysis into pure deformation modes of global, distortional or local nature. There are no restrictions regarding the element cross-

ABSTRACT: This paper presents an experimental investigation into the behaviour of ultra light-gauge steel storage rack uprights subjected to compression. Two different types of members with varying lengths are tested and while the combined effects of local and distortional buckling are investigated, special attention is given to longer specimens that fail by flexural–torsional buckling in combination with local and distortional buckling. Deformations experienced during testing by all of the specimens were measured and observations regarding failure modes have been documented. In addition, the geometric imperfections of each member were measured before testing, as were the material properties of the cold-rolled sections and the virgin steel from which the sections were formed. This paper details the observed failure modes, the recorded ultimate strengths and the load-deflection responses. Design capacities calculated from AS/NZS 4084 (2012) [1], RMI (2012) [2] and EN 15512 (2009) [3] specifications are then evaluated and compared to the experimental results obtained. The evaluation of international specifications determined that EN 15512 (2009) [3] is more accurate in predicting ultimate loads of sections undergoing interactive buckling than both AS/NZS 4804 (2012) [1] and RMI (2012) [2].

ABSTRACT: Global buckling behaviour, with or without interaction with distortional buckling, of storage rack members is evaluated by tests carried out according to EN 15512 (2009) [1] on compression and out-of-plane bending of upright frame modules. Based on test results for both single upright sections and frame modules, completed by numerical simulation, the present paper attempts to demonstrate that the design buckling strength of uprights can be conveniently estimated by single section tests, providing that the length of these members is calibrated for the distortional–global interaction mode.

Pedro B. Dinis (1), Ben Young (2) and Dinar Camotim (1)
ABSTRACT: Experimental and numerical results concerning the post-buckling behaviour and strength of fixed-ended cold-formed steel rack-section columns experiencing local–distortional (L–D) interaction are reported. The experimental results, obtained from tests carried out at The University of Hong Kong include initial imperfection measurements, equilibrium paths and failure loads/modes – they provide clear evidence of the above coupling phenomenon. After presenting and discussing a comparison between test results and the values yielded by the corresponding Abaqus shell finite element numerical simulations, the experimental failure loads are used to assess the quality of their estimates provided by design approaches based on the Direct Strength Method (DSM) that were recently developed exclusively for fixed-ended lipped channel columns affected by L–D interaction. The work also includes a comparison between the ultimate strength and DSM design of lipped channel and rack-section columns undergoing similar L–D interaction effects.

ABSTRACT: The paper reports experimental and numerical results concerning the post-buckling behaviour, strength and failure of fixed-ended cold-formed steel web-stiffened lipped channel columns that buckle in distortional modes. The experimental results, obtained from the tests carried out at The University of Hong Kong, (i) include initial imperfection measurements, equilibrium paths and failure loads and modes, and (ii) provide evidence of the occurrence of flange-triggered local-distortional interaction. After presenting and discussing a comparison between some test results and the values yielded by the corresponding Abaqus shell finite element numerical simulations, the experimental failure loads obtained in this work, together with additional data reported in the literature, are used to assess whether the available Direct Strength Method (DSM) design approaches are capable of predicting them efficiently (safely and accurately). It is found that this is not the case, mainly because of the fact that the mechanics of the flange-triggered and web-triggered local-distortional interactions are quite different. Although fairly good failure load predictions are provided by a new DSM design approach proposed in this work, further research is required on the mechanics of local–distortional interaction in web-stiffened lipped channel columns.

“Effects of modal coupling on the dynamics of parametrically and directly excited cylindrical shells”, Thin-Walled Structures, Vol. 81, pp 210-224, August 2014, DOI: 10.1016/j.tws.2013.08.004
ABSTRACT: Cylindrical shells exhibit a dense frequency spectrum, especially in the lowest frequency range. In addition, due to the circumferential symmetry, frequencies occur in pairs. So, in the vicinity of the lowest natural frequencies, several equal or nearly equal frequencies may occur, leading to multiple internal resonances. The aim of the present work is to investigate the dynamic behavior and stability of cylindrical shells under lateral and axial forcing with equal natural frequencies. The shell is modeled using the Donnell nonlinear shallow shell theory. A consistent modal solution for this problem is deduced and used to discretize the equations of motion by applying the Galerkin method. A parametric analysis is conducted to clarify the influence of the modal interaction among these nonlinear vibration modes on coexisting solutions, bifurcations, resonances curves and stability boundaries of the shell.

ABSTRACT: This paper examines the response of stiffened plates with plain flat outstands when subjected to in-plane shear loading in the form of applied in-plane shear displacement. The buckling and post-buckling failure capabilities of thin plates subjected to in-plane shear, can, of course, be improved through the introduction of stiffening elements whose flexural and torsional rigidities can contribute significantly towards a more stabilised structural system. This paper details appropriate suitable finite element modelling strategies and procedures to enable the determination of the post-buckled failure response of the stiffened shear panels and to highlight the significant influence of the stiffeners. The modelling procedures are able to describe the complete loading history of the stiffened panel structures from the onset of initial buckling through the elastic post-buckling phase of behaviour involving the considerable interaction between plate and stiffener and then through initial material yielding and yield propagation to ultimate conditions and elasto-plastic unloading.

ABSTRACT: The sandwich panel roof supported by continuously connected thin-walled cold-formed Z-purlins with overlapping over intermediate supports is a practical case of very frequent use. Among the two possible directions of investigation mentioned in the code when studying torsional/distortional instability of Z-purlins (i.e. rotational stiffness and linear stiffness) the authors have chosen to look at the notional linear spring placed at the free flange of the purlin. The linear spring is defined by EN 1993-1-3 Annex A5, as an equivalent or alternative to the stabilizing rotational spring generated by the continuous connection of the sandwich panels to purlin upper flange. This type of approach, on authors' opinion, has the advantage to include into the experimental phase, the real imperfections, and support conditions characteristic to such roof systems, having a very important impact on purlin stability behaviour. A description of the proposed full scale arrangement and experimental conditions, plus values of obtained results are given in the paper.

ABSTRACT: Stowell's solution [1] for the buckling behaviour of flange elements in compression was premised on the assumption that the element was fixed against flexural rotations at the ends, a condition representing relatively thick elements for which the thickness dimension is adequate to prevent rotations. This paper presents a solution similar to Stowell's which is applicable to pin-ended flange elements. Aspects not considered in Stowell's work, such as the use of elliptic functions to describe the gradual change of mode shape from sinusoidal to essentially linear, and the gradual and asymptotic changes in axial rigidity in the post-buckling range are described in the paper. The paper also presents comparisons between the behaviour of pin-ended and fixed-ended flange elements. Finally, simple strength equations for flange elements in uniform compression based on the first yield criterion are derived.

“Experimental and numerical study of circular, stainless thin tube energy absorber under axial impact by a control rod”, Thin-Walled Structures, Vol. 82, pp 24-32, September 2014, DOI: 10.1016/j.tws.2014.03.020

ABSTRACT: In this study, several crashworthiness parameters of a circular, thin tube energy-absorbing structure, which is used in a high-temperature, gas-cooled reactor (HTR), are studied experimentally and numerically at various tube thicknesses, temperatures and impact velocities. The average crushing force is fundamentally dependent on strain hardening, strain rate hardening, and, particularly, temperature softening of the material. The peak forces during buckling are significantly affected by the local strain rate in the material and exhibit a decreasing trend in sequentially formed folds. Reducing the tube thickness is an effective method to weaken the average crushing force, but it does not weaken the maximum crushing force. Additionally, the stress concentration at the edge of the backplate–graphite contact surface is evaluated in detail to ensure the structural security of the energy absorber.

“Experimental study on local buckling of axially compressed steel stub columns at elevated temperatures”, Thin-Walled Structures, Vol. 82, pp 33-45, September 2014, DOI: 10.1016/j.tws.2014.03.015

ABSTRACT: There are few design provisions in codes and standards on local buckling of steel columns under fire conditions. To examine the local stability of steel stub columns at elevated temperatures, 12 stub columns were tested under simultaneous application of load and fire conditions. The test variables included Grade (type) of steel, buckling resistance, temperature and load levels. During fire tests, cross sectional temperatures, axial displacement, buckling deflection, and local buckling failure modes of flange and web of stub columns were recorded at various temperatures. Data from the tests is utilized to evaluate buckling resistance of flange and web both at room and elevated temperatures by applying the ultimate strain method and curve inflexion point
method. Results from fire tests are utilized to validate a finite element model developed for tracing local buckling of steel columns at elevated temperatures. Results from fire tests and finite element analysis show that failure mode of columns at room and elevated temperatures follow similar pattern but the load bearing capacity of Q460 steel columns degrade much more rapidly under fire conditions than that of Q235 steel columns. Further, Eurocode 3 provisions for local buckling produce non-conservative results in certain situations.

Mihai Nedelcu (Faculty of Civil Engineering, Technical University of Cluj-Napoca, Str. C. Daicoviciu nr 15, 400020 Cluj-Napoca, Romania), “Buckling mode identification of perforated thin-walled members by using GBT and shell FEA”, Thin-Walled Structures, Vol. 82, pp 67-81, September 2014, DOI: 10.1016/j.tws.2014.04.005
ABSTRACT: The paper presents an original method based on the Generalised Beam Theory (GBT) whereby the general buckling modes, provided by the shell Finite Element Analysis (SFEA) of perforated thin-walled members, are expressed in terms of the fundamental (pure) buckling types (global, distortional and local). The contribution of each pure buckling mode to a coupled instability can be quantified, allowing a better understanding of the member buckling behaviour and post-buckling strength reserve. The main advantage of this method lies in using only the GBT cross-sectional pure deformation modes instead of member pure modal shapes. There are no restrictions regarding the element cross-sectional shape, loading and boundary conditions.

“Semi-analytical models for the post-buckling analysis and ultimate strength prediction of isotropic and orthotropic plates under uniaxial compression with the unloaded edges free from stresses”, Thin-Walled Structures, Vol. 82, pp 82-94, September 2014, DOI: 10.1016/j.tws.2014.04.003
ABSTRACT: This paper introduces two semi-analytical models developed for the nonlinear analysis of stability of isotropic and orthotropic plates under uniaxial compression. The possibility of considering fully free in-plane displacements at longitudinal edges (or unloaded edges) is the innovation of these models over existing models, where these displacements are always assumed constrained to remain straight. Contributions for the large deflection theory of plates related to the derivation of analytical solutions for the Airy stress function which satisfy Marguerre’s equations for isotropic and orthotropic plates are presented. Namely, the extension of the Coan and Urbana solution for isotropic plates in order to consider all the terms of the unknown amplitudes of the out-of-plane displacements and the derivation of a solution for orthotropic plates. Comparisons between the semi-analytical model and nonlinear finite element model results are presented in order to discuss the effect of in-plane displacement boundary conditions on behaviour and strength of plates similar to bottom flanges used in steel box girder bridges. This study shows that the semi-analytical models have a clear potential to provide accurate solutions, requiring only a short computer time. It is also shown that the in-plane displacement boundary conditions for the unloaded edges significantly influence the behaviour and strength of plates and this problem cannot be neglected in the definition of the design rules.

Feng Wang (1), Yimin Mo (1), Juncheng Lv (2), Feng Huang (1) and Qing He (1)
ABSTRACT: A new type of spot-weld double-hat section with symmetrically distributed tilt flanges (STFD-HAT) is introduced in this paper to improve the crushing performance, especially crushing stability. LS-DYNA code has been employed here to analyze the effect of several parameters on the collapse modes of STFD-HAT sections under axial dynamic impact loading condition. Some variables, such as tilt angle, size of core cross-section and thickness of sheet shell, have been proved to be effective in controlling the collapse mode and crushing performance of STFD-HAT sections by analysis on energy absorption and RSS of result curves. Compared with traditional double-hat sections, the STFD-HAT sections with reasonable designed profiles can effectively improve the crushing resistances and stabilities, especially, the bending mode.

“Effect of reinforcement stiffeners on square concrete-filled steel tubular columns subjected to axial compressive load”, Thin-Walled Structures, Vol. 82, pp 132-144, September 2015, DOI: 10.1016/j.tws.2014.04.009
ABSTRACT: Eight stiffened square concrete-filled steel tubular (CFST) stub columns with slender sections of encasing steel and two non-stiffened counterparts were tested subjected to axial compressive load. Four types of reinforcement stiffeners and steel tensile strips were introduced to postpone local buckling of steel tubes, in which the tensile strip was first used as stiffener in CFSTs. The stiffening mechanism, failure modes of concrete and steel tubes, strength and ductility of stiffened square CFSTs were also studied during the experimental research. A numerical modeling program was developed and verified against the experimental data. The program incorporates the effect of the stiffeners on postponing local buckling of the tube and the tube confinement on concrete core. Extensive parametric analysis was also conducted to examine the influencing parameters on mechanical properties of stiffened square CFSTs.

“Theoretical prediction and crashworthiness optimization of multi-cell triangular tubes”, Thin-Walled Structures, Vol. 82, pp 183-195, September 2014, DOI: 10.1016/j.tws.2014.03.019
ABSTRACT: The triangular tubes with multi-cell were first studied on the aspects of theoretical prediction and crashworthiness optimization design under the impact loading. The tubes’ profiles were divided into 2-, 3-, T-shapes, 4-, and 6-panel angle elements. The Simplified Super Folding Element theory was utilized to estimate the energy dissipation of angle elements. Based on the estimation, theoretical expressions of the mean crushing force were developed for three types of tubes under dynamic loading. When taking the inertia effects into account, the dynamic enhancement coefficient was also considered. In the process of multiobjective crashworthiness optimization, Deb and Gupta method was utilized to find out the knee points from the Pareto solutions space. Finally, the theoretical prediction showed an excellent coincidence with the numerical optimal results, and also validated the efficiency of the crashworthiness optimization design method based on surrogate models.

S. Koczubiej and C. Cichon (Faculty of Management and Computer Modelling, Kielce University of Technology, Al. Tysiclecia Państwa Polskiego 7, 25-314 Kielce, Poland), “Global static and stability analysis of thin-walled structures with open cross-section using FE shell-beam models”, Thin-Walled Structures, Vol. 82, pp 196-211, September 2014, DOI: 10.1016/j.tws.2014.04.014

ABSTRACT: The finite shell-beam models for static and global stability analysis of thin-walled structures with open cross-section are proposed. The discretization using thin-walled beam elements is connected with the space discretization of some parts of the frame. The space joint element, formulated using only translational degrees of freedom on cross-sections connecting the joint with the thin-walled beams and the so-called transition elements, defined between the beam and the shell nodes are used for consistent coupling beams and shell parts.

Zhen-hua Ji and De-yu Wang (State Key Laboratory of Ocean Engineering, Shanghai Jiao Tong University, Shanghai 200240, China), “Influence of load shape on dynamic response of cross-stiffened deck subjected to in-plane impact”, Thin-Walled Structures, Vol. 82, pp 212-220, September 2014, DOI: 10.1016/j.tws.2014.04.007

ABSTRACT: Under severe sagging condition or wave slamming, ship deck is dynamically loaded in nature with impact type load. Based on the nonlinear explicit finite element method, the paper aims at studying influence of load shape on dynamic response of a cross-stiffened deck subjected to in-plane impact, accounting for strain rate effect, strain hardening, and potential contact of compressive components. Axial residual displacement of the impacted end is selected as main detected dynamic response of the deck. Four parameters depicting load shape are considered; they are impact duration, peak load, the decaying type after reaching the peak load (here refers to second order derivative of the load), ratio between rise time of the load and total impact duration. The first three load shape parameters, impact duration, peak load and decaying type, are related to impulse. The longer the impact duration, the larger the peak load, the slower the decaying of the load, which can result in the larger impulse. The larger the impulse is, the larger the dynamic response of the impacted deck is, on the condition that the impact duration is finite with the order of milliseconds. While the fourth load shape parameter, ratio of rise time and impact duration, although it is not related to impulse, it is also an important influential factor on dynamic response of the impacted deck. The smaller the ratio is, the larger the dynamic response of the impacted deck is; if the impact duration is longer, the effect is more significant. So the parameter, ratio of rise time and impact duration, deserves more concern in future research.

Zarei (Department of Mechanical Engineering, School of Engineering, Persian Gulf University, Bushehr 7516913798, Iran), “Free vibration of quadrilateral laminated plates with carbon nanotube reinforced composite layers”, Thin-Walled Structures, Vol. 82, pp 221-232, September 2014
DOI: 10.1016/j.tws.2014.04.016

ABSTRACT: The free vibration behavior of quadrilateral laminated thin-to-moderately thick plates with carbon nanotube reinforced composite (CNTRC) layers is studied. The governing equations are based on the first-order shear deformation theory (FSDT). The solution procedure is based on transforming the governing differential equations from an arbitrary straight-sided physical domain to a regular computational one, and discretization of the spatial derivatives by employing the differential quadrature method (DQM) as an efficient and accurate numerical tool. Four different profiles of single walled carbon nanotubes (SWCNTs) distribution through the thickness of layers are considered, which are uniformly distributed (UD) and three others are functionally graded (FG) distributions. The fast rate of convergence of the presented approach is numerically demonstrated and to show its high accuracy, wherever possible comparison studies with the available results in the open literature are performed. Then, the effects of volume fraction of carbon nanotubes (CNTs), geometrical shape parameters, thickness-to-length and aspect ratios, different kinds of CNTs distribution along the layers thickness and different boundary conditions on the natural frequencies of laminated plates are studied.

ABSTRACT: The structural configuration and method of analysis of the single-layer inverted catenary cylindrical reticulated shell are introduced in this paper, and the elastic as well as elastic–plastic stability of this kind of reticulated shell is then investigated. The stability of the structures with different types of grid patterns is compared, and the reasonable grid pattern is hence recommended. The structural buckling mode and ultimate load–carrying capacity are studied in detail by parametric analysis. Influence of various factors on structural ultimate load is investigated, and the fitting formula of ultimate load is thus presented. Comparison analysis between the inverted catenary and circular cylindrical reticulated shells is also carried out. The work will provide guidance in theory for practical applications of this kind of structure.

ABSTRACT: In this paper, a numerical method is presented for the free vibration and stability analyses of tapered thin-walled beams with arbitrary open cross sections. The proposed method takes the flexural–torsional coupling effect of tapered thin-walled beams with arbitrary open cross sections into account. The total potential energy is derived for an elastic behavior from the strain energy, the kinetic energy and work of the loads applied on the cross section contour. Free vibration is considered in the presence of harmonic excitations. The effects of the initial stresses and load eccentricities are also considered in stability analysis. The governing equilibrium
equations, motion equations and the associated boundary conditions are derived from the stationary condition. As in the presence of tapering, stiffness quantities are not constant; therefore, the power series approximation is used to solve the fourth-order differential equations. Displacement components and cross-section properties are expanded in terms of power series of a known degree. Then, the shape functions are obtained by deriving the deformation shape of tapered thin-walled member as power series form. Finally, stiffness and mass matrices are carried out by means of the principle of virtual work along the member’s axis. In order to measure the accuracy and check the validity of this method, the natural frequencies and buckling loads of non-prismatic thin-walled beams with web and flange tapering and various boundary conditions are obtained and compared to the results of finite element analysis using Ansys software and those of other available numerical and analytical ones. It can be seen that the results of present study are in a good agreement with other available theoretical and analytical methods.

“Quasi-static response and multi-objective crashworthiness optimization of oblong tube under lateral loading”, Thin-Walled Structures, Vol. 82, pp 262-277, September 2014, DOI: 10.1016/j.tws.2014.03.012
ABSTRACT: This paper addresses the energy absorption responses and crashworthiness optimization of thin-walled oblong tubes under quasi-static lateral loading. The oblong tubes were experimentally compressed using three various forms of indenters named as the flat plate, cylindrical and a point load indenter. The oblong tubes were subjected to inclined and vertical constraints to increase the energy absorption capacity of these structures. The variation in responses due to these indenters and external constraints were demonstrated. Various indicators which describe the effectiveness of energy absorbing systems were used as a marker to compare the various systems. It was found that unconstrained oblong tube (FIU) exhibited an almost ideal response when a flat plate indenter was used. The design information for such oblong tubes as energy absorbers can be generated through performing parametric study. To this end, the response surface methodology (RSM) for the design of experiments (DOE) was employed along with finite element modeling (FEM) to explore the effects of geometrical parameters on the responses of oblong tubes and to construct models for the specific energy absorption capacity (SEA) and collapse load \( F \) as functions of geometrical parameters. The FE model of the oblong tube was constructed and experimentally calibrated. In addition, based on the developed models of the SEA and \( F \), multi-objective optimization design (MOD) of the oblong tube system is carried out by adopting a desirability approach to achieve maximum SEA capacity and minimum \( F \). It is found that the optimal design of FIU can be achieved if the tube diameter and tube width are set at their minimum limits and the maximum tube thickness is chosen.

Mohamed Elchalakani (Higher Colleges of Technology, Dubai Men’s College, PO Box 15825, Dubai, UAE), “Plastic collapse analysis of CFRP strengthened and rehabilitated degraded steel welded RHS beams subjected to combined bending and bearing”, Thin-Walled Structures, Vol. 82, pp 278-295, September 2014
DOI: 10.1016/j.tws.2014.05.002
ABSTRACT: Innovative techniques using the lightweight, high strength and corrosion resistance of carbon fibres reinforced polymers (CFRP) composites have been proposed in a recent paper by the author. The present paper presents plastic mechanism analyses of CFRP strengthened and rehabilitated rectangular hollow sections (RHS) under quasi-static large deformation 3-point bending. The strengthening series was for un-degraded RHS beams from the manufacturer reinforced using externally wrapped CFRP sheets. The rehabilitation series was
for artificially degraded RHS beams repaired using externally wrapped sheets or bonded plates. The main parameters examined in this paper were the section type, section and member slenderness and the type and number of the CFRP sheets. Three different phases of plastic deformation were observed during the test, namely, denting, denting and bending, and structural collapse. Two methods were used to model the large plastic deformation measured during plastic collapse of the composite RHS beams, namely, equilibrium and energy methods of analysis. It was found that the predicted collapse curves using the equilibrium approach were in good agreement with the measured curves for the bare and composite specimens examined in the strengthening and rehabilitation series, particularly for the latter series. This may be caused by a number of factors such as the specimens in the rehabilitations series were comparatively longer and had larger bearing width. The energy theory was found to have deficiencies represented in the simplified linear polygon shape adopted for the mechanism geometry, and adopting the plastic 1/2-wave length used for I-sections, as well as the use of a simplified formulae to describe the relationship between the local denting displacement and global bending rotation angle for the three phases of deformation observed during the test.

“Multiobjective crashworthiness optimization of hollow and conical tubes for multiple load cases”, Thin-Walled Structures, Vol. 82, pp 331-342, September 2014, DOI: 10.1016/j.tws.2014.05.006

ABSTRACT: Much attention of current design analysis and optimization of crashworthy structures have been largely paid to the scenarios with single load case in literature. Nevertheless the designed structures may often have to be operated in other load conditions, thus raising a critical issue of optimality. This paper aims to understand and optimize the dynamic responses and energy absorption of foam-filled conical thin-walled tubes under oblique impact loading conditions by using multiobjective optimization method. The crashworthiness criteria, namely specific energy absorption (SEA) and crushing force efficiency (CFE), are related to loading parameters and design variables by using D-optimal design of experiments (DoE) and Kriging model. To obtain the optimal Pareto solutions of hollow and foam-filled conical tubes, design optimization is first performed under different loading case (DLC) using multiobjective particle swarm optimization (MOPSO) algorithm separately. The optimal designs indicate that hollow tube has better crashing performance than the foam-filled tube under relatively high impacting velocity and great loading angle. To combine multiple load cases (MLC) for multiobjective optimization, a double weight factor technique is then adopted. It is found that the optimal foam-filled tube has better crashing performance than empty conical tube under any of overall oblique loading cases concerned. The study gains insights in deriving multiobjective optimization for multiple load cases, providing a guideline for design of energy absorber under multiple oblique loading.

ABSTRACT: The objective of this paper is to develop a design method for stainless steel columns subjected to flexural buckling. In this method, the strength curve for every type of stainless steel in common use is generated by using the base strength curves and a slenderness conversion formula. A validated finite element model is employed to generate the strength curves for different types of stainless steels. According to the strain hardening exponent $n$ in the Ramberg-Osgood material model, cluster analysis is conducted to separate these strength curves into two groups. In each group, one type of material parameter is selected as the base material and the corresponding strength curve is expressed in the form of a modified Perry formula that serves as the base strength curve. A slenderness conversion formula is derived for any two stainless steel columns with the same section type and boundary conditions, but with different types of stainless steel. Based on the base strength curves and the slenderness conversion formula, the strength curve for every type of stainless steel in common use can be generated. The predictions of the proposed method show a good agreement with the results of the finite element analysis.

Petr Hradil and Asko Talja (VTT, Technical Research Centre of Finland, P.O. Box 1000, FI-02044 VTT, Finland), “Numeric verification of stainless steel overall buckling curves”, Thin-Walled Structures, Vol. 83, pp 52-58, October 2014, DOI: 10.1016/j.tws.2014.01.011

ABSTRACT: The introduction of new material grades or fabrication methods in engineering structures always raises concerns about the validity of current design rules, especially those based on earlier material or member testing. One of the fundamental structural checks is the overall stability of beams and columns. In this paper, a series of virtual buckling tests is calculated and compared to the Eurocode buckling curves. The main focus is on the applicability of ferritic steels that generally have different stress–strain behaviour than austenitic or duplex grades.

Yuner Huang and Ben Young (Department of Civil Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong, China), “Structural performance of cold-formed lean duplex stainless steel columns”, Thin-Walled Structures, Vol. 83, pp 59-69, October 2014, DOI: 10.1016/j.tws.2014.01.006

ABSTRACT: The structural performance of cold-formed lean duplex stainless steel columns was investigated. A wide range of finite element analysis on square and rectangular hollow sections and other available data, with a total number of 259 specimens, were considered. An accurate finite element model has been created to simulate the pin-ended cold-formed lean duplex stainless steel columns. Extensive parametric study was carried out using the validated finite element model. The column strengths predicted from the parametric study together with the available data are compared with the design strengths calculated from various existing design rules for cold-formed stainless steel structures. It is shown that the existing design rules, except for the ASCE Specification as well as the stub column and full area approach, are conservative. Modifications are proposed for the AS/NZS Standard, EC3 Code, and direct strength method. Reliability analysis was performed to assess the existing and modified design rules. It is also shown that the modified design rules are able to provide a more accurate and reliable predictions for lean duplex stainless steel columns. In this study, it is suggested that the modified design rules in the AS/NZS Standard and the modified direct strength method to be used in designing cold-formed lean duplex stainless steel columns.

Shenggang Fan, Fang Liu, Baofeng Zheng, Ganping Shu and Yuelin Tao (School of Civil Engineering, Key Laboratory of Concrete and Prestressed Concrete Structures of Ministry of Education, Southeast University, Sipailou 2, Zip: 210096, Nanjing, China), “Experimental study on bearing capacity of stainless steel lipped C section stub columns”, Thin-Walled Structures, Vol. 83, pp 70-84, October 2014,
ABSTRACT: This paper studies the failure mechanism and the bearing capacity of stainless steel lipped C section stub columns under axial and eccentric compression. A series of tests were performed on S30408 stainless steel, including 16 mechanical property tests, 10 axially loaded and 28 eccentrically loaded stub column tests. Flat and corner coupon tests were conducted to investigate the anisotropy, the hardening index and the stress–strain behavior of stainless steel. Stub column tests were carried out to obtain the load–displacement curves, the bearing carrying capacity and the section strain variation. Comparison of test results with code predictions indicates that the design strengths are lower than the experimental strengths, and that the deviation between test and predicted results reduces as the section plate slenderness coefficient increases.

ABSTRACT: When compared with carbon steel, stainless steel exhibits a more pronounced non-linearity and no well-defined yield plateau, as well as appealing features such as aesthetics, higher corrosion resistance and lower life cycle cost. Due to its considerably high ductility/strength and cost, stainless steel structural solutions tend to be adopted mostly for slender/light structures, thus rendering the assessment of their structural behaviour rather complex, chiefly because of the high susceptibility to instability phenomena. The first objective of this paper is to present the main concepts and procedures involved in the development of a geometrically and materially non-linear Generalised Beam Theory (GBT) formulation and numerical implementation (code), intended to analyse the behaviour and collapse of thin-walled members made of materials with a highly non-linear stress–strain curve (e.g., stainless steel or aluminium). The second objective is to validate and illustrate the application of the proposed GBT formulation, by comparing its results (equilibrium paths, ultimate loads, deformed configurations, displacement profiles and stress distributions) with those provided by shell finite element analyses of two lean duplex square hollow section (SHS) columns previously investigated, both experimentally and numerically, by Theofanous and Gardner (Eng Struct 2009; 31(12): 3047–3058.). The stainless steel material behaviour is modelled as non-linear isotropic and the GBT analysis includes initial geometrical imperfections, but neglects corner strength enhancements and membrane residual stresses. It is shown that the GBT unique modal nature makes it possible to acquire in-depth knowledge concerning the mechanics of the column behaviour, by providing “structural x-rays” of the (elastic or elastic–plastic) equilibrium configurations: modal participation diagrams showing the quantitative contributions of the global, local, warping shear and transverse extension deformation modes - moreover, this feature makes it possible to exclude, from future similar GBT analyses, those deformation modes found to play a negligible role in the mechanics of the behaviour under scrutiny, thus further reducing the number of degrees of freedom involved in a GBT analysis, i.e., increasing its computational efficiency.

“Stub column tests on stainless steel built-up sections”, Thin-Walled Structures, Vol. 83, pp 103-114, October 2014, DOI: 10.1016/j.tws.2014.01.007

ABSTRACT: This paper presents twenty-eight stub columns tests on stainless steel built-up sections. The test specimens, including I-sections, square hollow sections (SHS) and rectangular hollow sections (RHS), were fabricated by shielded metal arc welding (SMAW) from hot-rolled plates of nominal thicknesses 6 mm and 10 mm. The twenty-eight stub columns, of two stainless steel alloys (austenitic EN 1.4301 and duplex EN 1.4462), were tested in pure axial compression. Both tensile and compressive material properties were obtained by means of coupon tests in three directions – longitudinal, diagonal and transverse to the rolling direction. Geometric imperfection measurements for each specimen were conducted by means of a calibrated electric guideway, and residual stress distributions in the built-up sections were determined by means of the sectioning method. The test strengths were used to evaluate the design strengths predicted by EN 1993-1-4, the Continuous Strength Method (CSM) and the direct strength method (DSM). It was demonstrated that the predicted strengths from EN 1993-1-4 provisions were generally conservative, while both the CSM and the DSM predicted values were closer to the test strengths.

ABSTRACT: An experimental study of stainless steel continuous beams not susceptible to lateral torsional buckling is reported in this paper and the applicability of plastic design methods to such structures is considered. A total of 18 two-span continuous beams were tested. Three cross-section types – cold-formed square hollow sections (SHS), cold-formed rectangular hollow sections (RHS) and welded I-sections, and two material grades – austenitic EN 1.4301/1.4307 and lean duplex EN 1.4162, were considered. The geometric and material properties of the continuous beam test specimens were carefully recorded and supplemented by tests on simply supported specimens of the same cross-sections. The test specimens covered a wide range of cross-section slendernesses and two different loading positions were adopted. The experimental results were used to assess the degree of moment redistribution in indeterminate stainless steel structures and the applicability of both conventional and novel plastic design methods, including an extension of the continuous strength method (CSM). Comparisons indicated that conventional plastic design is applicable to stainless steel structures, while greater efficiency can be achieved by considering strain-hardening through the CSM.

ABSTRACT: The present investigation studies the overall stability bearing capacities of stainless steel welded I-section beams. Experimental tests of 8 specimens have been conducted. In addition, complementary finite element (FE) models, which have been validated by the test results, are adopted to calculate the overall stability bearing capacities of the beams. Based on the results of FE analyses and experimental tests, as well as the comparisons of design standards for buckling reduction factor calculations of stainless steel structural components, two calculation methods for buckling reduction factors of welded I-section beams are proposed. One is the modification of Chinese code for design of steel structures, and the other is regressed by the FE analysis results. Both methods are conservative and have simple formulations for engineering design.

P. Malekzadeh and M. Daraie (Department of Mechanical Engineering, Persian Gulf University, Bushehr 7516913798, Iran), “Dynamic analysis of functionally graded truncated conical shells subjected to asymmetric moving loads”, Thin-Walled Structures, Vol. 84, pp 1-13, November 2014, DOI: 10.1016/j.tws.2014.05.007
ABSTRACT: The dynamic behavior of functionally graded (FG) truncated conical shells subjected to asymmetric internal ring-shaped moving loads is studied. The material properties are assumed to have continuous variations in the shell thickness direction. The equations of motion are derived based on the first-order shear deformation theory (FSDT) using Hamilton’s principle. The finite element method (FEM) together with Newmark’s time integration scheme is employed to discretize the equations of motion in the spatial and temporal domain, respectively. The formulation and method of solution are validated by studying their convergence behavior and carrying out the comparison studies in the limit cases with existing solutions in the literature. Then, the influences of material graded index, radius-to-length ratio, semi-vertex angle, thickness, boundary conditions and moving load velocity on the dynamic behavior of the FG truncated conical shells are
studied. In addition, the difference between the responses of the FG shells under symmetric and asymmetric loadings is compared.

ABSTRACT: Buckling of functionally graded plates under tension has not been investigated so far. In this paper critical buckling load of functionally graded plates containing a crack has been obtained using classical plate theory through the finite element method. Displacement in vicinity of crack tips has been approximated using previous solutions related to bending of cracked plates. Effect on buckling of plate under uni-axial and bi-axial tension of different parameters, such as plate dimensions and material properties, are studied. Results show that the critical load decreases as material gradient index increases, while bi-axial loading leads to higher critical loads compared to uni-axial case.

“Web crippling failure using quasi-static FE models”, Thin-Walled Structures, Vol. 84, pp 34-49, November 2014, DOI: 10.1016/j.tws.2014.05.003

ABSTRACT: This paper presents an investigation on the use of quasi-static analyses with explicit integration to evaluate the web crippling behaviour of cold-formed steel beams. Web crippling failure occurs due to the application of transverse concentrated loads, which can be applied statically or dynamically. In the majority of the examples found in the literature, the web crippling phenomenon has been investigated by means of purely static shell finite element (SFE) models with implicit integration. In this work, the ABAQUS code was employed to implement SFE models aimed at replicating an experimental test and quasi-static analyses with an explicit integration scheme were adopted. First, a brief literature review on the topic of the numerical investigation of web crippling of cold-formed steel members is presented. Then, the paper addresses the characterisation of the quasi-static analysis concept with particular emphasis on the control of dynamic effects and the SFE model of a lipped channel beam under External Two Flange (ETF) loading is described. Several conventional parameters of standard SFE analysis, such as the SFE type, mesh selection, steel model, hardening effects due to cold-forming, residual stresses, initial imperfections and support conditions are explained, as well as additional specifications pertaining to the adoption of quasi-static analyses, such as the load rate, mass scaling, contact and friction, smoothed amplitude curves and inhibition of inertia (noise) effects. Finally, the results obtained are presented in the context of the ETF case, including load–displacement curves, curves of kinetic-to-internal energy ratio vs. displacement and beam deformed shapes (failure modes). It is concluded that explicit analysis leads to rigorous simulations of experimental test results, in terms of ultimate load, post-collapse load–deflection curve and failure mechanism. The failure mode obtained with the quasi-static analysis provides a better approximation of the one observed experimentally than its non-linear static analysis counterpart. Indeed, the failure mechanism emerges considerably more clearly when the quasi-static analysis is adopted.

**ABSTRACT:** In spite of numerous papers in the literature on the buckling behavior of cylindrical shell structures, the effect of local large imperfections caused by physical contacts has not been exhaustively examined yet. To this end, this paper reports on an experimental program on the buckling and post-buckling response of thin cylindrical shells with local dent imperfections under uniform external pressure. The results of this study can be used in practical structures with similar geometric features, i.e. $D/t$ ratio.

Fei Xu, Ju Chen and Wei-liang Jin (Department of Civil Engineering, Zhejiang University, China), “Experimental investigation of thin-walled concrete-filled tube columns with reinforced lattice angle”, Thin-Walled Structures, Vol. 84, pp 59-67, November 2014, DOI: 10.1016/j.tws.2014.05.015

**ABSTRACT:** Experimental investigation of thin-walled concrete-filled steel tube columns with reinforced lattice angle was conducted in this study. The lattice angle was designed to reinforce the concrete-filled steel tube columns by increasing the percentage of steel cross-sectional area. Column specimens having different lengths ranged from 500 mm to 3500 mm were tested. The behavior and strengths of concrete-filled steel tube columns with lattice angle were investigated. In addition, concrete-filled steel tube columns having the same size but without reinforced lattice angle were also tested for comparison. Material properties of the concrete and steel used in the test specimens were measured. The test strengths are compared with the design strengths calculated using the AISC Specification and Eurocode for the design of composite structural members. A new design method was also proposed for the concrete-filled steel tube columns with reinforced lattice angle. It is shown that the design predictions from the proposed method agree with test results well.

“Post-local-buckling of fiber-reinforced plastic composite structural shapes using discrete plate analysis”, Thin-Walled Structures, Pp 68-77, November 2014, DOI: 10.1016/j.tws.2014.05.008

**ABSTRACT:** In this paper, post-buckling of rectangular composite plates rotationally restrained at the longitudinal unloaded edges and subjected to end shortening strain at the simply-supported loaded edges is analyzed using the first-order shear deformation plate theory-based spline finite strip method, and its application to post-local-buckling of fiber-reinforced plastic (FRP) composite structural shapes is illustrated with discrete plate analysis. Two cases of elastically- and rotationally-restrained plates are analyzed using the spline finite strip method: rotationally-restrained along both the unloaded boundary edges (RR) and one rotationally-restrained and the other free along the unloaded edges (RF). The two cases of rotationally-restrained plates (i.e., the RR and RF plates) are further treated as the discrete plates of closed and open section FRP shapes, and by considering the effect of elastic restraints at the joint connections of flanges and webs, post-local-buckling of various FRP shapes under end shortening is studied. The numerical comparisons with the finite element modeling demonstrate that the proposed discrete plate analysis technique and spline finite strip method can be used as an efficient and valid tool for post-local-buckling analysis of FRP shapes.
Elsayed B. Machaly, Sherif S. Safar and Mostafa A. Amer (Cairo University, Giza, Egypt), “Numerical investigation on ultimate shear strength of steel plate shear walls”, Thin-Walled Structures, Vol. 84, pp 78-90, November 2014, DOI: 10.1016/j.tws.2014.05.013

ABSTRACT: Ultimate shear strength of steel plate shear walls, SPSW, was conventionally computed as the sum of base shear supported by in-fill plate and boundary frame elements. The base shear supported by the in-fill plate was computed assuming that it was fully yielded after buckling whereas the base shear supported by the boundary frame elements was computed by plastic analysis assuming uniform yielding mechanism. In this paper the ultimate shear strength of SPSW was investigated by the finite element method. A detailed three-dimensional finite element model was established using ANSYS software at which the in-fill plate and the boundary frame elements were modeled using finite strain iso-parametric shell elements. The analysis included material and geometric non-linearities. Numerical results obtained from cyclic and pushover loading of SPSWs were verified by comparison to test results published in the literature. A comprehensive parametric analysis was conducted to assess the effect of geometric and material parameters of the wall on its ultimate shear strength. Discrepancies between numerical results and conventional theory were attributed to interaction of in-fill plate and boundary frame elements at ultimate load. When the flexural rigidity of boundary frame elements decreased, the in-fill plate did not achieve full yield strength. On the other hand, the base shear supported by boundary frame elements increased when thicker in-fill plates were utilized. Numerical results were used to update the theoretical expression of ultimate shear strength of SPSWs. The proposed expression was assessed by comparison to test results published in the literature.

Vaibhav Mittal, Tanusree Chakraborty and Vasant Matsagar (Department of Civil Engineering, Indian Institute of Technology (IIT) Delhi, Hauz Khas, New Delhi 110016, India), “Dynamic analysis of liquid storage tank under blast using coupled Euler-Lagrange formulation”, Thin-Walled Structures, Vol. 84, pp 91-111, November 2014, DOI: 10.1016/j.tws.2014.06.004

ABSTRACT: A growing number of terror attacks all over the world have become a threat to the human civilization. In the last two decades, bomb blasts in crowded business areas, underground railway stations and busy roads have taken numerous lives and destroyed properties in different parts of the world. However, blast response of many important civil infrastructures has still not been well understood due to the complexities in their material behavior, loading and higher nonlinearities. One such example of important civil infrastructure is liquid storage tanks which are undividable parts of any society for storage of water, milk, liquid petroleum, chemicals in industries etc. Blast loading on liquid storage structures may lead to disaster due to water and milk crisis, health hazard owing to the spread of chemicals and fire hazard due to the spread of liquid fuel. Hence, understanding the dynamic behavior of liquid storage structures under blast loading through numerical simulations is of utmost importance. In the present study, three dimensional (3D) finite element (FE) simulations of a steel water storage tank for different tank aspect ratios, percentages of water stored in the tank, tank wall thicknesses, boundary conditions at the bottom of the tank and magnitudes of blast loading have been performed using the FE software Abaqus. The coupled Euler–Lagrange (CEL) formulation in Abaqus has been adopted herein which has the advantage of considering the coupling of structural mechanics and fluid mechanics fundamental equations. The maximum hoop stress and shear stress in the tank wall, the water sloshing heights in tanks and the energy response of the tanks have been studied. It is observed that stresses and liquid sloshing heights in the tank increase with decreasing scaled distance of the explosive material and increasing aspect ratio, i.e. height to radius ratio.

“Eccentric low-velocity impact analysis of transversely graded plates with Winkler-type elastic foundations and fully or partially supported edges”, Thin-Walled Structures, Vol. 84, pp 112-122, November 2014
DOI: 10.1016/j.tws.2014.05.011

ABSTRACT: Impact analysis of plates with either elastic foundations or partially supported edges has not been accomplished, even for the homogeneous isotropic plates. In the present paper, eccentric low-velocity impact analysis of a functionally graded plate with fully/partially supported edges and a Winkler-type elastic foundation is performed. In contrast to the available researches, stiffness of the underneath layers is also taken into account in determination of the apparent stiffness of the contact region, employing Mori–Tanaka micromechanics-based model instead of the traditional rule of mixtures. The governing equations are derived based on the principle of minimum total potential energy and the first-order shear-deformation plate theory. Some of the included novelties are: modification of the contact law, incorporation of effects of the elastic foundation, considering the material heterogeneity and partially supporting the edges, and proposing various semi-analytical and (Galerkin-type) numerical solutions. Numerical time integration schemes are used to trace time variations of the responses. A sensitivity analysis is performed to investigate influences of the specifications of the plate and the indenter, the eccentricity, and the supporting length ratio on time histories of the indentation and contact force.

DOI: 10.1016/j.tws.2014.06.002

ABSTRACT: In this paper the generalization of the constrained finite strip method (cFSM) is provided. cFSM is an extension of the semi-analytical finite strip method (FSM), where carefully defined constraints are applied to enforce the thin-walled member to deform in accordance with desired deformations, e.g., to buckle in flexural, lateral-torsional, distortional, or local buckling mode. This paper is a companion to [1], where the method is introduced and where the primary modes are defined, i.e., modes that are associated with minimal cross-section discretization, when nodal lines are located at folds and ends only. In this paper the so-called secondary modes are defined, i.e., those with no displacements at folds and edges, which thus exist only if flat plates are discretized into multiple strips. Moreover, some practical aspects are also discussed, including how the individual base vector of the deformation spaces can be defined in a practically useful and meaningful manner. The applicability of the method is demonstrated by numerical examples.

“Effective width method to account for the local buckling of thin plates at elevated temperatures”, Thin-Walled Structures, Vol. 84, pp 134-149, November 2014, DOI: 10.1016/j.tws.2014.06.003

ABSTRACT: The local buckling of thin steel plates exposed to fire is investigated using a finite element model. The reduction of strength and stiffness that occurs at elevated temperatures needs to be taken into account in the design, as it increases the susceptibility to local buckling of the plates thus affecting their load carrying capacity. The obtained results show that the current existing design method of Eurocode 3 to take into consideration the local buckling in the calculation of the ultimate strength of steel thin plates at elevated temperatures needs to be improved. These methods are based on the same principles as for normal temperature but using for the design yield strength of steel, at elevated temperatures, the 0.2% proof strength of the steel instead of its strength at 2% total strain as for the cases where the local buckling is not limiting the ultimate strength of the plates. This consideration, however, leads to an inconsistency if cross-sections are composed simultaneous of plates susceptible and not to local buckling. To address this issue, new expressions for calculating the effective width of internal compressed elements (webs) and outstand elements (flanges) are proposed, which have been derived from the actual expressions of the Part 1.5 of the Eurocode 3 and validated against numerical results. It is also demonstrated that it is not necessary to use for the yield stress at elevated temperatures the 0.2% proof strength of the steel instead of the yield stress at 2% total strain, given that the necessary allowances are considered in these new expressions, thus leading to a more economic design.

