ABSTRACT: A study is presented of the out-of-plane buckling strength of rings attached to cone-cylinder intersections. Simple formulae which can be used to estimate the stiffness of the rotational restraint provided by adjacent shell walls are first developed from a finite element parametric study. These formulae are then combined with an existing closed-form solution based on thin-walled member theory to predict the flexural-torsional buckling strength of rings with an elastic rotational restraint. Numerical results are obtained for angle section rings from the closed-form solution and a finite element shell buckling analysis which is able to model cross-section distortion. Comparisons between the two approaches show that when the restraint stiffness is small, they agree with each other closely. Beyond a certain level of restraint stiffness, the buckling strength predicted by the finite element analysis falls increasingly below that given by the closed-form solution due to cross-section distortion and approaches the strength of an inner edge clamped ring. The paper concludes with suggestions for safely approximating the stiffness of the shell wall rotational restraint for use in design.

ABSTRACT: In many practical applications, thin shells are in contact with soils or other solids. Such situations arise in cylindrical bulk solid storage silos, above-ground and underground liquid storage tanks, underground pipelines, ballistic missiles filled with solid propellants, and concrete-filled steel tubular columns. As a result, many studies have been carried out on the analysis and behavior of shells on elastic foundations. However, little has been done on shells on nonlinear elastic foundations, despite the fact that foundation behavior is generally nonlinear. This paper presents a finite element formulation for the buckling analysis of shells of revolution on nonlinear elastic foundations. To achieve a versatile foundation model, the foundation reaction–displacement relationship is represented by a number of discrete data points (referred to as the Discrete-Point or DP Model in this paper). Any specific nonlinear functions such as polynomials can be treated as special cases of this model and accurately represented by a sufficiently large number of data points. The validity and capability of the present analysis are demonstrated through numerical comparisons. The paper also presents the first set of verified numerical results for buckling of shells on nonlinear elastic foundations, which can be used to benchmark results from other sources in the future.

ABSTRACT: Theories for the out-of-plane buckling of rings under uniform circumferential compression are well established. However these theories are not applicable to rings in column-supported bins where the circumferential stress in the ring varies significantly over the cross-section and around the circumference. This paper deals with the out-of-plane buckling of annular plate rings in column-supported bins and tanks. The stress distributions in such rings are first examined using a finite element shell analysis. A closed-form solution for the buckling of rings under non-uniform circumferential stresses is then derived. Numerical results from the closed-
form solution are compared with those from a finite element shell buckling analysis, and close agreement is found. The significant effect of stress non-uniformity on the buckling predictions is demonstrated. Finally, simplified equations are given which are suitable for structural design purposes, and which closely model the predictions of the more rigorous solution.