Sandor Adany and Benjamin W. Schafer, “Generalized constrained finite strip method for thin-walled members with arbitrary cross-section: Primary modes”, Thin-Walled Structures, Vol. 84, pp 150-169, November 2014 DOI: 10.1016/j.tws.2014.06.001

ABSTRACT: In this paper the generalization of the constrained finite strip method (cFSM) is discussed. cFSM is a special version of the semi-analytical finite strip method (FSM), where carefully defined constraints are applied which enforce the thin-walled member to deform in accordance with specific mechanics, e.g., to allow buckling only in flexural, lateral–torsional, or a distortional mode. In the original cFSM only open cross-section members are handled, here the method is extended to cover any flat-walled member, including those with closed cross-sections or cross-sections with open and closed parts. Moreover, in the original cFSM only 4 deformation classes are defined, here the deformation field is decomposed into additional, mechanically meaningful, sub-fields. Formal mechanical criteria are given for the deformation classes, and implementation of the criteria regardless of cross-section topology is illustrated. In this paper, the primary deformation classes are presented in detail. Primary deformations are associated with minimal cross-section discretization, i.e. nodal lines located at folds and ends only. This paper is accompanied by a companion, where secondary modes and additional practical aspects in the selection of base vectors for the deformation classes are discussed. With the proposed modifications the powerful cFSM capabilities of buckling mode decomposition and identification are extended to essentially arbitrary thin-walled cross-sections.

“Quasi-static axial compression of concentric expanded metal tubes”, Thin-Walled Structures, Vol. 84, pp 170-176, November 2014, DOI: 10.1016/j.tws.2014.06.012
ABSTRACT: Previous studies have demonstrated that the failure mechanism and energy absorption capacity of expanded metal tubes strongly depends on the orientation of the cells. This paper presents an experimental investigation on the collapse of concentric expanded metal tubes subjected to quasi-static axial compression. Square tubes with two different cell orientations are tested to failure, and the energy absorption characteristics are calculated. The results show that the combination of cell geometries lead to a complex buckling mode interaction, which enhances the energy absorption capacity of expanded metal tubes.

ABSTRACT: This paper addresses the free vibration behaviour of single-cell thin-walled tubes with regular convex polygonal cross-section (RCPS) and provides an extensive analysis of the resulting natural frequencies and associated vibration mode shapes. A semi-analytical approach is adopted, which is based on the generalised beam theory (GBT) specialisation for RCPS recently proposed by Gonçalves and Camotim (2013) and subsequently employed to obtain insightful conclusions concerning the buckling behaviour of RCPS tubes (Gonçalves and Camotim (2013) 2 and 3). This approach makes it possible to obtain closed-form analytical solutions and also acquire in-depth knowledge concerning the mechanics of the vibration problem, through the well-known GBT modal decomposition features. Attention is paid to local (plate-like), extensional, torsional and distortional vibration modes, as well as their interaction.

ABSTRACT: This paper examines the design and load-carrying capacity of fixed-ended web-stiffened lipped channel columns eroded by mode interaction behaviour combined with distortional and local deformations. Initially, the paper presents the results of an experimental investigation of compressive tests on web-stiffened lipped channel columns fabricated from cold-formed mild steel with a thickness of 1.50 mm, which is aimed at determining their failure load-carrying capacity; the experimental investigation also aims to provide experimental evidence of the occurrence of such coupling phenomena concerning distortional and local modes, namely, local-distortional interaction and distortional-local interactive failures. Then, the paper examines the ultimate strength data of experimental columns, both reported in this paper and collected from the literature, and concludes that the current direct strength method (DSM) provides very unsafe predictions concerning such a detrimental interaction nature. Next, two DSM-based design approaches, namely, the nominal strength against local-distortional (NLD) and distortional-local (NDL) procedures, are presented and evaluated on the basis of all available experimental ultimate strength data. Finally, proposals and design considerations based on the
DSM-shape for the thin-walled cold-formed steel sections, which fail in mixed modes of distortional and local buckling, are presented.

Lazzarino 1, 56126 Pisa, Italy), “Numerical analysis of partly wrinkled cylindrical inflated beams under bending and shear”, Thin-Walled Structures, Vol. 84, pp 204-213, November 2014
DOI: 10.1016/j.tws.2014.06.009

ABSTRACT: This paper is aimed at assessing the nonlinear elastic response of an inflatable cylindrical beam through a simple mechanical model recently proposed by the authors for studying the equilibrium configurations of highly pressurised elastic membranes with general shapes. The attention is focused on beams loaded at mid-span with two different constraints, corresponding to simply-supported ends and built-in ends. The geometrical nonlinearities due to both the cross-sectional ovalization and wrinkling are carefully considered. In particular, the wrinkling of the membrane, clearly visible for load values much lower than the collapse load, is taken into account by means of an equivalent physical non-linearity. A two-states constitutive law for the material is assumed: when a fibre is stretched (the active state), its response is elastic, while when the fibre is contracted, no compressive force can be engendered in it (the passive state). The evolution of the cross-sectional ovalization, the size of the wrinkled regions and the magnitude of longitudinal and transverse stresses in the membrane are accurately determined for increasing levels of loads, up to collapse. The numerical results for the corresponding values of load and internal pressure, obtained through an expressly developed incremental-iterative algorithm, are compared with the experimental ones available in the literature.

“Experimental investigation on flexural behavior of concrete-filled pentagonal flange beam under concentrated loading”, Thin-Walled Structures, Vol. 84, pp 214-225, November 2014, DOI: 10.1016/j.tws.2014.06.008

ABSTRACT: The flexural behavior of simply supported concrete-filled pentagonal flange beams (CFPBs) under mid-span loading is experimentally and numerically investigated. There are two CFPFB specimens tested to failure under static load condition to determine the beam flexural capacity. One of the test specimens is designed with a pair of transverse stiffener at mid-span while the other is without any stiffener to resist the load. Both the test specimens have identical geometrical and material properties. From the experimental results, the flexural capacity of the specimen with stiffener is found to be 10% higher than that of the specimen without stiffener. The failure behavior shows the importance of transverse stiffener to enhance the ultimate flexural capacity and to avoid the localized web distortion of the beam. In the numerical study based on finite element (FE) analysis, the concrete and steel materials are modeled using the eight-node solid and four-node shell element respectively. A comparison of the ultimate capacity of the CFPFBs with and without stiffener reveals that the FE models simulate very well the flexural behavior of the test specimens and the difference of maximum load is found to be less than 10%.

“Wind buckling of tanks with conical roof considering shielding by another tank”, Thin-Walled Structures, Vol. 94, pp 226-240, November 2014, DOI: 10.1016/j.tws.2014.06.007

ABSTRACT: Oil storage tanks are usually arranged in groups in tank farms, and this configuration may affect their buckling and postbuckling strength under wind loads. The assessment of wind action on tank structures is performed in this work by means of wind tunnel experiments to evaluate the pattern of pressure distribution for a tank which is shielded by another tank under various configurations and separation between them. The experimental results show significant changes in pressures due to shielding effects. In a second stage the structural response under the pressures previously evaluated is performed by finite element analysis using both linear bifurcation and geometrically nonlinear analysis. Results of two-tank interaction are compared with those of an isolated tank. Based on the results, it is concluded that the changes in wind pressures due to group effects induce changes in buckling loads and in the associated deflected patterns.

ABSTRACT: Based on the vibro-acoustical model, an effective new approach to nondestructively predict the elastic critical hydrostatic pressure of a submerged elliptical cylindrical shell is presented in this paper. Based on the Goldenveizer–Novozhilov thin shell theory, the vibration equations considering hydrostatic pressures of outer fluid are written in the form of a matrix differential equation which is obtained by using the transfer matrix of the state vector of the shell. The fluid-loading term is represented as the form of Mathieu function. The data of the fundamental natural frequencies of the various elliptical cylindrical shells with different hydrostatic pressure and boundary conditions are obtained by solving the frequency equation using Lagrange interpolation method. The curve of the fundamental natural frequency squared versus hydrostatic pressure is drawn, which is approximately straight line. The elastic critical hydrostatic pressure is therefore obtained while the fundamental natural frequency is assumed to be zero according to the curve. The results obtained by the present approach show good agreement with published results.

“Axial crushing and optimal design of square tubes with graded thickness”, Thin-Walled Structures, Vol. 84, pp 263-274, November 2014, DOI: 10.1016/j.tws.2014.07.004

ABSTRACT: Introducing thickness gradient in cross-section is a quite promising approach to increase the energy absorption efficiency and crashworthiness performance of thin-walled structures. This paper addresses
the deformation mode and energy absorption of square tubes with graded thickness during axial loading. Experimental study is firstly carried out for square tubes with two types of thickness distributions and numerical analyses are then conducted to simulate the experiment. Both experimental and numerical results show that the introduction of graded thickness in cross-section can lead to up to 30–35% increase in energy absorption efficiency (specific energy absorption) without the increase of the initial peak force. In addition, structural optimization of the cross-section of a square tube with graded thickness is solved by response surface method and the optimization results validate that increasing the material in the corner regions can indeed increase the energy absorption efficiency of a square tube.

ABSTRACT: The potentiality of cold-formed steel structures (CFS) in terms of lightness, rapid on-site erection and high structural performance is spreading the use of the technology in the most industrialized countries. In particular, the overall recognized capability to assure a good structural response in high seismic areas is allowing the adoption in some of the most conservative communities. On the other hand, despite the many ongoing research in different countries, the current seismic design codes are often inadequate if compared to the evolutionary process. In this context, the new British Force School (BFS) represents one of the first cold-formed steel structures realized in Italy and, therefore, it required a long and complex verification process. Indeed, the seismic performance at the global and local scale had to be verified during the construction phase. This paper focuses on the evaluation of lateral response of the sheathed cold-formed steel (SCFS) shear walls, which represent the seismic resisting system of this structural typology through the presentation and discussion of the experimental campaign carried out to support the design.

“Elastic distortional buckling of doubly symmetric steel I-section beams with slender webs”, Thin-Walled Structures, Vol. 84, pp 289-301, November 2014, DOI: 10.1016/j.tws.2014.05.010

ABSTRACT: Doubly symmetric steel I-section members with thin webs and stocky flanges have a tendency to buckle in a so-called distortional buckling mode, involving distortion of the web of the I-section in the plane of its cross-section. As this mode is more complicated than the local or global buckling, analytical expressions take empirical forms and vary in between different proposals. This paper has two main objectives. The first objective is to propose a complex finite strip method for distortional buckling analysis of I-section beams with slender webs and check the suitability for such analysis by comparing its accuracy with other methods and the second objective is to propose a simple method for predicting the distortional buckling loads of I-beams. The latter objective is superior to current methods with respect to the weight of the sections.

Niyazi Tanlak and Fazil O. Sonmez (Department of Mechanical Engineering, Bogazici University, Istanbul, Bebek 34342, Turkey), “Optimal shape design of thin-walled tubes under high-velocity axial impact loads”, Thin-Walled Structures, Vol. 84, pp 302-312, November 2014, DOI: 10.1016/j.tws.2014.07.003
ABSTRACT: In this study, the objective is to maximize the crashworthiness of thin-walled tubes under axial impact loads by shape optimization. As design variables, parameters defining the cross-sectional profile of the tube as well as parameters defining the longitudinal profile like the depths and lengths of the circumferential ribs and the taper angle are used. The methodology is applied to the design optimization of a crash-box supporting the bumper beam of a vehicle for the loading conditions in standard EuroNCAP crash tests. The crash event is simulated using explicit finite element method. While the crash-box is fully modeled, the structural response of the remaining parts during the test is taken into account by developing a lumped-parameter model. A hybrid search algorithm combining Genetic and Nelder & Mead algorithms is developed. The results indicate significant improvement in the crashworthiness over the benchmarks designs.

ABSTRACT: The main objectives of this study are to describe the compressive behavior and to determine the squash load of steel plate–concrete (SC) wall structures using ordinary and eco-oriented cement concrete. The major parameters in this research were the material of the concrete and width–thickness (B/t) ratio of surface steel plate. Six SC wall specimens were tested in compression in this test. In the three specimens, to reduce emissions of carbon dioxide (CO₂), some of the cement in weight was replaced by the Hwangtho (red clay) which is traditional and environmental material. The failure behavior, buckling behavior of the surface steel plate, the effective buckling length factors and plate buckling coefficient are discussed. Based on the test results, simplified rule was suggested to evaluate the buckling stress for surface steel plate. Several comparisons were made to evaluate the predicted strengths and test results.

ABSTRACT: This paper extends previous work concerning the determination of cross-section deformation modes in thin-walled members with arbitrary polygonal cross-section, in the framework of Generalized Beam Theory (Gonçalves et al., 2010 [1]). In particular, the paper addresses the so-called “natural shear deformation modes” (i.e. the deformation modes that involve non-null membrane shear strains and are independent of the cross-section discretization employed), which are relevant for capturing the behaviour of thin-walled members with complex multi-cell cross-sections undergoing torsion and/or distortion. The contributions of the paper are (i) the derivation of fundamental properties of the shear modes, (ii) the proposal of an efficient mode extraction procedure and (iii) the development of analytical results for several particular cases. In order to illustrate the application of the proposed mode extraction procedure and demonstrate the validity of the derived properties, several cross-sections are analyzed, including complex multi-cell tubes.

ABSTRACT: Thin-walled open section beams are carefully analysed by Vlasov’s theory of the sectorial areas. It allows to take into account their peculiar warping deformation which appears in the presence of torsional actions. This behaviour determines a further stress state along the axis of the element which is rarely considered in structural analyses. The aim of the present paper is the evaluation of the warping deformation of thin-walled open section beams subjected to torsion. Firstly, the analytical theory proposed by Vlasov is verified through an experimental test on a steel specimen defined by a U profile. Specific analyses are performed with the aim of a sophisticated optical device in order to assess the transverse distortion of the section. Then, the results obtained experimentally and confirmed by a Finite Element (FE) programme permit to validate a computer programme based on the analytical theory and devised to study the structural behaviour of high-rise buildings stiffened by thin-walled open section shear walls. In order to evaluate the effectiveness of the programme, an example which highlights the benefits provided by the present method compared to FE programme is carried out.

ABSTRACT: The buckling of cylindrical steel silos is caused by the wall friction force due to shearing between the silo fill and silo wall. The aim of this paper is to investigate the stability process in a silo composed of thin-walled isotropic plain rolled sheets using a static and dynamic finite element analysis by taking both the geometric and material non-linearity into account during eccentric discharge. Silo shells were subjected to axisymmetric and non-axisymmetric loads imposed by a bulk solid following Eurocode 1. The differences between the results of static and dynamic analyses were comprehensively discussed. The advantages of a dynamic approach were outlined.

ABSTRACT: This paper numerically deals with the influence of cracks (in terms of length and location) on the ultimate compressive strength characteristics of unstiffened and stiffened plate elements used in thin-walled structures. The cracks were presumed to be through-thickness, having no contact between their faces and no propagation was allowed. A series of nonlinear finite element analyses was conducted using ANSYS commercial finite element code in which the Newton–Raphson method has been employed to solve the nonlinear governing equations. This study indicates that the length of cracks and especially its location can significantly affect the ultimate strength characteristics of unstiffened and stiffened plate elements subjected to axial compressive action.
“Computational modeling of flange crushing in cold-formed steel sections”, Thin-Walled Structures, Vol. 84, pp 393-405, November 2014, DOI: 10.1016/j.tws.2014.07.006

ABSTRACT: The computational modelling of the flange crushing phenomenon in cold-formed steel profiles is described in this paper, with particular emphasis to the development of shell finite element (SFE) models and performance of quasi-static analyses with an explicit integration scheme. Web crippling failure is widely recognised as the most relevant collapse mode of cold-formed steel members subjected to transverse concentrated loads. However, it has been experimentally and numerically observed that a somewhat different collapse mode may occur, due to the heavy stress concentrations stemming from the adoption of narrow bearing plates. This phenomenon, termed flange crushing, should not be confused with web crippling. Usually, the web crippling phenomenon is numerically investigated by means of non-linear static SFE models with an implicit integration scheme. In this study, SFE models are developed in ABAQUS code to study the flange crushing failure of a plain channel beam subjected to Internal Two Flange (ITF) loading conditions. These models are described in detail, as well as additional modelling concerns regarding quasi-static analyses and the explicit integration method. Different parameters are discussed in this article and the numerical results obtained are commented throughout. Such parameters include the (i) SFE type and mesh, (ii) load rate, mass scaling, adoption of smoothed displacement amplitude curves and control of inertial effects, (iii) contact and friction definitions, (iv) effects of forming cold-work and manufacturing process and (v) geometrical imperfections. Finally, the load–displacement response obtained with the quasi-static model and an equivalent non-linear static analysis are compared with the experimental test curves. It is concluded that very good results are achieved with the quasi-static approach, not only in terms of the ultimate load prediction, but also regarding the post-collapse load–deflection curve and the failure mechanism.

ABSTRACT: The full potential of carbon-fiber and aluminum-honeycomb sandwich panels and structures has been limited by the huge property mismatch between the high-stiffness carbon fiber and low-stiffness aluminum honeycomb. In this study, an orthogrid structure was added into the sandwich structure to raise the stiffness of soft honeycomb and therefore reduce the interfacial mismatch. The core then became an aluminum orthogrid structure filled with aluminum-honeycomb blocks. Three point bending tests were conducted to compare carbon fiber sandwiches with different types of core: (1) aluminum-honeycomb core; (2) aluminum-plate orthogrid core; and (3) aluminum-plate orthogrid core filled by aluminum-honeycomb blocks. The honeycomb filled orthogrid core sandwich was a bit heavier than the honeycomb or grid sandwich, but the critical load, specific
strength and energy absorption ability were all improved. The results indicated that the honeycomb filled orthogrid core sandwich with carbon fiber face sheet could provide improved structural properties for thin walled engineering structures.

ABSTRACT: In this article, behavior of honeycomb core against compressive force along cell axis was investigated. The samples were laterally compressed quasi-statically between rigid platens under displacement control. First, for some samples with different cell wall thicknesses and sizes, compressive strength was made by finite element using LSDYNA 971 program. It was determined that decreased cell size and increased cell wall thickness resulted in the increased compressive strength of the honeycomb. Afterwards, homogeneous and non-homogeneous methods were used for modeling the whole honeycomb and the relationship of sample modeling from smaller size to the original ones was stated.

ABSTRACT: This work presents a new formulation of the geometrically exact thin walled composite beam theory. The formulation assumes that the beam can undergo arbitrary kinematical changes while the strains remain small, thus compatibilizing the hypotheses of the strain measure and the constitutive law of the composite material. A key point of the formulation is the development of a pure small strain measure written solely in terms of scalar products of position and director vectors; the latter is accomplished through the obtention of a generalized small strain vector by decomposition of the deformation gradient. The resulting small strain measure is objective under rigid body motion. The finite element implementation of the proposed formulation is simpler than the finite strain theory implementation previously developed by the authors. Numerical experiments show that the present formulation is very accurate and computationally more efficient than the finite strain formulation, thus it is more convenient for most practical applications.

Helder D. Craveiro, Joao Paulo C. Rodrigues and Luis Laim (ISISE – Institute for Sustainability and Innovation in Structural Engineering, University of Coimbra, Portugal), “Cold-formed steel columns made with open cross-sections subjected to fire”, Thin-Walled Structures, Vol. 85, pp 1-14, December 2014

DOI: 10.1016/j.tws.2014.07.020

ABSTRACT: An experimental study on the fire behaviour of cold-formed steel lipped channel (C) and built-up I (2C) slender columns with restrained thermal elongation is presented. The studied parameters were the stiffness of the surrounding structure, type of cross-section, end support conditions and initial applied load level on the columns. The results showed that increasing the stiffness of the surrounding structure and initial applied load level for the semi-rigid support conditions and both cross-sections, lead to a significant reduction of the critical temperature whereas for the pin-ended support conditions the reduction is supposed to be smaller.
ABSTRACT: So far, the equations for buckling capacity of web panels focus on thin-walled beams with very strong flanges. In this paper, elastic buckling behavior of web panels of thin-walled beams with weak flanges is further studied, aiming at a buckling coefficient formula unifying the effect of both weak and strong flanges. A new parameter, the flange-to-web ratio of moment of inertia, is proposed to characterize the effect of flanges. Then, a semi-analytical method is applied to investigate the buckling behavior of simply supported web panels, in two cases, inclusive or exclusive of effect of the moment of inertia of flanges. It is revealed that elastic buckling load, in particular, the buckling coefficient of web panel is a function of two key parameters, web aspect ratio and flange-to-web ratio of moment of inertia. Meanwhile, a finite element analysis (FEA) model allowing for the sensitivity of boundary conditions is validated by comparing with the semi-analytical solution to the case exclusive of effect of the moments of inertia of flanges. Next, numerical results are utilized to illustrate the influence of the previous parameters, which verify the increase of buckling coefficient with flange-to-web ratio of moment of inertia or the decrease of buckling coefficient with web aspect ratio. Besides, it also verifies that for the same flange-to-web ratio of moment of inertia, the buckling behavior of square web panels is closer to the uniform shear buckling than other rectangular web panels. Finally, an accurate design formula is proposed to calculate bucking coefficient of web panel.

ABSTRACT: This paper presents an investigation on the structural behavior of flattened expanded metal tubes subjected to axial crushing. At first, the study is carried out experimentally to investigate the effect of the angle formed between the expanded metal cell and the applied load. Secondly, the results are compared with experimental results for standard expanded metal sheets. Thereafter, numerical analyses are conducted by means of nonlinear finite element models, to investigate the enhancement in the energy absorption characteristics due to flattening of the expanded metal. Both results, experimental and numerical show a significant increase in energy absorbing capacity and mean force for the flattened tubes.
the effect of pore pressure on critical magnetic field of plate and the effect of important parameters of poroelastic material on buckling capacity are investigated. Also the compressibility of fluid and porosity on the buckling strength are being investigated.

DOI: 10.1016/j.tws.2014.08.003
ABSTRACT: To improve the behaviour of conventional T-shaped concrete-filled steel tubular (CFST) columns, multi-cell composite T-shaped concrete-filled steel tubular (MT-CFST) columns are proposed in this paper. Experimental study of 25MT-CFST columns, including 13 short specimens with various cross sections and material properties and 12 slender specimens with different slenderness ratios, subjected to axial loads was conducted. The failure modes, axial load–strain curves for short specimens and axial load–lateral deflection curves for slender specimens were investigated. The test results were compared with design approaches for conventional CFST columns presented in Eurocode 4, AISC specification, Australian standard AS51006, Chinese code CECS159, and Hong Kong steel code, and it was found that all the design codes underestimate the bearing capacity of both short and slender MT-CFST columns to some extent.

Liping Wang and Ben Young (Department of Civil Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong), “Design of cold-formed steel channels with stiffened webs subjected to bending”, Thin-Walled Structures, Vol. 85, pp 81-92, December 2014, DOI: 10.1016/j.tws.2014.08.002
ABSTRACT: The objectives of this study are to investigate the structural behaviour and evaluate the appropriateness of the current direct strength method on the design of cold-formed steel stiffened cross-sections subjected to bending. The stiffeners were employed to the web of plain channel and lipped channel sections to improve the flexural strength of cold-formed steel sections that are prone to local buckling and distortional buckling. An experimental investigation of simply supported beams with different stiffened channel sections has been conducted. The moment capacities and observed failure modes at ultimate loads were reported. A nonlinear finite element model was developed and verified against the test results in terms of strengths, failure modes and moment–curvature curves. The calibrated model was then adopted for an extensive parametric study to investigate the moment capacities and buckling modes of cold-formed steel beams with various geometries of stiffened sections. The strengths and failure modes of specimens obtained from experimental and numerical results were compared with design strengths predicted using the direct strength method specified in the North American Specification for cold-formed steel structures. The comparison shows that the design strengths predicted by the current direct strength method (DSM) are conservative for both local buckling and distortional buckling in this study. Hence, the DSM is modified to cover the new stiffened channel sections investigated in this study. A reliability analysis was also performed to assess the current and modified DSM.

DOI: 10.1016/j.tws.2014.07.021
ABSTRACT: The web crippling design guides are based on empirical adjustments of available test data. These equations differ from the basic concept underpinning most of the other instabilities, the so-called strength
curves. This investigation presents a new design approach for web crippling design of stainless steel hat sections based on strength curves controlled by slenderness-based functions $\chi (\lambda)$. The effects of web crippling on such cross-sections were studied numerically and the obtained results were used to derive the design expressions. Comparisons with tests and FE data, and with design guides show that the proposed design approach provides more accurate web crippling resistance.

“Buckling measurement and numerical analysis of M-type ribs stiffened composite panel”, Thin-Walled Structures, Vol. 85, pp 117-124, December 2014, DOI: 10.1016/j.tws.2014.08.008

ABSTRACT: A combination of methods of strategy which combines optical measurements and numerical calculations was developed to study the buckling behavior and failure modes of composite panel with M-type stiffeners under compression. Utilizing the non-contact optical means for non-destructive testing, the full-field buckling deflections/evolution and compressive failure of the panel surface were systematically collected for mechanical analysis. Based on continuum mechanics modeling, the buckling and post-buckling behaviors of the composite panel were predicted and compared with the buckling shapes that are obtained from experiments. The numerical simulation methods and experimental test technique in the work provides a useful tool to study the compressive buckling behaviors of composite panel with M-type stiffeners.

ABSTRACT: A geometrically nonlinear beam model suitable for describing complex 3D effects due to non-uniform warpings including non-standard in-plane distortions of the cross-section is presented and applied to the buckling analysis of beams. Each section is endowed with a corotational frame where statics and kinematics are described using a refined linear elastic model which exploits a semi-analytical solution of the Cauchy continuum problem based on a FEM discretization of the cross-section. The stress field in this way is fully 3D, allowing both the exact recovery of the standard Saint Venant solution and the consideration of some additional relevant strain modes of the cross-section that are evaluated in a simple and effective way. Numerical results are presented and compared with 3D shell reference solutions obtained by using the commercial code ABAQUS.

ABSTRACT: A shear deformable thin-walled beam theory is developed for the analysis of steel beams reinforced with a GFRP plate to one of the flanges. Starting with the principle of stationary potential energy, the governing equilibrium equations and boundary conditions are formulated for the problem. The theory results in two sets of fully coupled systems of equilibrium equations. The first system describes the longitudinal-flexural response of the system and involves four generalized displacement fields and the second system governs the
lateral-torsional response and involves six generalized displacement fields. The resulting coupled systems are then solved numerically for practical problems. Detailed comparisons with three dimensional and shell solutions under ABAQUS show that the present theory provides reliable predictions for displacements and stresses. A comparison with results from a non-shear deformable theory illustrates the necessity of incorporating shear deformation effects in cases involving predominantly twisting responses.

“FRP strengthening of lean duplex stainless steel hollow sections subjected to web crippling”, Thin-Walled Structures, Vol. 85, pp 183-200, December 2014, DOI: 10.1016/j.tws.2014.08.010

ABSTRACT: This paper presents the experimental and numerical investigations of lean duplex stainless steel hollow sections subjected to web crippling. The test specimens were strengthened with different fibre-reinforced polymer (FRP). The web crippling tests were conducted under end-two-flange, interior-two-flange, end-one-flange and interior-one-flange loading conditions. A series of web crippling tests was conducted. The investigation was focused on the effects of surface treatment, web slenderness, different adhesives and FRPs for the strengthening of lean duplex stainless steel hollow sections against web crippling. The lean duplex stainless steel type EN 1.4162 was used in the investigation. Two different surface treatments, three different adhesives and six different FRPs were investigated in this study. The tests were performed on five different sizes of square and rectangular hollow sections that covered a wide range of web slenderness ratio from 8.1 to 57.3. Three different failure modes were observed in the tests of the strengthened specimens, namely the adhesion, interlaminar failure of FRP plate and combination of adhesion and interlaminar failure of FRP plate. Finite element models have been developed and verified against the test results of the specimens subjected to two-flange loading conditions.

ABSTRACT: Current design codes provide two design methods: allowable stress/strain design and limit state design. Design in the current pipework composite repair codes is based on the allowable design method and only two safety factors are applied to the ultimate strain of the composite layer and to the yield stress of steel. On the other hand, safety factors are applied to each of the load and resistance parameters in the limit state design method. The limit state design method is probabilistic based in which the safety factors are calibrated based on a target reliability index. In this study, an investigation into the reliability of rehabilitated pipelines is conducted. The limit state function is defined based on ASME PCC-2, and reliability analysis is conducted using the AFOSM method. Results show that ASME PCC-2 generally provides adequate safety although the level of safety is not uniform for different percentages of corrosion. Comparing the achieved results and the ISO 2394 target reliability indices, some resistance factors are proposed.
Poologanathan Keerthan, Mahen Mahendran and Edward Steau (Science and Engineering Faculty, Queensland University of Technology, Brisbane, Australia), “Experimental study of web crippling behaviour of hollow flange channel beams under two flange load cases”, Thin-Walled Structures, Vol. 85, pp 207-209, December 2014, DOI: 10.1016/j.tws.2014.08.011

ABSTRACT: This paper presents the details of an experimental study of a cold-formed steel hollow flange channel beam known as LiteSteel beam (LSB) subject to web crippling under End Two Flange (ETF) and Interior Two Flange (ITF) load cases. The LSB sections with two rectangular hollow flanges are made using a simultaneous cold-forming and electric resistance welding process. Due to the geometry of the LSB, and its unique residual stress characteristics and initial geometric imperfections, much of the existing research for common cold-formed steel sections is not directly applicable to LSB. Experimental and numerical studies have been carried out to evaluate the behaviour and design of LSBs subject to pure bending, predominant shear and combined actions. To date, however, no investigation has been conducted on the web crippling behaviour and strength of LSB sections. Hence an experimental study was conducted to investigate the web crippling behaviour and capacities of LSBs. Twenty-eight web crippling tests were conducted under ETF and ITF load cases, and the ultimate web crippling capacities were compared with the predictions from the design equations in AS/NZS 4600 and AISI S100. This comparison showed that AS/NZS 4600 and AISI S100 web crippling design equations are unconservative for LSB sections under ETF and ITF load cases. Hence new equations were proposed to determine the web crippling capacities of LSBs based on experimental results. Suitable design rules were also developed under the direct strength method (DSM) format.

DOI: 10.1016/j.tws.2014.08.021

ABSTRACT: This paper investigates the effect of long-duration blast loads on the structural response of aluminium cylindrical shell structures containing varying fluid levels. A detailed non-linear numerical model comprising remapped Lagrangian analysis examines localised plate buckling and deformation. The relative computational accuracy of an uncoupled numerical model developed in this paper is compared with experimental results obtained at one of the world’s most powerful air blast testing facilities. Evaluating structural response for blast loads with an extended dynamic pressure phase is exceptionally difficult using only Eulerian controlled CFD methods; due to domain constraints incorporating restrictive cell sizes engulfing the target structure before remapping. The further complexity of shock transmission through a structure damped by an internal fluid is examined experimentally. Fibre optic controlled instrumentation and high speed photography provide a vital insight towards coupled flow-field behaviour of the shell structure. Surface mounted pressure gauges on the cylindrical wall accurately record the pressure time history throughout the passage of the shock wave. This paper highlights the key influence on blast response due to varying internal fluid levels and the relative importance pertaining to a conservative design solution for varying operational states. Numerical modelling in this paper demonstrates the robust accuracy achievable for a remapped Lagrangian solution. The routine analytical assumption of uniform drag forces acting on the structural body was shown to be both misleading and inaccurate by comparison. This research will be of direct interest to both practitioners and researchers considering high power explosive blasts from sources such as hydrocarbon vapour cloud ignition.

**ABSTRACT:** The postbuckling behaviour and load carrying capacity of thin-walled composite channel sections subjected to uniform compression are presented. An analysis of the influence of parameters of the composite manufacturing process on strength properties and load carrying capacity of the thin-walled structure made of this composite has been conducted. The microstructure characteristics of composites is presented and discussed. The postbuckling behaviour and load carrying capacity of thin-walled channel section columns subjected to compression have been determined with the finite element method. The ANSYS software has been employed.

“Shape optimization of cold-formed steel columns with fabrication and geometric end-use constraints”, Thin-Walled Structures, Vol. 85, pp 271-290, December 2014, DOI: 10.1016/j.tws.2014.08.014

**ABSTRACT:** The objective of this paper is to present constrained optimization results for a cold-formed steel (CFS) cross-section shape with maximum axial capacity. In the authors’ previous work unconstrained shape optimization was performed via stochastic search and gradient-based algorithms. Unconstrained shape optimizations produced a significant capacity increase, more than 140%, above standard CFS cross-sections, but many of the solutions are highly unconventional and have potential limitations both with respect to end use (e.g. attaching boards for walls and floors) and cost of manufacturing. Column capacity is determined using the Direct Strength Method (DSM) which requires inputs for the local, distortional and global critical buckling loads. These critical loads are obtained using the finite strip method, as implemented in the open source software CUFSM, which allows essentially any potential cross-section to be evaluated. To advance the applicability of the optimized results, end-use constraints and manufacturing constraints on the number of rollers employed in forming were both successfully incorporated in the shape optimization presented in this paper, resulting in optimized cross-sections that are more practical and economical with only marginally decreased capacity (usually less than 10%) from the earlier unconstrained optimized solutions. The constraints are implemented within a simulated annealing (SA) algorithm for the optimization. Optimized sections from multiple runs show uniformity, partially indicating the robustness of the final optimized shapes. The implemented constrained shape optimization provides a thorough search with high computational efficiency. The optimized cross-sections from this research provide promising potential shapes for the development of new commercial product families, and the member-level optimization methodology can also be integrated into building optimization in the future.

ABSTRACT: In the structural design of the sandwich plate, the inner core plays a key role to have its maximum performance. A shaped pyramidal truss core is proposed in order to increase the strength and productivity of the sandwich core. In this paper, the design guidelines of the shaped pyramidal truss core, which is enhanced by forming a cross-section of an arc shape at the strut of the inner core, is described. The inner core is composed of a stiffened section and a transient section with a varying cross-section. The critical load for bifurcation in compressive instability is calculated using an analytical and FEM simulation. The analytical equation for the critical load of the shaped column is derived using the energy method. The various buckling modes (global, distortional, local) occur due to these effects. Therefore, complications induced by such effects must be taken into account in the design. Parametric studies for the stiffened core are conducted. The effect of geometric parameters is investigated for optimal design of the inner core and their influence have been discussed.

Jian-xing Yu, Zhen-zhou Sun, Xiao-xie Liu and Yu-xuan Zhai (State Key Laboratory of Hydraulic Engineering Simulation and Safety, Tianjin University, Tianjin 300072, China), “Ring-truss theory on offshore pipelines buckle propagation”, Thin-Walled Structures, Vol. 85, pp 313-323, December 2014
DOI: 10.1016/j.tws.2014.08.015
ABSTRACT: Buckle propagation is an essential concern in offshore pipeline design. Once the propagation occurs, it may cause unavoidable failure of an entire pipeline. With the consideration of both longitudinal and hoop deformation behavior of pipeline, a ring-truss theory was analytically established in this study. Laboratory experiments were conducted in full-scale hyperbaric chamber in order to verify the analytical equation. It was observed that the length of transition zone has great influence on determination of propagation pressure. Due to the difficulties of measurement during test process, the length of transition zone was obtained using the finite element simulation. The comparison of propagation pressure between the current study and published model shows that for small diameter to thickness ratio, the ring-truss model is the one that is closest to the actual situation.

ABSTRACT: The paper deals with buckling of short thin-walled lipped-channel columns, simply supported on both ends and subjected to uniformly distributed compressive load. The main objective of the study was to investigate the structure’s work in far post-buckling state and at collapse corresponding to the moment of the column’s stiffness loss. The following measuring devices and methods were applied: electrical strain gauges for strain measurements, a laser sensor to measure the displacements, and the Acoustic Emission method. Along with running the experimental tests, the non-linear stability of compressed composite columns was analyzed with the Finite Element Method. The numerical and experimental results showed good agreement.

DOI: 10.1016/j.tws.2014.09.003
ABSTRACT: In this present article, large amplitude free vibration behaviour of doubly curved composite shell panels have been analysed using the nonlinear finite element method. The nonlinear mathematical model is
derived using Green Lagrange type geometric nonlinearity in the framework of higher order shear deformation theory. In addition to that all the nonlinear higher order terms are included in the mathematical model to achieve more general case. The nonlinear governing equation of free vibrated curved panel is derived based on Hamilton’s principle and solved numerically by using the direct iterative method. The developed mathematical model has been validated by comparing the responses with those available numerical results. Finally, some new numerical experimentation (orthotropy ratio, stacking sequence, thickness ratio, amplitude ratio and support conditions) have been carried out to show the significance and the efficacy of the proposed mathematical model.

M. Shakouri and M.A. Kouchakzadeh (Department of Aerospace Engineering, Sharif University of Technology, Azadi Street, P.O. Box 11155-8639, Tehran, Iran), “Free vibration analysis of joined conical shells: Analytical and experimental study”, Thin-Walled Structures, Vol. 85, pp 350-358, December 2014 DOI: 10.1016/j.tws.2014.08.022

ABSTRACT: Natural frequencies and mode shapes of two joined isotropic conical shells are presented in this study. The joined conical shells can be considered as the general case for joined cylindrical–conical shells, joined cylinder–plates or cone–plates, conical and cylindrical shells with stepped thicknesses and also annular plates. Governing equations are obtained using thin-walled shallow shell theory of Donnell and Hamilton’s principle. The continuity conditions at the joining section of the cones are appropriate expressions among stress resultants and deformations. The equations are solved assuming trigonometric response in circumferential and series solution in meridional directions and all combinations of boundary conditions can be assumed in this method. The results are compared and validated with the available results in other investigations and also modal testing. The effects of semi-vertex angles and meridional lengths on the natural frequency and circumferential wave number of joined shells are investigated.

ABSTRACT: It has long been identified that stiffening of steel shells is one of the most effective ways of enhancing the capacity of these structures. Stiffeners largely in the form of welded elements have been employed to strengthen shell structures in which the stiffeners generally cover the whole length of the structure. In this research the effect of partial and full length stiffening of shells was studied in which the stiffeners were attached without welding to avoid the adverse effect of the residual stresses. Furthermore, local thickening of the shells by the same stiffening strips was investigated and the results were evaluated against the plain specimen. The effect of strengthening provided by local thickening was slightly less but comparable to that provided by the stiffeners.

ABSTRACT: This present work aims to investigate the effect of debonds on the structural performance of adhesively bonded curved carbon fiber reinforced plastic (CFRP) panels under compressive loading environment. Representative curved panels are fabricated with a quasi-isotropic lay-up. Two types of specimens are prepared for the studies, one without debonds and the other with debonds of specified size, artificially introduced within the lap region. Pulsed thermography non-destructive technique is employed for the detection of debonds on the specimens. A set of experiments are conducted with displacement, strain and acoustic emission sensors to ascertain the performance of adhesively bonded joints under compression loading. Computational analyses are carried out using commercial finite element code MSC/NASTRAN to reproduce the experimental behavior and to aid in understanding the effect of closed debonds on the bonded joints. The computational model predictions are in good agreement with experimental observations. The effects of location of debond and panel curvatures are studied computationally incorporating debonds of different sizes. It is observed that debond location along the specimen length has significant effect and the buckling load reduces when the panel curvature increases for the same debond size.

Junyuan Zhang, Linan Wu, Guang Chen and Hao Zhou (State Key Laboratory of Automobile Simulation and Control, Jilin University, Changchun 130000, China), Bending collapse theory of thin-walled twelve right-angle section beams”, Thin-Walled Structures, Vol. 85, pp 377-387, December 2014, DOI: 10.1016/j.tws.2014.09.016

ABSTRACT: The present paper focuses on the bending collapse behavior of the twelve right-angle section (TTRS) beams. This paper presents the theoretical bending collapse mechanism of the TTRS beams around two axes based on the kinematic approach, and derives the expressions of the bending moments. The accuracy of the theoretical calculations are validated respectively by performing 36 groups finite element simulations including three kinds of materials, three different section dimensions and four different thicknesses. The results show that for $17.5 < c/h < 48.6$, the theoretical bending collapse mechanism of the TTRS beams presented in this paper can describe the collapse process accurately, and the moment–rotation curves calculated by theory show a good consistency with simulation results.

Recep Gumruk (Mechanical Engineering Department, Karadeniz Technical University, 61080 Trabzon, Turkey), “A numerical investigation of dynamic plastic buckling behaviour of thin-walled cylindrical structures with several geometries”, Thin-Walled Structures, Vol. 85, pp 388-397, December 2014 DOI: 10.1016/j.tws.2014.08.016

ABSTRACT: In this study dynamic buckling behaviors of an aluminum alloy cylindrical shell with axial linear variable thickness, discontinuity and conical shaped have been numerically investigated for high velocity impact by means of finite element method. The validation of finite element model was provided by the results of previous studies in literature. Throughout study commerce finite element package program LS-DYNA3D was used and all simulations were fulfilled as explicitly. According to results obtained, the minor changes in the geometry are able to convert the dynamic plastic buckling into dynamic progressive buckling behavior. This study indicates that which of the dynamic buckling or progressive buckling mechanism will be dominant is sensitive to geometrical properties for cylindrical aluminum alloy shells under the high velocity impact.

DOI: 10.1016/j.tws.2014.09.011
ABSTRACT: The residual ultimate strength of stiffened panels with locked cracks under axial compressive loading is analyzed. The influences of various geometrical characteristics of cracks and panels, such as the length and the orientation angle of cracks, are investigated by the nonlinear finite element analysis. The cracks are prevented from further propagation by holes with a diameter of 2 mm drilled at their tips. The finite element model has two bays in the longitudinal direction, employing periodical symmetrical boundary conditions at the ends of the loading edge. Beam tension test results are used to define the true stress–strain relationship of the material, which is used in the FE analyses to account for the nonlinear material property of steel.

ABSTRACT: The majority of gravity pipes with a non-circular cross section have an egg-shaped profile and an inner surface that can be geometrically delineated by three interconnecting circles on each side of a vertical axis of symmetry. Renovation of these pipes can be undertaken at low cost and with minimal surface disruption by installation of a close-fitting polymeric liner, most commonly by the ‘cured-in-place pipe’ technique. There are two pre-existing methodologies for the structural design of such liners. Although these procedures have served the international wastewater industry well over an extended period, detailed consideration of both methods suggests that an improved methodology which is straightforward to apply and addresses all relevant issues in a consistent manner would be both technically and financially beneficial. Accordingly a new design method is here proposed, which is based on an assumed displacement distribution in a manner consistent with previous work on close-fitting liners of circular cross section. The new design procedure addresses all the relevant issues in a rational manner, and is readily implemented as a small computer software simulation mountable on any current generation personal computer.

DOI: 10.1016/j.tws.2014.09.012

ABSTRACT: A recently developed nonlinear analytical model for axially loaded thin-walled stringer-stiffened plates based on variational principles is extended to include local buckling of the main plate. Interaction between the weakly stable global buckling mode and the strongly stable local buckling mode is highlighted. Highly unstable post-buckling behaviour and a progressively changing wavelength in the local buckling mode profile are observed under increasing compressive deformation. The analytical model is compared against both physical experiments from the literature and finite element analysis conducted in the commercial code Abaqus; excellent agreement is found both in terms of the mechanical response and the predicted deflections.

Licai Yang, Ying Luo, Tian Qiu, Min Yang, Gaobin Zhou and Guofu Xie (National Key Laboratory of Reactor System Design Technology, Nuclear Power Institute of China, 25 South Section 3, 2nd Ring Road, Chengdu, Sichuang 610041, People’s Republic of China), “An analytical method for the buckling analysis of cylindrical

ABSTRACT: This article presents an analytical method for the buckling analysis of laterally pressured cylindrical shells with non-axisymmetric thickness variations. The previous results for thickness variations under external pressure are reviewed firstly. Then, a general analytical method that combines the perturbation method and Fourier series expansion is developed to derive buckling load formulas, which is in terms of thickness variation parameter up to arbitrary order. A classical non-axisymmetric thickness variation is discussed in detail by the presented analytical method. When non-axisymmetric modal thickness variation becomes axisymmetric, the buckling loads degenerate to the known results. Furthermore, the influence of circumferential modal thickness variation with mode corresponding to twice the circumferential buckling mode on the buckling of laterally pressured cylindrical shells is analytically investigated and the results show a great agreement with previous numerical ones by Gusic et al. Thus we confirm the presented method. In addition to theoretical analysis, calculations and comparisons are also performed. The general analytical method presented in the article can be utilized to determine the buckling loads of shells with general thickness variations.

DOI: 10.1016/j.tws.2014.09.019

ABSTRACT: Buckling behaviors of web-posts in a cellular steel beam at elevated temperatures in a fire were studied using the Finite Element Method (FEM) analysis and available analytical models. The buckling temperatures obtained by the analytical models differed greatly to those obtained from the FEM simulation. Among these analytical models, the buckling temperature obtained through the strut model based on BS5950-1 agreed with the FEM result the best. It is more reasonable to take the width of the compression stress band in the web-post as the effective width of the strut. Numerical parametric studies showed that the width of the compression stress band varied with the opening diameter, the opening distance and the web thickness. A simplified method was proposed to calculate the effective width of the strut. The accuracy of the strut model integrating the new effective width was validated against the FEM simulations. The obtained buckling temperature of the web-post using the modified strut model agreed well with the FEM simulation result.

Lei Zhu, Yan Zhao, Shuwen Li, Yuxing Huang and Liren Ban (School of Civil and Transportation Engineering, Beijing Higher Institution Engineering Research Center of Structural Engineering and New Materials, Beijing University of Civil Engineering and Architecture, Beijing, China), “Numerical analysis of the axial strength of CHS T-joints reinforced with external stiffeners”, Thin-Walled Structures, Vol. 85, pp 481-488, December 2014
DOI: 10.1016/j.tws.2014.09.018

ABSTRACT: This study reinforced circular hollow section (CHS) T-joints with external stiffeners and analyzed the axial strength of both the unreinforced and reinforced T-joints. The SHELL181 element in ANSYS was used to establish FE models of the T-joints. A comparison between the experimental results indicated that the numerical method could be used to compute the strength for the unreinforced and reinforced CHS T-joints. To further investigate the reinforcement effect of the external stiffeners, a numerical parametric study was conducted. The study then evaluated the variations in strength of differently sized stiffeners. It was found that the joint strength increased significantly as the size of the stiffener increased. The reinforcement effect is more dependent on the stiffener length than on the stiffener height, but it is reasonable to adopt stiffeners with equal lengths and heights since this shape is commonly-used in engineering projects.

ABSTRACT: Most existing studies on single-layer spatial structures with semi-rigid joints were focused on spherical domes. The present paper analyzed the squared plan-form single-layer structures, examining the influence of joint-rigidity on the mechanical performances of the structures. An experiment has been conducted on a 5×6 m single-layer cylindrical reticulated shell with semi-rigid bolt-ball joints. The mechanical performance of the latticed shell is investigated in detail. Finite element analysis (FEA) model of the latticed shell is established taking material and geometric nonlinearities into account. The results show that the behavior determined using the FEA models correlates well with the experimentally observed behavior for the single-layer structures with semi-rigid joints.

DOI: 10.1016/j.tws.2014.09.004
ABSTRACT: The present paper deals with a dynamic interactive response of square FGM plates subjected to in-plane pulse loading. The structures are assumed to be simply supported along all edges. In order to obtain the equations of motion of individual plate, the classical laminate plate theory (CLPT) has been modified in such a way that it additionally accounts for all components of inertial forces. An effect of the imperfection sign (sense) influence on the dynamic response of plates made of functionally graded materials (FGMs) has been analyzed. In the case of the static problem, Koiter’s theory explains this sign (sense) sensitivity by an unsymmetrical stable equilibrium path of the FGM plate. The investigations deal with a comparison of the semi-analytical method (SAM) and the finite element method (FEM) applied to the dynamic postbuckling nonlinear analysis of thin-walled FG plated structures.

Hancock GJ, Pham CH., “Buckling analysis of thin-walled sections under localised loading using the semi-analytical finite strip method”, Thin-Walled Structures, Vol. 86, pp 35–46, January 2015,
DOI: 10.1016/j.tws.2014.09.017
ABSTRACT: Thin-walled sections under localised loading may lead to web crippling of the sections. This paper develops the Semi-Analytical Finite Strip Method (SAFSM) for thin-walled sections subject to localised loading to investigate web crippling phenomena. The method is benchmarked against analytical solutions, Finite Element Method (FEM) solutions, as well as Spline Finite Strip Method (SFSM) solutions. The paper summarises the SAFSM theory then applies it to the buckling of plates, and channel sections under localised loading. Multiple series terms in the longitudinal direction are used to compute the pre-buckling stresses in the plates and sections, and to perform the buckling analyses using these stresses. Solution convergence with increasing numbers of series terms is provided in the paper. The more localised the loading and buckling mode,
the more series terms are required for accurate solutions. The loading cases of Interior One Flange (IOF) and Interior Two Flange (ITF) are investigated in this paper using simply supported boundary conditions.

ABSTRACT: In practice, there is a wide variety of commercially available channel sections with complex shapes where the web is stiffened by adding longitudinal intermediate stiffeners. These stiffeners may improve the shear capacity of the channels. Recently, the Direct Strength Method (DSM) of design of cold-formed sections has been extended in the North American Specification for Cold-Formed Steel Structural Members (NAS S100:2012) to include shear based on research by the authors. The prequalified sections include flat webs and webs with small intermediate longitudinal stiffeners. To extend the range to larger intermediate stiffeners as occurs in practice, a series of predominantly shear tests of lipped channel sections with one web stiffener of different shapes and various sizes has been performed at the University of Sydney. Six different types of stiffened web channel sections were tested along with an additional reference plain section. All tests were conducted with straps screwed on the top flanges adjacent to the loading points. These straps provide torsion/distortion restraints which may enhance the shear capacities of the sections. The test failures were observed mainly in the combined bending and shear modes. Numerical simulations based on the Finite Element Method (FEM) using the software package ABAQUS/Standard are also performed to compare with and calibrate against the tests. The accurate results from the FEM models allow extension of the test data. Based on the reliable FEM models, a series of FEM modelling of predominantly shear tests for stiffened web channels has been performed without straps attached to the top flanges adjacent to loading points. The test and FEM results are subsequently plotted against the DSM interaction curves between bending and shear where the interaction is found to be significant. An extended range of DSM prequalified sections with longitudinally stiffened web channels in shear is proposed in this paper.

ABSTRACT: One of the most important advantages of steel plate shear wall (SPSW) is to create openings with different sizes and arbitrary locations on the infill plate depending on their application. In this research, the effects of two openings on the structural behavior of SPSWs were studied experimentally. Experimental testing was performed on three one-third scaled single-story SPSW specimens with two rectangular openings under quasi-static cyclic loading. The differences between the three perforated experimental specimens were the interval between two openings and their closeness to the frame columns. The structural parameters of perforated specimens were compared to the similar specimen without any opening. The experimental results were utilized (a) to compare the ultimate shear strength, stiffness and energy absorption of specimens; (b) to evaluate the performance of central, lateral, top and bottom panels; (c) to investigate the effect of distance between the openings and the columns on the formation of plastic hinges on the column flanges; (d) to study the behavior of stiffeners around the openings. Test results showed that the ultimate shear strength, stiffness and energy absorption were the same in all three perforated specimens and the interval between the two openings had no effect on these values. Moreover, existence of openings will lead to reduction in values of structural parameters.

ABSTRACT: To reduce the vulnerability of both civilian and military aircraft, it is essential to take the Hydrodynamic Ram (HRAM) pressure into account when designing their fuel tanks. In particular HRAM is especially dangerous for thin walled lightweight structures that cannot be armoured due to weight penalty reasons. Similarities in bubble behaviour between HRAM and underwater explosion situations were observed in recent high-speed tank penetration/water entry experiments. The present work concerns the application of a confined version of the Rayleigh–Plesset equation – which is classically used for bubble dynamics analysis (including underwater explosion) – to simulate a bubble created by an HRAM event induced by projectile penetration at ballistic speed in a confined geometry filled with a liquid. This equation is applied to a case of impact in a small closed tank. The initialisation of the model is based on experimental data and a conservation principle of the initial energy (of the projectile). To apply this equation, a relationship between the pressure applied on the structure and the structure deformation is needed. However it can only be obtained explicitly for spherical containers. The authors discuss the parameters needed in this equation and compare their calibrated values to theoretical ones calculated with analytical plates formulae.

ABSTRACT: We investigate the effects of warping on the dynamic stability of non-trivial equilibrium configurations for non-symmetric open thin-walled beams. We use a direct one-dimensional model coarsely describing warping; the rest of the kinematics is exact. Dynamic derives from the balance of power; constitutive relations are non-linear, hyper-elastic, and distinguish the roles of the centroids and shear centres; inertial actions account for warping, too. By centred finite differences, the warping inertial action is found ineffective on the natural angular frequencies. Then, we follow non-trivial equilibrium paths and investigate their Ljapounov stability, by examining the small superposed oscillations. Results for generic, non-symmetric cross-sections are presented and discussed, showing the effects of warping and of coupling constitutive coefficients.

ABSTRACT: The quasi-static and dynamic crushing response and the energy absorption characteristics of combined geometry shells composed of a hemispherical cap and a cylindrical segment were investigated both experimentally and numerically. The inelastic deformation of the shells initiated with the inversion of the hemisphere cap and followed by the axisymmetric or diamond folding of the cylindrical segment depending on the loading rate and dimensions. The fracture of the thinner specimens in dynamic tests was ascribed to the rise of the flow stress to the fracture stress with increasing strain rate. The hemisphere cap absorbed more energy at dynamic rates than at quasi-static rates, while it exhibited lower strain rate and inertia sensitivities than the
cylinder segment. For both the hemisphere cap and the cylinder segment, the inertial effect was shown to be more pronounced than strain rate effect at increasing impact velocities.

ABSTRACT: This paper addresses the energy absorption behaviour and crashworthiness optimisation of short length circular tubes under quasi-static lateral loading. Finite element (FE) models were developed using implicit FE code ANSYS to simulate the deformation behaviour and energy absorption of circular tube under lateral loading. These FE models were validated using experimental techniques to ensure that they can predict the responses of circular tube with sufficient accuracy. Response surface methodology (RSM) for design of experiments (DOE) was used in conjunction with finite element modelling to evaluate systematically the effects of geometrical parameters on the energy absorption responses of laterally crushed circular tubes. Statistical software package, design-expert, was used to apply the response surface methodology (RSM). The energy absorbing responses (specific energy absorbing capacity (SEA) and collapse load (F)) were modelled as functions of geometrical factors (tube diameter, tube thickness, and tube width). These developed functions allow predictions of the energy absorption response of laterally crushed tubes, based on their geometry parameters. Based on DOE results, parametric studies were conducted to generate design information on using the laterally crushed tubes in energy absorbing systems. Finally, the approach of multi-objective optimization design (MOD) was employed to find the optimal configuration of the proposed energy absorption structures. Design-expert software, which employs the desirability approach as optimization algorithm, was used for solving the MOD problem.

ABSTRACT: In this paper, an analytical simplified method for derivation of the average stress–average strain relationship of imperfect steel plates taking into account of both geometric and material nonlinearities is presented. The method utilizes the theory of elastic large deflection analysis of plates in the elastic region, and also the theory of rigid-perfectly plastic mechanism analysis of plates in the plastic region. The ultimate strength of the plate is predicted using an empirical formulation. The steel plates may be entirely un-corroded or both-sides randomly corroded. The algorithm can be easily implemented in methods for evaluation of ship hull girder ultimate strength as well as in the estimation of the ultimate capacity of offshore structures.

ABSTRACT: This paper researches a type of absorber of kinetic collision energy that works on the principle of shrinking and splitting a tube of circular cross section. During collision, a seamless tube is thrust through a cone
bush, squeezing the tube. Energy is absorbed by the plastic deformation, and through the friction between the tube and the bush. After passing through the cone bush, the tube presses against a splitter, and further energy is lost to friction and plastic deformation during the splitting process. Grooves on the inner wall of the tube prevent uncontrolled longitudinal tearing of the wall during the splitting. This new combined method of energy absorption enables greater absorption power with compact dimensions. Scaled samples have been tested in the laboratory. The influence of geometry and manufacturing technology of the samples, as well as the benefits of using such an absorber, are presented and discussed in this paper. The results show that the combined absorber has approximately 60% higher absorption power than the shrinking absorber by itself.

ABSTRACT: Buckling analysis of thin-walled functionally graded (FG) sandwich box beams is investigated. Material properties of the beam are assumed to be graded through the wall thickness. The Euler-Bernoulli beam theory for bending and the Vlasov theory for torsion are applied. The non-linear stability analysis is performed in framework of updated Lagrangian formulation. In order to insure the geometric potential of semitangential type for internal bending and torsion moments, the non-linear displacement field of thin-walled cross-section is adopted. Numerical results are obtained for FG sandwich box beams with simply–supported, clamped–free and clamped–clamped boundary conditions to investigate effects of the power-law index and skin-core-skin thickness ratios on the critical buckling loads and post-buckling responses. Numerical results show that the above-mentioned effects play very important role on the buckling analysis of sandwich box beams.

Rosario Montuori and Vincenzo Piluso (Department of Civil Engineering, University of Salerno, Salerno, Italy), “Analysis and modeling of CFG members: Moment curvature analysis”, Thin-Walled Structures, Vol. 86, pp 157-166, January 2015, DOI: 10.1016/j.tws.2014.10.010

ABSTRACT: The evaluation of the ultimate behaviour of Concrete Filled Tubular (CFT) members subjected to non-uniform bending moment is the main objective of this work. To this aim eight experimental tests have been performed at the Materials and Structures Laboratory of the Department of Civil Engineering of Salerno University. In particular, Square Hollow Section (SHS) CFT members have been investigated under monotonic loading conditions. The three point bending scheme is adopted for testing specimens, where an hydraulic actuator is used for the transmission of the transverse load at midspan under displacement control and an LVDT is used to measure the corresponding maximum transverse displacement. In addition, longitudinal deformations along the cross section perimeter have been measured by means of strain gauges, aiming to the experimental evaluation of moment–curvature relationship. This paper presents the structural details of the tested specimens and the corresponding experimental results. In addition, a fibre model able to predict the ultimate response of CFT members is also presented and compared with the experimental results. The presented fibre model accounts for all the effects influencing the ultimate behaviour of composite members, such as local buckling, confining effects on concrete, bi-axial stress state of the steel plate elements constituting the hollow profile and
hardening of its corners due to cold forming process. The comparison between experimental and numerical results shows a good agreement pointing out the accuracy of the proposed fibre model.

ABSTRACT: Lateral–torsional buckling (LTB) resistance of an I-beam depends on the minor axis moment of inertia of its compression flange and torsional rigidity of the section. A practical solution to increase lateral buckling of I-beams is to add two Delta stiffeners between the compression flange and web plates to form a hollow compression flange. Although these beams known as Delta hollow flange beams (DHFBs) have been introduced about half a century ago for bridge construction, however, their LTB behavior has not been investigated, yet. This paper develops a three dimensional finite-element model using ABAQUS for the inelastic nonlinear flexural–torsional analysis of DHFBs and uses it to investigate the effects of unbraced length and central off-shear center loading (located at center, top flange and bottom flange) on their moment gradient factor in different behavioral zones. It was found that the C b factor and moment resistance curve given by AISC-LRFD in Specification for structural steel buildings [2] are not accurate for intermediate (inelastic) and short plastic DHFBs leading to an unconservative design. Therefore, a modified moment resistance equation is proposed to be used instead of the code equation in inelastic zone for the investigated load cases in this paper.

Poologanathan Keerthan and Mahen Mahendran (Science and Engineering Faculty, Queensland University of Technology, Brisbane, QLD 4000, Australia), “Experimental investigation and design of lipped channel beams in shear”, Thin-Walled Structures, Vol. 86, pp 174-184, January 2015, DOI: 10.1016/j.tws.2014.08.024

ABSTRACT: Cold-formed high strength steel members are increasingly used as primary load bearing components in low rise buildings. Lipped channel beam (LCB) is one of the most commonly used flexural members in these applications. In this research an experimental study was undertaken to investigate the shear behaviour and strengths of LCB sections. Simply supported test specimens of back to back LCBs with aspect ratios of 1.0 and 1.5 were loaded at mid-span until failure. Test specimens were chosen such that all three types of shear failure (shear yielding, inelastic and elastic shear buckling) occurred in the tests. The ultimate shear capacity results obtained from the tests were compared with the predictions from the current design rules in Australian/NewZealand and American cold-formed steel design standards. This comparison showed that these shear design rules are very conservative as they did not include the post-buckling strength observed in the shear tests and the higher shear buckling coefficient due to the additional fixity along the web-flange juncture. Improved shear design equations are proposed in this paper by including the above beneficial effects. Suitable lower bound design rules were also developed under the direct strength method format. This paper presents the details of this experimental study and the results including the improved design rules for the shear capacity of LCBs. It also includes the details of tests of LCBs subject to combined shear and flange distortion, and combined bending and shear actions, and proposes suitable design rules to predict the capacities in these cases.

ABSTRACT: This paper presents the multi objective optimization of foam-filled tubular tubes under pure axial and oblique impact loadings. In this work, the double circular tubes, whose bottom is the boundary condition, while at the top, is the impacted rigid wall; with respect to the axis of the tubes. The optimal crash parameter solutions, namely the minimum peak crushing force and the maximum specific energy absorption, are constructed by the Non-dominated Sorting Genetic Algorithm-II and the Radial Basis Function. Different configurations of structures, such as empty empty double tube (EET), foam filled empty double tube (FET), and foam filled foam filled double tube (FFT), are identified for their crashworthiness performance indicators. The results show that the optimal foam filled foam filled tube (FFT) had better crashworthiness than the others under pure axial loading. However, the foam filled empty tube (FET) was the best choice for structures under an oblique loading.

ABSTRACT: The post-fire behaviour of slender reinforced concrete columns confined by circular steel tubes is investigated experimentally and numerically in this paper. Experiments were performed firstly to explore the fundamental behaviour of steel tube confined reinforced concrete (STCRC) slender columns after exposure to the ISO 834 standard fire, including the cooling phase. Temperature distributions, load versus lateral displacement curves, strains in the steel tube and failure modes were obtained and discussed. Next, a 3D finite element model was developed with the program ABAQUS using a sequentially coupled thermal-stress analysis. After validation of the FE model, parametric studies were carried out to identify the influence of key parameters on the load-bearing capacity and buckling reduction factor of slender STCRC columns. The considered parameters were the heating time, cross-sectional dimension, slenderness ratio, material strength, steel tube to concrete area ratio and reinforcement ratio. Finally, a simplified design method was proposed for predicting load-bearing capacity of STCRC slender columns after exposure to standard fires.

“Experimental and finite element analysis research on cold-formed steel lipped channel beams under web crippling”, Thin-Walled Structures, Vol. 87, pp 41-52, February 2015, DOI: 10.1016/j.tws.2014.10.017
ABSTRACT: This article presents the results of an investigation into web crippling behavior of cold-formed steel lipped channel beams subjected to end-one-flange (EOF), interior-one-flange (IOF), end-two-flange (ETF), and interior-two-flange (ITF) loading conditions. A total of 48 cold-formed steel lipped channel beams with different boundary conditions, loading conditions, bearing lengths, and section heights were tested. The experimental scheme, failure modes, concentrated load-general vertical deformation and strain intensity distribution curves are presented in the article. The effect of boundary condition, loading condition, bearing length and section height on web crippling ultimate capacity and ductility of cold-formed steel lipped channel
beams was also studied. Results of these tests show that the effect of bearing length on the web crippling ultimate capacity in EOF and ETF loading conditions is more obvious than those in IOF and ITF loading conditions. When bearing length is 50, 100, and 150 mm, web crippling ultimate capacity of cold-formed steel lipped channel beams with web slenderness=78 reaches its peak. The middle web enters plasticity and form plastic hinge zone. The values of web crippling ultimate capacity in interior-flange loading conditions are larger than those in end-flange loading conditions. It is shown that the specimens in the interior-flange loading conditions have higher ultimate capacity, larger initial stiffness and better ductility than those of specimens in the end-flange loading conditions. Finite element analysis can simulate experimental failure mode and web crippling ultimate capacity. The calculation equations of web crippling ultimate capacity put forward in the article can accurately predict experimental value.

ABSTRACT: This paper presents a combined experimental, numerical and theoretical study on the transverse impact behavior for ultra lightweight cement composite (ULCC) filled steel pipe structures. The drop weight impact test investigates the impact behavior of the pipe specimens. The numerical simulation using the non-linear finite element software LS-DYNA agrees closely with the experimental data. Meanwhile, this study develops a theoretical method to predict the impact response for cement composite filled pipes. Compared to the experimental results, the theoretical method provides reasonable predictions on the impact force and the global displacement response for the cement composite filled pipe specimens.

ABSTRACT: In civil engineering, shell structures are widely used as liquid-containment vessels. Understanding how the shell responds to relevant loading conditions is important for the design of safe and economical liquid-containment shell structures. This paper reviews recent research on the strength, stability and vibration behaviour of liquid-containment shell structures, and traces the developments pertaining to the design of these facilities to withstand various loading and environmental effects such as liquid pressure, wind pressure, ground movement and thermal effects. Results of recent feasibility studies of non-conventional shell forms for liquid containment are also reported, and areas of focus for future research are suggested.

“Elastic buckling of a sandwich beam with variable mechanical properties of the core”, Thin-Walled Structures, Vol. 87, pp 127-132, February 2015, DOI: 10.1016/j.tws.2014.11.014
ABSTRACT: This paper deals with the analytical and numerical studies of elastic buckling of a three-layered beam with metal foam core. Mechanical properties of the core are variable along the z-axis. There are two
schemes of displacement of the faces and core of the beam: a broken line hypothesis and a non-linear hypothesis. The mathematical models for both types of displacements are presented. The governing differential equations of the sandwich beam are derived. Numerical analysis of sandwich beams is conducted in ANSYS environment. The finite elements analysis has been performed using a linear elastic buckling model. The analysis with constant and variable Young’s modulus of the core of the beam is carried out. The values of the critical load obtained by the analytical and numerical (FEM) methods are compared.

ABSTRACT: The paper studies the influence of internal pressure on circular thin-walled pipes (D/t>150)/(D/t>150) subjected to pure bending. Both straight pipes and curved pipes are analysed. Both yield and buckling failures are considered. It is shown that internal pressure decreases the limiting load for yield but increases the limiting load for buckling. The study is mainly FEA-based. A formula to predict critical moment given by linear buckling analysis is proposed. Comments on difference between linear and non-linear analysis results are given. It is shown that a pipe curvature opposite to the bending moment can increase the critical load. It is shown that cylindrical thin-walled shells have an optimal value of internal pressure to which limiting load for yield and critical buckling moment are equal, corresponding to an optimal use of material.

ABSTRACT: Over the last several decades, various approaches to strengthening steel structures through the use of Carbon fibre reinforced polymer (CFRP) composites have been investigated; however, most of the studies have been focused on the steel tubes. This paper presents the feasibility analysis on the application of CFRP composite strips to strengthen the CFST column member under axial loading. CFRP strips having a width of 50 mm were used to confine the columns. The experimental parameters were the spacing between the CFRP strips (20 and 30 mm) and number of CFRP layers (one, two and three layers). All columns were tested under axial compression until failure. The experimental results revealed that bonding of CFRP composites effectively delayed the local buckling of the columns and also reduced the axial deformation by providing a confinement/restraining effect against the elastic deformation at both spacings. The confinement effect provided by CFRP composites was increased with the increase in the number of layers; however, the enhancement in buckling stress was not proportional. The load carrying capacity of the column increased with the application of CFRP strips, by up to 30% compared to the of un-strengthened column. From the test results it is suggested that the application of CFRP strips at a spacing of 20 mm or 30 mm is suitable for strengthening of a CFST circular column member; however, the application of strips at intervals of 30 mm recommended as an economical approach to strengthening compared to the 20 mm spacing. Finally, an analytical equation was proposed to predict the load carrying capacity of the CFRP strengthened CFST column, and the average difference between the calculated and experimental value was only ±5%.

El-Saadawy (Housing and Building National Research Center (HBRC), 87 El-Tahrir St., Dokki, Giza 11511, PO Box 1770, Cairo, Egypt), “Ultimate strength of singly symmetrical I-section steel beams with variable flange ratio”, Thin-Walled Structures, Vol. 87, pp 149-157, February 2015
DOI: 10.1016/j.tws.2014.11.016
ABSTRACT: Long steel beams in entrances of hotel lobbies and halls often support a masonry wall and are laterally unsupported. These beams do not reach their in-plane flexural capacity due to the occurrence of elastic or inelastic lateral–torsional buckling (LTB). Designers usually select doubly-symmetrical sections for these beams. In this paper the ratio of the compression flange size to the tension flange size is increasingly varied to obtain a higher resistance to lateral buckling of the compression flange. However, increasing the size of the compression flange and decreasing the size of the tension flange leads to the limiting case of a T-section which is weak in in-plane bending. Code provisions usually refer to generalized cases and special cases are always embedded in these and are not directly addressed. One of these special cases is the singly symmetric I-section. Special direct solutions for such problems are becoming more popular based on accurate inelastic ultimate load analysis. This paper develops a three dimensional finite element model, using ANSYS for the elastic and inelastic flexural–torsional buckling of I-beams, which is used to investigate the effect of varying the ratio of the flange sizes on the optimum performance of the beam. Slender webs are proposed and a study is made on the material of this web and the performance of its local and global buckling and its correlation to the total ultimate load of the beam system. The flange material consumption is kept constant and only the shares to the tension and compression flanges are varied to achieve the most economical system for design. The main goal of this research is to present a direct solution system that is simplified for the use of inexperienced designers, which provides the most economic system selection for design.

ABSTRACT: This paper deals with the development of novel procedures for the design of fixed-ended and pin-ended equal-leg angle columns with short-to-intermediate lengths, i.e., those buckling in flexural–torsional modes. Initially, numerical results concerning the buckling and post-buckling behaviour of the above angle columns are presented, (i) highlighting the main differences between the fixed-ended and pin-ended column responses, and (ii) evidencing the need for specific design procedures. Then, the paper gathers a large column ultimate strength data bank that includes (i) experimental values, collected from the available literature, and (ii) numerical values, obtained from Abaqus shell finite element analyses. The set of experimental results collected comprises 41 fixed-ended and 35 pin-ended columns, and the numerical results obtained concern 337 fixed-ended and 197 pin-ended columns – various cross-section dimensions, lengths and yield stresses are considered. Next, after reviewing the available methods to estimate the ultimate strength of angle columns, the paper develops new design approaches for fixed-ended and pin-ended columns, based on the direct strength method (DSM) – the mechanical reasoning behind the procedures proposed, which include the use of genuine flexural–torsional strength curves, is also provided. Finally, the paper closes with the assessment of the ultimate strength predictions yielded by the proposed DSM design procedures, through their comparison with the assembled experimental and numerical failure loads – it is shown that both the quality and reliability of these predictions are very good and slightly higher than those exhibited by the available design methods for angle columns.

DOI: 10.1016/j.tws.2014.11.008

ABSTRACT: There are considered thin periodic plates with moderately large deflections. To take into account the effect of the microstructure on behaviour of these plates the tolerance modelling method is applied, cf. Domagalski and Jedrysiak [2], Meccanica, 2012. This method makes it possible to derive model equations with constant coefficients involving terms dependent of the microstructure size. The paper contains an computational example of critical load calculations and postbuckling analysis.

ABSTRACT: To investigate the effect of corrosion on the axial capacity of steel bridge piles, a total of 13 H-shaped short columns were tested under monotonic axial load. The columns were machined to simulate different degrees and patterns of corrosion. The remaining axial capacity of the deteriorated members was assessed. To simulate the corrosion, webs and flanges were milled near the mid-height of the columns to reduce their thicknesses. The experimental results were compared to the axial capacities predicted by the design provisions of the American Institute of Steel Construction (AISC), American Association of State Highway and Transportation Officials (AASHTO), and American Iron and Steel Institute (AISI). The results of this study indicate that the degree of flange corrosion is the single factor that has the most significant effect on the column capacity. Other factors, including unsymmetry of the corrosion pattern or reduction of the flange width had a
minor influence on the capacity. The results also indicate that, among the design methods considered, the effective width method recommended by AISI provides the best prediction of the capacity of severely deteriorated steel columns.

Hong-Xia Shen (School of Civil Engineering, Xi’an University of Architecture and Technology, Xi’an 710055, PR China), “Behavior of high-strength steel welded rectangular section beam-columns with slender webs”, Thin-Walled Structures, Vol. 88, pp 16-27, March 2015, DOI: 10.1016/j.tws.2014.11.019

ABSTRACT: This paper develops a double nonlinear finite element model that can take account of both geometric and material imperfections. On verified the numerical model the behavior and ultimate carrying capacity of eccentrically loaded welded thin-webbed rectangular section columns made from high strength steel with a nominal yield stress of 460 MPa are analyzed, and further the influences of the slenderness ratio, web depth-to-thickness ratio, flange width-to-thickness ratio, and relative eccentricity ratio on the ultimate carrying capacity are investigated. On the basis of these, the simple calculation formulas, which use the gross cross-section properties, for predicting the in-plane maximum strength of high strength steel beam–columns with large depth-to-thickness ratios are proposed. It shows that the developed finite element model can simulate the local–overall interaction buckling behavior of the eccentrically loaded welded box-section compression members. A brittle failure characteristic is found with a relatively steeper drop just after the peak in the load–displacement curve. A nonlinear and complex stress distribution, in the longitudinal direction, when reaching the ultimate capacity, seriously deviates from an elastic stress distribution, on the basis of which, the effective width is determined. The non-dimensional ultimate bearing capacity is approximately linear with the slenderness, depth-to-thickness ratio and width-to-thickness ratio, respectively. The interaction curves between the axial force and flexural moment for the high-strength steel thin-webbed rectangular section beam–columns are nearly linear. After introducing a steel yield strength modification factor, the formula based on the edge fiber yielding criterion can precisely predict the local–overall interactive buckling strength of high strength steel beam–columns.

ABSTRACT: A series of tests on dodecagonal section double skin concrete-filled steel columns (DCS) were carried out in this study. Column specimens having different lengths ranged from 1000 mm to 3500 mm were tested. The behavior and strengths of dodecagonal section double skin concrete-filled steel columns were investigated. In addition, local bucking of inner and outer steel tubes were also investigated. Material properties of the concrete and steel used in the test specimens were measured. The test strengths are compared with the design strengths calculated using the proposed methods based on current AISC Specification and Eurocode for the design of composite structural members. The suitability of design method proposed by other researcher for circular section double skin concrete-filled steel columns for dodecagonal section specimens was also evaluated.

ABSTRACT: In order to prevent vehicle access to a protected area, vehicle barriers can be installed around the perimeter of the area. Bollards are commonly used as vehicle barriers. This is due to the fact that they can be readily blended with other architectural features and present fewer disturbances to a building’s functionality when compared to other barrier systems. Hollow steel tubes are used in a variety of barrier system applications where they are required to absorb deformation energy. Varying methods, such as finite element analysis or experimental observation, can be used to determine the collapse behaviour and energy absorption of these steel structures under lateral impact load. These methods have high accuracy but demand a significant amount of time and computational resources. Apart from experimental and numerical analyses, Yield Line Mechanism (YLM) is an approach that can provide the collapse response of sections. This is when a section fails and the YLM of failure forms at its localised plastic hinge point. The YLM analysis approach is commonly used to investigate the performance of thin-wall structures that have local failure mechanisms. This paper investigates the collapse behaviour and energy absorption capability of hollow steel tubes under large deformation due to lateral impact load. The YLM technique is applied using the energy method, and is based upon measured spatial plastic collapse mechanisms from experiments. Analytical solutions for the collapse curve and in-plane rotation capacity are developed, and are used to model the large deformation behaviour and energy absorption. The analytical results are shown to compare well with the experimental values. The YLM model is then used to verify the finite element model (FEM), and then the failure behaviour and energy absorption of hollow steel tubes under lateral impact load is investigated in more detail.

ABSTRACT: The present paper focuses on the ultimate shear strength analysis of intact and cracked stiffened panels. Several potential parameters influencing the ultimate shear strength of intact panels are discussed, including the patterns and amplitudes of initial deflection, the slenderness and aspect ratios of the plates, and the boundary conditions defined by the torsional stiffness of support members. An empirical formula for the ultimate shear strength of intact stiffened panels is proposed based on parametric nonlinear finite element analyses in ANSYS. Furthermore, the ultimate shear strength characteristics of cracked stiffened panels are investigated in LS-DYNA with the implicit method. Three types of cracks are considered, namely vertical crack, horizontal crack and angular crack. A simplified method is put forward to calculate the equivalent crack length. And the formula for the ultimate shear strength of cracked stiffened panels is derived on the basis of the formula for intact stiffened panels.

Shutian Liu, Zeqi Tong, Zhiliang Tang, Yang Liu and Zonghua Zhang (State Key Laboratory of Structural Analysis for Industrial Equipment, Dalian University of Technology, Dalian 116023, China), “Bionic design modification of non-convex multi-corner thin-walled columns for improving energy absorption through adding bulkheads”, Thin-Walled Structures, Vol. 88, pp 70-81, March 2015, DOI: 10.1016/j.tws.2014.11.006
ABSTRACT: Collapse analysis of the non-convex multi-corner thin-walled columns under axial loads illustrates that the non-compact expansion-contraction deformation mode of collapse may occur in some cases, which reduces greatly the energy absorption property of these structures. Inspired from the way by which the bamboo nodes and nodal diaphragms enhance the transverse strength of bamboo, the non-convex multi-corner thin-walled column is modified by adding bulkheads in the column for improving the energy absorption property, and a new excellent energy absorption structure named as the bionic non-convex multi-corner column (BI-NCMC) is proposed in this article, which is a non-convex multi-corner thin-walled column with bulkheads. The energy absorption of BI-NCMC has been investigated numerically. A progressive deformation mode has been achieved and this structure shows a higher energy absorption than a similar column without the bulkheads. The role of the bulkheads is to change the deformation mode from an expansion-contraction mode to a progressive mode, while the bulkheads themselves absorb little energy. The influences of parameters in the energy absorption of BI-NCMC are analyzed. It was found that the column with highest energy absorption efficiency is the one with the smallest number of bulkheads while still maintaining the progressive deformation mode.

Saeed Ebrahimi and Nader Vahdatazad (Department of Mechanical Engineering, Yazd University, Yazd, Iran), “Multiobjective optimization and sensitivity analysis of honeycomb sandwich cylindrical columns under axial crushing loads”, Thin-Walled Structures, Vol. 88, pp 90-104, March 2015, DOI: 10.1016/j.tws.2014.12.004

ABSTRACT: This paper firstly investigates the energy absorption characteristics of honeycomb sandwich cylindrical columns such as square, triangle, kagome and diamond core under axial crushing loads by nonlinear finite element analysis. The interaction effects between the honeycomb and column walls greatly improve the energy absorption efficiency. The response surface method with cubic basis functions is employed to formulate specific energy absorption and peak crushing force which reduces considerably the computational cost of crush simulations by finite element method. Both the single objective and multiobjective optimizations are performed for columns under axial crushing load with design variables inner, outer and core thickness. Models are optimized by multiobjective particle swarm optimization algorithm to achieve maximum specific energy absorption capacity and minimum peak crushing force. Furthermore, local and global sensitivity analyses are performed to assess the effect of design variable values on the specific energy absorption and peak crushing force functions in design domain.

“Buckling and yielding behavior of unstiffened slender, moderate, and stocky low yield point steel plates”, Thin-Walled Structures, Vol. 88, pp 105-118, March 2015, DOI: 10.1016/j.tws.2014.11.022

ABSTRACT: Steel plates may be classified as slender, moderate, and stocky based on their distinctive behavior characterized by geometrical buckling and material yielding. Slender plates undergo elastic buckling first and then yield in the post-buckling stage, while stocky plates yield first and then undergo inelastic buckling. Moderate plates, on the other hand, buckle and yield simultaneously. The development of low yield point (LYP) steel enables the application of steel plates with improved buckling and energy absorption capacities as lateral force-resisting and energy dissipating elements in structures. On this basis, buckling and yielding behavior of LYP steel plates with various support and loading conditions is studied in this paper from the point of view of
their application in steel plate shear wall (SPSW) systems. The limiting thicknesses of standalone plates corresponding to concurrent geometrical buckling and material yielding are determined theoretically and verified through detailed numerical simulations. Effects of using LYP steel and plate aspect ratio parameter on the required limiting plate thickness as an effective parameter in seismic design of SPSW systems are investigated as well. In addition to the studies on the performance of plates with two and four restrained edges and also applicability of some extrapolation techniques for predicting the critical buckling load of moderate plates, detailed studies are performed on determination of the limiting plate thickness in code-designed SPSW systems. Based on the findings of this study, some practical recommendations are provided for efficient seismic design of SPSW systems with LYP steel infill plates.

DOI: 10.1016/j.tws.2014.11.021
ABSTRACT: Nowadays, girders with corrugated webs are used in bridges as an efficient alternative to conventional girders with flat stiffened webs. Particularly in bridge girders with corrugated webs (BGCWs), the corrugated webs are the main elements for bearing the shear forces. Instead of prismatic BGCWs, tapered BGCWs are currently used mainly due to their structural efficiency, providing at the same time aesthetical appearance. Available literature shows that tapered BGCWs may be classified into four typologies. Among these typologies, Case I is the most common case appearing commonly near to the intermediate supports of continuous bridges. Accordingly, in this paper, the finite element (FE) method is employed to investigate the inelastic behavior of tapered BGCWs of Case I, following to the fundamental behavior of such girders published recently by the current authors. Previously validated 3-D nonlinear FE models are developed and used in this study. The paper seeks, first, at finding the validity limit of the previously proposed design strengths for the tapered BGCWs with respect to the girder’s initial imperfection. This is made by considering different initial imperfection amplitudes. Accordingly, it is found that the proposed equation is valid with initial imperfections of \( h_{w1}/200hw1/200 \); \( h_{w1}/hw1 \) is the height of the long vertical edge of the web panel. However, the accuracy increases for initial imperfections similar to the web thickness (\( t_{w1} \)) for cases of \( t_{w1}/200hw1/200 \). Then, it investigates the effect of the aspect ratio of the web panels, different flange inclination angles and flange slenderness ratios. Finally, the paper checks the authors’ previously proposed design model using the results of the generated parametric studies. Overall, the outcomes of this study are expected to provide more insight into the behavior of tapered BGCWs and enable accurate prediction of the shear capacity of this special type of BGCWs.

ABSTRACT: This paper presents a column curve formula capable of producing accurate strengths for extruded members of 6082-T6 aluminium-alloys failing by flexural buckling under axial compression. The formula uses the Perry-type curve. The material properties are expressed in terms of the Ramberg–Osgood parameters \( E \), \( f_{0.2} \), and \( n \), obtained from tensile coupon tests of the finished product. 30 specimens of 6082-T6 aluminium alloy, including 15 H-section and 15 rectangular hollow-sections were tested under axial load using a pin-ended condition. Numerical models were then developed using the FE software ANSYS, and were verified against the
experimental results. The coefficient of stability was determined and compared with the coefficients of stability from different codes such as American standard (American specification for aluminium structures), Eurocode 9 (European code for design of aluminium structures), GB50017-2003 (Chinese Code for design of steel structures) and GB50429-2007 (Chinese Code for the design of Aluminium Structures). The experiment column curve was then derived and compared with the curves of columns of different codes. Lastly a comparison between the present test results and the results of Rasmussen and Rondal (2000) [1] is presented.

ABSTRACT: This article studies the influence of the bimoment on the buckling of thin-walled beams with open cross section subjected to axial loading. In the case of torsional and torsional-flexural buckling of thin-walled Z-section beam, it is shown that influence of the bimoment could be of importance in the assessment of buckling loads. In order to verify the accuracy and validity of this analysis, the obtained results are compared with those calculated by ANSYS software.

ABSTRACT: Plastic deformation of structures absorbs substantial kinetic energy when impact occurs. Therefore, energy-absorbing components have been extensively used in structural designs to intentionally absorb a large portion of crash energy. On the other hand, high peak crushing force, especially with regard to mean crushing force, may lead to a certain extent and indicate the risk of structural integrity. Thus, maximizing energy absorption and minimizing peak to mean force ratio by seeking for the optimal design of these components are of great significance. Along with this analysis, the collapse behavior of square, hexagonal, and octagonal cross-sections as the baseline for designing a newly introduced 12-edge section for stable collapse with high energy absorption capacity was characterized. Inherent dissipation of the energy from severe deformations at the corners of a section under axial collapse formed the basis of this study, in which multi-cornered thin-walled sections was focused on. Sampling designs of the sections using design of experiments (DOE) based on Taguchi method along with CAE simulations was performed to evaluate the responses over a range of steels grades starting from low end mild steels to high end strength. The optimization process with the target of maximizing both specific energy absorption (SEA) and crush force efficiency (CFE), as the ratio of mean crushing load to peak load, was carried out by nonlinear finite element analysis through LS-DYNA. Based on single-objective and multi-objective optimizations, it was found that octagonal and 12-edge sections had the best crashworthiness performance in terms of maximum SEA and CFE.
DOI: 10.1016/j.tws.2014.12.008

ABSTRACT: In this article, bitubal circular energy absorbers consist of two AL-6063-O tubes with unequal diameters placed coaxially and compressed under quasi-static axial load are studied experimentally. The effects of diameter and wall-thickness of each tube and the interaction between two tubes on the crashworthiness parameters are investigated in detail. In order to reduce the high value of peak load induced in the bitubal absorbers, two worthwhile solutions are proposed. The first one is to use two tubes with different lengths and the other one is to cut groove at the end portion of one of the tubes.

ABSTRACT: 6082 is a relatively new alloy that currently provides the best combination of properties in 6xxx series alloys. A series of tests was conducted on the stability of heat-treated aluminium alloy 6082-T6 circular tube columns to check the reliability of buckling strength predictions of 6082-T6 alloy circular tube columns using current design rules. First, nine stub columns were tested to obtain stress–strain curves and three parameters of the Ramberg–Osgood expression (E, σ₀.2 and n). The experimental stress–strain curves were in good agreement with the Ramberg–Osgood expression, and the mean value of σ₀.2/n obtained from the tests was close to the Steinhardt assumption. Second, prior to column tests, the initial out-of-straightness of 15 circular tubes was accurately measured. Third, these 15 tubes, with five nominal slenderness ratios varying from 20.4 to 69.6, were tested between two pinned ends under axial compression to obtain failing modes and buckling strengths. Finally, the experimental buckling strengths were compared with the buckling strengths predicted by several current aluminium structure design codes, including the American Aluminium Design Manual (AA), Australian/New Zealand Standard 1664 (AS/NZS), and Eurocode 9 (EC9), as well as the general column curve formulation proposed by Rasmussen and Rondal [13]. These comparisons shows that the AA predictions are too conservative at small slenderness ratios, the AS/NZS predictions are unsafe at large slenderness ratios, the EC9 predictions are conservative, and the Rasmussen–Rondal formulation provides the closest and generally conservative strength predictions.

Chao Wu, Yu Bai and Xiao-Ling Zhao (Department of Civil Engineering, Monash University, Clayton, VIC 3800, Australia), “Improved bearing capacities of pultruded glass fibre reinforced polymer square hollow sections strengthened by thin-walled steel or CFRP”, Thin-Walled Structures, Vol. 89, pp 67-75, April 2015
DOI: 10.1016/j.tws.2014.12.006

ABSTRACT: Pultruded glass fibre reinforced polymer (GFRP) square hollow sections (SHS) are emerging as an alternative construction material in civil engineering. Different from thin-walled steel SHS, GFRP SHS is an orthotropic material and exhibits reduced capacity when concentrated bearing load is applied in the transverse to pultrusion direction. This paper examined two approaches to enhance the bearing capacity of the GFRP SHS, by using carbon fibre reinforced polymer (CFRP) sheets or thin-walled steel channel sections. Experimental studies were conducted on the strengthened pultruded GFRP SHS with two different dimensions. Two loading conditions, end-two-flange (ETF) and interior-two-flange (ITF), were applied to investigate the effect of
loading position on the bearing capacity of the GFRP SHS. Experimental results were discussed with relation to the failure modes and load–displacement responses. It was found that the bearing capacity of pultruded GFRP SHS was effectively improved by up to 70% after CFRP sheets strengthening, and by over 380% after steel strengthening. Finally, equations were proposed for calculation of the improved bearing capacities of pultruded GFRP SHS with either CFRP sheets strengthening or steel strengthening. A reasonable agreement was achieved between predicted capacities and the experimental results.

Box-71555-313, Iran), “Free vibration analysis of FG plate with piezoelectric layers using four-variable refined plate theory”, Thin-Walled Structures, Vol. 89, pp 76-83, April 2015
DOI: 10.1016/j.tws.2014.12.010
ABSTRACT: This study presents an analytical solution for free vibration analysis of a functionally graded (FG) plate integrated with piezoelectric layers using four-variable refined plate theory. Equations of motion for simply supported rectangular plates are derived using Hamilton’s principle and Maxwell’s equation, and Navier method is employed for solution of equations. The obtained natural frequencies for different examples are compared with the results of other common plate theories. The results demonstrate the simplicity, accuracy and efficiency of presented formulation in vibration analysis of investigated problems.

ABSTRACT: Unstiffened cylindrically curved panels constitute a common subset of shell structures and therefore share the advantages and disadvantages of such structural solution. One of the bigger disadvantages of shells is their sensitivity to imperfections that lower significantly their ultimate strength. At the European level, in the scope of plate design by FEM, imperfections are treated in EN 1993-1-5 (Annex C) and in shell structures designed by global numerical analysis using GMNIA, recommendations are given in EN 1993-1-6 (clause 8.7.2). Since curved panels are neither flat nor full revolution cylinders, rules for estimating equivalent geometric imperfections remain unclear. In order to tackle this problem, this paper introduces a numerical parametric study on the imperfection sensitivity of cylindrically curved panels. The effect of the amplitude and shape of initial geometric imperfections (together with different values of curvature and aspect ratio) on the ultimate strength of unstiffened cylindrically curved steel panels is studied, results are presented and conclusions are drawn.

ABSTRACT: Sandwich structures with foldcores are regarded as a promising alternative to conventional honeycomb sandwich structures as lightweight structural materials. One of the proposed applications of foldcore sandwich structures is on the aircraft fuselage and the interstage of a rocket. While flat foldcore sandwich structures have been intensively studied in the literature, there lacks a general design tool to create foldcores for a given cylindrical sandwich structure and the mechanical properties of such structures have not been well investigated. In this paper, a geometrical design protocol for foldcores that will fit into the space between the external and internal walls of a given cylindrical sandwich structure is developed based on the vertex method. A parametric study on the mechanical properties of several selected cylindrical foldcore models and a honeycomb core model virtually tested in axial compression, internal pressure and radial crush using the finite element method is performed. It is shown that foldcores outperform the honeycomb core model in axial compression and radial crush but have lower radial stiffness when subjected to internal pressure. The design protocol together with the virtual test results can serve as a useful tool for researchers to design cylindrical foldcore sandwich structures for many potential applications including but not limited to aircraft fuselage, submarine shell and other pressurized cylinders.