ABSTRACT: Large modern steel silos are either elevated or supported on the ground. The main structural components are a cylindrical body, stiffeners (rings and stringers etc), a roof, and in the case of elevated silos, a hopper and supporting column. Silo structures are designed chiefly as containers, therefore the load from the contained material comprises the major part of the load which silos experience. The stored bulk solid exerts both internal pressure and downward frictional drag on the wall, the latter causing a potential for buckling of the wall. In addition to loading the wall by gravity, the bulk solid has a strengthening effect against buckling under axial compression. This is because, unlike fluids, bulk solids have finite strength and stiffness. The effect of imperfections on the buckling strength of cylinders under axial compression has been studied extensively in the past, as has the effect of internal pressure. The stiffening effect due to bulk solids in silos has, however, not been systematically studied. In this thesis a study of the stability of thin-walled steel silos is presented. The strengthening effect of the bulk solid is modelled theoretically using a Winkler foundation. The theoretical studies are carried out using the finite element technique. The formulation of an isoparametric doubly curved shell element for the linear elastic static analysis of shells of revolution with attached elastic restraints along the three curvilinear directions is described first. Non-symmetric loads are decomposed into Fourier components. The linear elastic buckling analysis is followed by the analysis of the shell-spring system under axisymmetric load, and nonlinear large-displacement and material analysis. Linear analysis is often not sufficient to describe the real behaviour of shells. Non-linear effects from both the change of geometry and stresses which exceed the elastic limit may need to be considered. This formulation, including the effect of restraints, is given. The analysis includes full non-linearity on both shell geometry and material. The effect of non-linear springs is taken into account in the formulation. Recently-developed non-linear strain-displacement relations for thin shells of revolution are used. An efficient and accurate state determination algorithm is adopted. The arc-length method implemented by other researchers is used to trace both the pre- and post-collapse load deflection curve. Non-symmetric bifurcation including prebuckling large deflections is given, after the primary equilibrium state is reached. The linear and non-linear analyses are applied to a number of example problems of restrained shells. Results are compared with published theoretical and numerical results, wherever it is possible. Several comprehensive theoretical studies of the buckling and collapse of steel silo shells are performed using the finite element analysis developed in this thesis. A study of silos filled with bulk solids with axisymmetric imperfections caused by weld joint depressions is firstly given. Attempt is made to relate any buckling strength gain of the shell wall by bulk solids to the mechanical properties of bulk solids, which has been a difficult task. A comprehensive study of the collapse failure of light gauge steel silos made of thin corrugated sheets is made. One of the common failure modes in thin corrugated silos is that in which a few corrugations are squashed together to form a fold. Two simple collapse mechanisms are presented, each valid for a range of geometry. The proposed theories are verified using the finite element technique. Another common failure mode for silos built of thin corrugated sheets is buckling of wall under axial or circumferential compression. The wall is idealised as an orthotropic shell. The orthotropic properties are therefore important to the stability analysis of corrugated shells. A number of expressions have been proposed in the past for the orthotropic properties of a flat corrugated sheet. The circumferential curvature influences these properties. A numerical study using the finite element analysis is given in this thesis for the accurate definition of these properties, and the results are
compared with existing proposals. Finally, tests of thin steel model cylinders filled with different bulk materials are conducted under several load conditions. The purpose of the experiments is to measure the strength gains of cylinders filled with bulk solids and compare with predictions of the finite element studies of restrained cylinders. Three series of tests were conducted: (a) Empty cylinders under axial compression; (b) Cylinders filled with pressurised water under axial compression; and (c) Cylinders filled with bulk solids under axial compression. Two types of bulk solids are selected; one is the relatively softer wheat and the other the stiffer Sydney sand. The bulk solids inside the models are stressed to different levels to achieve different ratios of axial and hoop stress in the wall. The results indicate that the buckling strength of the wall can be increased significantly by the presence of bulk solids, and in some cases, it can be well above the classical buckling stress for a perfect cylinder under axial compression. Information on the quasi-elastic behaviour of bulk solids inside silos is limited. A study is presented here to add to the available data. The mechanical properties of sand and wheat inside silos are given and compared with predictions suggested in the design specifications and in the literature.

J.M. Rotter and P.T. Jumikis (School of Civil and Mining Engineering, University of Sydney), “Nonlinear strain-displacement relations for axisymmetric thin shells”, Research report / University of Sydney, School of Civil and Mining Engineering ; no. R563, 1988

ABSTRACT: Nonlinear deformation and stability analyses are based on nonlinear relations between the strains and the corresponding displacements of the body. Many attempts have been made to develop nonlinear strain-displacement relations for thin shells, and many of these are quoted in specialised form for shells of revolution. Shells of revolution have many more applications than most other shell forms, so it is natural that specialised analyses should be developed for them. The differences between existing nonlinear relations for thin shell lie principally in the number of terms which have been rejected using the assumption that they would be unimportant. The purpose of rejecting these small terms has usually been to produce simple relations which could be used in algebraic or classical theories. In modern finite element analysis, there is little advantage in reducing the number of terms slightly, but a theory which has omitted a term which is vital in even a small number of practical structures has a major flaw. This paper describes a new set of nonlinear strain-displacement relations for thin shells, subject to large displacements with moderate rotations, and which retains more terms than most existing theories. The new relations are proposed only for use in finite element calculations. The chief difference between the new relations and previous work is the recognition that nonlinear strains arising from products of in-plane strain terms may be important in certain buckling problems. It is shown that the widely-used relations of Sanders (1963) lead to the wrong answer for a simple practical problem, and that this disadvantage is overcome by the present formulation.