ABSTRACT: An investigation into the material response and local buckling behaviour of ferritic stainless steel structural cross-sections is presented in this paper. Particular attention is given to the strain hardening characteristics and ductility since these differ most markedly from the more common austenitic and duplex stainless steel grades. Based on collated stress-strain data on ferritic stainless steel, key aspects of the material model given in Annex C of EN 1993-1-4 [1] were evaluated and found to require adjustment. Proposed modifications are presented herein. The local buckling behaviour of ferritic stainless steel sections in compression and bending was examined numerically, using the finite element (FE) package ABAQUS. The studied section types were cold-formed square hollow sections (SHS), rectangular hollow sections (RHS) and channels, as well as welded I-sections. The models were first validated against experimental data collected from the literature, after which parametric studies were performed to generate data over a wide range of section geometries and slendernesses. The obtained numerical results, together with existing experimental data from the literature were used to assess the applicability of the slenderness limits and effective width formulae set out in EN 1993-1-4 [1] to ferritic stainless steel sections. The comparisons of the generated FE results for ferritic stainless steel with the design provisions of EN 1993-1-4 [1], highlighted, in line with other stainless steel grades, the inherent conservatism associated with the use of the 0.2% proof stress as the limiting design stress. To overcome this, the continuous strength method (CSM) was developed as an alternative design approach to exploit the deformation capacity and strain hardening potential of stocky cross-sections. An extension of the method to ferritic stainless steels, including the specification of a revised strain hardening slope for the CSM material model, is proposed herein. Comparisons with test and FE data showed that the CSM predictions are more accurate and consistent than existing provisions thus leading to significant material savings and hence more efficient structural design.
ABSTRACT: Mechanical and thermal post-buckling analysis is presented for FGM rectangular plates resting on nonlinear elastic foundations using the concept of physical neutral surface and high-order shear deformation theory, and investigations on post-buckling behavior of FGM rectangular plates with two opposite simply supported edges and other two opposite clamped edges are also new. Approximate solutions of FGM rectangular plates are given out using multi-term Ritz method, and influences played by different supported boundaries, foundation stiffnesses, thermal environmental conditions and volume fraction index are discussed in detail. It is worth noting that the effect of nonlinear elastic foundation is small at the pre-buckling and initial post-buckling state and is significant with increasing deflection at the deep post-buckling state. Especially, comparisons of post-buckling for FGM rectangular plates resting on nonlinear elastic foundations with movable simply supported edge subjected to compression acting on the geometric middle surface and the physical neutral surface are innovative, and may be helpful to clarify typical mistakes in literature.

ABSTRACT: In this paper, the structural strength and stability of cold-formed steel lipped channel beam-columns under bi-axial moments and axial force are experimentally investigated. The results are employed to evaluate the reliability of the current North American cold-formed steel design standard, AISI-S100-12, for predicting the strength of beam-columns, by both the effective width method (EWM) and the direct strength method (DSM). Fifty-five 600S137-54 (AISI-S200-12 nomenclature) lipped channel beam-column sections with three different lengths: 305 mm (short), 610 mm (intermediate), and 1219 mm (long) are tested under combined bi-axial bending moments and axial force to characterize the failure modes and the member capacity. A loading rig specifically designed to apply eccentric axial load, in order to provide bi-axial bending and compression to the specimens, was developed and detailed herein. The experimental observations reveal that the failure modes are highly dependent on the stress distribution applied on the cross-section by the combined actions. The results show a considerable potential for improvement in current specification approaches which utilize a simple interaction equation, as this typically results in conservative strength predictions. The potential for further improvement of the current specification for predicting the strength of cold-formed steel beam-columns is discussed.

ABSTRACT: To improve the efficiency of the numerical simulation of the crushing of a honeycomb structure, the equivalent solid model of an aluminium honeycomb core was established. Comparison between the numerical simulation results and experimental evidence revealed that the numerical model of the honeycomb structure was effectively verified as representative. Secondly, the response surfaces for the variation of specific energy absorption (SEA) with side length \( l \) and thickness \( t \) of the aluminium foil were constructed by surrogate models. Then the relationship between SEA variation and the length \( l \) and thickness \( t \) of the aluminium foil was investigated. Results indicated that SEA increased with increasing \( t \) and decreased with increasing \( l \). The optimum SEA and associated structural parameters (\( l=1.0 \) mm, and \( t=0.16 \) mm) of an aluminium honeycomb were obtained.

Jia-Hui Zhang and Ben Young (Department of Civil Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong), “Numerical investigation and design of cold-formed steel built-up open section columns with longitudinal stiffeners”, Thin-Walled Structures, Vol. 89, pp 178-191, April 2015

ABSTRACT: A built-up I-section with longitudinal stiffeners is expected to have better performance to resist against local and distortional buckling compared to conventional built-up I-section by simply connecting two plain channels back-to-back. This paper presents a non-linear finite element analysis to investigate the behaviour of cold-formed steel built-up open section columns with edge and web stiffeners. A finite element model was firstly developed and verified against tests of cold-formed steel built-up compression members, in which the initial geometric imperfections and material properties of the test specimens were included. Secondly, the verified finite element model was used for an extensive parametric study of fixed-ended cold-formed steel built-up open section columns. The parametric study was designed to investigate the effect of edge and web stiffeners in the built-up open sections. The finite element results together with the test results were compared with the design predictions calculated from the current design rules in the North American Specification and the Australian/New Zealand Standard. Furthermore, design rules of the current direct strength method were modified. It is shown that the design strengths predicted by the modified direct strength method are generally in good agreement with the ultimate loads of the built-up open section columns. In addition, the current design rules and the modified direct strength method were evaluated by reliability analysis.

ABSTRACT: To research mechanical behaviour of square hollow section (SHS) brace-H-shaped steel chord T-joints under axial compression, eight different \( \beta \) joint specimens with different external stiffeners arrangements at the foot of SHS brace were tested under axial compression in brace. The axial compression force was applied to the top end of the SHS brace member, which was weld to the center of the chord member. The test procedures, joint failure modes, jack load–vertical displacement curves and jack load–strain intensity curves were presented in the paper. The effect of \( \beta \) (defined as the brace width to the flange of H-shaped steel chord
width ratio) and the external stiffeners at the foot of SHS brace on the mechanical behaviour of the T-joints was also studied. The corresponding finite element analysis was also performed and calibrated against the test results. An extensive parametric study was carried out to evaluate the effect of geometric parameters on mechanical behavior of the T-joints under axial compression. Results of these tests show that local buckling failure of brace member was the main failure mode observed during the tests. 45° oblique external stiffeners could not improve the ultimate capacity of unstiffened joints under axial compression, while 90°normal external stiffeners could effectively improve the ultimate capacity of unstiffened joints with large $\beta$, even decrease the ultimate capacity of unstiffened joints with small $\beta$. Increasing the thickness of stiffeners can slightly improve the ultimate axial compressive capacity of stiffened joints. It is shown that the design strengths predicted by the current design rules are conservative for the unstiffened test specimens. The joint strengths obtained from the parametric study were compared with the design strengths calculated using current Eurocode 3. It is shown from comparison that the current Eurocode 3 is dangerous for the SHS brace-H-shaped steel chord T-joints under axial compression. The new design equations were proposed for the SHS brace-H-shaped steel chord T-joints under axial compression, which were verified to be safe and accurate.

ABSTRACT:
A shear deformable theory and a computationally efficient finite element are developed to determine the lateral torsional buckling capacity of beams with mono-symmetric I-sections under general loading. A closed-form solution is also derived for the case of a mono-symmetric simply supported beam under uniform bending moments. The finite element is then used to provide solutions for simply supported beams, cantilevers, and developing moment gradient factors for the case of linear moments. The formulation is shown to successfully capture interaction effects between axial loads and bending moments as well as the load height position effect. The validity of the element is verified through comparisons with other established numerical solutions.

ABSTRACT: Deformation and energy absorption studies with single, double and multi-wall square and circular tube structure with and without aluminum foam core are carried out for assessing its effectiveness in crashworthiness under the identical test conditions. Modeling and numerical simulation of aluminum foam filled square tubes under axial impact loading is presented. The foam-filled thin-walled square tubes are modeled as shell wherein, foam core is modeled by incorporating visco-elastic plastic foam model in Altair® RADIOSS™. It is observed that the multi-wall tube structure with foam core alters the deformation modes considerably and results in substantial increase in energy absorption capacity in comparison with the single and multi-wall tube without foam core. Moreover, the multi-wall tube foam filled structure shows mixed deformation modes due to the significant effect of stress wave propagation. This study will help automotive industry to design superior crashworthy components with multi-tube foam filled structures and will reduce the experimental trials by conducting the numerical simulations.
ABSTRACT: The paper deals with a solution of three-dimensional problems of natural vibrations and stability of loaded cylindrical shells with circular and arbitrary cross sections containing a quiescent ideal compressible fluid. A mathematical formulation of the problem has been developed based on the variational principle of virtual displacements taking into account the pre-stressed undeformed state caused by the action of static forces on the shell. The motion of potential compressible non-viscous fluid is described by a wave equation, which is transformed using the Bubnov–Galerkin method. The solution of the problem reduces to the computation of complex eigenvalues of a coupled system of two equations. Based on the developed finite element algorithm several numerical examples have been considered to analyze the influence of fluid levels, ratio of ellipse semi-axes, shell thickness and boundary conditions on the natural frequencies and vibration modes of circular and elliptical cylindrical shells loaded by mechanical forces. It has been found that the value of the external uniformly distributed pressure giving rise to instability does not depend on the level of fluid in the shell. The results allow us to conclude that the dynamic characteristics of the system are specified not only by the equivalent added mass of the fluid but also by hydroelastic interaction at the wetted surface.

ABSTRACT: The paper is devoted to the stability analysis of a five layer sandwich beam. The goal is to elaborate a mathematical model of this beam and to check the influence of the binding glue layers on the stability of this structure. The simply supported sandwich beam consists of five layers which are two metal faces, the metal foam core and two binding layers (the glue) between faces and the core. The mechanical properties vary through the thickness of the beam and depend on the material of each layer. The field of displacement for the flat cross section of the beam is defined. Based on Hamilton’s principle the system of three partial differential equations of motion is obtained. This system is approximately solved. The forms of unknown functions are assumed and the system of equations is reduced to a single ordinary differential equation of motion. The equation is then numerically processed. The results of solutions of the vibration problem analysis are shown in graphs and figures.

ABSTRACT: Foldcore is an origami-like structural sandwich core which is manufactured by folding a planar base material into a three dimensional structure. The manufacturing technology is open to a variety of base materials and also a range of unit cell geometries is feasible. This results in a wide spectrum of homogenized mechanical properties which can be achieved by foldcores. Aluminium was found to be a suitable base material for building high performance foldcores with high stiffness, strength and energy absorption capabilities. In this
study aluminium foldcores are built and tested in compression, shear, bending and impact. Simulation methods are developed and validated along these test series. Simulation shows good agreement to experiments and is therefore a good method for further foldcore developments.

ABSTRACT: The numerical method was adopted in this paper to study the performance of water tank under blast loading. The established numerical model was verified by comparing with the test results and then utilized to study the effects of water on the response of water tank under blast loading. The numerical results showed that water can significantly reduce the response of water tank under blast loading through reducing the external work. As for the boundary reaction force, although the maximum boundary reaction force was increased by filling in water, the increase in maximum boundary reaction force was less significant as compared to the decrease in response. Besides, the positive duration of boundary reaction force was reduced by filling in water. The simply supported and axially restrained boundary conditions were compared to study their effects on the response of water tank. It was found that the blast resistant performance of axially restrained water tank could be significantly improved as compared to the simply supported water tank. This can be attributed to the increased internal energy and reduced external work by adopting the axially restrained boundary condition.

ABSTRACT: This paper presents the details of experimental and numerical research study on web crippling property of aluminum tubular under concentrated web crippling loadings. A total of 48 aluminum square hollow sections with different boundary conditions, loading conditions, bearing lengths and section heights were tested. The experimental scheme, failure modes, load–displacement curves and strain intensity distribution curves were also presented. The investigation was focused on the effects of different boundary conditions, loading conditions, bearing lengths and web slenderness on web crippling ultimate capacity and ductility of aluminum square hollow sections. The results obtained from the experiments are shown that the effect of bearing length on the web crippling ultimate capacity under End-One-Flange (EOF) and End-Two-Flange (ETF) loading and boundary conditions is more obvious than those under Interior-One-Flange (IOF) and Interior-Two-Flange (ITF) boundary and loading conditions. The web crippling ultimate capacities under EOF and ETF loading conditions decreased as the slenderness ratio increased. As the bearing length was 150, the web crippling ultimate capacity under IOF and ITF loading conditions reached its peak when the value of the web slenderness was minimum. The web crippling ultimate capacities of aluminum tubular with bearing length=50 mm and 100 mm under IOF, ITF, EOF and ETF boundary and loading conditions decreased progressively. The web crippling ultimate capacity of aluminum tubular with bearing length=150 mm was approximately equal. Finite
element models were developed to numerically simulate the tests performed in the experimental investigations. Based on the results of the parametric study, a number of design formulas proposed in this paper can be successfully employed as a design rule for predicting web crippling ultimate capacity of aluminum tubular sections under four loading and boundary conditions.

ABSTRACT: A semi-analytical model for the non-linear analysis of simply supported, unstiffened laminated composite cylinders and cones using the Ritz method and the Classical Laminated Plate Theory is proposed. A matrix notation is used to formulate the problem using Donnell’s and Sanders’ non-linear equations. The approximation functions proposed are capable to simulate the elephant’s foot effect, a common phenomenon and a common failure mode for cylindrical and conical structures under axial compression. Axial, torsion and pressure loads can be applied individually or combined, and solutions for linear static, linear buckling and non-linear buckling analyses are presented and verified using a commercial finite element software. The presented non-linear buckling analyses used perturbation loads to create the initial geometric imperfections, showing the capability of the method for arbitrary imperfection patterns. The linear stiffness matrices are integrated analytically and for the conical structures an approximation is proposed to overcome the non-integrable expressions.

ABSTRACT: In this paper, a generalised complex finite strip method is proposed for buckling analysis of thin-walled cold-formed steel structures. The main advantage of this method over the ordinary finite strip method is that it can handle the shear effects due to the use of complex functions. In addition, distortional buckling as well as all other buckling modes of cold-formed steel sections like local and global modes can be investigated by the suggested complex finite strip method. A combination of general loading including bending, compression, shear and transverse compression forces is considered in the analytical model. For validation purposes, the results are compared with those obtained by the Generalized Beam Theory analysis. In order to illustrate the capabilities of
complex finite strip method in modelling the buckling behavior of cold-formed steel structures, a number of case studies with different applications are presented. The studies are on both stiffened and unstiffened cold-formed steel members.

ABSTRACT: Cylindrical bolted steel tanks with H/D~1 can be made from very thin steel courses the thickness of which is determined by tension. The important issue is to stiffen the whole shell with intermediate stiffeners to prevent from stability loss in situations when the tank is empty and exposed to a strong wind. The FEM package Abaqus with nonlinear Riks algorithm was used for analysis. A parametric study programmed in python, internal Abaqus language was conducted to establish the influence of number and position of intermediate stiffeners on buckling resistance of the tank. After calculating nearly one thousands tasks, results were gathered with python script and compared with classic design recommendations proposed in Eurocode 3, DIN 18 800 Part 4 and AWWA D103-09. Simplified analytical approaches present in current standards are rather conservative and one may want to look for more sophisticated methods of analysis of tank shells presented in this paper for more economical design of such structures. From the comparison of the results obtained with different numerical strategies such as linear buckling analysis (LBA), geometrically nonlinear analysis of perfect (GNA) and imperfect (GNIA) structure a necessity of taking into account imperfections in GNA arises. Otherwise a capacity of the shell structure may be overestimated even over the value obtained from LBA.

ABSTRACT: A novel methodology for imperfection sensitivity analysis is presented. Koiter’s perturbation method is used to calculate the imperfection paths emanating from mode interaction bifurcations, which occur on the post-buckling paths of the single modes. The Monte Carlo method is used to test a large number of modes and all possible interactions among them. The computational cost is low because of the efficiency of Koiter’s method. The demands of Koiter’s method for accurate evaluations of higher order derivatives of the potential energy are met by a mixed, corotational element.

ABSTRACT: A comprehensive experimental programme has been carried out to investigate the local buckling and postbuckling strengths of aluminium alloy I-section stub columns. A total of 15 test specimens made of two heat-treated aluminium alloys (6061-T6 and 6063-T5) were fabricated by extrusion. The material properties were acquired by the tensile coupons cut directly from the extruded cross-sections. The local geometric imperfections in sections were accurately measured prior to the tests. The stub column specimens were tested under axial compression between two fixed end supports, during which the local plate buckling featured visibly for each test specimen before reaching the peak load. The critical local buckling strengths were determined from the measured out-of-plane deflections and surface strains corresponding to the plate elements, which were further compared with the theoretical and analytical values taking into account element interaction and material non-linearity. Based on the obtained experimental postbuckling strengths, the design provisions in current design standards, including the American, Australian/New Zealand, European and Chinese specifications, were all evaluated. It was revealed that the predicted compressive strengths from the four design standards were generally conservative, especially for the cross-sections made of aluminium alloys with pronounced strain hardening properties.

ABSTRACT: In this work, finite element method is used to obtain elastic buckling loads and mode shapes of plates. The effect of four different in-plane boundary conditions on the elastic buckling load of simply supported plates subjected to in-plane uni-axial compressive loading is studied. Elastic buckling behavior of plates with cut-outs (circular and square with curved corners) is also studied to illustrate the effect of the size, shape and the eccentricity of the cut-out on buckling loads. Results of the study show that the in-plane boundary conditions affect the elastic buckling behavior of the plate to a significant extent. Aspect ratio influences both the mode shape and the elastic buckling load for perforated plates, whereas its influence is generally limited to mode shape only in case of a solid plate. Restraints on the in-plane movements of plate’s unloaded edges have different influence on the elastic buckling behavior of the plate when the position of cut-out is changed along the x-axis (loading direction) and along the y-axis (normal to loading direction) of the plate. Also, results show that a large cut-out in the vicinity of edges makes the plate unstable at a much lower load compared to the plate with no cut-out. It is envisioned that the results of this study may provide insight to predict buckling loads in practical scenarios.

ABSTRACT: This paper deals with numerical procedure for the vibration analysis of rectangular plates and stiffened panels subjected to point excitation force and enforced displacement at boundaries. The procedure is based on the assumed mode method, where natural response is determined by solving an eigenvalue problem of a multi-degree-of-freedom system matrix equation derived by using Lagrange’s equation of motion. Mode superposition method is applied to calculate plate/stiffened panel frequency response. The Mindlin plate theory is adopted for a plate, while the effect of stiffeners having the properties of Timoshenko beams is taken into account by adding their potential and kinetic energies to the corresponding plate energies. The accuracy of the proposed procedure is justified by several numerical examples which include forced vibration analysis of plates and stiffened panels with different dimensions and framing sizes and orientations, having various combinations of boundary conditions. The results obtained by the developed in-house code are compared to those obtained by the finite element method (FEM) and experimental results from the relevant literature. The presented procedure is confirmed to be highly accurate.

ABSTRACT: A minimum mass design study applicable to thin circular tube is performed for various modes of eccentric compressive loading. Axial crushing failure mode, frequently noticeable in uniform axial compressive loading of thin circular tube, does not appear in eccentric compression. Hence, other compressive failure modes, e.g., global buckling, yield and local buckling are studied with respect to non-dimensional load and geometric shape factors for a fixed-free condition. These modes are predominant in ductile engineering alloys. A failure mode map in terms of non-dimensional load and shape-factor for a given load-eccentricity are obtained and the prescription for minimum mass is given.

ABSTRACT: This paper introduces an accurate and computationally efficient GBT-based finite element, specifically tailored to capture the materially non-linear behaviour of wide-flange steel and steel-concrete composite beams up to collapse. The element incorporates reinforced concrete cracking/crushing, shear lag effects and steel beam plasticity (including shear deformation of the steel web). A set of numerical examples is presented, showing that the proposed element is capable of capturing all relevant phenomena with a very small
computational cost. In addition, analytical solutions for elastic shear lag are derived and the GBT modal decomposition features are employed to extract valuable information concerning the effect of shear lag phenomena up to collapse. For validation and comparison purposes, results obtained with shell/brick finite element models are also presented.

ABSTRACT: This paper presents an alternative design procedure for lateral–torsional buckling of cantilever I-beams which aims to simplify the calculation of critical loads and design moments. In the first part of the study, a closed-form equation is proposed to determine elastic critical lateral–torsional buckling load. The accuracy of the equation is validated through ABAQUS which is a software suite for finite element analysis. The second part includes bending tests conducted on European IPE100 section cantilevers. The purpose of the experiments is to determine the failure modes and loads in order to obtain baseline data for the design curve and comparison with analytical results. Finally, a design procedure is presented for cantilever I-beams which considers elastic buckling, inelastic buckling and full plastic strength. Design moments calculated by the presented design procedure, Eurocode 3-2005 and AISC360-10 are compared. It is found that the design moments obtained by the presented design procedure are in good agreement with those obtained by the procedures introduced in mentioned codes.

ABSTRACT: Oil storage tanks are short cylindrical shells fabricated with an external fixed roof or floating roof on the inside. Some features of the structure tend to be simplified in practice and research in order to perform stability and strength analyses using a much simpler model. This paper considers the structural consequences of such simplifications, including the substitution of a supporting structure of the roof or a wind girder by an equivalent thickness or by a fictitious boundary condition. Three load cases are investigated: thermal loads due to an adjacent fire, uniform external pressure, and wind pressure. Results of finite element analyses to evaluate bifurcation loads and modes are reported as estimates of buckling. Equivalent thickness models are derived by establishing equivalences in moment of inertia or sectional modulus of the components that are not represented in detail. The differences in buckling loads associated with equivalent thickness models depends on the load case considered, but range between 7-15% for a case studied with a fixed roof, with smaller differences (3%) for opened top tanks with wind girders. Substitution of a wind girder by a boundary condition, on the other hand, yields large errors under thermal loads exceeding 80% of buckling loads.

ABSTRACT: Crash components in automobiles are probably subjected to multiple loading conditions in real life, such as axial crushing and lateral bending. Unlike most of the existing work that solely focuses on the pure axial crushing or lateral bending, this paper attempts to accommodate both by proposing a novel structure, namely foam-filled thin-wall tube with functionally lateral graded thickness (FLGT). From numerical study of FLGT structures, they are found to exhibit noticeable advantage over the corresponding traditional uniform thickness (UT) structures with the same weight under both axial crushing and lateral bending. Moreover, the gradient governing the varying thickness shows significant influence on the crashworthiness performance of FLGT. To seek for the optimal gradient, a multi-objective optimization is carried out using multi-objective particle swarm optimization (MOPSO) algorithm, where response surface models are established to formulate
the objectives functions, i.e. specific energy absorption (SEA) and peak impact force \(F_{\text{peak}}\). The optimization results show that the foam-filled structure with FLGT can produce more promising Pareto solutions than traditional UT counterparts. Therefore, the FLGT structure could have potential applications subjected to different loading conditions.

“Internally nested circular tube system subjected to lateral impact loading”, Thin-Walled Structures, Vol. 91, pp 72-81, June 2015, DOI: 10.1016/j.tws.2015.02.014

ABSTRACT: The paper presents a theoretical, numerical and experimental investigation into the dynamic behavior of internally nested tube systems subjected to lateral impact loading. A theoretical model based on rigid, perfectly plastic material idealization is proposed, in which the effects of strain-hardening and strain-rate are considered. The analytical solutions to the crushing behavior of nested tube systems are obtained. Numerical simulations based on finite element method using the explicit code LS-DYNA and experiments are performed and the response of force and displacement versus time impacted by a drop hammer are compared with the theoretical predictions, resulting in good agreement.

ABSTRACT: Stainless steels are ideal for sustainable structural performances due to their excellent corrosion resistance, appropriate mechanical properties, aesthetic appearance and easy maintenance. However, the nonlinear behaviour and strain-hardening effects characterizing these materials make them different from carbon steel and some specific guidance is necessary. Although some investigations regarding the behaviour of stainless steel beam–columns subjected to combined compression and bending moment have already been published, most of them are based on the most commonly used austenitic and duplex grades. Hence, the work presented in this paper deals with the flexural buckling resistance of ferritic stainless steel RHS and SHS columns subjected to combined loading. The assessment of several design approaches codified in EN1993-1-4 and proposed in the literature has been conducted by comparing numerical results with the predicted ultimate capacities. The partial safety factor \(\gamma_{\text{ult}}\) currently coded in EN1993-1-4 has been found to provide unsafe ultimate flexural buckling resistance predictions and new coefficients for the \(k\) interaction factor for ferritic RHS and SHS elements are proposed.

ABSTRACT: This paper presents the experimental and theoretical studies on square tubed reinforced-concrete (TRC) short columns under eccentric compression. The main parameters of the test specimens included
eccentricity and width-to-thickness ratio of the steel tube. The axial load versus lateral deformation curves, stresses in the steel tubes and the observed failure modes were discussed. The test results indicated that the eccentrically loaded specimens exhibited good ductile behavior with a bending failure mode. A new approach to determine the effective lateral confining pressure for TRC columns with square section was proposed. A numerical analysis model was developed to simulate the mechanical behaviors of square TRC short columns. Valuable attempts were made to describe the variation rules between the parameters in stress block method for tubed concrete and the magnitude of confinement. Furthermore, the axial force versus moment capacity interaction diagrams of square TRC columns were calculated.

ABSTRACT: Dynamic crushing and energy absorption characteristics of sandwich structures with combined geometry shell cores were investigated experimentally and numerically. The effect of strain rate on the crushing behavior was presented by the crushing tests at quasi-static, intermediate and high strain rate regimes. It was shown that absorbed energy increased with increasing impact velocity. The effect of confinement on crushing behavior was shown by conducting confined experiments at quasi-static and dynamic rates. Higher buckling loads at lower deformation were observed in confined quasi-static crushing due to additional lateral support and friction provided by confinement wall. By using fictitious numerical models with strain rate insensitive material models, the effect of inertia and strain rate on crushing were shown. It was observed that, increase in impact velocity caused increase in inertial effects and strain rate effects were nearly independent from the impact velocity. The effects of multilayering were also investigated numerically.

ABSTRACT: This paper presents experimental and analytical studies on the behavior of square tubed SRC (TSRC) columns subjected to eccentric compression. Eight square TSRC columns were tested to investigate the effects of eccentricity ratio of the compression force, width-to-thickness ratio ($B/t$) of the steel tubes, and use of shear connector studs on the steel sections. The test results indicated that local buckling of the square tubes was delayed effectively since axial load was not directly applied on the steel tube. Buckling of the tube initially occurred when the load reached the ultimate value for the specimens with $B/t$ ratio of 100, and buckling occurred earlier for the specimens with $B/t$ ratio of 133 when the load reached 88% to 94% of the ultimate load. A nonlinear finite element (FE) model was developed using ABAQUS, in which the nonlinear material behavior and initial geometric imperfections were included. Good agreement was achieved between the predicted results using the proposed FE model and the test results. A modified Eurocode 4 design method was adopted to calculate the ultimate strength of square TSRC columns.

Linus Friedrich (1), Theodor-Andres Schmid-Fuertes (2) and Kai-Uwe Schroeder (1)
ABSTRACT: Thin walled circular cylindrical shell structures are prone to buckle and very sensitive towards geometrical imperfections. The influence of imperfections on the load carrying capacity of shell structures, as they are applied in launcher vehicles is considered by reducing theoretical buckling loads with empirical knock down factors. In general, these knock down factors may lead to a conservative estimate of the load carrying capacity since a worst case scenario is considered. In order to exploit the lightweight design potential of a structure, theoretical approaches to account for geometrical imperfections may lead to more adequate buckling load predictions. Within this contribution different theoretical approaches to account for geometrical imperfections of isotropic shell structures subjected to axial compression are investigated, and the influence of these approaches on the buckling load obtained is studied.

ABSTRACT: Few researches have focused on elastoplastic mechanical performances of functionally graded plates and shells. In this paper, elastoplastic and plastic buckling behaviors of externally pressured cylindrical shells made from functionally graded materials are investigated by using Donnell shell theory. Either $J_2$ flow theory or $J_2$ deformation theory helps to found the constitutive relation of functionally graded materials. The material properties vary smoothly through the thickness, and a multi-linear hardening elastoplasticity is used in the analysis. The buckling governing equations are solved by Galerkin method, and the expression of the elastoplastic critical external pressure is given analytically. Numerical results from the present theory are derived by an iterative arithmetic developed in MATHEMATICA code. The theoretical critical loads of the present $J_2$ deformation theory are well verified by experimental and numerical results in literature. The elastic, elastoplastic, and plastic buckling regions of functionally graded cylindrical shells can be effectively distinguished by the present method, and various effects of the dimensional parameters, the power law exponent, and the elastoplastic material parameters are investigated.

ABSTRACT: This paper examines the effect of large local imperfections, known as dents, on the plastic buckling capacity of short steel tubes under axial compression. A total of 11 tests on such short columns were carried out. The specimens were indented through a separate process and the ultimate axial capacity was subsequently obtained through compression tests. Dent imperfections with various depths were introduced to different locations on the body of the specimens. Plastic buckling modes as well as the ultimate capacity of the specimens were thoroughly investigated. The adverse effect of such a local damage on the load carrying capacity was quantified for different values and types of imperfections.
ABSTRACT: In storage tanks, intermediate wind girders are used to prevent the buckling failure of tank wall caused by wind load. For the design of the intermediate wind girders, two key parameters must be determined: the size of intermediate wind girders and the spacing between the girders. In the code API650, the spacing is expressed as the maximum height of the unstiffened tank wall and the size is referred to the minimum section modulus. In this paper, the design approach for the maximum height of the unstiffened tank wall and the simplified mechanical model for the minimum section modulus adopted in API650 were presented to reveal the simplification regarding the magnitude and action zone of wind load and the negligence of the strengthening effects of the tank bottom. A 3D finite element model was built to study the wind pressure distribution around the tank and strengthening effects of the tank bottom. Optimal analysis to minimize the weight of the wind girders for a given wind load was performed numerically and formulas for the size and spacing of the wind girders according to the optimal results were given. Based on the optimal design proposed in this paper, the material consumed for the winder girders were significantly reduced.

ABSTRACT: The behaviour of square hollow section AA6060 aluminium profiles subjected to quasi-static axial crushing was investigated experimentally and numerically. The profiles were artificially aged to three different tempers (under-aged, peak-aged and over-aged) using two different cooling rates (water quench or air cooling) after the solution treatment, thus obtaining six different materials. The materials’ microstructures were characterized by scanning and transmission electron microscopy and mechanical testing was used to determine the stress–strain curves in uniaxial tension. Axial crushing tests were carried out on profiles made of the six different materials to study the influence of the heat treatment on the energy-absorbing capability of the profile. The nanometre-scale material model NaMo was employed to predict the stress–strain curves of the three water-quenched materials based on the chemical composition and the thermal history. A new feature was introduced in NaMo in order to account for the incubation period, which cannot be ignored for low-alloy materials such as the AA6060 alloy. The stress–strain curves predicted using the improved nano-scale material model showed good agreement with the experimental curves for the three tempers when the incubation period was considered. Using the predicted stress–strain curves in finite element simulations of axial crushing of the profiles, gave excellent predictions of the experimentally obtained force–deformation curves and thus the energy absorption. The results indicate that two-scale simulation based only on chemical composition and thermal history is now possible in designing AA6xxx structural components for safety applications.

ABSTRACT: Experimental investigation of built-up cold-formed steel section batten columns”, Thin-Walled Structures, Vol. 92, pp 137-145, July 2015, DOI: 10.1016/j.tws.2015.03.001
ABSTRACT: This paper presents an experimental investigation on behaviour and design of built-up cold-formed steel section batten columns. The built-up columns were pin-ended and consisted of two cold-formed steel channels placed back-to-back at varied spacing of intersection. The two channels were connected using batten plates, with varying longitudinal spacing. The cold-formed steel channel sections were manufactured by brake-pressing flat strips having a plate thickness of 2 mm. The built-up cold-formed steel section batten columns had different slenderness and geometries but had the same nominal length of 2200 mm. The column strengths, load–axial shortening, load–lateral displacement and load–axial strain relationships were measured in the tests. In addition, the failure modes and deformed shapes at failure were observed in the tests and reported in this paper. Overall, the built-up column tests provided valuable experimental data regarding the column behaviour that compensated the lack of information on this form of construction as well as used to develop nonlinear 3-D finite element models. The column strengths measured experimentally were compared against design strengths calculated using the North American Specification, Australian/New Zealand Standard and European Code for cold-formed steel columns. Generally, it is shown that the specifications were unconservative for the built-up cold-formed steel section batten columns failing mainly by local buckling, while the specifications were conservative for the built-up columns failing mainly by elastic flexural buckling.

M.A. Eder and R.D. Bitschi (Technical University of Denmark, Frederiksborgvej 399, 4000 Roskilde, Denmark), “A qualitative analytical investigation of geometrically nonlinear effects in wind turbine blade cross sections”, Thin-Walled Structures, Vol. 93, pp 1-9, August 2015, DOI: 10.1016/j.tws.2015.03.007

ABSTRACT: This paper analytically investigates the Brazier effect on asymmetric thin-walled sections subject to biaxial bending. In the latter case a torsional moment – in this paper referred to as Brazier torsion – is induced, which proved to be a vital part of the solution. By means of a generic cross section, that was inspired by a wind turbine blade, it is demonstrated that geometric nonlinear effects can induce an in-plane opening deformation in re-entrant corners that may decrease the fatigue life. The opening effect induces Mode-I stress intensity factors which exceed the threshold for fatigue crack growth at loads well below the load-carrying capacity of the beam. The findings in this paper are twofold: Firstly, the investigated analysis procedure can be integrated into the design process of wind turbine blade cross sections. Secondly, the proposed approach serves as a basis for computationally efficient numerical analysis approaches of structures that comprise complex geometry and anisotropic material behaviour – such as wind turbine rotor blades.

“Dynamic instability of three-layered cylindrical shells containing an FGM interlayer”, Thin-Walled Structures, Vol. 93, pp 10-21, August 2015, DOI: 10.1016/j.tws.2015.03.006

ABSTRACT: In this study, the dynamic instability of three-layered cylindrical shells containing a functionally graded (FG) interlayer subjected to static and time dependent periodic axial compressive loads are investigated. The governing relations, modified Donnell type dynamic stability and deformation compatibility equations are derived. The governing equations are reduced Mathieu–Hill equation by using Galerkin’s method and the expressions for boundaries of unstable regions of three-layered cylindrical shell with an FG interlayer are found. Finally, the effects of variations of volume fractions of FG interlayer and shell characteristics on the magnitudes of boundaries of unstable regions are studied numerically.

“Behaviour of circular concrete filled double skin tubes subjected to local bearing force”, Thin-Walled Structures, Vol. 93, pp 36-53, August 2015, DOI: 10.1016/j.tws.2015.03.004
ABSTRACT: This paper presents the behaviour of circular concrete filled double skin tubes (CFDST) subjected to local bearing forces. This is an extension of a previous work on concrete filled steel tubes (CFST). A series of tests were conducted where some key parameters were varied, including loading angle, hollow ratio, chord wall thickness, as well as brace to chord diameter ratio. A finite element analysis (FEA) modelling was established and verified by the test data. Comparative analysis was conducted between the full-range behaviour of CFDST and CFST under local bearing. It was found that the performance of CFDST is considerably affected by the interaction of the outer tube, inner tube and the sandwiched concrete, whilst its bearing capacity depends on the hollow ratio. Finally, based on the load-transfer mechanism analysis, simplified formulae for predicting the strength of CFDST under local bearing forces are presented. Reasonable agreement between the predicted and measured values is achieved.

ABSTRACT: In this paper the impact of a hollow elastic ellipsoidal thin shell with an elastic flat half space is analyzed. Due to the nonlinearity and complexity of the impact equation, classical numerical solutions cannot be employed. A closed-form solution for this problem is accomplished, using Hertzian theory [6] and the Vella’s analysis [17] in conjunction with the Newtonian method and a linearization scheme. The closed-form solution facilitates a parametric study of this problem. In next step, the closed-form analytical solution is validated by other research studies and explicit finite element method. Good agreement between the closed-form solution and other numerical results is observed. Based on the closed-form solution the maximum total deformation of the shell, the maximum transmitted force and the time duration of the contact were determined. The variations of the total deflection and the transmitted force as a function of the shell thickness and the different geometry of the shell were also determined. Finally it is concluded that the closed form equations are trustworthy and appropriate to investigate the impact of elastic ellipsoidal shells.

“Effects of elastic-plastic behaviour on the axial crush response of square tubes”, Thin-Walled Structures, Vol. 93, pp 64-87, August 2015, DOI: 10.1016/j.tws.2015.02.023
ABSTRACT: Axial crushing of square tubes is widely studied for their energy absorption characteristics that are similar to automotive structural components. In this paper, the effects of the elastic–plastic behaviour of lightweight alloys on the steady state crush force, peak crush force, energy absorption and crush efficiency response of the axial crushing of square tubes are studied. Axial crush simulations are performed on square crush tubes where the yield stress and strain, ultimate tensile strength, hardening rate, and failure strain of the
material are varied. New definitions and analytical equations for crush efficiency and energy absorption are developed and calibrated with the axial crush simulations to develop a framework for optimal material selection for axial crush. This work shows that the yield stress increases the energy absorption, peak crush force and steady state crush force, while tending to decrease the crush efficiency. After sufficient increase in the hardening capabilities, positive gains are obtained in the crush efficiency when increasing the yield stress. The ultimate tensile strength, hardening rate and the yield stress of the material have a strong effect on improved energy absorption. Lightweight alloys with a low yield stress that have significant work hardening capabilities outperform materials with a high yield stress and very little work hardening in terms of energy absorption when a constraint is imposed on the peak crushing force.

DOI: 10.1016/j.tws.2015.03.012

ABSTRACT: The paper is devoted to a new shape of a shell of revolution with negative Gaussian curvature. The main part of the meridian of the shell is a plane curve of the Huygens tractrix. Geometrical properties of the middle surface of the shell of revolution are presented. The membrane state of stress for a family of shells with constant capacity and constant mass under uniform external pressure is analysed. The critical pressure, buckling modes and equilibrium paths for the family of shells are calculated with the use of the FEM (the ANSYS system). Results of the analytical and numerical investigations are presented in tables and figures. A stable post-critical behaviour of presented shells is pointed out which is not typical for most shell structures.

“Selected problems concerning determination of the buckling load of channel section beams and columns”, Thin-Walled Structures, Vol. 93, pp 112-121, August 2015, DOI: 10.1016/j.tws.2015.03.009

ABSTRACT: The issue of buckling load determination in composite channel section beams subjected to pure bending and channel section columns subjected to uniform compression is considered. Some selected problems with determination of buckling load on the basis of the collected and processed experimental data are discussed. The data necessary to determine buckling load (applied load and the corresponding displacement, strains at chosen points of beam-columns and displacements in three perpendicular directions of all visible points of the considered beam-columns) were collected with a strain gauge system, an Aramis® 3D optical system and a universal testing machine. Buckling load was determined by means of the following well-known methods: the mean strain method, the method of straight-lines intersection on the graph of load vs. mean strains, the curve inflection point method, the load-square of deflection curve method and Koiter’s method. All results were obtained during the experimental investigations and the numerical FEM analysis of the channel section profile made of a GFRP laminate with the symmetrical eight-layer arrangement [45/-45/90/0]s. The profiles under consideration were subjected to compression or pure bending (four-point bending test). The rules for each methods of buckling load determination are proposed on the basis of the obtained results.
ABSTRACT: The paper presents 3D results on stability of thin-walled cylindrical metal silos made from isotropic rolled plates containing bulk solids. The behaviour of bulk solids was described with a hypoplastic constitutive model. Non-linear FE analyses with both geometric and material non-linearity were performed with a perfect and an imperfect silo shell wherein 3 different initial geometric imperfections were taken into account. The influence of a stored bulk solid (dry medium-dense cohesionless sand) during filling on the buckling strength of silos was compared with the strength of an empty silo and with the experimental results available in the literature. Our numerical results indicate a clear strengthening effect of the stored solid on the silo buckling strength as in the experiments, depending upon the wall thickness, wall loading way and imperfection type and amplitude.

ABSTRACT: This study investigates the effect of radial distance of concentric thin-walled tubes on their energy absorption capability through simulation by LS-Dyna finite element software and experimental tests. Concentric cylindrical tubes made of aluminum 1050 with different radii were exposed to axial dynamic and quasi-static loading and optimum radial distance in maximum energy absorption condition was obtained. In overall, 24 states for simulation and 8 states for experimental tests have been investigated. Dynamic loading has been applied in form of hitting of a 75 kg mass with speed of 8 m/s and quasi-static loading of the structures has been done with speed of 150 mm/min and elongated to 70% of the initial length of tubes. Comparison of results of the two concentric tubes and single-tube system with equal mass of structures showed that energy absorption of two-tube system is more than single-tube system. Furthermore, in concentric tubes’ system, in the state where the distance of both tubes has changed, the energy absorption is more than the state where the radius of the outer tube is constant and just the radius of the inner tube changes.

ABSTRACT: Nowadays, foam-filled multi-cell thin-walled structure (FMTS) has been widely used in the field of automotive due to their extraordinary energy absorption capacity and light weight. In this study, nine kinds of FMTSs with different cross-sectional configurations under lateral crushing load conditions were investigated using nonlinear finite element method through LS-DYNA. The complex proportional assessment (COPRAS) method was used to make clear which kind of FMTSs has the most excellent crashworthiness. According to this method, it can be found that FMTSs with 2, 3 and 9 cells are the top-3 excellent structures in our considered
cases. In order to improve the crashworthiness of the three FMTSs, they were optimized by metamodel-based multiobjective optimization method which was developed by employing polynomial regression (PR) metamodel and multiobjective particle swarm optimization (MOPSO) algorithm. In the optimization process, we aimed to achieve maximum value of specific energy absorption (SEA) and minimum value of maximum impact force (MIF). Based on the comparison of the Pareto fronts obtained by multiobjective optimization, we can find that FMTS with 9 cells (FTMT9) performs better than FMTSs with 2 and 3 cells. Thus, the optimal design of FMTS9 is exactly an excellent energy absorption candidate under lateral impact and can be used in the future vehicle body.

Junyuan Zhang, Hao Zhou, Linan Wu and Guang Chen (State Key Laboratory of Automobile Simulation and Control, Jilin University, Changchun 130000, China), “Bending collapse theory of thin-walled twelve right-angle section beams filled with aluminum foam”, Thin-Walled Structures, Vol. 94, pp 45-55, September 2015 DOI: 10.1016/j.tws.2015.03.024

ABSTRACT: This paper aims at studying the bending collapse behavior of the thin-walled twelve right-angle section (TTRS) beams filled with aluminum foam. This paper presents the theoretical bending characteristics of the TTRS-typed aluminum foam around two axes. Considering the contribution degree of thin-walled beam and aluminum foam in different angle range, the expressions of the bending moments are derived. The accuracy of the theoretical calculations are validated by performing 14 groups finite element simulations respectively including three kinds of aluminum foams with certain scope of plateau stress (1–12.5 MPa) and corresponding density (0.2–0.52 g/cm³). The results show that the bending collapse theory proposed in this paper can reflect the mechanical properties of the TTRS beams filled with aluminum foam accurately, and the moment–rotation curves calculated by theory are in good agreement with simulation results.

“Multi-cornered thin-walled sheet metal members for enhanced crashworthiness and occupant protection”, Thin-Walled Structures, Vol. 94, pp 56-66, September 2015, DOI: 10.1016/j.tws.2015.03.029

ABSTRACT: Crash energy management in frontal crumple zone of the automotive body is one of the key elements for the design of automotive structure. Improving energy absorption characteristics reduces the magnitude of forces transferred to the occupant compartments. Here, a new strategy has been proposed to improve energy absorption efficiency of thin-walled columns by introducing extra stable corners in the cross-section. Several profiles of multi-corner thin-walled columns obtained through this strategy were presented and their crashworthiness capacities under axial crush loading were investigated analytically, experimentally, and numerically. First, explicit formulations for predicting the mean crushing force of multi-corner thin-walled columns were derived using the theory of super folding element (SFE). Predicted results of these formulations showed a good agreement with the results of quasi-static experiments and CAE simulations, which were performed by explicit non-linear finite element code through LS-DYNA. Based on this agreement, other significant crashworthiness assessment parameters were then investigated experimentally and numerically. Newly introduced 12-edge section with high energy absorption capacity was developed and its dominance was established through the responses in quasi-static experiments and CAE simulations. Finally, the foundational dominance of the 12-edge section was extended to the dynamic environment through a full vehicle crash test simulation to evaluate overall reduction in crashworthiness parameters which reflected occupant safety.
Interestingly, in the case of using 12-edge section as crush absorbers, specific energy absorption (SEA), dash intrusion and maximum occupant’s chest deceleration showed significant improvement, compared to the baseline design which used a rectangular section.

ABSTRACT: Shells in textile reinforced concrete (TRC) can be made very thin thanks to their non-corroding reinforcement. Consequently, buckling becomes an important parameter. Because of the lack of data in literature, this paper presents the experimental and numerical analysis on the buckling behaviour of a TRC dome (2 m span, 0.2 m height, 3.7 mm thick), which is subjected to a uniform pressure load until it buckles. This experiment is simulated using the Riks method in Abaqus and implementing geometrical imperfections. The simulations correspond well to the experimental data and validate the model, which enables the prediction of buckling, necessary when designing thin TRC shells.

ABSTRACT: A novel layerwise theory based on the first order shear deformation theory (FSDT) has been proposed to evaluate the buckling and post-buckling behavior of delaminated composite plates with multiple through-the-width delaminations. The Rayleigh–Ritz Method has been adopted and displacement fields are obtained by incorporating simple and complete polynomial series which result in much less computational cost. The proposed layerwise theory provides a more realistic description of the kinematics of composite laminates when compared to Equivalent Single Layer theories. Both local buckling of the delaminated sublaminates and global buckling of the whole plate can be handled. The method is capable of predicting response of thick delaminated composite plates. Presence of multiple delaminations can also be handled. In order to prevent unacceptable penetration, contact constraints are imposed on the delaminated area. The three dimensional finite element analysis is performed using ANSYS5.4 commercial software. The results show a very good agreement with those obtained by the analytical Model.

ABSTRACT: Numerical simulation is carried out to investigate the crushing characteristics of a single cell in a fan-shaped deployable energy absorber (FDEA) under quasi-static axial loading. FDEA can effectively improve the crashworthiness behavior of aircrafts with the advantages of saving space and deploying actively. Hinges are added to the single cell to meet the need of fan-shaped deployment. The finite element model is established to study the effects of hinge’s parameters, including material properties such as Young’s modulus, yield strength and the tube thickness, on the single cell’s energy absorption characteristics. The relationship between the deployment angle and the specific energy absorption (SEA) of the single cell is also studied. The numerical results indicate that the energy absorption increases rapidly as yield strength and the hinge’s thickness increase, while it only has minor correlation with Young’s modulus of the material. Three different modes of the cell appear during its axial crushing as the deployment angle increases. Besides, experiments were conducted to observe the crushing mode of the straight single cell, and the results are compared with the numerical simulation results. Finally, a theoretical model of a straight single cell with hinges is proposed to predict the mean crushing force, which is in good agreement with the numerical simulation.

ABSTRACT: This paper presents the numerical and analytical models to predict the response behaviour of Steel–Concrete–Steel (SCS) sandwich composite beams subjected to drop-weight impact loading. The sandwich composite beam has an ultra-lightweight concrete core of density 1440 kg/m³ sandwiched between two thin steel face plates which are interconnected by J-hook connectors. Explicit nonlinear finite element analysis was carried out and the results obtained are verified against the impact test data to establish its accuracy in predicting the permanent deformation, vertical displacement–time history and impact force–time history of the sandwich beams. The numerical analysis also shows that the J-hook connectors are subjected to tension force during impact in addition to shear force due to flexural action in the beam. This signifies the important role of J-hook connectors in preventing tensile separation of the steel face plates when subjected to impact load. An analytical approach based on energy balance model was also developed to predict the impact response of SCS sandwich beams. A good agreement was observed between the analytical solution and the experimental data indicating that the approach provides a reasonable and conservative estimation of the impact resistance of the sandwich beams.

DOI: 10.1016/j.tws.2015.06.007
ABSTRACT: At present, strength-curves approaches are used within European standards to deal with stability problems in steel structures. In this regard, three parameters require special attention; those are the yield load for plastic resistance, the resistance function depending on element slenderness and the buckling load. This paper presents a systematic review of current developments for the resistance of longitudinally stiffened girders to patch loading. Firstly, a historical overview of the mainstream within the field of patch loading is presented. At the end, an illustrative design example is presented in order to further discuss the improvements in the calculation of the resistance.

ABSTRACT: Based on the Galerkin method, a semi-analytical solution for the shear buckling of composite laminated plates with all four edges elastically-restrained against rotation is presented. The considered laminated plates are loaded in pure shear or combined shear and compression. The deformation shape function is constructed through a unique weighting combination of vibration eigenfunctions of simply-supported and clamped conditions, and it is an effective method for solving the considered eigenvalue problem. A parametric study is conducted to evaluate the effect of the rotational restraint stiffness, plate aspect ratio, material orthotropy and anisotropy on the buckling behavior of the rotationally-restrained laminated plates under pure shear or combined shear and compression action. The semi-analytical solution presented can be used to analyze the restrained laminated plates under shear-dominated loading and applied to predict the web local buckling of thin-walled composite beams.

ABSTRACT: This paper presents a combined experimental and numerical study on the behavior of both circular and square concrete-filled steel tube (CFT) stub columns under local compression. Twelve circular and eight square CFT stub columns were tested to study their bearing capacity and the key influential parameters. A 3D finite element model was established for simulation and parametric study to investigate the structural behavior of the stub columns. The numerical results agreed well with the experimental results. In addition, analytical formulas were proposed to calculate the load bearing capacity of CFT stub columns under local compression.
Stanislav Kitarovic, Jerolim Andric and Karlo Piric (University of Zagreb, Faculty of Mechanical Engineering and Naval Architecture, Ivana Lucica 5, 10000 Zagreb, Croatia), “Rational magnification of the plate elastic shear buckling strength”, Thin-Walled Structures, Vol. 94, pp 167-176, September 2015
DOI: 10.1016/j.tws.2015.04.016

ABSTRACT: Various feasible approaches to magnification of the plate elastic shear buckling strength are comprehensively investigated. Based on derived theoretical envelopes of the considered approaches, stiffening parallel to the longer plate edges is identified as the most effective approach to the considered problem. An accompanying analytical formulation, convenient for utilization in structural analysis and design of the plated structures, is approximated. Various recommendations and formulations relevant for determination of the rational stiffened plate design (with respect to the considered problem) are proposed. All derived conclusions and proposed formulations are based on results of the numerous rationally designed numerical simulations.

Mei Liu, Lulu Zhang, Peijun Wang and Yicun Chang (School of Civil Engineering, Shandong University, Jinan 250061, China), “Experimental investigation on local buckling behaviors of stiffened closed-section thin-walled aluminum alloy columns under compression”, Thin-Walled Structures, Vol. 94, pp 188-198, September 2015
DOI: 10.1016/j.tws.2015.04.012

ABSTRACT: Six aluminum alloy tensile coupon tests were carried out and stress–strain curves obtained from tests were compared with a Ramberg–Osgood model. Comparison showed that the Ramberg–Osgood model can precisely describe stress–strain relationship of 6063-T5 aluminum alloy. Totally, 10 axial compression tests on thin-walled aluminum alloy members with four stiffened closed-section were carried out. Local buckling occurred in all specimens eventually. The axial displacement, lateral deflection, strain development and failure modes of the tested specimens were recorded. A finite element method (FEM) model was presented to simulate local buckling behaviors of the tested columns under axial load. The ultimate strength, strain development and failure modes obtained from FEM agreed well with the test results. Current design codes on aluminum alloy structures, such as the American aluminum design manual (AA), the European code (EC9), Chinese design specifications for aluminum structures (GB50429), the North American Specification for the design of cold-formed steel structural members (AISI) and the direct strength method (DSM), were used to calculate the ultimate strength of the tested columns. Comparison showed that current design codes overestimated the ultimate strength of stiffened closed-section thin-walled aluminum alloy columns under axial compression loads.

ABSTRACT: This master thesis presents research into buckling of thin hyperboloid shells structures. This type of structure is typically applied as the large cooling towers at coal fired electricity plants. However, modelling cooling towers is not the objective of this research. The objective of this research is to understand the buckling behaviour of shells with negative Gaussian curvature, which cooling towers have. In previous research it was found that negatively curved shells are not very sensitive to imperfections and that the first buckling mode provides the most critical imperfection. This research starts from the assumption that a design formula can be derived for predicting the ultimate load of negatively curved shells. A step in this direction is understanding how hyperboloid shells buckle and determining what parameters influence the ultimate load. A finite element model was developed with suitable properties. The influence of the boundary conditions has been studied. The element size and the aspect ratio have been optimised. Various methods of adding imperfections have been considered. The buckling modes have been studied for a large range of curvatures. The influence of the
imperfection amplitude on the load displacement curve has been determined by geometrical nonlinear analysis and the arc length method. A parameter study has been performed of a large range of geometries. Varied are the radii of curvature, the thickness, the height of the hyperboloid. Also varied are Young’s modulus and Poisson’s ratio. In total 700 geometrical nonlinear analysis have been performed. The results have been stored in a large data base in Matlab. This includes the support reactions, membrane forces, moments and stresses at each load step. A series of Matlab scripts were developed to generate various graphs. The graphs were used to form a detailed understanding of the buckling behaviour of negatively curved shells and to identify remarkable features. A two-phased curve fitting method has been used is to obtain a formula for the ultimate buckling load and a formula for the peak membrane force of inward buckles. The main conclusion is that hyperboloid shells of significant curvature carry load in three ways: the outward buckles, the inward buckles and the material in-between. First the outward buckles fail then the inward buckles fail and finally the material between the buckles fails. A design method is proposed based on the local linear elastic stress state.

ABSTRACT: Rectangular thin walled tubes are commonly used in front rail structures of automotive chassis, and are designed to absorb maximum amount of energy during frontal impact. With increasing emphasis over the last few decades on building lighter and faster vehicles by auto manufacturers, researchers are actively exploring opportunities to improve crashworthiness of vehicles by exploiting structural and material optimization approaches. In this paper, two new shapes, Pentagon and Cross, were studied for two materials, aluminum and steel, with the objective of improving the crashworthiness of automobiles without adding any additional weight (within the same type of material) to the chassis. The tubes were initially analyzed using finite element method. The performances of proposed tubes were compared with a rectangular cross-section tube by
comparing the average mean force (required to crush the tube under 35 mph impact velocity) and the total specific energy absorbed. A theoretical plastic analysis was carried out by evaluating the folding mechanisms of tubes for Pentagon and Cross shapes and an analytical model was developed that predicted the mean force necessary to crush the tubes. The numerical and theoretical analysis showed that for equivalent tube wall areas, the aluminum and steel Pentagon and Cross tubes absorbed 31–60% and 48–92% more energy than the rectangular tube. The outputs of proposed predictive theoretical model for the Pentagon and Cross tubes were compared reasonably well with the mean force values calculated through numerical method. An experimental study was conducted on cross tube samples machined from Aluminum AA6061–T6511 blocks with the purpose of validating numerical and theoretical approaches used in the present study. Experimental results for the mean force demonstrated a good correlation with numerical and theoretical approaches with approximately 1% and 6% variation, respectively. In addition, the deformation modes observed in the experiment matches reasonably well with the ones observed in the finite element analysis (FEA) simulations.

ABSTRACT: A relaxation method is applied to estimate and predict a critical set of parameters responsible for stability loss (buckling) of spherical circle axially symmetric shells. The buckling phenomenon under static loading was investigated by solving the Cauchy problem for a set of ordinary differential equations and the Hausdorff metrics was applied while quantifying the data obtained within the novel approach.

ABSTRACT: This paper discusses aspects related to the mechanics underlying the distortion of thin-walled members with symmetric and periodic open cross-section, such as those commonly employed in cold-formed steel construction. The Generalised Beam Theory (GBT) framework is employed to determine the cross-section distortional deformation modes and obtain insight into the problem under consideration. Besides reviewing the well known case of reflectional symmetry, the implications of rotational symmetry and periodicity through translation or glide reflection are examined. For each case, computationally efficient procedures to obtain the distortional modes are provided. Several examples are presented throughout the paper, in order to enable a better grasp of the concepts and procedures addressed.

“Comparison of functionally-graded structures under multiple loading angles”, Thin-Walled Structures, Vol. 94,
ABSTRACT: This paper provides a comparative study on the crashworthiness of different functionally-graded
thin-wall tubes under multiple loading angles, which include hollow uniform thickness (H-UT), hollow
functionally graded thickness (H-FGT), foam-filled uniform thickness (F-UT) and foam-filled functionally
graded thickness (F-FGT) configurations. First, finite element analyses of these differently graded circular tubes
reveal that the F-FGT tube has the best crashworthiness under multiple loading angles. Second, parametric
study on the F-FGT tube indicates that the thickness gradient and variation range significantly influence its
crashworthiness. Third, the Non-dominated Sorting Genetic Algorithm (NSGA-II) is used to optimize the F-
FGT tube, in which the optimal thickness variation is sought for maximizing specific energy absorption (SEA)
and minimizing initial peak force (IPF) under multiple loading angles. The optimized F-FGT tube exhibits
better crashworthiness than other three equivalent tube configurations, indicating that the F-FGT tube can be a
potential energy absorber when oblique impact loading is inevitable.

Tysiąclecia Państwa Polskiego 7, 25-323 Kielce, Poland), “Stability of cantilever walls of steel thin-walled bars
with open cross-section”, Thin-Walled Structures, Vol. 94, pp 348-358, September 2015
DOI: 10.1016/j.tws.2015.04.029
ABSTRACT: In thin-walled bars with open cross-section, built from flat walls, cases are found in which, the
cantilever wall, elastically restrained in the web, is compressed, and at the same time, longitudinal variation in
stresses along its length occurs. Such a wall can be analyzed as a cantilever thin plate, elastically restrained
against rotation on the longitudinal supported edge. The paper presents the results of investigations into the
stability of elastically restrained cantilever plates for varied stress intensity in the longitudinal direction. Graphs
of plate buckling coefficients ($k$) were determined and approximation formulas were derived for technically
crucial stress distributions and different degrees of the plate edge elastic restraint. The impact of longitudinal
stress variation and of the degree of elastic restraint on the plate buckling modes was analyzed.

“Neural networks for inelastic distortional buckling capacity assessment of steel I-beams”, Thin-Walled
ABSTRACT: An Artificial Neural Network (ANN) model is developed as a reliable modeling method for
simulating and predicting the ultimate moment capacities for intermediate doubly-symmetric steel I-beams. The
training and testing data for neural network are generated using Finite Element Analysis (FEA). In other word,
an extensive numerical study was also undertaken to investigate the distortional buckling behavior of simply
supported compact steel I-beams. A series of nonlinear elasto-plastic FE analyses have been carried out to
simulate the distortional buckling behavior of doubly-symmetric steel I-beams, and the effects of six
independent parameters as input in a lateral-distortional buckling mode has been investigated. Moreover, unlike
the existing design codes the model considers the effect of web distortions in a lateral-distortional buckling
mode. Then a new formula based on the ANNs has been proposed to predict the member moment capacities of
steel I-beams subjected to distortional buckling. The attempt was done to evaluate a practical formula
considering all parameters which may affect distortional capacity. Then, a comparison has been made between
the proposed formula and the predictions from the current design rules in some structural steel codes. The
results show that the proposed formula is more accurate and applicable than existing design codes. Finally, a
sensitivity analysis using Garson’s algorithm has been also developed to determine the importance of each input
parameters.

ABSTRACT: Experimental studies on the behaviour of concrete filled double-skin steel tube (CFDST) subjected to local bearing forces are presented in this paper. Sixteen specimens were prepared and tested with the included angle between bearing member (BM) and compression member of 45° and 90°, whilst both the inner and outer steel tubes of the CFDST specimens are square hollow sections (SHS). The main parameters in the tests were: 1) outside width ratio between BM and compression member: from 0.4 to 0.6; 2) hollow ratio of CFDST: from 0 to 0.6; 3) wall thickness of outer steel tube: 3.05 mm and 3.95 mm; and 4) cross-section of BM: solid and hollow. The failure pattern, load versus deformation curve, bearing capacity and corresponding deformation at bearing capacity of the tested specimens are presented and analyzed. The experimental results show that, while subjected to local bearing forces, CFDST specimens have a high bearing capacity and a good deformation-resistant ability. The calculated bearing capacities of CFDST under local bearing forces using the proposed formulae in the paper are evaluated by comparison with the experimental results.

ABSTRACT: Steel moment frame buildings face severe collapse potentials when subjected to earthquakes beyond the design level. Reliable numerical modeling of steel moment frames is significant to assess the critical parameters affecting collapse behavior. A fiber-element model is presented to evaluate post-local buckling behavior for steel structures. A constitutive relationship was defined for material properties taking into account of post-local buckling degradation in strength and stiffness. The model is compared with quasi-static test databases related to H-shaped steel, circular and rectangular hollow steel section (HSS) members. Three parameters, including strength, associated deflection and post-peak degradation were reasonably simulated. Significant strength degradation was triggered by the local buckling in the thin-walled HSS beam–columns. The numerical model well presented the collapse of a steel moment frame tested by E-Defense shaking table. The results show that the thin-walled square HSS column components induced low-ductile collapse behavior due to the prior local buckling at the bottom storey. The proposed fiber-element model provides a simple alternative method for predicting deterioration and collapse of steel frames under extreme earthquakes.

Qingsong Li, Xiao Guo, Qiang Qing and Jinghai Gong (Department of Civil Engineering, Shanghai Jiao Tong University, Shanghai 200240, China), “Dynamic deflation assessment of an air inflated membrane structure”, Thin-Walled Structures, Vol. 94, pp 446-456, September 2015, DOI: 10.1016/j.tws.2015.05.008
ABSTRACT: As a critical safety performance index, the emergency evacuation capacity of air inflated membrane structures subjected to accidental deflation deserves in-depth study. Although conventional static
analysis can be applied to predict its potential collapsed shapes, it cannot provide details of collapse behavior and the internal air state variation. Dynamic analysis is recommended. The focus of this paper is to apply the Control Volume method to deflation simulation of a large-scale air inflated arch frame, which is designed for a temporary pavilion, and to validate numerical analysis results by full-scale testing. Through a series of preliminary studies on air inflated single arches, practical analytical parameters and solutions are concluded regarding proper numerical modeling, pre-stressing, and precision controlling. A full-scale frame is then modeled and simulated. Results appear to agree with experimental tests of the corresponding real-life structure with minor differences in collapse behavior and deflation duration time. Several general guidelines for design and deflation simulation analysis are proposed as a result of research. Feasible measures to ensure emergency evacuation capacity of the air inflated arch frame are adopted in the design based on results of this dynamic assessment.

ABSTRACT: Buckling collapse of thin-walled structures under compression is one of the critical type of failures. These structures also may be locally buckled under tensile load with special conditions. In this paper, compressive and tensile buckling of thin cracked cylindrical panels are investigated. Effects of various factors such as the position, length and direction of crack, length, width and thickness of the panel and boundary conditions on the compressive and tensile buckling loads are determined. The results show that the dimensions of panels have lowest while characteristics of crack and closing to edges have greatest effects on the buckling load.

“Buckling and post-buckling behaviour of elastic seven-layered cylindrical shells – FEM study”, Thin-Walled Structures, Vol. 94, pp 478-484, September 2015, DOI: 10.1016/j.tws.2015.05.017
ABSTRACT: The paper is devoted to buckling and post-buckling problems of an elastic seven-layered cylindrical shell under uniformly distributed pressure. The shell is an untypical sandwich structure composed of main corrugated core and two three-layer faces. Numerical FEM model for the shell has been elaborated. The calculations have been performed with the use of the ANSYS code for elastic shells of different dimensions. The linear and non-linear analyses of the shells have been performed with the use of the finite elements method. Critical pressure and equilibrium paths for the family of seven-layered shells subjected to uniformly distributed external pressure are calculated. The influence of corrugation pitch of main core and the length of the shell on the critical pressure has been determined. The results of these investigations are presented on the graphs.

Kodjo Attipou (1,2), Heng Hu (3), Foudil Mohri (2), Michel Potier-Ferry (2) and Salim Belouettar (1)
ABSTRACT: The thermal wrinkling behavior of thin membranes is investigated in this paper. Wrinkles often occur at multiple length scales where induced compressive stresses are located during thermal loading. In the present study, the method of double scale Fourier series is used to deduce the macroscopic membrane wrinkling equations. The obtained equations account for the global and local wrinkling modes. Numerical examples are conducted to assess the validity of the approach developed. The present membrane’s model needs only few degrees of freedom to recover more accurately the post-buckling equilibrium curves and the wrinkling shapes. Different parameters such as membrane’s aspect ratio, wave number, and pre-stressed membranes are discussed from a numerical point of view and the properties of the wrinkles (critical load, wavelength, size, and location) are presented.

“Ship structural integrity using new stiffened plates”, Thin-Walled Structures, Vol. 94, pp 545-561, September 2015, DOI: 10.1016/j.tws.2015.05.018

ABSTRACT: The objective of the present paper is to use novel longitudinal Y (Hat+Conventional) stiffener profiles instead of the conventional stiffener profiles. That helps obtaining more safety margin (the ultimate strength minus the applied compression stress) to weight ratio. Using the hat section (closed section) gives more torsional rigidity and more effective plate allowing an increase of the stiffener spacing, hence a reduction in the number of stiffeners. During the replacement process the following constraints are taken into account: the weight of the stiffened bottom and deck panels, and the unstiffened plate width using the Y-stiffener profiles are less than those of panels with the original conventional stiffeners, whereas the section modulus of the Y-stiffener with the attached effective plate is larger than that of the original conventional stiffener. The safety margin of bottom and deck panels with Y-stiffeners is to be more than that of panels with the original conventional stiffeners. The ultimate strength of stiffened panels with either longitudinal conventional or Y-stiffener profiles were calculated according to the International Association of Classification Societies-Common Structural Rules for double hull oil tanker based on the following failure modes: unstiffened plate buckling, stiffener beam-column buckling, and stiffener torsional/flexural buckling (tripping). The attached effective plate for the Y-stiffener was calculated according to Eurocode. The Y-stiffener is a built-up section and the simplest production method is to weld the lower end of the web of a conventional stiffener to the top of the hat part. The conventional stiffener as a part of the Y-stiffener is fabricated according to the ratios stated in the International Association of Classification Societies-Common Structural Rules, while the hat part of the Y-stiffener is made by a hot-rolling process with inclination angle of the two webs of the hat taken as 30°, 45°, 60°, and 90°.

H. Ramezannezhad Azarboni, M. Darvizeh, A. Darvizeh and R. Ansari (Department of Mechanical Engineering, University of Guilan, P.O. Box 3756, Rasht, Iran), “Nonlinear dynamic buckling of imperfect
rectangular plates with different boundary conditions subjected to various pulse functions using the Galerkin method”, Thin-Walled Structures, Vol. 94, pp 577-584, September 2015, DOI: 10.1016/j.tws.2015.04.002

ABSTRACT: In this paper, the nonlinear dynamic pulse buckling of imperfect rectangular plate subjected to sinusoidal, exponential, damping and rectangular pulse functions with six different boundary conditions is investigated. In order to solve the large deformation equations of plate, Galerkin method together with trigonometric mode shape functions is applied. Also, the nonlinear coupled time integration of the governing equation of plate is a solved employing fourth-order Runge–Kutta method. The effects of boundary conditions, pulse functions, initial imperfection, force pulse amplitude and geometrical parameters of the shock spectrum of a plate and deflection histories of plate for impulsive, dynamic and quasi-periodic force loads are studied. In this study, the effects of boundary conditions, pulse functions, initial imperfection, force pulse amplitude and geometric parameter in nonlinear dynamic response are investigated. According to the results for impulsive loading, the displacement response reaches its peak after shock duration and in the dynamic and quasi-static pulse loading, the maximum response of plate occurs during and before shock duration. Moreover, with increasing the loading amplitude, length of the plate and initial imperfection, the maximum displacement of plate increases. Different boundary conditions and various pulse functions have significant influence on the dynamic response of the plate. By increasing the restriction in supports, the resistance ability against deformation and stability of plate increases.

“General distortional buckling formulae for both fixed-ended and pinned-ended C-section columns”, Thin-Walled Structures, Vol. 94, pp 603-611, September 2015, DOI: 10.1016/j.tws.2015.04.032

ABSTRACT: This paper presents general explicit analytical formulae to provide distortional critical stress estimates for cold-formed steel C-section columns subjected to uniform compression. These formulae are derived by employing the Lau and Hancock model and by introducing a new factor for considering the web rotational restraint reduced by web bending. The results obtained from the general explicit analytical formulae are compared with the numerical results obtained from the computer programs CUFSM or/and GBTUL. For pinned-ended columns, these values are also compared with those yielded by the formulae developed by Lau and Hancock, Schafer, and Silvestre and Camotim. In particular, the distortional critical stress of fixed-ended C-section columns is validated by comparing the corresponding ultimate load based on Schafer’s DSM expressions with numerical results from the research literature. The formulae derived here are validated and their application, accuracy and capabilities are illustrated by these comparisons and validations.

“Behaviour and strength of hollow flange channel sections under torsion and bending”, Thin-Walled Structures, Vol. 94, pp 612-623, September 2015, DOI: 10.1016/j.tws.2015.05.013

ABSTRACT: Hollow flange channel section is a cold-formed high-strength and thin-walled steel section with a unique shape including two rectangular hollow flanges and a slender web. Due to its mono-symmetric
characteristics, it will also be subjected to torsion when subjected to transverse loads in practical applications. Past research on steel beams subject to torsion has concentrated on open sections while very few steel design standards give suitable design rules for torsion design. Since the hollow flange channel section is different from conventional open sections, its torsional behaviour remains unknown to researchers. Therefore the elastic behaviour of hollow flange channel sections subject to uniform and non-uniform torsion, and combined torsion and bending was investigated using the solutions of appropriate differential equilibrium equations. The section torsion shear flow, warping normal stress distribution, and section constants including torsion constant and warping constant were obtained. The results were compared with those from finite element analyses that verified the accuracy of analytical solutions. Parametric studies were undertaken for simply supported beams subject to a uniformly distributed torque and a uniformly distributed transverse load applied away from the shear centre. This paper presents the details of this research into the elastic behaviour and strength of hollow flange channel sections subject to torsion and bending and the results.

Soren Randrup Henrichsan, Esben Lindgaard and Erik Lund (Department of Mechanical and Manufacturing Engineering, Aalborg University (AAU), Fibigerstræde 16, 9220 Aalborg East, Denmark), “Robust buckling optimization of laminated composite structures using discrete material optimization considering “worst” shape imperfections”, Thin-Walled Structures, Vol. 94, pp 624-635, September 2015, DOI: 10.1016/j.tws.2015.05.004

ABSTRACT: Robust buckling optimal design of laminated composite structures is conducted in this work. Optimal designs are obtained by considering geometric imperfections in the optimization procedure. Discrete Material Optimization is applied to obtain optimal laminate designs. The optimal geometric imperfection is represented by the “worst” shape imperfection. The two optimization problems are combined through the recurrence optimization. Hereby the imperfection sensitivity of the considered structures can be studied. The recurrence optimization is demonstrated through a U-profile and a cylindrical panel example. The imperfection sensitivity of the optimized structure decreases during the recurrence optimization for both examples, hence robust buckling optimal structures are designed.

ABSTRACT: A computational parametric finite element analysis was carried out, investigating closely spaced cellular beams with double concentric transverse stiffeners. An unstiffened perforated beam section was initially designed and validated against existing finite element analysis results found in the literature. Then, thirty-one models were studied, while altering the spacing between the web openings, the web thicknesses, and the stiffener thicknesses. The results showed that Vierendeel shearing failure occurred more frequently for very closely spaced sections. However, as the spacing increased, the contribution of the stiffener to strength of the section was decreased, and out-of-plane buckling failure occurred more often. A maximum distance for the spacing between the openings was suggested in order to optimally use the derived formulae. At last, a design model was proposed, where for very closely spaced openings the compressive stresses were given by the Vierendeel moment capacity, while for the maximum distance of the spacing between the openings studied, the compressive stresses were given by a strut analogy, as found in BS5950-1.

ABSTRACT: A deep doubly curved shell element is developed for free vibration analysis of general shells of revolution. The mid-surface of the shell may have an arbitrary shape as well as a variable thickness, and the shell can be closed circumferentially or not. For both the circumferential and meridian directions of the shell element, Lagrange polynomials are used to interpolate the displacement variables. Stringer stiffeners are modeled as discrete curved beams to investigate the free vibration of stiffened shells. The frequencies are compared with the published data, and new examples of axisymmetric shells with positive and negative Gaussian curvature are presented.

M. Capuzzi, A. Pirrera and P.M. Weaver (Advanced Composites Centre for Innovation and Science, Department of Aerospace Engineering, University of Bristol, Queen's Building, University Walk, Bristol BS8 1TR, UK), “Structural design of a novel aeroelastically tailored wind turbine blade”, Thin-Walled Structures, Vol. 95, pp 7-15, October 2015, DOI: 10.1016/j.tws.2015.06.006

ABSTRACT: The structural design for a recently presented aeroelastically-tailored wind turbine blade is produced. Variable elastic twist has been shown to improve performance in response to load variation across different wind conditions. This load variation is exploited as a source of passive structural morphing. Therefore, the angle of attack varies along the blade and adjusts to different operating conditions, hence improving both energy harvesting and gust load alleviation capability, below and above rated wind speed, respectively. The twist variation is achieved by purposefully designing spatially varying bend–twist coupling into the structure via tow steering and using a curved blade planform. This process enables the blade sections to twist appropriately while bending flapwise. To prove the feasibility of the proposed adaptive behaviour, a complete blade structure is analysed by using refined finite element models, with structural stability and strength constraints imposed under realistic load cases. Nonlinear structural effects are analysed as well as modal dynamic features. In addition, the weight penalty due to aeroelastic tailoring is assessed using structural optimisation studies.

“A new method to investigate the energy absorption characteristics of thin-walled metal circular tube using finite element analysis”, Thin-Walled Structures, Vol. 95, pp 24-30, October 2015 DOI: 10.1016/j.tws.2015.06.001

ABSTRACT: A numerical study is made to investigate the energy absorbing rule of thin-walled metal circular tube made of three different materials (steel, copper, aluminum) by using response surface methodology (RSM). At the same time, the application prospect of RSM in terms of the research on the energy absorption rule of energy absorption structure can be explored. The test result shows that, the compression process of thin-walled metal circular tube can be divided into three stages: elastic stage, yielding plateau stage, compact stage; To get the greatest value of average plateau force (APF), a tube with a shorter height and thicker wall should be adopted; To get the greatest length energy absorption (LEA), a tube with thicker wall should be adopted and the ratio of its height and diameter should be as big as possible; To get the greatest specific energy absorption
(SEA), a tube with a thicker wall should be adopted and the ratio between its height and diameter should be as big as possible. Thus, it can be seen that, RSM is an advanced experiment design method, and it can be widely used in the research on the energy absorption characteristics of thin-walled metal circular tube and has a promising application prospect in the development of new energy absorbing material and structure.

Yan-lin Guo, Bo-hao Zhang, Si-yuan Zhao, Chao Dou and Yong-Lin Pi (Department of Civil Engineering, Tsinghua University, Beijing 100084, PR China), “Ultimate resistance design of shuttle-shaped steel tubular latticed columns”, ASCE Journal of Structural Engineering, Vol. 140, 04014076, October 2014
ABSTRACT: As a new type of nonprismatic built-up columns, the shuttle-shaped steel tubular latticed (SSTL) column is widely used in engineering structures. However, there are no methods available to test its ultimate resistance design and little research about its behavior. This article investigates the elastic buckling behavior of three-tube SSTL columns only with horizontal web members and subject to an axial load, and it is found that the SSTL column may buckle in a symmetric flexure-dominated mode or an antisymmetric shear-dominated mode, depending on distributions of sectional flexural stiffness and shear stiffness along the column length. The formulas for predicting elastic buckling loads are derived by accounting for the effects of sectional shear deformations. With the elastic buckling loads obtained, formulas for the effective slenderness and the normalized effective slenderness are proposed. The resistance design procedure for SSTL columns only with horizontal web members is developed in association with Chinese code GB50017 and Eurocode 3. Comparisons with finite element results demonstrate the proposed procedure can provide reasonably accurate predictions for the resistances of SSTL columns.

Jing-Zhong Tong and Yan-Lin Guo (Department of Civil Engineering, Tsinghua University, Beijing 100084, PR China), “Elastic buckling behavior of steel trapezoidal corrugated shear walls with vertical stiffeners”, Thin-Walled Structures, Vol. 95, pp 31-39, October 2015, DOI: 10.1016/j.tws.2015.06.005
ABSTRACT: This paper investigates the elastic buckling behavior of steel trapezoidal corrugated shear walls (STCSWs) with vertical stiffeners. On the basis of an orthotropic plate model, by utilizing the theorem of minimum potential energy and the Ritz method, the buckling loads of stiffened STCSWs can be precisely calculated using MATLAB. Then, a value of transition rigidity of stiffener is suggested and, hence formulas of elastic buckling coefficients of stiffened STCSWs are proposed. Finally, the verification of proposed formulas using a FE model shows that the formulas are validated and applicable in estimating the elastic buckling loads of stiffened STCSWs.

Yangqing Dou and Yucheng Liu (Department of Mechanical Engineering, Mississippi State University, Mississippi State, MS 39762, USA), “Computational investigation of lateral impact behavior of pressurized pipelines and influence of internal pressure”, Thin-Walled Structures, Vol. 95, pp 40-47, October 2015
DOI: 10.1016/j.tws.2015.06.012
ABSTRACT: This paper presents a computational study to examine lateral impact behavior of pressurized pipelines and to determine influence of internal pressure on the pipelines on their impact behaviors. A total of more than 300 numerical simulations were carried out on mild steel pipe models with different internal pressure levels and were struck at the mid-span and at the one quarter span positions. These numerical simulations of the impact tests were performed using 3D dynamic nonlinear finite element analysis (FEA) through LS-DYNA,
where both geometrical and material nonlinearities were considered. The computational results for the first time systematically revealed the effects of internal pressure, impact position, and outside diameter on the lateral impact behavior of the pipeline models. The outcomes of this study will have potential benefits on research of safety and reliability of civil pipelines and development of advanced pipeline materials.

“Axial crushing analysis of empty and foam-filled brass bitubular cylinder tubes”, Thin-Walled Structures, Vol. 95, pp 60-72, October 2015, DOI: 10.1016/j.tws.2015.05.019
ABSTRACT: To reduce loss from collision, energy absorbers are used which dissipate energy upon deformation and folding in order to prevent damage to critical parts of a structure. In this study, the empty and polyurethane foam-filled bitubular tubes made from brass with circular section were subjected to quasi-static axial compression loading. Nonlinear dynamic finite element analyses are carried out to investigate the details concerning crushing process by using explicit finite element code ABAQUS. Satisfactory agreements are achieved between the finite element and the experimental results. The validated finite element model was then used for the parametric studies, in order to determine the effect of the empty and filler tube geometry parameters (i.e. wall thickness, semi-apical angle) and loading parameters (i.e. impact mass, impact velocity) on the Dynamic Amplification Factor. The results highlight the advantages of using the brass bitubular circular tubes as energy absorber.

Weiqiang Wang, M. Neaz Sheikh and Muhammad N.S. Hadi (School of Civil, Mining and Environmental Engineering, University of Wollongong, NSW 2522, Australia), “Behaviour of perforated GFRP tubes under axial compression”, Thin-Walled Structures, Vol. 95, pp 88-100, October 2015,
DOI: 10.1016/j.tws.2015.06.019
ABSTRACT: This study investigates the influences of various parameters on the behaviour of perforated Glass Fibre Reinforced Polymer (GFRP) tubes under axial compression. A total of 15 GFRP tubes with and without perforations were tested under axial compression. All the GFRP tubes were divided into two groups: 12 tubes with 89 mm outer diameter and 6 mm wall thickness and 3 tubes with 183 mm outer diameter and 8 mm wall thickness. The influences of hole diameter, vertical hole spacing, tube diameter, perforation pattern, transverse hole spacing, and hole reinforcement on the axial compressive behaviour of perforated GFRP tubes were experimentally investigated. Considerable decreases in the axial stiffness, axial critical load, and axial deformation capacity of perforated GFRP tubes have been observed. The hole diameter, tube diameter, perforation pattern, and transverse hole spacing significantly influence the axial compressive behaviour of perforated GFRP tubes. However, the influences of vertical hole spacing and hole reinforcement have been observed not significant. Design-oriented equations for the prediction of the axial stiffness, axial critical load and axial deformation capacity of perforated GFRP tubes under axial compression have been proposed. The proposed equations have been found to be in good agreement with experimental results and can be used for the reliable design of perforated GFRP tubes.

ABSTRACT: Multi-cell tubes have been drawn increasing attention for their excellent energy-absorbing ability. However, the effect of cell number and oblique loads on crashing behaviors has seldom been studied to date. In this paper, a group of multi-cell tubes with different cell numbers were comprehensively investigated under both axial and oblique loads. The finite element models were first established and then validated by experimental tests. The simulation results showed that the increase in cell number can be beneficial to the energy absorption (EA) but detrimental due to increase in peak force (F_{max}) under axial load. When the oblique loads were taken into account, the tubes could undergo global bending, which is an inefficient deformation mode. By applying complex proportional assessment (COPRAS) method, the 7x7 tube was selected as the best based on multi-criteria under multiple loading angles. Then the Kriging modeling technique and multiobjective particle optimization (MOPSO) algorithm were integrated to address the optimization problems, where EA and F_{max} were taken as objectives and tube sizes as design variables. The results demonstrated that different loading angles have different requirements on cell allocation and optimizations of multiple load cases (MLC) can yield better solutions in a weighted average fashion, whereas the optimization for separate single load cases (SLC) could result in inferior performance under other load cases.

Xi Zhang, Kim J.R. Rasmussen and Hao Zhang (School of Civil Engineering, The University of Sydney, Australia), Beam-element-based analysis of locally and/or distortional buckled members: Application”, Thin-Walled Structures, Vol. 95, pp 127-137, October 2015, DOI: 10.1016/j.tws.2015.06.021

ABSTRACT: The companion paper [1] presents a theory to account for the effects of local and/or distortional buckling in a seven degrees of freedom beam finite element analysis. The theory considers the effect of local and/or distortional buckling as a reduction in tangent rigidities, and determines the reduced tangent rigidities by an a priori post-local or post-distortional buckling analysis of a short length of section. In this paper, the presented method is incorporated into the open source software package OpenSees which was previously modified to account for warping effects [2]. The accuracy of the method is validated by comparison with shell element results for beams, columns and frames.

“Study on distortional buckling performance of cold-formed thin-walled steel flexural members with stiffeners in the flange”, Thin-Walled Structures, Vol. 95, pp 161-169, October 2015, DOI: 10.1016/j.tws.2015.07.006

ABSTRACT: This paper presents a finite strip program CUFSM used to calculate and analyze the elastic distortional buckling of cold-formed thin-walled steel flexural members with stiffeners in the flange, which has different sectional geometric parameters. According to the classical buckling stress formula, the distortional buckling coefficient of the flange can be calculated so as to analyze the influence of changed sectional geometric parameters on it. On this basis, this study provides a simplified formula of distortional buckling stress to calculate 40 members with different sections which are selected from the Technical Code of Cold-Formed
Thin-Wall Steel Structures of China but not contained in this paper. Compared with the analysis results of CUFSM, it shows that the two simplified formulas have quite high accuracy and wide applicability for general members provided by the specification. So it is suggested that they can be used for engineering design and standard revision.

“On nonlinear thermal buckling analysis of cylindrical shells”, Thin-Walled Structures, Vol. 95, pp 170-182, October 2015, DOI: 10.1016/j.tws.2015.06.013
ABSTRACT: In this article, the nonlinear buckling behavior of imperfect cylinders made of isotropic, composite and functionally graded materials is studied. A continuum-based semi-analytical finite element formulation is introduced to study the nonlinear behavior of cylinders under thermal loads. A method is proposed to implement the initial geometric imperfection of the cylinder by transformation of structure due to deformation gradients. The influences of geometrical parameters, different materials and imperfection factors are investigated on pre- and post-buckling paths. A comparison is made between the classical von Kármán-based and continuum-based approaches to ensure the validation of the results and to study the applicability of the von-Kármán approximation.

Nicola Tondini and Andrea Morbioli (Department of Civil, Environmental and Mechanical Engineering, University of Trento, via Mesiano 77, Trento 38123, Italy), “Cross-sectional flexural capacity of cold-formed laterally-restrained steel rectangular hollow flange beams”, Thin-Walled Structures, Vol. 95, pp 196-207, October 2015, DOI: 10.1016/j.tws.2015.06.018
ABSTRACT: This paper presents the results of a comprehensive experimental-numerical study aimed at determining the flexural performance of cold-formed laterally-restrained steel rectangular hollow flange beams (RHFBs). Two RHFBs of different dimensions were considered as representative of typical secondary beams in small steel-framed houses. Results of the experimental study that consisted of (i) material characterisation and (ii) tests on full-scale specimens are thoroughly presented. Moreover, a numerical work was performed in order to develop a model able to reproduce the experimental outcomes and used to expand the available findings over a wider slenderness range through parametric studies.

“Design of progressively folding thin-walled tubular components using compliant mechanism synthesis”, Thin-Walled Structures, Vol. 95, pp 208-220, October 2015, DOI: 10.1016/j.tws.2015.06.010
ABSTRACT: This work introduces a design method for the progressive collapse of thin-walled tubular components under axial and oblique impacts. The proposed design method follows the principles of topometry optimization for compliant mechanism design in which the output port location and direction determine the folding (collapse) mode. In this work, the output ports are located near the impact end with a direction that is
perpendicular to the component's longitudinal axis. The topometry optimization is achieved with the use of hybrid cellular automata for thin-wall structures. The result is a complex enforced buckle zone design that acts as a triggering mechanism to (a) initiate a specific collapse mode from the impact end, (b) stabilize the collapse process, and (c) reduce the peak force. The enforced buckle zone in the end portion of the tube also helps to avoid or delay the onset of global bending during an oblique impact with load angles higher than a critical value, which otherwise adversely affects the structure's capacity for load-carrying and energy absorption. The proposed design method has the potential to dramatically improve thin-walled component crashworthiness.

M.F. Hassanein (Department of Structural Engineering, Faculty of Engineering, Tanta University, Tanta, Egypt), “Fundamental behaviour of concrete-filled pentagonal flange plate girders under shear”, Thin-Walled Structures, Vol. 95, pp 221-230, October 2015, DOI: 10.1016/j.tws.2015.07.003
ABSTRACT: Hollow tubular flange plate girders are found to possess higher flexural and shear strengths over those of I-section plate girders with flat flanges. Recently, concrete-filled pentagonal flange girders (CFPFGs) have been suggested in literature to increase the out-of-plane flexural strength of the girders. The geometrical configuration of the section is assumed identical to that of the girder with the rectangular concrete-filled flanges, but the flange depth-to-width ratio is designed to be larger in order to reduce the local buckling of the web. In this paper, the fundamental shear behaviour of these CFPFGs with slender stiffened webs is investigated. Nonlinear three-dimensional finite element (FE) analyses using ABAQUS are employed to conduct parametric studies, having first validated the models against available experimental data. For comparison purposes and to examine the effect of the infill concrete, steel pentagonal flange girders (SPTGs) are also generated. It is found that CFPFGs and SPFGs with the same dimensions have similar buckling shapes but with different loads with the buckling load of the CFPFG being higher than that of the corresponding SPFG. In the post-buckling stage, the width of the inclined tension field becomes greater in the CFPFGs relative to that of the SPFGs. This highlights the influence of the infill concrete which increases the stiffness of the upper flanges, and hence allows the webs to carry additional shear loads compared to SPFGs. Several affecting parameters are, additionally, examined and important conclusions are remarked. The FE strengths are compared with the design strength of the webs following the EN 1993-1-5, indicating that it can conservatively be used with the SFPFGs. On the other hand, it becomes highly conservative for the CFPFGs.

DOI: 10.1016/j.tws.2015.07.012
ABSTRACT: Optimization of a simply supported cylindrical shell stiffened by inner rings is considered in this paper. The shell is loaded by external pressure. The first critical buckling load is maximized. A material volume and a slope of a post-critical path are assumed as optimization constraints. The inner rings are made from the material obtained from the shell by decreasing its thickness. This way the volume of the material remain constant. The structure is modelled and solved by the finite element method (FEM). The linear and nonlinear stability analyses are done in the ANSYS software. An effect of geometric imperfections on a shape of equilibrium path is discussed. The optimization was performed numerically using the modified particle swarm optimization method (MPSO). The results are compared with a reference cylindrical shell with no rings. The single ring placed in the middle of the shell is good enough for stabilization of a post-buckling path for a shorter shell, regardless of its thickness. It is necessary to use three rings optimally distributed along the shell length, for a longer shell. The additional optimization profit was obtained by varying internal diameters of the rings.
The proposed concept of shell stiffening by inner rings eliminates a major disadvantage of smooth cylindrical shells, namely an unstable post-buckling path.

Genshu Tong, Yixiao Feng and Lei Zhang (Department of Civil Engineering, Zhejiang University, Hangzhou 310058, PR China), “A unified analysis for distortional and lateral buckling of C-purlins in flexure”, Thin-Walled Structures, Vol. 95, pp 244-254, October 2015, DOI: 10.1016/j.tws.2015.07.001

ABSTRACT: This paper developed a unified model for the distortional and lateral buckling of cold-formed C-purlins subjected to bending in the plane of symmetry. It can study not only the distortional buckling, but also the global lateral buckling. Different from Hancock's model, the new model includes two interactive springs between lateral and rotational restraints provided by the web to the flange-lip section. A closed-form solution is acquired by the Ritz method. And the elastic buckling coefficients of 20 purlin sections predicted by the solution are compared with those from Finite Element Method (FEM), showing excellent agreement between them. Comparison is also provided with Hancock's method. The closed form solutions are also substituted into the Direct Strength Method to obtain nominal flexure strength of the purlins, and it is found that the proposed model predicted almost the same strength as the software Schafer's CUFSM with differences less than 1%. A good correlation is observed between test results and the proposed method.

“The energy absorption of bamboo under dynamic axial loading”, Thin-Walled Structures, Vol. 95, pp 255-261, October 2015, DOI: 10.1016/j.tws.2015.06.017

ABSTRACT: The energy absorption characteristics and material parameters of the bamboo species Phyllostachys pubescens are studied by drop-weight and dynamic tensile tests. The dynamic tensile test shows that 1-year-old bamboo has the greatest tensile strength (251 MPa), which is 1.85 times that of a 2A12 aluminium alloy. The drop-weight test shows that the energy absorption of nodal samples is greater than that of the internode samples, and the specific energy absorption (SEA) values of the nodal and internode samples are 11.85 kJ/kg and 9.78 kJ/kg, respectively. The SEA of nodal samples is close to that of aluminium alloy and steel tube, and the SEA of the internode samples is close to that of copper tube. The energy absorption increases with increasing moisture content and decreases with growth age. Analyses show that the bamboo nodes and the vascular bundle are the main factors affecting bamboo energy absorption. The results indicate that bamboo is a tubular structure with excellent mechanical and energy absorption properties.