A Review of the paper dated 19 May, 2009:
This is the first known study that defines the strength of a cylindrical shell under internal pressure and axial load leading to an elastic-plastic stability failure in the Elephant's Foot mode. The paper gives design equations that have been widely adopted into standards to cover this failure mode. It is easy to read and is worth studying if you are concerned with elephant's foot buckling.

ABSTRACT: Elevated steel silos commonly consist of a cylindrical shell, a conical hopper, and a skirt. At the intersection of these shell segments, a ring is often provided to sustain the high circumferential compressive stress developed. The cone/cylinder/skirt/ring junction, known as the transition, may fail by plastic collapse under the large circumferential compression. In this paper, an elastic-plastic large-deflection finite element analysis is employed to study the plastic collapse behavior of this junction. A typical structure is first examined to study the distribution of stresses, the effect of large deflections, the formation of a plastic collapse mechanism, and the collapse process. A simple theory proposed by Rotter, which is based on a reinterpretation of the classical limit analysis of ring-loaded cylinders, is next outlined and its background further clarified. An improved version of Rotter's equation, which applies to a wider range of geometries, is then proposed for use in design.

“Buckling in thin elastic cylinders on column supports”, in Buckling of shell structures on land, in the sea, and in the air, edited by J. F. Jullien, Elsevier, 1991

PARTIAL ABSTRACT: Elevated silos and tanks are often supported on a number of columns. The discrete supports of the columns induce high stresses adjacent to the column terminations. In particular very high meridional compressive stresses arise above the column termination, and these can lead to buckling of the shell at a load much lower than that for a uniformly supported shell. This paper presents a brief summary of recent theoretical work on the elastic buckling strength of column-supported cylinders...

J.G. Teng and Hong-Wei Ma (Department of Civil and Structural Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong, China), “Elastic buckling of ring-stiffened cone–cylinder intersections under internal pressure”, International Journal of Mechanical Sciences, Vol. 41, No. 11, November 1999, pp 1357-1383

ABSTRACT: Cone–cylinder intersections are commonly found in pressure vessels and piping. Examples include conical end closures to cylindrical vessels and conical reducers between cylinders of different radii. In the case of a cone large end-to-cylinder intersection under internal pressure, the intersection is subject to a large circumferential compressive force. Both the cone and the cylinder may be thickened near the intersection to resist this compression, but it is often convenient and necessary to augment further the strength of the intersection using an annular plate ring stiffener. Under this large circumferential compression, the intersection may fail by elastic buckling, plastic buckling or plastic collapse. This paper describes an investigation of the elastic buckling strength of ring-stiffened cone–cylinder intersections. Two buckling modes are identified: a shell mode for thin intersections with a shallow cone (a cone with its apex half angle approaching 90°) and/or a relatively stocky ring stiffener, and a ring mode for other cases. An existing elastic buckling approximation for annular plate rings in steel silos is found to be applicable to the intersection when it buckles in the ring mode. New approximate design equations are also established for the shell mode. In addition, simple expressions are identified which relate the number of circumferential buckling waves to the geometric parameters of the intersection.
ABSTRACT: Fibre-reinforced polymer (FRP) jackets have been widely used to confine reinforced concrete (RC) columns for enhancement in both strength and ductility. This paper presents the results of a recent study in which the benefit of FRP confinement of hollow steel tubes was explored. Axial compression tests on FRP-confined steel tubes are first described. Finite element modelling of these tests is next discussed. Both the test and the numerical results show that FRP jacketing is a very promising technique for the retrofit and strengthening of circular hollow steel tubes. In addition, finite element results for FRP-jacketed thin cylindrical shells under combined axial compression and internal pressure are presented to show that FRP jacketing is also an effective strengthening method for such shells failing by elephant’s foot collapse near the base.