Edward Steau, Mahen Mahendran and Poologanathan Keerthan (Science and Engineering Faculty Queensland University of Technology, Brisbane, Australia), “Web crippling tests of rivet fastened rectangular hollow flange channel beams under two flange load cases”, Thin-Walled Structures, Vol. 95, pp 262-275, October 2015 DOI: 10.1016/j.tws.2015.06.008

ABSTRACT: Recent research on hollow flange beams has led to the development of an innovative rectangular hollow flange channel beam (RHFCB) for use in floor systems. The new RHFCB is a mono-symmetric structural section made by intermittently rivet fastening two torsionally rigid closed rectangular hollow flanges to a web plate element, which allows section optimisation by selecting appropriate combinations of web and
flange widths and thicknesses. However, the current design rules for cold-formed steel sections are not directly applicable to rivet fastened RHFCBs. To date, no investigation has been conducted on their web crippling behaviour and strengths. Hence an experimental study was conducted to investigate the web crippling behaviour and capacities of rivet fastened RHFCBs under End Two Flange (ETF) and Interior Two Flange (ITF) load cases. It showed that RHFCBs failed by web crippling, flange crushing and their combinations. Comparison of ultimate web crippling capacities with the predictions from the design equations in AS/NZS 4600 and AISI S100 showed that the current design equations are unconservative for rivet fastened RHFCB sections under ETF and ITF load cases. Hence new equations were proposed to determine the web crippling capacities of rivet fastened RHFCBs. These equations can also be used to predict the capacities of RHFCBs subject to combined web crippling and flange crushing conservatively. However, new capacity equations were proposed in the case of flange crushing failures that occurred in thinner flanges with smaller bearing lengths.

ABSTRACT: The axial crushing of circular structures with rectangular insert was investigated. Literature available experimental data were used to validate the numerical models of the structures investigated. Results are compared in order to set up the simulation layout. To increase the efficiency of the simulation process a software module was developed and some explanations related to the generation of the numerical model are provided. Based on the theoretical models of the symmetric crushing of circular tubes and the model developed to investigate multi-cell square thin-walled structures a formula for the evaluation of the mean crushing force for the proposed structure was derived. Results obtained from the experiments and different numerical simulations of structures with different number of cells, different thicknesses and main dimensions were evaluated and compared with theoretical results. The theoretical model predicted the mean crushing force with and error of 20% in case of structures with a reduced number of cells (four cells) or with a very thin insert while for structures with a higher number of cells or thicker insert (comparable with the thickness of the tube) the predicted value is within 5% range. Some plots based on the theoretical model are presented and can provide the start point for an optimisation process.

ABSTRACT: Many shell structures used in modern technology consist of regular shell parts joined together along their common boundaries. We review different theoretical, numerical, and experimental approaches to modelling, analyses and design of the compound shell structures with junctions. Several alternative forms of boundary, continuity and jump conditions at the singular midsurface curves modelling the shell junction are reviewed. We also analyse the results obtained for special shell structures containing the cylinder–cylinder intersections, cone–, sphere–, and plate–cylinder junctions, tubular joints as well as other special types of junctions appearing in complex multi-shell structures.

ABSTRACT: The paper deals with stability of steel cylindrical silos composed of corrugated walls and vertical open-sectional stringers. Comprehensive three-dimensional finite element analyses were carried out with perfect slender, semi-slender and squat silos by means of a linear buckling approach. Corrugated walls were simulated as an equivalent orthotropic shell and vertical open-sectional stringers as beam elements. The FE results were compared with the Eurocode approach. In addition, comprehensive FE computations for axially compressed cylindrical shells composed of an orthotropic shell and stringers were carried out. An improvement of standard formulae was proposed.

ABSTRACT: The literature lacks exhaustive study on CFDST hybrid columns circumscribed by FRP layers. Extended FEM analysis was carried out on 70 real-scale models with varying parameters including the material and number of FRP layers, concrete strength, length-to-diameter ratio (specific length), and hollow section ratio. Carbon fibers proved stronger than glass fibers, leading to higher ultimate stress associated with lower strain. Specimens with high specific lengths suffered from steel premature buckling, thus stiffened with steel plates. Specimens with various hollow section ratios were finally compared, showing an increase range of 70% between the maximum (0.75) and minimum (0.25) ratios.

A.R. Vosoughi and M.R. Nikoo (Department of Civil and Environmental Engineering, School of Engineering Shiraz University, Shiraz, Iran), “Maximum fundamental frequency and thermal buckling temperature of laminated composite plates by a new hybrid multi-objective optimization technique”, Thin-Walled Structures, Vol. 95, pp 408-415, October 2015, DOI: 10.1016/j.tws.2015.07.014

ABSTRACT: In this paper, a hybrid method for simultaneously maximizing fundamental natural frequency and thermal buckling temperature of laminated composite plates is developed. This method is a new combination of the differential quadrature method (DQM), non-dominated sorting genetic algorithm II (NSGA-II) and Young bargaining model. The governing equations are obtained within the framework of the first-order shear deformation theory (FSDT) of plates and are discretized using the DQM. Then, the DQM is linked with the NSGA-II optimization model and the trade-off between the objectives with respect to fibers orientations is obtained. Finally, by applying Young bargaining model the best fibers orientations which maximize the objectives of laminated composite plates with different boundary conditions, thickness-to-length and aspect ratios are obtained.

ABSTRACT: The blast performance of water tank with an innovative energy absorbing support was studied to reduce the support reaction force and mitigate the damage on the water tank. The aluminum foam was adopted as the energy absorbing material, since it has high energy absorbing potential during crush plateau and safety backup zone after the compaction strain. Finite element model considering fluid and structural interaction in which the water is modeled using the Eulerian formulation and the steel tank by Lagrangian formulation is proposed. The proposed numerical model of water tank was verified by comparing the predicted results with the test results obtained from dynamic pressure tests on steel tanks filled with water. The numerical results showed that the support reaction force depends on the density and yield strength of the aluminum foams and the reaction force could be reduced significantly if softer aluminum foam was chosen. The total displacement of the water tank was increased by up to 38% due to the increase in deformation of the energy absorbing foam. The aluminum foam was proposed to absorb the blast energy and reduce the damage on the water tank. However, more damage on the water tank was observed when a very low density aluminum foam support was used. This was attributed to the increased external work done by blast loading which was higher than the energy absorbed by the aluminum foam support.

ABSTRACT: The optimal design of cold-formed steel columns is addressed in this paper, with two objectives: maximize the local-global buckling strength and maximize the distortional buckling strength. The design variables of the problem are the angles of orientation of cross-section wall elements—the thickness and width of the steel sheet that forms the cross-section are fixed. The elastic local, distortional and global buckling loads are determined using Finite Strip Method (CUFFSM) and the strength of cold-formed steel columns (with given length) is calculated using the Direct Strength Method (DSM). The bi-objective optimization problem is solved using the Direct MultiSearch (DMS) method, which does not use any derivatives of the objective functions. Trade-off Pareto optimal fronts are obtained separately for symmetric and anti-symmetric cross-section shapes. The results are analyzed and further discussed, and some interesting conclusions about the individual strengths (local-global and distortional) are found.

ABSTRACT: This paper is based on an investigation into the performance of cold-formed C-channels stiffened with cover plates and subjected to pure bending and primarily shear condition tests. Cover plates with three different thicknesses (1.6, 2 and 2.4 mm) were installed at top flanges only as it would be the predicted location for local and distortional buckling. The local and distortional buckling capacities were evaluated via Direct Strength Method, DSM, in accordance with AISI 2007. The accuracy of the interaction equation between the required flexural strength, $M$, and the required shear strength, $V$, prescribed by AISI 2007 was also investigated in this paper. A nonlinear finite element model was developed and verified against the test results in terms of maximum strength and buckling failure modes. The results explicitly showed that by attaching the cover plate on top flanges, the non-dimensional slenderness decreased resulted in improved buckling capacities, where the nominal flexural moment of sections, $M_n$, were close to the plastic moment, $M_p$. Besides, it was concluded that the interaction equation between $M$ and $V$ predicted by AISI was conservative for sections with small non-dimensional slenderness values.

ABSTRACT: The toroidal shell with stiffened ribs is a new-style structure in ocean engineering especially in underwater engineering. This paper attempts to provide a simple theoretical method to obtain the stress solution of toroidal shell with ribs for its strength assessment. Firstly according to the structural property of toroidal shell with ribs and theory of curve-beam, a simple model for toroidal shell with ribs has been developed; then coupled with theory of thin-shell and elastic beam, its stress and deformation have been solved and can be expressed into analytic formulas; lastly by finite element method (FEM) and model experiment method, this simple theoretical solution has been verified to be reasonable and quite accurate. Thus this simple theoretical solution could be applied for analysis and design of pressure equipment in such toroidal structure type.

ABSTRACT: Thermoplastic polymers such as HDPE are nowadays widely used as lining materials for oil and gas pipelines. However, during maintenance or unexpected service stoppages, these liners can undergo external pressure induced buckling collapse. The objective of this work is to assess the mechanical response of HDPE liners undergoing buckling collapse by means of Finite element modeling (FEM) simulations on Abaqus 6.10. To accomplish this, an advanced constitutive model, namely the Three Network Model (TNM) was employed. In order to determine the input parameters for the model, a series of tensile and compressive uniaxial tests were conducted. The suitability of the model for this particular application was assessed by contrasting the simulation and the experimental results of a diametral compression test. The complex strain rate and pressure dependent mechanical response of HDPE liners was analyzed by modeling the buckling collapse dynamic event as an increasing volume of fluid entering the gap cavity between liner and host pipe. The model predictions allowed
establishing a mathematical relationship between the depressurization velocity of the tubes and the resulting collapse pressure. These relations can be used to improve the current design guidelines for plastic liners.

“Strength and stiffness requirements for intermediate ring stiffeners on discretely supported cylindrical shells, Thin-Walled Structures, Vol. 96, pp 64-74, November 2015, DOI: 10.1016/j.tws.2015.08.004
ABSTRACT: Silos in the form of a cylindrical metal shell are often supported on a ring beam which rests on discrete column supports. This support condition produces a circumferential non-uniformity in the axial membrane stresses in the silo shell. One way of reducing the non-uniformity of these stresses is to use a very stiff ring beam which partially or fully redistributes the stresses from the local support into uniform stresses in the shell. A better alternative is to use a combination of a flexible ring beam and an intermediate ring stiffener. Recent research by the authors has identified the ideal location of the intermediate ring stiffener to provide circumferentially uniform axial membrane stresses above the stiffener. To be fully effective, this intermediate ring should locally prevent both radial and circumferential displacements in the shell. This paper explores the strength and stiffness requirements for this intermediate ring stiffener. Pursuant to this goal, the cylindrical shell below the intermediate ring stiffener is analysed using the membrane theory of shells and the reactions produced by the stiffener on the shell are identified. These reactions are then applied to the intermediate ring stiffener. Vlasov’s curved beam theory is used to derive closed form expressions for the variation of the stress resultants around the circumference to obtain a strength design criterion for the stiffener. A stiffness criterion is then developed by considering the ratio of the circumferential stiffness of the cylindrical shell to that of the intermediate ring stiffener. The circumferential displacements of the ring and the shell are found for the loading condition previously obtained to determine the required strength. A simple algebraic expression is developed for this intermediate ring stiffness criterion. These analytical studies are then compared with complementary finite element analyses that are used to identify a suitable value for the intermediate ring stiffness ratio for practical design.

Cenk Kilicasian (Department of Mechanical Engineering, Faculty of Engineering, Adnan Menderes University, Aydın, Turkey), “Numerical crushing analysis of aluminum foam-filled corrugated single- and double-circular tubes subjected to axial impact loading”, Thin-Walled Structures, Vol. 96, pp 82-94, November 2015
DOI: 10.1016/j.tws.2015.08.009
ABSTRACT: In this paper, aluminum foam-filling method was applied to corrugated tubes numerically, offering a novel structure that may have excellent energy absorption capacity. The study aims to provide a comparative study on the crushing responses of aluminum foam-filled corrugated single- and double-tubes with different corrugation lengths. The effects of geometric parameters like radius and wall thickness of inner tube in double-tubes on the energy absorption were also discussed. Dynamic crushing simulations were performed on finite element software LS-DYNA at impact velocity of 16.7 m/s (corresponding to 60 km/h). The comparisons revealed that tubes with corrugations experienced progressive and concertina type of deformation and tubes with smaller corrugation length showed smooth force–displacement curve with low initial peak force. SEA of foam-filled corrugated double-tubes was found to be superior to foam-filled straight tubes.

ABSTRACT: This study concentrates on a comparison between steel plate and stiffened panels subject to localised corrosion. A finite element analysis is used to investigate the effect of random corrosion on the compressive strength capacity of marine structural units. Variables include the extent of corrosion; slenderness ratio and aspect ratio. A corrosion prediction model is incorporated to determine the thickness reduction with time. Corrosion-induced volume loss results in a greater reduction of ultimate strength for slender plates compared to stiffened panels, up to 45%, showing the structural element selection can strongly influence the accuracy of the estimated corrosion damage effect.

ABSTRACT: This paper investigates the effect of cross-section thickness, flat length and curvature of end parts, on the load capacity of fixed ended LDSS (Lean Duplex Stainless Steel) flat oval stub columns, using the commercial finite element software, Abaqus. Based on the FE analyses, it has been found that sections with semicircular elements provided the maximum load capacity, and for flatters, the rate of decrement in load capacity is seen to be small. The effect of flat length on the load capacity, for thinner sections, is found to be relatively insignificant, however for thicker sections, an increase in load capacity is observed, with the slope of increment getting relatively higher as the thickness increases. Strength gain per unit increase in area by 1) increasing thickness, increases with increasing curvature radius and decreases with increasing flat length; 2) increasing flat length, increases with increasing thickness; while the decrease in strength per unit decrease in area by increasing curvature radius decreases with increasing thickness. The FE results have been compared with ASCE 8-02, AS/NZS 4673, EN 1993-1-4, DSM, CSM predictions, and it has been found that ASDM, DSM and CSM are applicable for the design of flat oval LDSS columns.

“Counter-intuitive collapse of single-layer reticulated domes subject to interior blast loading”, Thin-Walled Structures, Vol. 96, pp 130-138, November 2015, DOI: 10.1016/j.tws.2015.08.001

ABSTRACT: A commercial finite element package, LS-DYNA, was employed to simulate the response of a single-layer reticulated dome to an interior blast. The dome, which was initially stressed by static preloading, encountered an interesting phenomenon namely counter-intuitive collapse, which was found during the blast analysis. The Johnson–Cook constitutive model for mild steel was used to identify different failure modes of the dome for more than 2430 samples. A seemingly counter-intuitive collapse was identified due to dynamic instability. This unusual collapse was explained using total potential curves, and the critical blast load was defined. The effect of different static preloads, which is the other determination factor of counter-intuitive collapse, was investigated. A relationship between collapse and static/dynamic loads was also obtained. The
results indicate that single-layer reticulated domes, with large initial stresses, may collapse at lower dynamic loads than expected.

ABSTRACT: This paper presents an analytical approach to investigate the nonlinear stability analysis of eccentrically stiffened thin FGM cylindrical panels on elastic foundations subjected to mechanical loads, thermal loads and the combination of these loads. The material properties are assumed to be temperature-dependent and graded in the thickness direction according to a simple power law distribution. Governing equations are derived basing on the classical shell theory incorporating von Karman–Donnell type nonlinearity, initial geometrical imperfection, the Lekhnitsky smeared stiffeners technique and Pasternak type elastic foundations. Explicit relations of load–deflection curves for FGM cylindrical panels are determined by applying stress function and Galerkin method. The effects of material and geometrical properties, imperfection, elastic foundations and stiffeners on the buckling and postbuckling of the FGM panels are discussed in detail. The obtained results are validated by comparing with those in the literature.

ABSTRACT: Two major requirements for crush analysis of thin-walled cylindrical tubes are being lightweight and having good crashworthiness. Thin-walled cylindrical tubes, which are either empty or foam filled, can potentially be used in all vehicles and moving parts such as road vehicles, trains, aircrafts, ships, lifts and machinery to protect passengers and the structure itself during impact. This paper discusses an idea of utilizing the initiator on the foam-filled thin-walled circular tubes with stiffened annular rings to increase the specific energy absorption (SEA) and prevent the sudden force applied to the main part of the automotive and its occupants. Effect of initiator, at the top of the foam-filled aluminum tube, different densities of rigid polyurethane foam, and number of annular rings under axial compression were described through energy absorption, crush force efficiency (CFE), and mass of structure. In order to verify the numerical results, a series of quasi-static axial compression tests was performed, and both load–displacement curves and deformation mechanism of the structure were analyzed. The results of multi-criteria decision analysis (MCDA), by incorporating numerical and experimental data, showed that in the considered material and geometry, the design with an initiator, four rings tube, and higher density of foam have superior performance in terms of energy absorption, CFE, and mass. More debate on effect of initiator would help to reach the simultaneous improved crashworthiness structure and lightweight design with greater degree of accuracy in the hope of reducing the occupant injury in a collision.
DOI: 10.1016/j.tws.2015.08.010
ABSTRACT: This paper presents a rational procedure for implementing geometric imperfections into inelastic large displacement (“advanced”) analysis. The procedure uses a statistical approach that considers the reliability of the structural strength of a selection of well-documented tests of thin-walled members and frames. The aim of the study is to derive a statistical procedure for implementing imperfections in shell-element based advanced analyses and to determine an appropriate interval of half-wavelengths and number of eigenmodes to incorporate when modeling geometric imperfections. To achieve this, a analysis of strength as a function of imperfection spectra for 20 storage rack uprights and 56 frame members was conducted using finite element analysis (FEA). All FEA models were calibrated against completed experimental results. Based on the results, practical recommendations for modelling cross-sectional and member imperfections in advanced analysis for individual uprights and storage rack frames are provided.

ABSTRACT: Steel girders with corrugated webs are increasingly used in the field of bridges, especially in case of composite bridges. During launching of a bridge structure the girder can be subjected by the combination of bending moment (M), shear (V) and transverse forces (F) which result in a complex stress field in the girder and in an interacting stability problem. Previous research activities related to the corrugated web girders showed that the structural behavior of the girders with corrugated webs differ from the conventional I-girders, especially in the stress distribution of the flanges and the web. On the other hand the stability behavior of the corrugated web girders are also different from the flat web girders due to the corrugation profile therefore the interaction equations developed for conventional I-girders cannot be used for corrugated web girders. There is a lack of investigations analyzing the effect of the complex loading situation for corrugated web girders, therefore the current paper focuses on the investigation of the structural behavior under all of the aforementioned actions and their combinations. Based on the previous and current investigations design interaction equation is developed for the combined M–V–F loading situation.

Kun Xie, Meixia Chen, Naiqi Deng and Wenchao Jai (School of Naval Architecture and Ocean Engineering, Huazhong University of Science and Technology, 1037 Luoyu Road, Wuhan 430074, China), “Free and forced vibration of submerged ring-stiffened conical shells with arbitrary boundary conditions”, Thin-Walled Structures, Vol. 96, pp 240-255, November 2015, DOI: 10.1016/j.tws.2015.08.013
ABSTRACT: An analytic approach is presented to analyze free and forced vibration of submerged ring-stiffened conical shell with arbitrary boundary conditions at low frequencies. According to the junctions of shell-stiffener, the shell is firstly divided into multiple substructures, e.g. conical segments and stiffeners. To take into account fluid loading, conical segments are divided into more narrow strips and those strips are approximately considered as local cylindrical shells. Then, Flügge theory is used to describe the motion of conical strips and displacement functions are expressed as power series. Instead of utilizing smeared out method, ring stiffeners are treated as discrete members and the equations of motion of annular plate, rather than curve beam, are adopted to describe the motion of stiffeners with rectangular cross-section. Lastly, boundary
conditions and continuity conditions of adjacent substructures are used to assemble the final governing equation. Comparisons of free and forced vibration results of present method and those in literature and/or calculated by finite element method show the validity of present method. The effects of boundary conditions, ring stiffeners and fluid loading on free vibration are studied. The effects of external point force and fluid loading on forced vibration are also discussed.

Nan Hu and Rigoberto Burgueño (Department of Civil and Environmental Engineering, Michigan State University, East Lansing, MI 48824, USA), “Elastic postbuckling response of axially-loaded cylindrical shells with seeded geometric imperfection design”, Thin-Walled Structures, Vol. 96, pp 256-268, November 2015, DOI: 10.1016/j.tws.2015.08.014

ABSTRACT: Elastic instabilities (such as buckling) have been recognized as a promising phenomenon to design smart materials and mechanical systems. Thin-walled cylindrical shells under axial compression can attain multiple bifurcation points in their postbuckling regime due to the natural transverse deformation restraint provided by their geometry; but harnessing such behavior for smart purposes is lacking extensive study due to its notoriously high imperfection sensitivity. In this paper, the concept of seeded geometric imperfection (SGI) design is proposed to modify and control the elastic postbuckling behavior of cylindrical shells. Eigenvalue-based mode shapes were used as basic geometric forms to generate a seeded imperfection. Prototyped SGI cylindrical shells were fabricated through 3D printing and tested under loading–unloading cycles. Numerical and experimental results suggest that the SGI cylindrical shells are less sensitive to initial imperfections and load variation than uniform ones. Cylindrical shells with seeded geometry can be potentially used in the design of smart devices and mechanical systems such as energy harvesters and self-powered sensors.

Adel Elsabbagh (Group for Advanced Research in Dynamic Systems, Design and Production Engineering Department, Ain Shams University, 1 Elsarayat Street, Abbasya, Cairo 11517, Egypt), “Nonlinear finite element model for the analysis of axisymmetric inflatable beams”, Thin-Walled Structures, Vol. 96, pp 307-313, November 2015, DOI: 10.1016/j.tws.2015.08.021

ABSTRACT: Inflatable structures are already being used for decades now especially in aerospace applications. The Inflatoplane and inflatable space habitats are just examples. On the other hand, the modeling and simulation techniques of inflatable structures are lacking far behind. Most of the available models are concerned with cylindrical beams. In this paper, a nonlinear Finite Element model for axisymmetric inflatable structures is developed using beam elements. The model is validated by comparing its predictions to two cases of cylindrical beams in the literature. The model is then utilized to predict the effect of two parameters on the wrinkling load of the beam. Results show that the wrinkling load is proportional to the square root of the inflation pressure. For the beam radius, it is proportional to the cube of the radius at small radii but then the relation is linear afterwards. The model is also used to predict the performance of an inflated truncated cone as a function of the inflation pressure and the root radius. The proposed nonlinear Finite Element model is a step towards analyzing real-life inflatable structures.

ABSTRACT: This paper focuses on understanding the effect of disbonds on stability aspects of adhesively bonded aluminum structures. In order to utilize that a numerical methodology was developed and it consisted of a parametric finite element model that coupled non-linear buckling analysis with calculation of the critical strain energy release rate on the disbonds tip. The structure under investigation was representative of those used in aerospace industry, an aluminum plate with 4 adhesively bonded J-profile stiffeners subjected to compression loading. Disbonds of several sizes were located in different positions along the second stiffener. A critical disbond size observed after which the compression load capacity of the structure decreased significantly. Moreover, the position of the disbond played a critical role both on the buckling load and the buckling mode and as a consequence, the mechanisms that triggered the disbond onset.

ABSTRACT: In this paper, the mechanical behaviors and failure mechanism of steel-reinforced concrete-filled steel tubular (SRCFST) columns were numerically investigated with the software of ABAQUS/standard solver. Existing experimental results were employed to verify the validity of the finite element models of SRCFST columns. A total of 22 specimens were numerically studied to examine the effect of steel tube ratio ($\alpha_t$), section steel ratio ($\alpha_s$), concrete strength ($f_{ct}$), yield strength of steel tube ($f_{yt}$) and yield strength of section steel ($f_{ys}$) on the mechanical behaviors and ultimate resistance of the SRCFST columns under axial compression. The model in Eurocode 4 significantly underestimated the load bearing capacity of SRCFST columns, and a new model was then proposed to predict the strength of the SRCFST columns. Based on the comparison between the calculation results from the proposed model and experimental results, the proposed model can provide reliable prediction of the ultimate load carrying capacity for the SRCFST columns.

ABSTRACT: External confinement in the form of steel rings, tie bars, spirals and FRP wraps has been widely adopted for strengthening concrete-filled-steel-tube (CFST) columns. Previous experimental and theoretical studies have proved that it can improve the strength, elastic stiffness, ductility and interface bonding of CFST columns. However, in real engineering practise, CFST columns need to be strengthened are usually under pre-compressed axial load. The stress-lagging effect between the CFST columns and external confinement due to pre-loading has not yet been justified. In this paper, external confinement in the form of circular steel jacket is proposed to improve the uni-axial behaviour of CFST columns with and without pre-compressed axial load. An experimental study, consisting of 5 hollow-steel-tubes and 10 thin-walled CFST columns was conducted to examine the effectiveness of the proposed strengthening scheme. The main parameters were the concrete cylinder strength, jacket spacing and pre-compressed axial load level. Test results revealed that the steel jacket could improve the uni-axial behaviour of CFST columns and the stress-lagging could degrade this beneficial
effect. In addition, a theoretical model developed by the authors previously was adopted to predict the uni-axial behaviour of the strengthening columns. Very good agreement has been obtained between the theoretical and experimental results.

“Mechanical performances of concrete-silled steel tubular stub columns with round ends under axial loading”,
Thin-Walled Structures, Vol. 97, pp 22-34, December 2015, DOI: 10.1016/j.tws.2015.07.021

ABSTRACT: An experimental study of 22 concrete-filled round-ended steel tubular (CFRT) stub columns under axial compression is conducted compared with 4 circular concrete-filled steel tubular (CFT) stub columns. The influences of width–thickness ratio, concrete strength, steel yield strength and wall-thickness of steel tube on the ultimate bearing capacity of the CFRT columns are discussed. The 3D finite element (FE) model is also developed to analyze the behavior of the CFRT columns under axial compression. From the results, local buckling of the round-ended steel tube associated with shear failure of in-filled concrete could be observed. With the increasing width–thickness ratio, the corresponding load–strain curves have a shorter elastic–plastic stage. The parametric studies indicate that the concrete strength, tube thickness and width–thickness ratio of the steel tube also have a great effect on the ultimate bearing capacity. The numerical results also show that the confinement effect of the stub columns decreases with the increasing width–thickness ratio. A practical calculation formula for the bearing capacity of the CFRT stub columns is proposed, which is well in agreement with the experimental results.

J. Blachut (The University of Liverpool, School of Engineering, Liverpool L69 3GH, UK), “Locally flattened or dented domes under external pressure”, Thin-Walled Structures, Vol. 97, pp 44-52, December 2015
DOI: 10.1016/j.tws.2015.08.022

ABSTRACT: The paper provides comparisons of sensitivity of buckling pressures to initial shape imperfections, for the case of externally pressurised steel domes. A priori defined deviations from perfect shape include: Legendre polynomials, increased-radius patch, and localised inward dimple. The latter is created by a concentrated force acting radially. In this case the effects of spring back and/or annealing of the dented patch and the surrounding area on the load carrying capacity are assessed. Some of the elastic solutions related to the lower-bound approach are compared with the available experimental data.

ABSTRACT: Steel plate shear wall (SPSW) systems have dual characteristics, the frame and infill wall action. The connection flexibility of frame joint not only changes the force and moment distribution, but also increases the lateral displacement and weakens the overall stability in SPSW structure. This paper presents the influence of hinged, rigid and semi-rigid connection joints on the behavior of SPSW structures. The bearing capacity, energy dissipation mechanism, failure mode, stress and deformation development process of the semi-rigid composite frame with steel plate shear walls under different stiffener forms were studied using experimental tests and finite element analysis. It was observed that with stiffeners the specimen yield load increased about 20% on the elastic stage, the ultimate bearing capacity of the diagonal stiffener was about 5% larger than the cross stiffener on the plastic stage, but the overall failure modes were basically the same. Additionally, the quantitative indications of the effect of joint stiffness on load carrying capacity were presented.

Francesco Tornabene (1), Nicholas Fantuzzi (1), Michele Bacciocchi (1) and Rossana Dimitri (2) (1) DICAM – Department, School of Engineering and Architecture, University of Bologna, Italy (2) Department of Innovation Engineering, University of Salento, Via per Monteroni, 73100 Lecce, Italy “Free vibrations of composite oval and elliptic cylinders by the generalized differential quadrature method”, Thin-Walled Structures, Vol. 97, pp 114-129, December 2015, DOI: 10.1016/j.tws.2015.08.023

ABSTRACT: We use the generalized differential quadrature method (GDQ) and shell theories of different order to study free vibrations of laminated cylinders of oval and elliptic cross-sections. In the GDQ method partial derivatives of a function at a point are expressed as weighted sums of values of the function at several neighboring points. Thus, strong forms of equations of motion are analyzed. It is found that the computed frequencies rapidly converge with an increase in the number of grid points along the oval or elliptic circumference defining the cross-section of the mid-surface of the cylinder. For a clamped-free elliptic cylinder the converged frequencies match well with the corresponding experimental ones available in the literature. Furthermore, the lowest ten frequencies computed with either an equivalent single layer theory or a layer wise theory of first order and using shear correction factor are accurate.

Mahmoud Zohrabi, Abbas Niknejad and Sima Ziaee (Mechanical Engineering Department, Yasouj University, P.O. Box: 75914-353, Yasouj, Iran), “A novel method for enhancing energy absorption capability by thin-walled sections during the flattening process”, Thin-Walled Structures, Vol. 97, pp 140-153, December 2015 DOI: 10.1016/j.tws.2015.09.013

ABSTRACT: This article introduces a novel method to enhance energy absorption capability of thin-walled sections subjected to the quasi-static lateral loading by performing the saw cutting process on simple closed sections with rectangular columns and shaping them into open sections. For this purpose, some simple closed-sectional columns with square and rectangular cross-sections of aluminum were prepared and used to produce different types of open sections with different geometries and lip lengths through the saw cutting process on a face of the columns. Different paths were selected and performed for the saw cutting to obtain six types of square open section and five types of rectangular open sections with different forms of lips. Lateral compression tests between two rigid platens were employed to obtain variations of lateral load and absorbed energy versus lateral displacement and to calculate specific absorbed energy by thin-walled open sections during the flattening process. For each type of rectangular open sections, two similar specimens were prepared and one of them was compressed along the shorter edge and the other one was tested along the longer edge of the cross-section. Also, as benchmarks, some simple specimens with closed section were compressed in the lateral direction to compare their results with energy absorption capacity by the corresponding open sections. Experimental results show that in all types of square and rectangular open-sections, lip length has significant effects on energy absorption
capability by the structure; and there is an optimum value for lip length of open section and the column with optimized length of the lips has the maximum absorbed energy. Furthermore, experiments reveal that rectangular open sections which are laterally compressed along their shorter edges absorb higher energy, in compression with the corresponding loaded specimens along the longer edges. Results show that maximum absorbed energy/mass belongs to a square open section of type A with rectangular lips and it is 2.68 times of the corresponding value of the similar closed section, as a valuable result.

Hsuan-Teh Hu and Pei-Jen Chen (Department of Civil Engineering, National Cheng Kung University, Tainan 701, Taiwan, ROC), “Maximization of fundamental frequencies of axially compressed laminated truncated conical shells against fiber orientation”, Thin-Walled Structures, Vol. 97, pp 154-170, December 2015
DOI: 10.1016/j.tws.2015.09.004
ABSTRACT: Free vibration analyses of laminated truncated conical shells subjected to axial compressive forces are carried out by employing the Abaqus finite element program. The fundamental frequencies of these truncated conical shells with a given material system are then maximized with respect to fiber orientations by using the golden section method. Through parametric studies, the influences of the end condition, shell length, shell radius ratio and the compressive force on the maximum fundamental frequencies, the associated optimal fiber orientations and the associated vibration modes are demonstrated and discussed.

ABSTRACT: In practical applications, the load bearing capability of slender plates can be affected by the existence of flaws resulting from a number of material deterioration (corrosion, fatigue, etc.). In the present work, a numerical analysis on the residual strength and post-buckling behavior of flawed shear panels using FE method is performed. Using a continuum damage mechanics model, the possibility for a ductile crack to grow under loading is considered. This approach allows us to investigate the role of crack growth in materials with different capabilities to accommodate plastic deformations at the crack tip, as well as geometry effect on the material crack resistance, due to loss of constraint. The effect on the buckling load, ultimate load and postbuckling response of shear panels varying both geometry characteristics and materials (such as initial crack length, slenderness ratio, panel boundary conditions, material properties, etc..) is investigated. Results indicate that crack growth can play a relevant role in the response of shear panels, especially for those materials in which ductile tearing can occur in the early stages of loading. The damage mechanics model used in this work offered the possibility to simulate the occurrence of ductile crack growth based on material properties, without the need of arbitrary assumptions on the crack advance process.

ABSTRACT: While plate girders with perforated web are commonly used in ships, aircraft applications for their high efficiency. In spite of numerous papers in the literatures on plate girders with perforated web subjected to web crippling, the ultimate capacity load of plate girders with perforated web subjected to plate buckling has not been exhaustively examined. In this study, experimental and numerical studies are performed to investigate the failure behavior of plate girders with perforated web under axial compression and bending moment, which is the typical action pattern arising from cargo weight and water pressure together with hull girder motions in ships and ship-shaped offshore structures. Six specimens with one oval hole are tested to investigate the failure modes and ultimate load capacities of plate girders with perforated web. Test results show that computational model can predict the failure behavior of plate girders with perforated web, and an extensive numerical study is conducted to investigate the influence of hole location. It showed that hole location have more influence on ultimate capacity load of plate girders when hole close to the middle of the web, particularly. Based on the experimental and numerical investigations, an influence curve is proposed to account for effects of hole location.

DOI: 10.1016/j.tws.2015.09.014

ABSTRACT: In this study, forced vibration behavior of thin-walled composite circular cylindrical shells is investigated using the spline finite strip method (spline FSM). Spline FSM is one of the versions of finite element method (FEM) employing a special element called finite strip. The shells considered in this study are assumed to be thin; therefore, the classical bending theory of shells and Sanders–Koiter's strain–displacement relation are used in the theoretical formulation of developed method. Time-history response of shells concerning arbitrary type of forces, boundary conditions and damping effects are obtained using developed spline FSM. To check the validity of results a comparison has been performed with the results obtained by conventional finite element method using ANSYS software. As far as the time history response of cylindrical shells is available the natural frequencies are extracted using Fast Fourier Transform (FFT) approach. The evaluated natural frequencies of composite shells are then compared with those obtained from an eigenvalue analysis. The comparison of results revealed the fact that developed spline FSM is an accurate tool that can be used in transient and harmonic analyses of composite laminated cylindrical shells.

ABSTRACT: This paper presents a finite element model of square and diamond bird-beak SHS T-joints under axial compression, which was verified by the corresponding test results. The parametric study was carried out to
reveal the failure modes and plasticity propagation of square and diamond bird-beak SHS T-joints. The effects of SHS brace to SHS chord width ratio ($\beta$), SHS chord width to 2 times thickness ratio ($\gamma$), and SHS brace to SHS chord thickness ratio ($\tau$) on the ultimate strengths of square and diamond bird-beak SHS T-joints were evaluated. The typical failure modes of square bird-beak SHS T-joints were obtained from the finite element analysis, which included Brace End Buckling (BEB) and Chord Face Failure (CF). The typical failure modes of diamond bird-beak SHS T-joints were obtained from the finite element analysis, which included Brace Bending (BB), Brace End Buckling (BEB)+Chord Face Failure (CF), Chord Face Failure (CF). The bird-beak T-joints with $\tau=0.6–0.8$ was recommend in the paper. The design equations are proposed by using multiple linear regression for square and diamond bird-beak SHS T-joints under axial compression based on the current design rules of traditional SHS T-joints given in the CIDECT. It is shown from the comparison that the joint strengths of square and diamond bird-beak SHS T-joints calculated using the proposed design equations agreed well with the finite element analysis results, which means the proposed design equations are verified to be accurate.

ABSTRACT: The behaviour and ultimate strength of locally damaged plate panels is investigated in this study. The damage is in the form of a local imperfection and represents a dent that could be caused by a fall or strike of an object. Panels are made of nine identical plates – three plates transversally and three longitudinally – and only one of the plates is damaged. The influence of several parameters has been studied to establish their interaction with the presence of the local dent. The main focus, is however the influence of the adjacent intact plates. The large panel is compared with smaller transverse model made of three plates and with a single plate model in order to evaluate the effects of adjacent plates and define the minimum size of the model necessary to obtain proper results.

ABSTRACT: This paper presents an analytical study to investigate the effect of flange–web interaction on local buckling of welded steel I-sections subjected to bending. An inelastic local buckling stability model is presented that accounts for all the geometric and material variables of the problem. The deformation theory of plasticity was used to describe the behavior of steel beyond the elastic limit. The model results were verified through comparison with finite element model results and published experimental ones. A parametric study was conducted to investigate the effect of flange–web interaction on the width to thickness limits. Using the parametric study results, new width to thickness limits were proposed in which all the parameters of the section are reflected.

ABSTRACT: Thirty-one tests under low velocity drop weight impact were carried out to examine the residual failure modes and the time history of the impact forces, global deformations and strains of concrete filled double steel tubular (CFDST) members in this paper. The parameters varied in the testing program include the column type (straight and tapered), the boundary conditions (simply supported and fixed), the axial load level and the impact energy. The results showed that all CFDST members behaved in a ductile manner and the residual deformation consisted of local deformation at the impact section, as well as the overall bending deformation. Compared to hollow double steel tubes, the CFDST members under the same applied impact energy demonstrate superior impact behavior in terms of higher energy absorbed, smaller global deformation and local deformation due to the interaction of the sandwich concrete and double skin steel tubes. The influence of key parameters on the dynamic resistance ability of CFDST is discussed.

ABSTRACT: This paper deals with the nonlinear thermal stability of composite plate with embedded and through-the-width delaminations under uniform temperature rise. The formulation is established within the framework of the higher order shear deformation theory by taking into account the von Karman geometrical nonlinearity. The thermomechanical properties of the laminates are assumed to be temperature-dependent. The nonlinear equilibrium equations derived by the minimum total potential energy principle, are solved using the Rayleigh–Ritz method along with the Newton–Raphson iterative procedure. For modeling the embedded and through-the-width delaminations, the plate is divided into a number of smaller regions. The proposed model is capable of analyzing both local buckling of the delaminated base laminate and sublamine as well as the global buckling of the plate. Numerical results are presented to provide an insight into effects of delamination type, size of delamination and boundary condition on the critical buckling temperature difference, buckling mode and postbuckling behavior of the composite plate. It is found that presence of delamination leads to substantial reduction in the load carrying capacity of the composite plate. Furthermore, the results reveal that the buckling mode could be changed depending on the delamination area.

ABSTRACT: At elevated temperature, behaviour of Class 1 to 3 open cross-section beams have been investigated experimentally and numerically, whereas for slender Class 4 sections only few experimental data have been collected. Due to the economic assumptions of members with Class 4 cross section and general validity of the existing design rules, further investigation is desired. This paper presents tests and numerical simulation of welded slender (Class 4) I-section beams at elevated temperature. The design of the test set-up, as well as progress of the experiments is presented. Detailed information about the geometrical data, measured geometrical imperfections, temperature, load and actual mechanical properties were collected. The tests were
subsequently used for a FE model validation. The described research allows better understanding to the fire behaviour of steel members of Class 4 cross-section beams.

DOI: 10.1016/j.tws.2015.02.026
ABSTRACT: The paper is focused on presenting the thermal and mechanical response of sinusoidal corrugated web beams subjected to high temperatures. Two tests were performed to monitor the behavior of isolated elements and composite slabs designed with corrugated web beams. Different aspect ratio beams exposed to standard fire temperatures and one beam subjected also to mechanical load were tested in the first experiment. The second study was conducted on a real-scale building compartment designed using corrugated web beams–concrete slab composite floor. The results obtained from experimental works reveal the real temperature distribution in the steel profile and the fire performance of sinusoidal corrugated web beams.

DOI: 10.1016/j.tws.2015.02.028
ABSTRACT: Web-post buckling behaviors of fully and partially protected cellular steel beams at elevated temperatures in a fire were investigated through verified finite element models. The partially protected cellular steel beam represented a protected cellular steel beam with the hole edge left unprotected. The temperature distribution in the web-post was non-uniform, even for the unprotected CSB and the fully protected CSB. The fire resistance time of a CSB increased linearly with the increase in fire coating thickness. However, for the partially protected cellular steel beam, the temperature gradient in the web-post becomes greater with the increase in the fire protection thickness. And with the increase in the fire protection thickness, the increment in the fire resistance time decreased. Additional thermal stress occurred due to the non-uniform thermal strain in the web-post. When web-post buckled, the principle compression stress in the web-post decreased suddenly. The stress at the center of the web-post could change from compression to tension due to the membrane action caused by the large buckling deformation.

ABSTRACT: This paper presents the results of a wide-ranging experimental research carried on the flexural behaviour of cold-formed steel beams subjected to fire. The main purpose of this work was to evaluate the influence of different cross-sections, especially of compound cold-formed steel sections, the axial restraint to the thermal elongation of the beam and the rotational stiffness of the beam supports. The results showed above all that the critical temperature of a cold-formed steel beam might be strongly affected by the stiffness of the surrounding structure depending on the relation between its stiffness and the stiffness of the beam.
ABSTRACT: This paper presents critical factors that influence the onset of local buckling in steel beams when exposed to fire conditions. A three-dimensional nonlinear finite element model, capable of accounting for critical factors that influence local instability in fire exposed steel beams is developed. This model is applied to investigate the effect of beam-slab interaction, strength properties (Grade) of steel, and presence of fire insulation on the onset of local instability, and resulting capacity degradation in fire exposed steel beams. Results from numerical simulations are utilized to evaluate failure of beams under different limit states including flexure, shear, sectional instability and deflection. These results infer that web instability can occur at early stages of fire loading, leading to faster degradation of shear capacity and premature failure of steel beams before attaining flexural capacity. Also, results from the analysis indicate that the contribution of concrete slab to shear capacity can counterbalance the adverse effect of web local instability to a certain degree. Overall, neglecting the effect of fire-induced web local instability can lead to unconservative design in steel beams or girder subjected to high shear loading and/or local instabilities.

ABSTRACT: The large deflection behaviours of axially restrained corrugated web steel beam (CWSB) at elevated temperatures were investigated using a finite element method. The web of studied CWSB adopted commonly used trapezoidal shape. The applicability of finite element model presented was validated against test results on the restrained flat web steel beam (FWSB) in a fire. Studied parameters of CWSB included the load ratio, the axial restraint stiffness ratio, the span-depth ratio, the corrugation shape of the web, the web thickness and the flange thickness. The evolutions of the vertical deflection, the axial force and the bending moment at mid-span of the CWSB with the elevated temperatures were presented. For the axial stiffness of a CWSB was smaller than that of a FWSB with the same dimension, the compressive force due to the restrained thermal elongation in a CWSB at elevated temperatures was lower than that in a FWSB. In addition, the CWSB went into the catenary action phase at a lower temperature compared with the FWSB with the same load and axial restraint stiffness ratio. The corrugation shape and the thickness of the web had very little influences on the catenary action behaviour of the restrained CWSB at elevated temperatures. Parameters that greatly affected behaviours of CWSB at elevated temperatures were the load ratio, the axial restraint stiffness ratio, and the span-depth ratio. With the increase in load ratio, the temperature at which the restrained CWSB went into catenary action phase decreased. The axial restraint stiffness and the span-depth ratio did not affect the temperature at which the restrained CWSB went into catenary action phase. However, with the increase in the axial restraint stiffness, the maximum axial force that the CWSB experienced increased and the temperature at which the maximum axial force was reached decreased. With the increase in the span-depth ratio, the maximum axial force the CWSB experienced and the temperature at which the maximum axial force was reached decreased.

“Distortional failure and DSM design of cold-formed steel lipped channel beams under elevated temperatures”, Thin-Walled Structures, Vol. 98, Part A, pp 75-93, January 2016, DOI: 10.1016/j.tws.2015.06.004

ABSTRACT: The aim of this paper is to report an ongoing shell finite element investigation on the distortional post-buckling behaviour, ultimate strength and DSM design of cold-formed steel single-span lipped channel beams under elevated temperatures due to fire conditions. The beam ultimate strengths are computed by means of a steady-state loading strategy that consists of applying an increasing major-axis uniform bending moment to a beam under a uniform and constant (elevated) temperature distribution, until failure is reached. The steel constitutive law at elevated temperatures is simulated by means of the stress–strain–temperature models prescribed in EC3-1.2 for cold-formed steel. The materially and geometrically non-linear response of the cold-formed lipped channel beam is determined through ANSYS shell finite element analyses that incorporate critical-mode (distortional) initial geometrical imperfections. Finally, since there are no specific rules to predict the bending strength of cold-formed steel beams failing in distortional modes at elevated temperatures, the above failure moments and temperatures are used to establish preliminary guidelines for the design of cold-formed steel lipped channel beams under fire conditions. The approach followed is based on the Direct Strength Method (DSM) and has been already employed by other researchers – the currently available design/strength equations/curves, developed for ambient temperature, are modified to account for the appropriate Young’s modulus and yield stress reductions due to the temperature increase. The results presented in the paper provide solid numerical evidence that the currently codified DSM distortional strength curve is not appropriate to predict beam failure moments at elevated temperatures. This is because it either (i) does not account for the material non-linearity due to the elevated temperature (low-to-moderate slenderness range) or (ii) is already inadequate to predict room temperature failure moments (unsafe estimates obtained in the high slenderness range).

ABSTRACT: When subjected to elevated temperatures, steel displays a reduction in both strength and stiffness, its yield plateau vanishes and its response becomes increasingly nonlinear with pronounced strain hardening. For steel sections subjected to compressive stresses, the extent to which strain hardening can be exploited (i.e. the strain at which failure occurs) depends on the susceptibility to local buckling. This is reflected in the European guidance for structural fire design EN1993-1-2 [1], which specifies different effective yield strengths for different cross-section classes. Given the continuous rounded nature of the stress–strain curve of structural steel at elevated temperatures, this approach seems overly simplistic and improved accuracy can be obtained if strain-based approaches are employed [2]. Similar observations have been previously made for structural stainless steel design at ambient temperatures and the continuous strength method (CSM) was developed as a rational means to exploit strain hardening at room temperature. This paper extends the CSM to the structural fire design of steel cross-sections. The accuracy of the method is verified by comparing the ultimate capacity predictions with test results extracted from the literature. It is shown that the CSM offers more accurate ultimate capacity predictions than current design methods throughout the full temperature range that steel structures are likely to be exposed to during a fire. Moreover due to its strain-based nature, the proposed methodology can readily account for the effect of restrained thermal expansion on the structural response at cross-sectional level. ABSTRACT: Thermal gradients often occur in fire exposed structures. This paper considers thermal gradients over the cross-section of steel columns. By means of finite element simulations, the paper demonstrates that these gradients reduce the flexural buckling resistance of the columns. This is due to the eccentricity in the column created by the temperature gradient. Design equations in modern standards provide a gross approximation of the load bearing resistance of such columns in which the eccentricity is ignored and in order to compensate for this the yield stress and modulus of elasticity are to be determined at maximum temperature. Based on an in-depth analysis of the results of the finite element simulations, this paper provides an alternative design model which much better agrees with the actual behaviour of a fire exposed column.

ABSTRACT: This paper presents the results of a numerical and analytical study of the load–deflection behaviour of thin-walled bolted plates under bolt shear at elevated temperatures. This paper first presents validation of the numerical simulation results against the high temperature tests carried out by Hirashima and Uesugi. The validated numerical model was then used to conduct an extensive series of parametric studies, in which the connection temperatures, material properties, geometries were changed, to generate a database of results to check the applicability of an analytical model previously developed by the authors for evaluating the load–deflection behaviour of this type of connection at ambient temperature. The results of this comparison indicate that the ambient temperature model can be applied to the elevated temperature condition if the ambient temperature mechanical properties of steel (Young’s modulus, yield stress, elongation) are replaced by those at elevated temperatures.

ABSTRACT: Based on the prior experimental studies on the 6 square hollow section stainless steel columns without axial constraints in fire, the fire resistance performance of stainless steel columns under axial compression was investigated in this paper. The numerical simulation and analysis of the performance of stainless steel columns relative to fire resistance were conducted by the finite element software ABAQUS. The effects of various parameters on the fire resistance performance of the stainless steel columns were studied, focusing on the initial defect amplitude, the load ratio and the length of the stainless steel columns. Referring to the structural fire design methods of stainless steel in the European Code (EN 1993-1-2) and the Euro Inox/SCI Design Manual, the new formulae for ultimate bearing capacity at elevated temperatures were fitted for the axially compressed stainless steel columns. The comparison of fitting results with test results and code results indicates that the fitting formulae are highly accurate and can predict the capacity and critical temperature of the axially compressed stainless steel columns in fire.

ABSTRACT: To study the bearing capacity and failure mechanism of a square stainless steel column in fire, a series of tests were performed on S30408 stainless steel, including 6 material mechanical property tests at room temperature, 16 material mechanical property tests at elevated temperature and fire experiments on 8 square sections of stainless steel columns. Steady tests at elevated temperature were performed to investigate the mechanical properties of stainless steel. The stress–strain curve, elastic modulus, yield strength and the
reduction factor of the ultimate strength of stainless steel at elevated temperature were determined, and the test results were compared with the European Codes. The experiments studied the properties of the square section stainless steel columns without axial constraints in fire, which were compressed axially and eccentrically. The failure phenomenon, heating curve, deformation curve and critical temperature of the specimens were obtained. The effects of the load ratio, section dimension and eccentricity on the critical temperature and fire-resistance performance of the stainless steel column were examined. The test results show that load ratio and eccentricity are the key factors for critical temperature and fire-resistance performance of the stainless steel column without axial constraints.

ABSTRACT: Failure modes of the thin-walled aluminum alloy column with irregular shaped cross section at ambient temperature and elevated temperatures in a fire were studied using a verified finite element model. The studied failure modes included the sectional yielding, interaction of local buckling and sectional yielding, interaction of local and global buckling, and global buckling. The finite element model was verified by experimental results from the ultimate strength, the failure modes and the failure deformation. Deformation shape along the column failed by different failure modes was presented. Stresses development at the middle span section was greatly affected by the failure modes. Ultimate strengths of a series of aluminum alloy columns with different length, cross section dimension were analyzed by the finite element analysis and current design codes at different temperatures in a fire. The current design codes greatly underestimated the ultimate strength of the thin-walled aluminum alloy column with irregular shaped cross section. Design method provided by EN1999-1-2 can give an accurate prediction of the ultimate strength of a short thin-walled aluminum alloy column with irregular shaped cross section at temperatures lower than 250 °C. A modification to the design method in EN1999-1-2 was proposed for predicting the ultimate strength of the aluminum alloy column with length longer than 500 mm and at temperatures higher than 250 °C. Ultimate strength predicted by the modified equation agreed well with finite element analysis results.

Lei Zhu, Shuo Han, Qiming Song, Limeng Ma, Yue Wei and Shuwen Li (School of Civil and Transportation Engineering, Beijing Higher Institution Engineering Research Center of Structural Engineering and New Materials, Beijing University of Civil Engineering and Architecture, Beijing, China), “Experimental study of the axial compressive strength of CHS T-joints reinforced with external stiffening rings”, Thin-Walled Structures, Vol. 98, Part B, pp 245-251, January 2016, DOI: 10.1016/j.tws.2015.09.029

ABSTRACT: This paper studies circular hollow section (CHS) T-joints by conducting experiments on the comparative axial compressive strength of unreinforced and reinforced T-joints. Three pairs of unreinforced and reinforced T-joints, a total of six specimens with the ratio of brace to chord diameter equal to 0.26, 0.51, and 0.74 respectively, were tested to determine their compressive load capacity. The specimen parameters, experimental setup, and test results are presented. The failure modes of the unreinforced and reinforced T-joints were compared. The unreinforced joints failed due to chord plastification, while the reinforced joints failed due to chord bending. The experiment indicated that the external stiffening ring significantly increased the axial compressive strength of the T-joints. Every reinforced joint behaved like a beam when loaded by concentrated force at the brace end; the strength of the reinforced joint can be predicted by calculating the plastic bending moment at the crown section.
Lu Wang, Weiqing Liu, Yuan Fang, Li Wan and Ruili Huo (College of Civil Engineering, Nanjing Tech University, Nanjing 211816, China), “Axial crush behavior and energy absorption capability of foam-filled GFRP tubes manufactured through vacuum assisted resin infusion process”, Thin-Walled Structures, Vol. 98, Part B, pp 263-273, January 2016, DOI: 10.1016/j.tws.2015.10.004

ABSTRACT: Foam-filled circular metallic tube has been widely used in safety design of automobile, spacecraft recovery and so on due to its advantage of high energy absorption. But poor chemical stability and easily oxidized of metal materials seriously threaten the durability and safety of the traditional metallic tube. The application of fiber reinforcement polymer (FRP) can effectively address these issues. In this paper, a simple and innovative foam-filled GFRP tube, fabricated by vacuum assisted resin infusion process, is proposed to enhance the durability and improve the energy absorption capacity. An experimental study was conducted to validate the effectiveness of this kind of absorber for increasing the energy absorption capacity. Meanwhile, the influences of GFRP skin thickness, diameter of tube, foam density and fiber orientation angle of GFRP mat on failure mode, initial stiffness, stroke efficiency and specific energy absorption were also investigated. An analytical model, considered the confinement effect on foam core and local buckling of GFRP skin, was also developed to predict the ultimate peak strength of foam-filled GFRP tubes. The experimental and analytical results were shown to be well matched.

ABSTRACT: This paper presents a finite element model of circular hollow section (CHS) brace-to-H-shaped chord T-joints under axial compression, which was verified by the corresponding test results. The parametric study was carried out to reveal the failure modes and plasticity propagation of tubular joints. The effects of CHS brace diameter to H-shaped chord flange width ratio (\(\beta\)), H-shaped chord flange width to thickness ratio (2\(\gamma\)), and CHS brace to H-shaped chord flange thickness ratio (\(\tau\)) on the ultimate strengths of tubular joints were evaluated. The typical failure modes were obtained from the finite element analysis, which include local buckling failure of CHS brace (LBFB), local buckling failure of flange and web of H-shaped chord (LBFF+LBFW), and local buckling failure of CHS brace and H-shaped chord flange (LBFB+LBFF). The validity range of main geometric parameters was recommended to be \(\beta \geq 0.7\), \(2\gamma = 20–30\), and \(\tau = 0.25–0.5\). The design equations are proposed by using multiple linear regression for CHS brace-to-H-shaped chord T-joints under axial compression based on the current design rules given in the Eurocode 3. Current Eurocode 3 is dangerous for predicting the ultimate strengths of CHS brace-to-H-shaped chord T-joints under axial compression. It is shown from the comparison that the joint strengths calculated using the proposed design equations agreed well with the finite element analysis results, which means the proposed design equations are verified to be accurate.

ABSTRACT: The paper describes the derivation of a beam finite element method which enables the effects of local and/or distortional buckling deformations to be accounted for. The development of local/distortional buckling reduces the rigidity of the section against axial straining, minor and major axis flexure, as well as twisting. The reduction in rigidity can be determined by an analysis performed prior to the frame analysis, in which tangent rigidities ((\(EA_t\)), (\(EI_z\)), (\(EI_y\)), (\(EI_w\))) and other tangential stiffness terms are obtained for increasing values of generalised strains (\(\varepsilon\), \(\kappa_z\), \(\kappa_y\), \(\kappa_w\)). The paper sets out the tangential stiffness matrix for a locally/distortional buckled element and discusses in detail the determination of tangent rigidities. The companion paper [1] shows that close agreement can be obtained between the beam analysis which incorporates reduced rigidities and analysis using full shell finite element discretisation. The paper is limited in scope to doubly-symmetric open sections.

ABSTRACT: The behavior of thin-walled dodecagonal section double skin concrete-filled steel tubes under bending was studied in this paper. Both experimental investigation and finite element analysis (FEA) were carried out. A total of 7 specimens were tested with the beam length of 2000 mm. The width to thickness ratio of the outer steel tube ranged from 75 to 133. The load–displacement curves, failure mode and ultimate capacity of test specimens were obtained. A finite element model was developed for the thin-walled dodecagonal section double skin concrete-filled steel tube subjected to bending. The FEA results were verified against the test results and parametric study was conducted using the verified model. In addition, the suitability of Han's method, Uenaka's method and proposed method for thin-walled circular section double skin concrete-filled steel tubes subjected to bending was also evaluated.

"Stability improvement of thin isotropic cylindrical shells with partially filled soft elastic core subjected to external pressure", Thin-Walled Structures, Vol. 98, Part B, pp 301-311, January 2016

DOI: 10.1016/j.tws.2015.09.028

ABSTRACT: Improvement of stability of thin isotropic shell in the presence of soft elastic filler has been investigated. Critical buckling loads for empty and filled cylinder have been studied both experimentally and theoretically using FE analysis. Various percentage of cross sectional filling are examined as a parametric variation. Nonlinear analysis with proper geometric imperfection modeling is carried out to represent correct behavior of soft elastic filler. The experimental results and FE analysis corroborate well to establish this improvement in buckling strength. It is observed that critical buckling load of the cylinder subjected to external pressure improves up to an extent of five times depending upon percentage of filling. It is concluded that improved strength can be utilized for more efficient design of thin tubular shells.

“Quasi-static, impact and energy absorption of internally nested tubes subjected to lateral loading”, Thin-Walled Structures, Vol. 98, Part B, pp 337-350, January 2016, DOI: 10.1016/j.tws.2015.11.001

ABSTRACT: This paper presents the responses of nested tube systems under quasi-static and dynamic lateral loading. Nested systems in the form of short internally stacked tubes were proposed as energy absorbing structures for applications that have limited crush zones. Three configurations of nested tube systems were experimentally analysed in this paper. The crush behaviour and energy absorbing responses of these systems under various loading conditions were presented and discussed. It was found that the quasi-static and dynamic responses of the nested systems were comparable under an experimental velocity of v=4.5 m/sec. This is due to insignificant strain rate and inertia effects of the nested systems under the applied velocity. The performance indicators, which describe the effectiveness of energy absorbing systems, were calculated to compare the various nested systems and the best system was identified. Furthermore, the effects of geometrical and loading parameters on the responses of the best nested tube system were explored via performing parametric analysis. The parametric study was performed using validated finite element models. The outcome of this parametric study was full detailed design guidelines for such nested tube energy absorbing structures.

ABSTRACT: This paper deals with the ultimate strength, post-buckling behaviour and design of cold-formed steel lipped channel beams affected by local-distortional buckling mode interaction, subjected to uniform bending of the major axis. The cross-sectional dimensions and length of the beams were chosen to have almost equal local and distortional critical buckling stresses by using the $G_{BTUL\beta}^2$ and CUFSM software. The beams are analysed under pinned with warping free end conditions. 12 sections were selected for this study. The selected sections satisfy the geometric limitations for pre-qualified sections in AISI-S100:2007. Elastic buckling and non-linear finite element analyses were carried out using ABAQUS. The results were compared with corresponding results from experiments available in the literature. The numerical parametric study of 60 analyses of different geometries and yield stress values was undertaken. Based on the comparison of ultimate strengths obtained from the finite element analysis and Direct Strength Method (DSM), a design equation is proposed for lipped channel sections which have their elastic local and distortional buckling moments nearly equal.

(2) IDMEC, LAETA, Department of Mechanical Engineering, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais, 1049-001 Lisbon, Portugal

ABSTRACT: This paper proposes a new approach to predict the web crippling failure load of cold-formed steel beams under External Two Flange (ETF) loading using the Direct Strength Method (DSM). After the description of the existing test data, Eurocode 3 (Comité Européen de Normalisation (CEN), 2006) [1] and the North-American Specification (American Iron and Steel Institute (AISI), 2012) [2] are used to predict the corresponding web crippling failure loads and the accuracy of such predictions is briefly assessed. In order to obtain additional information on the web crippling behaviour of each test specimen, non-linear numerical simulations are performed. Since the calibration of the DSM-based design expressions requires the previous calculation of (i) elastic buckling loads and (ii) plastic strengths/loads, two procedures are presented to achieve these goals. While the buckling loads are determined using the GBTWEB software, specifically developed for this purpose, the plastic loads are calculated by means of analytical expressions based on yield-line models. By adopting a non-linear regression procedure, the coefficients of a DSM-based formula are determined on the basis of the set of 128 experimental results available and the corresponding buckling and plastic load values. In spite of the different cross-sections, fastening conditions and test set ups considered in the calibration procedure, it is possible to establish a clear relationship between the web crippling slenderness and the nominal-to-plastic load ratio. Finally, it is shown that the developed/proposed DSM-based formula for ETF web crippling design yields reliable predictions, since they are associated with a LRFD (Load and Resistance Factor Design) resistance factor $\phi = 0.81$, which is located within the range of values currently adopted in the 2012 NAS (American Iron and Steel Institute (AISI), 2012) [2].

ABSTRACT: Buckling of flexurally anisotropic composite plates under combined loading is considered. The purpose of the paper is to develop approaches for predicting buckling loads for the plates, basing on buckling analysis results for separate loadings. Theoretical aspects of the problem are explored. The derivatives of the buckling interaction curves are analytically derived. The finite predicting formulae are proposed. The Galerkin-type numerical method for combined loading buckling analysis is developed. The method is based on buckling modes of separate loadings. Numerical examples are discussed. Convergence of the method is shown. Influence of the flexural anisotropy on the buckling behavior is demonstrated.

ABSTRACT: Shell buckling experiments are mostly conducted in a displacement controlled manner, that is the displacement at the loaded shell edge is increased and the load applied is measured as reaction force. The corresponding boundary conditions are realized by potting the shell edges. Real shell structures, such as primary structures of space launcher vehicles, are loaded in a load controlled manner and boundary conditions are defined by the adjacent structures and stiffening rings. Within this contribution, the discrepancy between boundary conditions and load introduction of full-scale built-in and sub-scale experimental shell structures of space launcher vehicles is studied numerically. For this purpose, dynamic explicit load controlled buckling analyses were performed using theoretical boundary conditions to idealize built-in conditions in an extreme manner and taking localized perturbations, such as those due to a single perturbation load, geometrical dimple imperfections and circular unreinforced cut outs, into account. The results are compared to displacement...
controlled shell buckling predictions in which boundary conditions commonly used within shell buckling experiments of sub-scale structures are taken into account.

ABSTRACT: This paper presents an analytical solution for calculating the critical buckling load of simply supported cellular columns when they buckle about the major axis. The solution takes into account the influence of web shear deformation on the buckling of cellular columns and is derived using the stationary principle of potential energy. The formula derived for calculating the critical buckling load is validated using finite element analysis results. It is shown from the present analytical solution that the web shear deformation can significantly reduce the buckling resistance of cellular columns. The influence of the shear deformation on the critical buckling load increases with the cross-section area of the tee section and the radius of circular holes but decreases with the length and the web thickness of the cellular column.

ABSTRACT: The present paper deals with a dynamic interactive response of FG beam-columns subjected to in-plane pulse loading when the shear lag phenomenon and distortional deformations are taken into account. The structures are assumed to be simply supported at the ends. In order to obtain the equations of motion of individual plates, the classical laminate plate theory (CLPT) has been modified in such a way that it additionally accounts for all components of inertial forces. Thin-walled trapezoidal FGM beam-columns are considered. A dynamic interaction of the global mode with the lowest primary local buckling mode and the secondary local mode has been analysed. Attention has been drawn to some unexpected aspects related to the fact that a two- and three-modal approach has been assumed in the analysis of dynamic interactive buckling.

ABSTRACT: This paper presents a comparative study and a 3D finite element (FE) model of square stirrup-confined concrete-filled steel tubular (stirrup-confined CFT) stub columns. The FE results agreed well with the experimental results. The results indicated that: (1) The ultimate load-bearing capacity of CFT stub columns with internal studs was no improvement; (2) All three forms of stirrup confinement effectively reduced local buckling of the steel tube, and the cross ties was optimal, followed by spiral stirrups; (3) With the same overall
steel ratio, the behavior of the square stirrup-confined CFT stub columns was considerably higher than in the square CFT stub columns.

ABSTRACT: In general, the calculation of ultimate load capacity (UL) of a concrete-filled steel tubular (CFST) column is based on the assumption that the load is resisted by both the steel tube and the concrete core simultaneously as a composite member. However, steel tubes of CFST columns are preloaded due to self-weight, wet concrete weight as well as temporary construction loads before the composite action is formed. There is still no consensus on how the preload affects the loading resistance of CFST columns and how to quantify the effect of preload on the ultimate strength.

The paper reported an experimental study on circular CFST columns subjected to preload. The testing results showed that the preloading effect increased with the increase of slenderness, decreased the ultimate load capacity and increased the deformation significantly at high preloading ratio, but did not have much influence on the ultimate load capacity at light preload. Then, a parametric analysis of coupled effects of preloading ratio with other parameters, such as slenderness ratio, eccentric ratio, as well as material properties, is presented. Finally, a simplified method is proposed to predict the ultimate load capacity of CFST columns with preload. The preloading reduction factor of simplified methods of UL based on regressive analysis can be used to evaluate the UL of CFST columns with preload after verified by overall comparison of total preloading tests.

ABSTRACT: The structural strength and stability of cold-formed steel Zee-section beam-columns including 22 structural Zee-sections at a length of 305 mm and 21 at a length of 1219 mm were tested under several load combinations of biaxial bending moments and axial force. This testing on Zee-section beam-column specimens complements an earlier test series on lipped channel specimens and provides an exploration of the impact of the principal axis configuration and the differing location of shear center for Zee-sections as relative to their location in lipped channels. The short length specimens are intended to mobilize local buckling and avoid distortional and global buckling, while the long length specimens are intended to mobilize other buckling modes such as distortional and local-global buckling. The combined axial force and biaxial bending moments were applied via a special test rig designed to apply axial load with eccentricities. The results were used to evaluate the current AISI-S100-12 specification for beam-column strength prediction via both effective width and direct strength methods. Both methods employ a simple linear interaction equation for strength prediction of the members under combined actions. The experimental results showed a considerable prospective for
improvement in the current specification approach by providing more optimized and realistic results in design considering the actual stress resulted from combined actions on the cross-section. Accordingly, the potentials for further improvements of the direct strength design method for cold-formed steel beam-columns are discussed.

ABSTRACT: This paper describes a series of shear tests of plate girders fabricated from steel plates with a nominal yield stress of 235 MPa for the web and 315 MPa for flanges. The ultimate shear strength and performance of end web panels with a single double-sided transverse stiffener at support of plate girders undergoing a significant tension field action were investigated experimentally and theoretically. According to shear test results, post-buckling strength in the shear buckling mode has a significant effect on the ultimate shear strength of end web panels of plate girders. Design shear strength formulae for the direct strength method (DSM) for end web panels of plate girders were developed based on shear test results. The results verify that DSM shear curves can accurately predict the ultimate shear strength of web panels of plate girders showing a significant post-buckling behavior in the shear buckling mode.

ABSTRACT: Steel–concrete–steel (SCS) sandwich wall infilled with ultra-lightweight cement composite has been developed and proposed for applications in offshore and building constructions. A new form of J-hook connector is introduced to connect the external plates to improve the composite action between the steel face plates and cement composite core to form an integrated unit which is capable of resisting extreme loads. This research experimentally investigates the structural behaviour of SCS sandwich composite wall based on a series of combined compression and uniaxial bending tests on short SCS sandwich composite wall with interlocking J-hook connectors. From the tests, it is found that the SCS sandwich wall exhibits good ductility behaviour with a bending failure mode. Nonlinear finite element (FE) model is also developed to simulate the mechanical behaviour of sandwich wall in terms of ultimate strength and load-deflection curves. Analytical studies show that the N–M interaction model based on Eurocode 4 may over-predict the combined resistance of the SCS sandwich walls subjected to eccentric compression. Therefore, a new approach is proposed to evaluate the resistance of sandwich wall. The axial force versus moment capacity interaction diagrams of sandwich wall are calculated. The validation against the test and FE results shows a reasonable and conservative estimation on the combined resistance of SCS sandwich wall.

ABSTRACT: This paper presents a finite element (FE) model, which is validated and developed to simulate the axial load behavior of an existing experimental composite wall consisting of double-skinned profiled steel sheet (PSS) in-filled with normal concrete. This type of wall is designed to resist the axial load in the composite structure buildings. The performance of three FE models, namely, PSS only, in-filled concrete only and full composite wall system (two PSS in-filled with concrete) are accurately compared with an existing experimental test. Then, the validated FE models are utilized to perform comprehensive parametric studies which presented information about the effect of the ECFS thickness, number of the ECFS, and ECFS shapes on the load resisting behavior of the composite wall. After comparing all FE models with Euro Code 4 (EC4), the results showed reasonable degree of accuracy.

ABSTRACT: Crush behavior of different arrangements of multi-tubes filled by functionally graded foams (FGF) are evaluated in this study. Our study shows that the energy absorption of FGF filled multi-tubes is higher than their equivalent multi-tubes filled by uniform foams. Also, the results show that the type of function employed for grading foam has significant effect on their crush response. In this study, multi-objective optimization was carried out using geometrical average and multi-design objective (MDO) methods. The results give new design ideas under axial loading to improve energy absorption performance of FGF foam-filled tubes.

ABSTRACT: The cylinder had been wide applications in the industry especially in mechanical and nuclear applications. The most common type of failure which may be happen in this type of structure was the buckling when was subjected to external hydrostatic pressure which represents the aim of this work. The buckling happen due to transfer major amount of strain energy into bending energy which leads to sudden failure in the structure at load less than the yield point. To avoid this type of failure the cylindrical shell stiffened by adding a stiffeners ring along the shell from internal or external surface. In this work two types of stiffeners existed, longitudinal and circumferential stiffeners based on the direction of the installation on the shell surface.

ABSTRACT: Dynamics of contact free (levitated) drying of nanofluid droplets is ubiquitous in many application domains ranging from spray drying to pharmaceutics. Controlling the final morphology (macro to micro scales) of the dried out sample poses some serious challenges. Evaporation of solvent and agglomeration of particles leads to porous shell formation in acoustically levitated nanosilica droplets. The capillary pressure...
due to evaporation across the menisci at the nanoscale pores causes buckling of the shell which leads to ring and bowl shaped final structures. Acoustics plays a crucial role in flattening of droplets which is a prerequisite for initiation of buckling in the shell. Introduction of mixed nanocolloids (sodium dodecyl sulfate + nanosilica) reduces evaporation rate, disrupts formation of porous shell, and enhances mechanical strength of the shell, all of which restricts the process of buckling. Although buckling is completely arrested in such surfactant added droplets, controlled external heating using laser enhances evaporation through the pores in the shell due to thermally induced structural changes and rearrangement of SDS aggregates which reinitializes buckling in such droplets. Furthermore, inclusion of anilinium hydrochloride into the nanoparticle laden droplets produces ions which adsorb and modify the morphology of sodium dodecyl sulfate crystals and reinitializes buckling in the shell (irrespective of external heating conditions). The kinetics of buckling is determined by the combined effect of morphology of the colloidal particles, particle/aggregate diffusion rate within the droplet, and the rate of evaporation of water. The buckling dynamics leads to cavity formation which grows subsequently to yield final structures with drastically different morphological features. The cavity growth is controlled by evaporation through the nanoscale pores and exhibits a universal trend irrespective of heating rate and nanoparticle type.

“Curvature-induced stiffness and the spatial variation of wavelength in wrinkled sheets”, Proceedings of the National Academy of Sciences of the United States of America (PNAS), Vol. 113, No. 5, February 2016
ABSTRACT: Wrinkle patterns in compressed thin sheets are ubiquitous in nature and technology, from the furrows on our foreheads to crinkly plant leaves, from ripples on plastic-wrapped objects to the protein film on milk. The current understanding of an elementary descriptor of wrinkles—their wavelength—is restricted to deformations that are parallel, spatially uniform, and nearly planar. However, most naturally occurring wrinkles do not satisfy these stipulations. Here we present a scheme that quantitatively explains the wrinkle wavelength beyond such idealized situations. We propose a local law that incorporates both mechanical and geometrical effects on the spatial variation of wrinkle wavelength. Our experiments on thin polymer films provide strong evidence for its validity. Understanding how wavelength depends on the properties of the sheet and the underlying liquid or elastic subphase is crucial for applications where wrinkles are used to sculpt surface topography, to measure properties of the sheet, or to infer forces applied to a film.

ABSTRACT: Crashworthiness performance of conical tubes with various thickness distributions are investigated in the present work. Specimens are fabricated by tube shrinking process and axial crushing tests are carried out to study their energy absorption characteristics. The potential and benefit of tube shrinking to improve crashworthiness performance of tubes are analyzed. Both thickness increase and material hardening during tube shrinking lead to up to 120% increase in energy absorption with even less structural mass. Although the peak force of tubes is increased after shrinking, the load uniformity is still improved due to larger increase in mean crushing force. Numerical simulations are also conducted for tubes with quadratic thickness distributions. The material hardening during fabrication is included and the numerical results compare well with experiment. In addition, crashworthiness optimization of conical tubes with nonlinear thickness distribution is performed by surrogate method. Influences of relevant thickness parameters on performance of the structure are analyzed.

ABSTRACT: This research work investigated the axial crushing behavior of a circular aluminum extrusion in alloy AA6063-T5 internally reinforced with a glass–fiber structure and filled with polymeric foam. The components were experimentally tested under quasi-static and impact loading conditions supported by a material testing campaign. Energy absorption, crush force efficiency and specific energy absorption were experimentally measured in order to assess the performance of a design proposal. Besides, the interaction effects between the different materials have been analyzed in depth and compared to the results for aluminum foam filled extrusions available in the literature. The confinement effect of the foam on the glass fiber plates has been found to have a very remarkable contribution to the energy absorption levels of the component, whereas a negligible foam–extrusion interaction was observed due to the gaps in the initial geometry of the specimen. The investigated component showed an overall good performance: the absorbed energy increased by almost 100% compared to an empty extrusion, the specific energy absorption was reduced by approximately 15% and the crush force efficiency was increased from 0.41 to 0.83.

ABSTRACT: Several recent developments have shown that introducing sinusoidal patterns on square section automotive crash absorber beams increased the energy absorption. This paper studies the behaviour of patterned circular tubes when used as crash absorbers. The effect of varying parameters of radial and longitudinal geometrical pattern frequency on internal energy absorption and energy absorption effectiveness factor is also studied in this work. Different types of patterns were simulated in axial impacts in which two geometrical pattern frequencies (radial and longitudinal) are multiplied. A numerical investigation was carried out using the commercially available LS-DYNA™ solver. The investigation was verified using existing analytical models. Results indicate that the circular sinusoidal patterned tubes behave better in energy absorption in axial impact. However, circular tubes have an altogether different collapse mode therefore the pattern formation has to be modified and optimized differently as compared to square beams. A new set of patterns named as CBC patterns is proposed in the study which increased the energy absorption of circular tubes significantly. An increase of about 36.86% in energy absorption is noted and energy absorbing efficiency factor is escalated from 2.23 to 3.05 in the best case. This research may further endorse the feasibility of using sinusoidal patterned tubes in mainstream engineering applications.

ABSTRACT: This study presents the buckling analysis of radially loaded solid circular plate made of porous material. Properties of the porous plate, where pores are assumed to be saturated with fluid, vary across its thickness. The boundary condition of the plate is assumed to be clamped and the plate is assumed to be geometrically perfect. The higher order shear deformation plate theory (HSDT) is employed to derive the governing equations. The equilibrium and stability equations, derived through the variational formulation and based on the Sanders non-linear strain–displacement relation, are used to determine the prebuckling forces and critical buckling loads. The results are compared with the buckling loads of circular plates made of porous material and reported in the literature based on the classical plate theory (CPT) and the first order shear deformation plate theory (FSDT).

ABSTRACT: In this paper, simplified mechanical models for the design of the top wind girder of large storage tanks adopted in the codes SH3046 and API650 were presented to show their differences regarding the wind load magnitude and action zone. Finite element models for the tanks were built to study the strengthening effects of the bottom constraints. It is found that for a large storage tank with a small ratio of height to diameter, the strengthening effects of the bottom constraints are significant and should not be ignored. If based on two-dimensional models without considering the strengthening effects of the bottom constraints, the strength design of the top wind girder according to the present codes of SH3046 or API650 is too conservative.

ABSTRACT: The research investigates the axial splitting of E-glass/vinylester and E-glass/polyester composite columns with identical perimeters but different cross sections on polygonal aluminum dies, and the elimination of restrictions on the initial slit in the classical splitting process. A novel technique for the construction of mandrels using polystyrene foam is developed. Composite columns are produced by winding the fiber fabric layers around the mandrels using coarse and fine E-glass woven fibers. The deformation modes and energy absorption behavior of columns during the long stroke of the splitting process are compared. The effects of the initial slits, various cross sections, side lengths, number of fiber fabric layers, resin type, fiber fabric type and angle of polygon dies on the splitting and curling of the structures are investigated. The results of this study reveal that alternating cross sections of columns may affect deformation modes and energy absorption parameters.

ABSTRACT: Vertical connecting plates exist in the panel zones of spatial moment frames, which are used to link beam webs in the perpendicular direction. However, current provisions take no consideration of their effect on the panel zone shear stability. This paper aims to evaluate the effect of vertical connecting plates on panel zone shear stability through experimental studies on cruciform beam-to-column subassemblages with/without connecting plates under cyclic loading. The connecting plates are found to be effective in mitigating the shear buckling potential of the panel zone and thus improving the hysteresis behavior of slender panel zones. Based on current seismic provisions, a modified approach for evaluating the panel zone shear stability through its equivalent width-thickness ratio is proposed and proved to be appropriate and on the conservative side.

ABSTRACT: This paper considers local buckling of perforated square aluminium plates. Plates of various slenderness with simply supported edges and subjected to uniaxial compression are studied using the finite element method. Different perforation patterns are investigated, from a single circular hole to 25 circular holes distributed over the plate. A number of aluminium alloys are considered and compared to steel grade A36. Results show that the resistance of the plates containing a single central cut-out is higher than that of plates with more holes and of equal total cut-out size. A further refinement beyond 5 holes does not influence the resistance.

ABSTRACT: Lateral buckling is a main failure mode controlling the strength of C- and Z-section purlins under wind suction, as the compressive flange of cross-section is laterally free in this case. The lateral buckling of roof purlins is different from the normally considered simply supported beams, because the top flange of cross-section of these purlins is laterally restrained due to the bracing of the above roof sheeting. To reveal the lateral buckling of C- and Z-section purlins with their top flanges horizontally restrained, two representative buckling theories for the lateral buckling of thin-walled beams, the traditional buckling theory and a new theory recently proposed by the authors of this paper, are adopted in this study. Comparisons made in this study indicate that the total potentials derived from these two theories have different expressions for the considered purlins. Subsequently, the finite element (FE) analysis using the shell element modeling is adopted to examine the buckling loads of purlins based on these two buckling theories, which indicates that the buckling theory
proposed by the authors of this paper is more reasonable for this problem. Simple solutions are also proposed for buckling loads of C- and Z-section purlins with their top flange horizontally restrained, and very good agreements are achieved in the comparisons between the predictions of the proposed solutions and FE results.

ABSTRACT: This paper presents a combined experimental, numerical, and theoretical study on the mechanical behaviors of track-shaped concrete-filled steel tubular (SCFRT) stub columns stiffened by rebars under compressive load. A total of 18 track-shaped concrete-filled steel tubular specimens including 12 specimens stiffened by rebars and 6 non-stiffened counterparts are tested, with consideration of parameters including flakiness ratio, concrete strength, and stiffeners. Failure pattern, bearing capacity, and ductility are all analyzed and discussed based on the experimental results. The numerical simulation by finite element (FE) software ABAQUS is also conducted. Based on both experimental and numerical results, theoretical formula to predict the load-bearing capacity of SCFRT stub columns subjected to axial compression loading is established according to the superposition principle of ultimate load-bearing capacity with rational simplification. The proposed theoretical method provides accurate predictions on the load bearing capacity by comparing with experimental results from 18 groups of specimens.

ABSTRACT: To facilitate accurate but conservative design of cellular beams for resistance against lateral–torsional buckling (LTB), this study proposes rational design guidelines based on General method of EC3. The inelastic LTB resistance was the subject of parametric studies using nonlinear finite elements, covering various loading configurations and geometric parameters of practical cellular beams. End moment and shear loadings were considered. The design resistance is slightly conservative in cases with complete LTB behavior that is generally found with non-dimensional slenderness exceeding 2.50. With short beams and shear loads LTB failure may interact with the local failures web-post buckling and web distortional buckling. However, combinations of LTB and Vierendeel failure were not observed. Concentrated stresses in the flange occur with short beams and moment loads, and these can degrade the LTB resistance. Due to interactions of the local failures in short beams, the design resistance requires a correction to ensure it is conservative. The key parameters affecting resistance include load configuration, section ratio, spacing ratio, and slenderness. All these parameters reflect shear effects, but section ratio and slenderness significantly influence the accuracy of the design results. Therefore, a correction factor based on these parameters is proposed, such that improves the EC3 accuracy by minimizing overestimation. The proposed LTB resistance design approach remains mostly conservative relative to both FE simulations and experimental results.

ABSTRACT: We present a detailed asymptotic analysis of the point indentation of an unpressurized, spherical elastic shell. Previous analyses of this classic problem have assumed that for sufficiently large indentation depths, such a shell deforms by ‘mirror buckling’ — a portion of the shell inverts to become a spherical cap with equal but opposite curvature to the undeformed shell. The energy of deformation is then localized in a ridge in which the deformed and undeformed portions of the shell join together, commonly referred to as Pogorelov’s ridge. Rather than using an energy formulation, we revisit this problem from the point of view of the shallow shell equations and perform an asymptotic analysis that exploits the largeness of the indentation depth. This reveals first that the stress profile associated with mirror buckling is singular as the indenter is approached. This consequence of point indentation means that mirror buckling must be modified to incorporate the shell's bending stiffness close to the indenter and gives rise to an intricate asymptotic structure with seven different spatial regions. This is in contrast with the three regions (mirror-buckled, ridge and undeformed) that are usually assumed and yields new insight into the large compressive hoop stress that ultimately causes the secondary buckling of the shell.

References listed at the end of the paper:

ABSTRACT: Buckling is characterized by a sudden failure of a structural member subjected to high compressive stress and it is a structural instability leading to a failure mode. One of the major design criteria of thin shell structures that experience compressive loads is that the buckling load limit. Therefore it is important to know about the Buckling loads. The buckling load of thin shell structures are dominantly affected by the geometrical imperfections present in the cylindrical shell which are very difficult to alleviate during manufacturing process. In this paper, two types of geometrical imperfection patterns are considered for cylindrical shells with and without dent. Analysis for all the cases is carried out and results are compared with theoretical results with ANSYS results .It is found that buckling strength of plain cylindrical shell is different compare to cylindrical shell having dents.

ABSTRACT: Buckling analysis is of fundamental importance for the design and sizing of aerospace structures. These structures, which are essentially reinforced-shells, are commonly modelled by combining, via fictitious links, one-dimensional (1D/beam) and two-dimensional (2D/shell) finite elements that are implemented in commercial codes. This approach, however, introduces various physical and geometrical inconsistencies. For example, the out-of-plane warping of the stringers and the transverse normal stress in the panel are not considered. In the present paper, a geometrically exact higher-order beam model able to correctly characterize the three-dimensional strain/stress field is proposed for the accurate buckling analysis of reinforced aerospace structures. The proposed theory is based on the Carrera Unified Formulation (CUF), which, by employing a recursive index notation, allows to write the governing equations and the related finite element arrays of arbitrarily refined beam models in a very compact and unified manner. In fact, according to CUF, the three-
dimensional displacement field is expressed as a generic expansion of the primary mechanical variables by arbitrary functions of the cross-section coordinates. Namely, in this work, higher-order Lagrange polynomials are employed to formulate advanced beam theories in a hierarchical manner. The proposed models are referred to as Component-Wise (CW) because Lagrange polynomials are used to model the displacement variables in each structural component (i.e., stringers, panels, ribs, etc.) at the cross-sectional level. In a finite element framework, this means that different components are modelled using the same 1D finite element. By using the principle of virtual displacements and by considering the complete 3D stress field in formulating the geometrical stiffness, linearized buckling analysis of metallic, composite and reinforced panels as well as complex aerospace structures assemblies are investigated by CW models. Critical loads are also found as zero-frequency modes from vibration analysis of pre-stressed structures. Various boundary conditions and loadings are considered, including compression, combined traction/compression, and bending loads. The results, which are compared to those from the literature and commercial FEM tools, provide good confidence and widely demonstrate the high accuracy and numerical efficiency of the CW models when applied to buckling.

ABSTRACT: Modern composite materials and lightweight construction elements are increasingly replacing classic materials in practical applications of mechanical and civil engineering. Their high prevalence creates a demand for calculation methods which can accurately describe the mechanical behavior of a composite structure, while at the same time preserving moderate requirements in terms of numerical cost. Modeling the full microstructure of a composite by means of the classical finite element method quickly exceeds the capabilities of today’s hardware. The resulting equation systems would be extremely large and unsuitable for solution due to their enormous calculation times and memory requirements. Homogenization methods have been developed as a remedy to this issue, in which the complex microstructure is replaced by a homogeneous material using averaged mechanical properties that are determined via experiments or by analytical or numerical investigation. However, classical homogenization methods usually fail as soon as nonlinear system behavior is introduced and the effective properties, which are presumed to be constant, begin to change during the course of a simulation. In this work, a coupled global-local method will be presented specifically for sandwich panels with axially stiffened or honeycomb cores. Herein, a global model, in which the complete structure is discretized with standard shell elements, is coupled with multiple local models, describing the microstructure of the sandwich throughout the full thickness coordinate and using shell elements for discretization as well. The local formulation is implemented by means of a constitutive law for the global model, so that one local boundary value problem is evaluated in each integration point of the global structure. By reevaluating the local models in every iteration step in a nonlinear simulation, physical and geometrical nonlinearity can be described. For instance, it will be shown in numerical examples that elasto-plastic material behavior and pre- and postcritical buckling behavior can be described, contrary to most classical homogenization methods. Next to the derivation of theoretical fundamentals and the introduction of the coupled method as well as several numerical examples, additional chapters are detailing some issues concerning mesh generation and the implementation of a high-bandwidth data interface between global and local models.

ABSTRACT: Various manufacturing techniques exist to produce double-curvature shells, including injection, rotational and blow molding, as well as dip coating. However, these industrial processes are typically geared for mass production and are not directly applicable to laboratory research settings, where adaptable, inexpensive and predictable prototyping tools are desirable. Here, we study the rapid fabrication of hemispherical elastic shells by coating a curved surface with a polymer solution that yields a nearly uniform shell, upon polymerization of the resulting thin film. We experimentally characterize how the curing of the polymer affects its drainage dynamics and eventually selects the shell thickness. The coating process is then rationalized through a theoretical analysis that predicts the final thickness, in quantitative agreement with experiments and numerical simulations of the lubrication flow field. This robust fabrication framework should be invaluable for future studies on the mechanics of thin elastic shells and their intrinsic geometric nonlinearities.

ABSTRACT: The non-linear dynamic analysis of continuous systems, such as thin plates and shells, is a problem of relevance in many engineering fields. The finite element method is the most used approach for nonlinear dynamic analyses of these structures. However, the computational effort is very high. As an alternative to complex numerical approaches, analytical methods using simplified models can be successfully used to understand the main nonlinear features of the problem and may constitute efficient tools in the initial design stages. For plates and shells, the derivation of efficient reduced order models is in fact essential due to the complex nonlinear response of these structures. The usual procedure is to reduce the partial differential equations of motion of the continuous system to an approximate system of time-dependent ordinary differential equations of motion, which are in turn solved by numerical methods or, approximately, by perturbation procedures. However, the use of inappropriate modal expansions usually leads to misleading results or may require a rather large number of terms. The aim of the present work is to show how the application of a perturbation analysis together with the Galerkin method can be used to derive precise low order models for plates and shells, by capturing the influence of modal couplings and interactions.

ABSTRACT: The stiffened panels are often forming less thin wall. Consequently, the dynamic buckling is a major challenge to be addressed in the quest to increase the strength-to-weight ratio. Stiffened are subjected to various loading conditions can be static or dynamic, as they may suffer from degradation of the material and initial geometric distortions due to the welding assembly process used. Buckling of structures subject to sudden dynamic impulse load can be analyzed without detour to the approach based on the equations of motion. In this approach, which can be easily adapted to the methods of calculation using the finite element method, the motion equations are solved for various values of the parameters defining the loading. The value of the load parameter for which there is a big change in the response then defines the critical load according Budiansky and Roth criterion.

In this work, dynamic buckling of stiffened panels is analyzed numerically through a nonlinear incremental formulation using explicit time integration procedure under Abaqus software package. The dynamic buckling state is recovered from the curve giving the end-shortening as function of time when the structure is subjected to a compressive rectangular pulse loading applied parallel ally to the stiffeners direction. Fixing the pulse duration and the initial distortion magnitude as well as the ratio of material degradation in the heat affected zone, the dynamic buckling load was identified for each given configuration. This process has enabled the derivation of a response surface model which was used with Monte Carlo method to determine reliability of the stiffened panel with regards to the dynamic buckling state.

ABSTRACT: Thin shells made of high modulus material are widely used as lightweight deployable space structures. The focus of this chapter is the most basic deployable thin shell structure, namely a straight, transversely curved strip known as a tape spring. Following a review of the materials used for the construction of deployable thin shell structures, including constitutive models and failure criteria developed specifically for this type of structures, this chapter provides an introduction to the mechanics of tape springs and tape spring hinges. Finite element techniques to model deployable structures containing tape springs are presented and the ability of these models to accurately simulate experimentally observed behavior is demonstrated. These tools can be used to design structures able to achieve specific behaviors. As an example, the design of a two-hinge boom that can be wrapped around a small spacecraft without any damage, and can dynamically deploy and smoothly latch into the deployed configuration is presented.

ABSTRACT: Stiffened panels are basic building blocks of weight sensitive structures. Design of laminated composite stiffened panels is more involved and requires the use of an optimization approach, which needs a computationally efficient analysis tool. This paper deals with the development of an analytical and computationally efficient analysis tool using artificial neural networks (ANN) for predicting the buckling load of laminated composite stiffened panels subjected to in-plane shear loading. The database for training and testing is prepared using finite element analysis. Studies are carried out by changing the panel orthotropy ratio, stiffener depth, pitch length (number of stiffeners). Using the database, key parameters are identified and a
neural network is trained. The results show that the trained neural network can predict the shear buckling load of laminated composite stiffened panels accurately and will be very useful in optimization applications where computational efficiency is paramount.

ABSTRACT: Thin-walled tubes are widely used as energy absorption components. In this study, two different origami patterns were introduced to circular tubes. The influence of the origami patterns on the energy absorption capacity and the deformation mechanism of tubes under uniaxial loading were investigated both numerically and experimentally. The results showed that the initial peak force of origami tubes would be significantly reduced, while the energy absorption capacity could be improved or maintained. Brass tubes with and without origami patterns were fabricated using 3D printing and were tested to validate the finite element models.

ABSTRACT: The paper presents a theory of inelastic column buckling which is consistent with the principles of plastic flow theory. The theory accounts for flexural, torsional and flexural-torsional modes. While the use of the tangent modulus to describe inelastic flexural buckling has been common place for a long time, efforts to comprehensively unite the torsional and flexural-torsional modes with the principles of plastic flow theory have so far been hampered by the ‘plastic buckling paradox’. New theoretical developments presented in this paper provide a way to achieve this goal. The solution hinges on the derivation of the inelastic shear stiffness while considering an infinitesimal solid element embedded within the column at a stage immediately past the point of buckling. The proposed inelastic column theory is verified against selected experimental data pertaining to aluminium and stainless steel columns of various cross-sections. Particular attention is paid to the torsional buckling problem of the inelastic cruciform section column.

ABSTRACT: The transverse impact on a pipeline caused by a dropped anchor is among the main factors resulting in submarine pipeline failure. The impact could cause leakage of the pipeline, resulting in a huge environmental disaster and heavy economic losses. To investigate the deformations of a pipeline impacted by dropped anchors, a three-dimensional numerical method, known as the local Galerkin discretization method for shell structures, is developed under the condition of a rigid bed. The method has the advantages of higher-order
resolution and low computational cost. Small-scale model experiments were then carried out. Different bed conditions were considered, including rigid ground and ground covered by sandy soil. The dent depths of the pipes after the impacts were measured to study the pipeline deformations. The dent depths estimated by the local Galerkin discretization method were compared with the results of the experiment, which showed good consistency. The Galerkin numerical simulation method can also be applied to other pipe impact situations.

Godoy (Institute for Advanced Studies in Engineering and Technology, Science and Technology Research Council (CONICET) and Universidad Nacional de Córdoba, FCEFyN, PO Box 916, Correo Central, Córdoba 5000, Argentina), “Buckling of vertical oil storage steel tanks: Review of static buckling studies”, Thin-Walled Structures, Vol. 103, pp 1-21, June 2016, DOI: 10.1016/j.tws.2016.01.026

ABSTRACT: Research on the structural behavior and buckling of vertical, aboveground tanks employed to store oil and fuels have significantly increased during the past two decades. Interest in this shell form is related not just to the cost of the infrastructure, but also because failures in cases of accidents or natural disasters may cause huge economic, environmental and social losses. This review concentrates on buckling problems of such tanks under static or quasi-static loads, including uniform pressure, wind, settlement of foundation, and fire. In all cases, buckling is considered as a static process. Attention is given to the load definition in each case, followed by buckling studies under previously defined pressures or temperatures. The structural configuration of tanks is first described in order to understand what is specific about this structural form. Next, the theoretical framework for stability and buckling is briefly described to place each contribution in a wider context. Each loading case is first explained, experiments or case-studies are briefly described, and computational analytical modeling is reviewed; finally, efforts towards improving design are mentioned. Most papers published in the literature have been motivated by wind effects on tanks, but the review shows that other areas, such as thermal buckling under an adjacent fire, are currently receiving increasing attention.

ABSTRACT: This paper presents an analytical solution to predict the nonlinear forced vibrations of elastic thin-walled cylindrical shells under suddenly applied loads. Interest in this problem is motivated by effects due to explosions on fluid-storage metal tanks. The model is based on the energy criterion due to Lagrange, in which the kinematic nonlinear relations are assumed using Donnell's simplified shell theory. Solution is achieved as a series summation in terms of trigonometric functions in the axial and circumferential directions, whereas the degrees of freedom depend on time. A blast load is assumed to represent effects due to explosions on the shell as time-dependent pressures with a given circumferential distribution (a cosine square distribution in terms of the central angle). The procedure is validated by comparison with a nonlinear finite element model under the same load conditions. The influence of load level and shell geometry on the transient response is investigated by mean of parametric studies. Good accuracy is found in the results for the range of shells which are representative of horizontal, fuel storage tanks in the oil industry.

ABSTRACT: Starting from an Airy stress function in plane strain a new solution is presented for the buckling of plates on elastic foundations with in-plane loading. Saint Venant's Principle is shown to play an important part in plate buckling behaviour when ‘deep’ foundations are present. Results are compared with those from Winkler's and Pasternak's models and they demonstrate that, provided certain restrictions are satisfied, the latter can give reasonably accurate results.

ABSTRACT: To date, despite the significant development in the field of structural mechanics, there still remains a paradox in the solutions available for a classical shell buckling problem. The difference in strength between a cylindrical shell under uniform axial compression and that under pure bending is not quite well investigated. This lack of research is reflected in the wide variations in the elastic bending strength given in current international design standards. This paper presents a theoretical treatment of the stability of unstiffened thin cylinders under pure flexure. The results of the theory are in good agreement with experimental findings. The theoretical results confirm the classical 40% increase in bending strength over axial strength. The current design rules for thin-cylinders are compared, and a newly derived design method is proposed.

ABSTRACT: An efficient technique of Carbon Fiber Reinforced Polymer (CFRP) application was proposed to promote joint capacity of general tubular K-joints fabricated from Circular Hollow Section (CHS) members. Using this technique, in order to understand the static performance of CFRP-strengthened CHS joints, a systematic investigation was carried out by means of both experiments and finite element method. Three CHS gap K-joints strengthened with CFRP sheets were tested under static axial force in braces, whilst one additional joint was served as reference joint without CFRP. The results of failure modes, deformation, Mises stress, strain intensity and load-bearing capacity of the joints were presented and compared. A series of finite element models were developed and validated for the joints with and without CFRP reinforcement. A parametric study was conducted to evaluate the effect of variables (length, layers and mechanical properties of CFRP) on load-bearing capacity. The research results revealed that the proposed technique of CFRP installation was efficient to promote performance of in-service CHS gap K-joints. Moreover, the layer of CFRP sheets has significant effect on load-bearing capacity, but the effect was negligible for either length or mechanical properties of CFRP sheets. Finally, formulas were proposed for calculating ultimate load-bearing capacity of CHS gap K-joints with CFRP composites, and their calculation results matched well with the experimental and numerical results respectively.

ABSTRACT: In this study, the crashworthiness behavior of the tapered multi-cell tubes is theoretically and numerically investigated. The side wall tapering and the cross section dividing into the cells are used in order to improve the energy absorption of the thin walled structure. In order to estimate the non-constant mean crush load of the tapered multi-cell tubes, incorporating the theoretical relations on the energy absorption of the simple multi-cell and tapered single-cell tubes, in conjunction with numerical results, would lead to the development of the analytical formula. The analytical formula is based on the mean crush load calculation of the equivalent segmented simple multi-cell tubes. In order to prepare a realistic finite element model, the elastic–plastic-damage material assumption is introduced into the numerical simulation. The numerical predictions of the mean crush load are consisted with experimental data in literature. The results reveal that the increase of the taper angle, the wall thickness and the number of cells in the cross section would enrich the crashworthiness capacity of the structure. The results indicate that the crashworthiness improvement rate of the structure with number of cells in the cross section is decreased in such a way that the variation of the energy absorption efficiency in the thin walled structure with the 8×8, 9×9 and 10×10 cells in the cross section would
be negligible. The transition wall thickness in which the crashworthiness of the tapered multi-cell structure transits from thin to thick walled behavior are determined.

“Finite element limit load analysis of thin-walled structures by ANSYS (implicit), LS-DYNA (explicit) and in combination”, Thin-Walled Structures, Vol. 41, Nos 2-3, pp 227-244, February 2003,
DOI: 10.1016/S0263-8231(02)00089-7
ABSTRACT: After discussing general properties of implicit FE analysis using ANSYS and explicit analysis using LS-DYNA it is shown when and how quasi-static limit load analyses can be performed by a transient analysis using explicit time integration. Then we focus on the remaining benefits of implicit analysis and how a proper combination of ANSYS and LS-DYNA can be used to prepare the transient analysis by common preprocessing and static analysis steps. Aspects of discretization, solution control, consideration of imperfections and methods of checking the results are outlined.

“Theoretical prediction and optimization of multi-cell hexagonal tubes under axial crashing”, Thin-Walled Structures, Vol. 102, pp 111-121, May 2016, DOI: 10.1016/j.tws.2016.01.023
ABSTRACT: In this paper, the analytical formulas of mean crashing force for four different hexagonal tubes with multiple cells were first derived based on the Simplified Super Folding Element (SSFE) theory through several typical constituent elements: corner element, three-panel angular element I and three-panel angular element II. The numerical simulations of hexagonal multi-cell configurations were then correlated with the derived analytical solutions. Finally, both analytical formulas and finite element analysis (FEA) based surrogate models were employed to optimize the cross-sectional dimensions of the hexagonal tubes. From the optimization results, web-to-web (W2W) is the most efficient configuration in improving the crashing behavior, while corner-to-corner (C2C) is the worst of these four configurations. Importantly, the Pareto fronts obtained from the analytical formulas agree well with those from the FEA based surrogate models. As a result, analytical formulas could be recommended in crashworthiness optimization for the sake of computational efficiency.

“Application of high strength and ultra-high strength steel tubes in long hybrid compressive members: Experimental and numerical investigation”, Thin-Walled Structures, Vol. 102, pp 273-285, May 2016,
DOI: 10.1016/j.tws.2016.02.002
ABSTRACT: With the increasing application of high strength steel material in industries, there is a high potentiality for taking advantage of the exceptional load-bearing capacities of this material in construction
practice. In the present study, an innovative application for high and ultra-high strength steel material is proposed which enhances the overall behavior of structural elements. The high strength and ultra-high strength steel with nominal tensile strengths of 750 MPa and 1250 MPa, respectively, are proposed to be utilized as tube elements welded to corners of mild steel plates shaping an innovative hybrid section. This section takes advantage of the combined material properties of the two constituting elements in terms of strength, local buckling behavior and ductility. Large-scale tests and numerical analysis have been conducted to compare the behavior of the proposed sections against conventional welded sections. The effect of heat on the material properties of the hybrid section has also been considered. These effects are included in the finite element modeling of innovative columns where numerical outputs have been verified accordingly.

Tao Tang, Weigang Zhang, Hanfeng Yin and Han Wang (State Key Laboratory of Advanced Design and Manufacture for Vehicle Body, Hunan University, Changsha, Hunan 410082, PR China), “Crushing analysis of thin-walled beams with various section geometries under lateral impact”, Thin-Walled Structures, Vol. 102, pp 43-57, May 2016, DOI: 10.1016/j.tws.2016.01.017

ABSTRACT: Due to the advantages of light weight and excellent energy absorption capacity, thin-walled beams are widely used as strengthen parts or energy absorbers in vehicle body. Thus, the collapse behaviors and mechanical properties of thin-walled beams under the static and dynamic loadings have drawn great attentions of the researchers. In vehicle side crash accident, the contact parts of the vehicle usually deformed in bending mode. Thus, it is significantly important to investigate the bending collapse behaviors of these parts. In this study, the bending behaviors of several thin-walled beams with simple cross section subjected to lateral impact were investigated using analytical and numerical methods. The crashworthiness parameters such as energy absorption ($EA$), average crash force ($F_{avg}$), peak crash force ($F_{max}$) and crash force efficiency ($CFE$) were employed to evaluate the bending resistant property. In order to study how geometry shapes affect the bending performance, the main geometry parameters such as radius/radius ratio of circular/elliptical section, side length ratio of rectangular section, height and base angle of hat section were chosen as the design parameters. After investigating the beams with simple cross sections, some new beams with complex cross sections were constructed by combing these simple beams or adding reinforce ribs to these simple beams. Then, the bending performance of these new beams was studied by numerical simulation and compared with original section beams. Result shows that the section type b performs better in $SEA$ and $CFE$ than original simple section beams. It also can be concluded that adding ribs can greatly improve the bending resistant performance for circular, rectangular and hat section beams, and the vertical ribs can achieve the best reinforce effect for the circular and rectangular section beams.

ABSTRACT: This paper presents a novel thin-walled tube design with a pre-folded kite-shape rigid origami pattern as an energy absorption device. Numerical simulation of the quasi-static axial crushing of the new device shows that a smooth and high reaction force curve can be achieved in comparison with those of conventional square tubes, with an increase of 29.2% in specific energy absorption and a reduction of 56.5% in initial peak force being obtained in the optimum case. A theoretical study of the energy absorption of the new device has also been conducted, which matches reasonably well with the numerical results.
ABSTRACT: Thin-walled tubes are widely used as energy absorbers. In this study, we evaluated the energy absorbing behavior of empty and aluminum metal foam-filled tubes with different taper angles (0°, 5°, 10°, and 15°) by using the Finite Element Method (FEM)/Smooth Particle Hydrodynamics (SPH) with the Feed forward Neural Network (FNN). Within the scope of the study, tubes composed of AL6061 and AISI1018 materials were designed by using three different weld locations (L0/L=0.25, L0/L=0.50, and L0/L=0.75). In the welded tubes, the thickness of the lower part (AISI1018) was held constant (1.5 mm), while the thickness of the upper part (AL6061) and the foam density of the filler material were variable (0.5–2.5 mm and 100–800 kg/m³, respectively). Based on the analysis of the study results, it was determined that empty and foam-filled tubes with a 5° taper angle exhibited the best energy absorbing behavior. In addition, we also determined the optimum upper part thickness and foam density for obtaining the minimum peak force (Fpeak) and maximum specific energy absorption (SEA) values.

Francesco Tornabene, Nicholas Fantuzzi and Michele Bacciocchi (DICAM – Department, School of Engineering and Architecture, University of Bologna, Italy), “Higher-order structural theories for the static analysis of doubly-curved laminated composite panels reinforced by curvilinear fibers”, Thin-Walled Structures, Vol. 102, pp 222-245, May 2016, DOI: 10.1016/j.tws.2016.01.029
ABSTRACT: The main aim of this paper is the evaluation of the through-the-thickness profiles of strain, stress and displacement components of several doubly-curved panels reinforced by curvilinear fibers. The placement of the reinforcing phase along curved paths allows to obtain mechanical properties which change point by point and affects the static behavior of shell structures. Some numerical applications based on both higher-order Equivalent Single Layer (ESL) and Layer-Wise (LW) theories are shown in order to underline the curvilinear fiber influence on the static analysis. The structural model, which is based on the so-called Carrera Unified Formulation (CUF), is completely general and can deal easily with variable stiffness shells. An appropriate recovery procedure based on the three-dimensional elasticity equations in principal curvilinear coordinates is presented to compute strains and stresses. The equation system which governs the static problem under consideration is solved numerically through the Generalized Differential Quadrature (GDQ) method. The same numerical technique is employed to evaluate the geometrical parameters needed for the characterization of the shell reference surface, according to the differential geometry.

W. Hamouche, C. Maurini, A. Vincenti and S. Vidoli (Institut Jean Le Rond d’Alembert, Sorbonne Universités, UPMC Univ Paris 06, CNRS, UMR 7190, 4 place Jussieu, 75005, Paris, France), “Basic criteria to design and produce multistable shells”, Meccanica, pp 1-16, First online 02 February 2016, DOI: 10.1007/s11012-016-0375-5
ABSTRACT: A shell can have multiple stable equilibria either if its initial curvature is sufficiently high or if a suitably strong pre-stress is applied. Under the hypotheses of a thin and shallow shell, we derive closed form results for the critical values of curvatures and pre-stresses leading to bistability and tristability. These analytical expressions allow to easily provide guidelines to build shells with different stability properties.

Michael Imburgia and Alfred Crosby (University of Massachusetts, Amherst, MA, USA) “Rolling wrinkles on elastic substrates”, Abstract ID BAPS.2016.MAR.P40.1

ABSTRACT: The mechanics of rolling contact between an elastomer layer and a thin film present unique opportunities for taking advantage of elastic instabilities, such as surface wrinkling, to create patterned surfaces. Here we present a plate-to-roll(P2R) geometry to laminate a thin film onto an elastomer layer in order to induce surface wrinkling. First, a poly(dimethylsiloxane)(PDMS) layer is draped around a roller and pressed into contact with a poly(styrene)(PS) film supported on a plate. Once rolling begins, the PS film preferentially laminates onto the PDMS layer. During this process, the deformation of the PDMS layer can induce wrinkling when the contact load exceeds a critical value. Wrinkle feature size consists of amplitudes of $0.2-4 \mu m$ and wavelengths of $15-20 \mu m$. Wrinkle amplitude can be controlled by contact load and roller curvature, as well as the mechanical properties and thickness of the film and elastomer. We develop semi-empirical equations to describe the effect of contact load and roller curvature on the wrinkle aspect ratio. Finite-element modeling of
an elastomer layer in rolling contact with a rigid plate is used to support experimental results. Using these models, wrinkle-based technologies such as optoelectronics and enhanced adhesives can be envisioned.

“Poking around: how indentation reveals wrinkly isometries”, Abstract ID BAPS.2016.MAR.P40.2

ABSTRACT: When deforming extremely thin objects, deformation via stretching is relatively expensive. It is therefore natural to seek deformations that preserve lengths, or isometries. Two common examples of such isometries in mechanics are the ‘d’-cone (for a plate) and ‘mirror buckling’ (for a shell). I will show two examples for which the presence of a weak tension means that these isometries are not obtained experimentally. Instead, the systems in question wrinkle and tend to new ‘wrinkly isometries’: isometries that are only available to a wrinkled object.

ABSTRACT: A thin film confined to a liquid interface responds to uniaxial compression by wrinkling, and then by folding, that has been solved exactly before self-contact. Here, we address the mechanics of large folds, i.e., folds that absorb a length much larger than the wrinkle wavelength. With scaling arguments and numerical simulations, we show that the antisymmetric fold is energetically favorable and can absorb any excess length at zero pressure. Then, motivated by puzzles arising in the comparison of this simple model to experiments on lipid monolayers or capillary rafts, we discuss how to incorporate film weight, self-adhesion, or energy dissipation.

“Geometry-driven folding transitions in floating thin films”, Abstract ID BAPS.2016.MAR.P40.3

ABSTRACT: When a thin elastic sheet is compressed, it forms wrinkles to gather excess material, while deforming the fluid or solid substrate by only a small amount. Upon further compression, the sheet may fold, in order to lower the mechanical energy of the system. Here we demonstrate a folding transition that is independent of the mechanical properties of the sheet. We study the deformations of a thin polymer film that has an annular shape, floating on a planar air-water interface. By controlling the concentration of a surfactant outside the film, we vary the tension pulling on the outer boundary of the annulus. The sheet spontaneously folds at a threshold ratio of inner to outer surface tension that depends on the geometry of the sheet, but is independent of its bending rigidity. Our results are consistent with a simple geometric principle: the sheet adopts the unstretched shape that minimizes the interfacial energy of the exposed liquid. Finally, we consider the application of this geometric principle to the folding of a floating indented film.

ABSTRACT: Thin spherical shells range from nanometer-sized viruses to space vehicles. A pressure differential between the inner and outer part of the shell can result in the buckling and catastrophic failure of the structure. We revisit this classic buckling problem, depressurizing thin elastic shells, which are arrested from within by a concentric spherical mandrel. As a result, buckling is constrained to occur within the gap between the two. Above a critical pressure, dimples appear sequentially on the surface of the shell to form a robust periodic pattern. We perform precision desktop experiments to construct the bifurcation diagram of the process, and explore a range of geometric and material properties. A scaling analysis enables us to rationalize the dependence of the size of the dimples on both the radius of the shell and the radial gap between the shell and the inner rigid mandrel. Moreover, we characterize the process of nucleation and progression of the dimpled pattern front. Particular emphasis is given to the patterns obtained in the strongly nonlinear post-buckling regime where a network of sharp ridges forms.

ABSTRACT: We revisit the classic problem of buckling of spherical elastic shells under pressure loading, with an emphasis on determining the role that engineered imperfections have on the critical buckling pressure. Since
the 1960s numerous theoretical and computational studies have addressed this canonical problem in engineering mechanics, but there is a striking lack of precision experiments to corroborate these predictions. We perform an experimental investigation where thin shells of nearly uniform thickness are fabricated by the coating of hemispherical molds with a polymer solution, which upon curing yields the elastic structure. Moreover, our manufacturing technique allows us to introduce a single dimple-like defect with controllable geometric properties. By systematically varying the amplitude of this defect (smaller than the thickness of the shell) we study the effect that these imperfections have on the buckling strength of our spherical shells. Small deviations from the spherical geometry result in large reductions in the buckling pressure and our experimental results agree well with the existing theories. We then perform a broader exploration for other classes of defects, for which theoretical predictions are yet to be developed.

Sarah Selden, Arthur Evans, Nakul Bende, Ryan Hayward, Christian Santangelo (University of Massachusetts – Amherst), “Stress localization in elastic shells”, Abstract ID BAPS.2016.MAR.P40.6
ABSTRACT: Upon indentation, thin shells react by localizing strain energy in polygonal structures as opposed to a uniform axisymmetric distribution. While the formation of these localized structures are well-characterized for perfect shells, a change in shell thickness or the introduction of a crease fundamentally changes the nature of the shell deformation. We perform finite element simulations, in tandem with experiments to explore the effect of different shell geometries on the energy landscape. We find that the crease induces a new symmetry-breaking localization that does not appear in perfect shells, and we explore the deformation characteristics of the creased shell over a wide range of crease radii, and crease orientations.

Salem Al Mosleh and Christian Santangelo (University of Massachusetts – Amherst), “Regularizing rigidifying curves to understand the low-energy deformations of thin shells”, Abstract ID BAPS.2016.MAR.P40.7
ABSTRACT: It is much harder to stretch a piece of paper than bend it. We exploit this fact to simplify the elastic energy of a thin shell. We accomplish this by extending the linear isometric displacements, displacements that do not cause stretching to lowest order, to low energy Nambu-Goldstone modes. This approach fails in an interesting way in the vicinity of “rigidifying curves,” curves with zero normal curvature, because half of the linear isometries are divergent there. We use a renormalization group methods to show that nonlinearities in the strain regularize these divergences. We explore the relationship between these modes and folding along curves of zero normal curvature.

Michael Gomez, Derek E. Moulton and Dominic Vella (Mathematical Institute, University of Oxford), “Hunting for ghosts in elastic snap-through”, Abstract ID BAPS.2016.MAR.P40.8
ABSTRACT: Elastic ‘snap-through’ is a striking instability often seen when an elastic system loses bistability, e.g. due to a change in geometry or external loading. The switch from one state to another is generally rapid and hence is used to generate fast motions in biology and engineering. While the onset of instability has been well studied, the dynamics of the transition itself remain much less well understood. For example, the dynamics exhibited by children’s jumping popper toys, or the leaves of the Venus flytrap plant, are much slower than would be expected based on a naïve estimate of the elastic timescales. To explain this discrepancy, the natural conclusion has been drawn that some other effect, such as viscoelasticity, must play a role. We demonstrate here that purely elastic systems may show similar ‘slow’ dynamics during snap-through. This behaviour is due to a remnant (or ‘ghost’) of the snap-through bifurcation underlying the instability, analogously to bottleneck phenomena in 1-D dynamical systems. This slowness is a generic consequence of being close to bifurcation — it does not require dissipation. We obtain scaling laws for the length of the delay and compare these to numerical simulations and experiments on real samples.
Yiwei Sun, Benny Davidovitch and Gregory Grason (University of Massachusetts – Amherst), “Wrinkling instability induced by imposed Gaussian curvature in the zero-tension limit”, Abstract ID BAPS.2016.MAR.P40.9
ABSTRACT: The adhesion of thin stiff films onto spherical substrates introduces compressive stresses, which cause the laminated film to buckle out of plane. Previous studies addressed the emerging wrinkle pattern in the limit of zero bending modulus and the presence of surface tension at the boundary, and found the radius of the inner unwrinkled zone scales with the tension. Here we study another fundamental limit: finite bending modulus and zero exerted tension. In this limit, subtlety will arise from the fact that the singular expansion, which previous studies relied on, becomes ill-defined. To reveal the morphology in the zero-tension limit, we employ numerical simulations based on bead-bond model. Surprisingly, we find that the scaling law for the radius of the unwrinkled zone can be generalized from the finite tension to the zero tension limit, by applying a bending modulus dependent term to the tension dominated scale. The simulation results also highlight the residual compressive hoop stress, which is scaled by bending modulus in the absence of tension. The findings suggest the existence of a new, yet unstudied process, by which the deformed shape of the sheet approaches isometry as the bending modulus vanishes, in the absence of boundary loads.

Nicholas Nechitaiilo (Naval Surface Warfare Center, Dahlgren, Virginia), “Unpredictable motion and post-chaotic self-organization of flexible structures”, Abstract ID BAPS.2016.MAR.P40.10
ABSTRACT: Two physical phenomena, “reverse buckling” and “post-chaotic self-organization”, were discovered by the author of this paper. The phenomena were analyzed using Newton’s mechanics, Euler bifurcation and buckling theory, and Poincare’s theory of chaotic motion when “prediction becomes impossible.” However, our experimental and theoretical findings revealed a more complex nonlinear physics with some predictability of final states. Geometric and material nonlinearities in flexible plates, beams and shells lead to transient chaos and unexpected final shapes. In one experiment, an axisymmetric transverse pressure pulse was applied to a circular metal membrane. It buckled, lost axial symmetry and formed a folded six-corner star. In another test, an impulsively stretched rod buckled and obtained a final shape similar to that of a rod under static axial compression. “Reputable” finite element and finite difference codes could not reliably predict deformation of an aluminum beam under a transverse pressure pulse. The anomalous responses were observed in a narrow region of the load amplitude and duration. These were described by simple analytical equations. Similar phenomena were seen in nonlinear equations of motion representing various non-mechanical systems.

ABSTRACT: In this paper a hexahedral solid-shell element with in-plane reduced integration is developed. The element is intended to the analysis of thin/thick elastic–plastic shells with moderate to large strains. Developed within the framework of a total Lagrangian formulation, the element uses as strain measure the logarithm of the right stretch tensor \( \mathbf{F} \) obtained from a modified right Cauchy–Green tensor \( \mathbf{C} \). The modifications, in order to remove transverse shear, Poisson and volumetric locking, are three: a) a classical assumed mixed shear strain approximation for and b) an assumed strain approximation for the in-plane components and c) an enhanced assumed strain for the through the thickness normal component (one additional degree of freedom). The first five components of are interpolated to the integration points from values at the center of the top and bottom faces. An arbitrary number of integration points is used in the transverse direction and a stabilization scheme is used to avoid spurious modes due to the in-plane sub integration. Several examples are presented that show the locking-free behavior and the very good performance of the presented element for the analysis of shells with
geometric and material nonlinearities, including quasi-incompressible elastic and elastic–plastic with incompressible plastic flow models.

ABSTRACT: A recent paper (Healey et al., J. Nonlin. Sci., 2013, 23, 777-805.) predicted the disappearance of the stretch-induced wrinkled pattern of thin, clamped, elastic sheets by numerical simulation of the Foppl-von Karman equations extended to the finite in-plane strain regime. It has also been revealed that for some aspect ratios of the rectangular domain wrinkles do not occur at all regardless of the applied extension. To verify these predictions we carried out experiments on thin (20 µm thick adhesive covered), previously prestressed elastomer sheets with different aspect ratios under displacement controlled pull tests. On one hand the the adjustment of the material properties during prestressing is highly advantageous as in targeted strain regime the film becomes substantially linearly elastic (which is far not the case without prestress). On the other hand a significant, non-ignorable orthotropy develops during this first extension. To enable quantitative comparisons we abandoned the assumption about material isotropy inherent in the original model and derived the governing equations for an orthotropic medium. In this way we found good agreement between numerical simulations and experimental data. Analysis of the negativity of the second Piola-Kirchhoff stress tensor revealed that the critical stretch for a bifurcation point at which the wrinkles disappear must be finite for any aspect ratio. On the contrary there is no such a bound for the aspect ratio as a bifurcation parameter. Physically this manifests as complicated wrinkled patterns with more than one highly wrinkled zones on the surface in case of elongated rectangles. These arrangements have been found both numerically and experimentally. These findings also support the new, finite strain model, since the Foppl-von Karman equations based on infinitesimal strains do not exhibit such a behavior.

ABSTRACT: A new macroscopic approach to modelise membrane wrinkling is presented. Most of the studies of the literature about membrane behaviour are macroscopic and phenomenological, the influence of wrinkles being accounted by non-linear constitutive laws without compressive stiffness. The present method is multiscale and it permits to predict the wavelength and the spatial distribution of wrinkling amplitude. It belongs to the family of Landau-Ginzburg bifurcation equations and especially it relies on the technique of Fourier series with slowly varying coefficients. The result is a new family of macroscopic membrane models that are deduced from Föppl-Von Karman plate equations. Numerical solutions are presented giving the size of the wrinkles as a function of the applied compressive and tensile stresses.

ABSTRACT: Spatial pattern formation in stiff thin films on compliant substrates is investigated based on a nonlinear 3D finite element model. Typical post-bifurcation patterns include 1D sinusoidal, checkerboard and herringbone shapes, with possible spatial modulations, boundary effects and localizations. The post-buckling behavior often leads to intricate response curves with several secondary bifurcations that were rarely studied and only in the case of periodic cells. The proposed finite element procedure allows accurately describing these bifurcation portraits by taking into account the effect of boundary conditions. It relies on the Asymptotic Numerical Method (ANM) that offers considerable advantages to get a robust path-following technique and to detect multiple bifurcations. The occurrence and evolution of sinusoidal, checkerboard and herringbone patterns will be highlighted.

ABSTRACT: A wrinkling-based method is proposed to create various surface micropatterns regulated by a hardened skin layer with a periodic stiffness distribution on a soft material. It is shown that the surface patterns generated by this technique are controlled by three fundamental surface deformation modes that involve sinusoidal wrinkling, Euler buckling, and rigid rotation of the skin. Systematic experiments and a phase diagram validate the efficacy and robustness of the proposed method.

ABSTRACT: Numerically accurate simulation of the mechanical behavior of thin flexible structures is important in application areas ranging from engineering design to animation special effects. Subdivision surfaces provide a unique opportunity to integrate geometric modeling with concurrent finite element analysis of thin flexible structures. Their mechanics are governed by the so-called thin-shell equations. We present a concise treatment of thin-shell equations including dynamic behavior, scalable material models, and the treatment of collisions (detection as well as response). The resulting energy minimization problem is non-linear and in turn able to capture effects of far more realism than linear models. We demonstrate these claims with a number of simulations which exhibit characteristic effects of real world experiments.

unlike mesh refinement, basis refinement never creates incompatible meshes. Our contributions are (a) a basic principle of our approach is to refine basis functions, not elements. Our method is naturally compatible: simple, general method for adaptive refinement which applies uniformly in all these settings and others. The basic principle of our approach is to refine basis functions, not elements. Our method is naturally compatible: unlike mesh refinement, basis refinement never creates incompatible meshes. Our contributions are (a)
minimal mathematical framework, with (b) associated algorithms for basis refinement; furthermore, we (c) describe the mapping of popular methods (finite-elements, wavelets, splines and subdivision) onto this framework, and (d) demonstrate working implementations of basis refinement with applications in graphics, engineering, and medicine.

Our approach is based on compactly supported refinable functions. We refine by augmenting the basis with narrowly-supported functions, not by splitting mesh elements in isolation. This removes a number of implementation headaches associated with element-splitting and is a general technique independent of domain dimension, element type (e.g., triangle, quad, tetrahedron, hexahedron), and basis function order (piecewise linear, quadratic, cubic, etc.). The (un-)refinement algorithms are simple and require little in terms of data structure support. Many popular discretizations, including classical finite-elements, wavelets and multi-wavelets, splines and subdivision schemes may be viewed as refinable function spaces, thus they are encompassed by our approach. Our first contribution is the specification of a minimal mathematical framework, at its heart a sequence of nested approximation spaces. By construction, the bases for these spaces consist of refinable functions. From an approximation theory point of view this is a rather trivial statement; however it has a number of very important and highly practical consequences. Our adaptive solver framework requires only that the basis functions used be refinable. It makes no assumptions as to (a) the dimension of the domain; (b) the tesselation of the domain, i.e., the domain elements be they triangles, quadrilaterals, tetrahedra, hexahedra, or more general domains; (c) the approximation smoothness or accuracy; and (d) the support diameter of the basis functions. The specification of the nested spaces structure is sufficiently weak to accommodate many practical settings, while strong enough to satisfy the necessary conditions of our theorems and algorithms.

Our second contribution is to show that basis refinement can be implemented by a small set of simple algorithms. Our method requires efficient data structures and algorithms to (a) keep track of interactions between basis functions (i.e., to find the non-zero entries in the stiffness matrix), and (b) manage a tesselation of the domain suitable for evaluation of the associated integrals (i.e., to evaluate the entries of the stiffness matrix). We provide a specification for these requirements, develop the relevant theorems and proofs, and invoke these theorems to produce concrete, provably-correct pseudo-code. The resulting algorithms, while capturing the full generality (in dimension, tesselation, smoothness, etc.) of our method, are surprisingly simple.

Our third contribution is the mapping of finite-elements, wavelets and multi-wavelets, splines and subdivision schemes onto our nested spaces framework. No single discretization fits all applications. In our survey of classical and recently-popularized discretizations we demonstrate that our unifying algorithms for basis refinement encompass a very broad range of problems.

Our fourth contribution is a set of concrete, compelling examples based on our implementation of basis refinement. Adaptive basis refinement may be profitably applied in solving partial differential equations (PDEs) useful in many application domains, including simulation, animation, modeling, rendering, surgery, biomechanics, and computer vision. Our examples span thin shells (fourth order elliptic PDE using a Loop subdivision discretization), volume deformation and stress analysis using linear elasticity (second order PDE using linear-tetrahedral and trilinear-hexahedral finite elements respectively) and a subproblem of electrocardiography (the generalized Laplace equation using linear tetrahedral finite elements).

ABSTRACT: Current formulations of adaptive finite element mesh refinement seem simple enough, but their implementations prove to be a formidable task. We offer an alternative point of departure which yields equivalent adapted approximation spaces wherever the traditional mesh refinement is applicable, but our method proves to be significantly simpler to implement. At the same time it is much more powerful in that it is
general (no special tricks are required for different types of finite elements), and applicable for some newer approximations where traditional mesh refinement concepts are not of much help, for instance on subdivision surfaces.

ABSTRACT: Many computer graphics applications require high-intensity numerical simulation. We show that such computations can be performed efficiently on the GPU, which we regard as a full function streaming processor with high floating-point performance. We implemented two basic, broadly useful, computational kernels: a sparse matrix conjugate gradient solver and a regular-grid multigrid solver. Real time applications ranging from mesh smoothing and parameterization to fluid solvers and solid mechanics can greatly benefit from these, evidence our example applications of geometric flow and fluid simulation running on NVIDIA's GeForce FX.

ABSTRACT: In this paper we introduce a discrete shell model describing the behavior of thin flexible structures, such as hats, leaves, and aluminum cans, which are characterized by a curved undeformed configuration. Previously such models required complex continuum mechanics formulations and correspondingly complex algorithms. We show that a simple shell model can be derived geometrically for triangle meshes and implemented quickly by modifying a standard cloth simulator. Our technique convincingly simulates a variety of curved objects with materials ranging from paper to metal, as we demonstrate with several examples including a comparison of a real and simulated falling hat.

ABSTRACT: We introduce a method for simulating the inelastic deformation of thin shells: we model plasticity and fracture of curved, deformable objects such as light bulbs, egg-shells and bowls. Our novel approach uses triangle meshes yet evolves fracture lines unrestricted to mesh edges. We present a novel measure of bending strain expressed in terms of surface invariants such as lengths and angles. We also demonstrate simple techniques to improve the robustness of standard timestepping as well as collision-response algorithms.

ABSTRACT: We introduce a way of simulating the creation of simple Origami (paper folding). The Origami is created in a thin shell simulation that realistically models the behavior and physical properties of paper. We
demonstrate how to fold and crease the simulated paper wherever the user desires. This work employs cutting-edge advances in the field of discrete shell modeling to meet the challenge of simulating Origami. We found that the discrete shell model is capable of creating simple Origami that does not involve paper to paper collisions. For more advanced origami, however, some kind of collision detection and resolution scheme is required. Further research is necessary to implement collision handling while maintaining a practical simulation speed.

ABSTRACT: Hinge-based bending models are widely used in the physically-based animation of cloth, thin plates and shells. We propose a hinge-based model that is simpler to implement, more efficient to compute, and offers a greater number of effective material parameters than existing models. Our formulation builds on two mathematical observations: (a) the bending energy of curved flexible surfaces can be expressed as a cubic polynomial if the surface does not stretch; (b) a general class of anisotropic materials---those that are orthotropic---is captured by appropriate choice of a single stiffness per hinge. Our contribution impacts a general range of surface animation applications, from isotropic cloth and thin plates to orthotropic fracturing thin shells.

ABSTRACT: We combine the often opposing forces of artistic freedom and mathematical determinism to enrich a given animation or simulation of a surface with physically based detail. We present a process called tracking, which takes as input a rough animation or simulation and enhances it with physically simulated detail. Building on the foundation of constrained Lagrangian mechanics, we propose weak-form constraints for tracking the input motion. This method allows the artist to choose where to add details such as characteristic wrinkles and folds of various thin shell materials and dynamical effects of physical forces. We demonstrate multiple applications ranging from enhancing an artist's animated character to guiding a simulated inanimate object.

ABSTRACT: We present a method for simulating highly detailed cutting and fracturing of thin shells using low-resolution simulation meshes. Instead of refining or remeshing the underlying simulation domain to resolve complex cut paths, we adapt the extended finite element method (XFEM) and enrich our approximation by customdesigned basis functions, while keeping the simulation mesh unchanged. The enrichment functions are stored in enrichment textures, which allows for fracture and cutting discontinuities at a resolution much finer than the underlying mesh, similar to image textures for increased visual resolution. Furthermore, we propose harmonic enrichment functions to handle multiple, intersecting, arbitrarily shaped, progressive cuts per element in a simple and unified framework. Our underlying shell simulation is based on discontinuous Galerkin (DG) FEM, which relaxes the restrictive requirement of C^1 continuous basis functions and thus allows for simpler, C^0 continuous XFEM enrichment functions.

ABSTRACT: In this paper, we derive a variational integrator for certain highly oscillatory problems in mechanics. To do this, we take a new approach to the splitting of fast and slow potential forces: rather than splitting these forces at the level of the differential equations or the Hamiltonian, we split the two potentials with respect to the Lagrangian action integral. By using a different quadrature rule to approximate the contribution of each potential to the action, we arrive at a geometric integrator that is implicit in the fast force and explicit in the slow force. This can allow for significantly longer time steps to be taken (compared to standard explicit methods, such as Störmer/Verlet) at the cost of only a linear solve rather than a full nonlinear solve. We also analyze the stability of this method, in particular proving that it eliminates the linear resonance instabilities that can arise with explicit multiple-time-stepping methods. Next, we perform some numerical experiments, studying the behavior of this integrator for two test problems: a system of coupled linear oscillators, for which we compare the stability of this method against the resonance behavior of the r-RESPA method, and slow energy exchange in the Fermi–Pasta–Ulam (FPU) problem, which couples fast linear oscillators with slow nonlinear oscillators. Finally, we prove that this integrator accurately preserves the slow energy exchange between the fast oscillatory components, which explains the numerical behavior observed for the FPU problem.

ABSTRACT: We develop an accurate, unified treatment of elastica. Following the method of resultant-based formulation to its logical extreme, we derive a higher-order integration rule, or elaston, measuring stretching, shearing, bending, and twisting along any axis. The theory and accompanying implementation do not distinguish between forms of different dimension (solids, shells, rods), nor between manifold regions and non-manifold junctions. Consequently, a single code accurately models a diverse range of elastoplastic behaviors, including buckling, writhing, cutting and merging. Emphasis on convergence to the continuum sets us apart from early unification efforts.

“Discrete Viscous Sheets”, (an on-line pdf file, no date or publisher given; most recent reference is 2011)

ABSTRACT: We present the first reduced-dimensional technique to simulate the dynamics of thin sheets of viscous incompressible liquid in three dimensions. Beginning from a discrete Lagrangian model for elastic thin shells, we apply the Stokes-Rayleigh analogy to derive a simple yet consistent model for viscous forces. We incorporate nonlinear surface tension forces with a formulation based on minimizing discrete surface area, and preserve the quality of triangular mesh elements through local remeshing operations. Simultaneously, we track and evolve the thickness of each triangle to exactly conserve liquid volume. This approach enables the simulation of extremely thin sheets of viscous liquids, which are difficult to animate with existing volumetric approaches. We demonstrate our method with examples of several characteristic viscous sheet behaviors, including stretching, buckling, sagging, and wrinkling.

ABSTRACT: We propose an interactive, optimization-in-the-loop tool for designing inflatable structures. Given a target shape, the user draws a network of seams defining desired segment boundaries in 3D. Our method computes optimally-shaped flat panels for the segments, such that the inflated structure is as close as possible to the target while satisfying the desired seam positions. Our approach is underpinned by physics-based pattern optimization, accurate coarse-scale simulation using tension field theory, and a specialized constraint-
optimization method. Our system is fast enough to warrant interactive exploration of different seam layouts, including internal connections, and their effects on the inflated shape. We demonstrate the resulting design process on a varied set of simulation examples, some of which we have fabricated, demonstrating excellent agreement with the design intent.

DOI: 10.1109/IROS.2015.7354231
ABSTRACT: Robotic manipulation of deformable objects remains a challenging task. One such task is folding a garment autonomously. Given start and end folding positions, what is an optimal trajectory to move the robotic arm to fold a garment? Certain trajectories will cause the garment to move, creating wrinkles, and gaps, other trajectories will fail altogether. We present a novel solution to find an optimal trajectory that avoids such problematic scenarios. The trajectory is optimized by minimizing a quadratic objective function in an off-line simulator, which includes material properties of the garment and frictional force on the table. The function measures the dissimilarity between a user folded shape and the folded garment in simulation, which is then used as an error measurement to create an optimal trajectory. We demonstrate that our two-arm robot can follow the optimized trajectories, achieving accurate and efficient manipulations of deformable objects.

Allen (Dept. of Computer Science, Columbia University, NY, USA), “Regrasping and unfolding of garments using predictive thin shell modeling”, IEEE International Conference on Robotics and Automation (ICRA), May 2015
DOI: 10.1109/ICRA.2015.7139370
ABSTRACT: Deformable objects such as garments are highly unstructured, making them difficult to recognize and manipulate. In this paper, we propose a novel method to teach a two-arm robot to efficiently track the states of a garment from an unknown state to a known state by iterative regrasping. The problem is formulated as a constrained weighted evaluation metric for evaluating the two desired grasping points during regrasping, which can also be used for a convergence criterion. The result is then adopted as an estimation to initialize a regrasping, which is then considered as a new state for evaluation. The process stops when the predicted thin shell conclusively agrees with reconstruction. We show experimental results for regrasping a number of different garments including sweater, knitwear, pants, and leggings, etc.

ABSTRACT: This thesis focuses on the task of dexterous manipulation of deformable objects, and in particular, clothing and garments. The task of manipulating deformable objects such as clothing can be broken down into a series of sub-tasks: (1) perceive and pick up garment, and then identify garment and recognize its pose; (2) using a manipulation strategy, regrasp the object to put it into a canonical state; (3) scan the surface of the object to find wrinkles, and use an iron to remove the wrinkles; (4) starting from the wrinkle-free state, fold the garment according to pre-planned sequence of manipulations with optimized trajectories; In this thesis, we will address all the phases of this process. A key contribution of the work is innovative use of simulation. We use offline simulation results to predict states of deformable objects (i.e. cloth, fabric, clothing) that are then recognized by a robotic vision/grasping system to correctly pick up and manipulate these objects. The
recognition will use the simulation engine to deform the models in real time to find correct matches. The simulation will also be used to find the optimized trajectories for the manipulation of the garments, such as the garment folding.

“Wrinkling, creasing, and folding in fiber-reinforced soft tissues”, Extreme Mechanics Letters, available online

4 November 2015, DOI: 10.1016/j.eml.2015.10.005

ABSTRACT: Many biological tissues develop elaborate folds during growth and development. The onset of this folding is often understood in relation to the creasing and wrinkling of a thin elastic layer that grows whilst attached to a large elastic foundation. In reality, many biological tissues are reinforced by fibers and so are intrinsically anisotropic. However, the correlation between the fiber directions and the pattern formed during growth is not well understood. Here, we consider the stability of a two-layer tissue composed of a thin hyperelastic strip adhered to an elastic half-space in which are embedded elastic fibers. The combined object is subject to a uniform compression and, at a critical value of this compression, buckles out of the plane — it wrinkles. We characterize the wrinkle wavelength at onset as a function of the fiber orientation both computationally and analytically and show that the onset of surface instability can be either promoted or inhibited as the fiber stiffness increases, depending on the fiber angle. However, we find that the structure of the resulting folds is approximately independent of the fiber orientation. We also explore numerically the formation of large creases in fiber-reinforced tissue in the post-buckling regime.

ABSTRACT: Silos in the form of cylindrical metal shells are usually supported on evenly spaced columns in applications where an access space is needed for the discharge of contained solids. In large silos a ring beam is used to distribute the column forces into the shell. The presence of discrete supports results in a circumferential non-uniformity of axial stresses in the shell. This non-uniformity leads to high local stresses that must be considered in assessing the possibility of shell buckling. Design standards provide recommendations for the buckling of shells under uniform axial compression, but are largely silent concerning stress peaks that may vary in width. Designers must resort either to onerous finite element analyses that include both geometric and material nonlinearities with imperfections (GMNIA) or trust to their own judgment. This paper presents a parametric study to develop resistance or capacity curves which can be used directly in design without the need for complicated analysis. The proposed design method uses only hand calculations apart from a simple linear finite element analysis to determine the degree of non-uniformity in the axial stresses.

ABSTRACT: The design of thin shell structures against buckling has a long and tricky history. The sensitivity of elastic buckling loads to geometric imperfections and the challenges in relating research findings to practical construction have required extensive research work over many decades. The wide range of geometries, construction forms and loading conditions has also led to many distinct solutions to individual situations. But recent innovations have enabled a new all-embracing perspective to be developed, which gives great potential for addressing new problems in a systematic manner. The new method of Reference Resistance Design provides a hand calculation process that can address all shell buckling and collapse situations, with particular attention to unsymmetrical and local loading conditions, including imperfections, geometric nonlinearity, plasticity and strain hardening all within a consistent framework.