ABSTRACT: Shell structures are widely used in a great variety of applications from space rockets to domestic food and drink containers. Civil engineers are principally concerned with steel shell structures such as silos, tanks, pipelines, chimneys, towers and masts, though other examples may be found in offshore structures and stadium roofs. This paper describes the treatment of terrestrial shell structures in Eurocode 3: Steel structures. It outlines the principles which are guiding the development of the standard, the range of applications covered, and some details of the current proposals. The axially compressed cylindrical shell is then chosen as an example illustrating the range of real problems which need to be addressed, and the paucity of current data on many aspects of these problems. This example is also used to outline the complexity involved even in this one area, recent progress and current needs.

J. Michael Rotter (University of Edinburgh, Scotland, UK, School of Civil and Environmental Engineering), “Pressures, Stresses and Buckling in Metal Silos containing Eccentrically Discharging Solids”, Greiner Institute for Steel and Shell Structures, TU Graz, 2001

ABSTRACT: The eccentric discharge of stored solids from moderately slender metal silos has caused many dramatic and catastrophic buckling failures. Despite these many failures, eccentric discharge failures are poorly understood even by specialists in shell structures, and the cause of failure is often misinterpreted. In particular, buckles occurring well up the wall of a silo are often thought to be difficult to explain. This paper sets out the theory of pressures occurring in silos under eccentric pipe flow where part of the flow channel is in contact with the silo wall. It then uses pressures predicted by this theory to analyse an example structure, with different flow channel geometries. The stress patterns are seen to be such that local axial compression buckles are likely to occur well up the wall, and it is found that certain sizes of flow channel are critically dangerous to the structural integrity of the silo shell.

ABSTRACT: The high efficiency of shell structures leads them to be widely used in a huge variety of applications: food and drink containers, cars and vehicles, aircraft and spacecraft, and large storage structures. Steel shell structures are most used in civil engineering as silos, tanks, pipelines, chimneys, towers and masts. Offshore structures present another example.

PARTIAL ABSTRACT: Cylindrical shell structures are often subjected to compressive stresses in the direction of the cylinder axis, which can be either uniform or varying throughout the cylinder. The buckling strength of a thin cylindrical shell under axial compression is particularly sensitive to imperfections in the shell, and the changing patterns of behaviour with changing geometry, loading and boundary conditions make the axially compressed cylinder a classical exemplar for behaviours that may be found in a less marked form in other structures or in shells under other loading conditions. For these reasons, the axially compressed cylinder has probably been the most extensively studied of all shell buckling conditions, giving a wealth of evidence from both experimental and theoretical work.

ABSTRACT: Metal cylindrical bins, silos and tanks are thin shell structures subject to internal pressure from stored materials together with axial compression from the frictional drag of stored materials on the walls and horizontal loads. The governing failure mode is frequently buckling under axial compression. The internal pressure exerted by the stored fluids or solids can significantly enhance the buckling strength, but high internal pressures lead to severe local bending near the base. Local yielding then precipitates an early elastic-plastic
buckling failure. This failure mode, commonly known as “elephant's foot buckling”, has received relatively little attention to date and until recently was often ignored in tank and silo design. This problem is an unusual buckling condition, because it involves very high tensile stresses in one direction, coupled with rather small compressive stresses in the orthogonal direction. Thus, although it is a buckling failure involving considerable plasticity, it occurs at low buckling stresses and under conditions that appear to be classically “slender”. The normal concatenation of “slender” with “elastic” in buckling formulations does not apply at all here. This paper describes alternative approaches to the formulation of design rules for the elastic-plastic instability and collapse of axially-loaded internally-pressureurised thin cylindrical shells adjacent to the base support. The differences between the different approaches arise from different conceptual models for the manner in which an elastic-plastic slender structure instability should be treated.

ABSTRACT: Externally bonding of fibre reinforced polymer (FRP) composites has become a popular technique for retrofitting existing structures worldwide. Extensive research has been conducted in the last two decades on various topics such as strengthening concrete, masonry and timber structures as well as metallic structures. The vast majority of these studies have focussed on the failure strength, rather than on stability considerations. A study is currently being conducted at Edinburgh University on the strengthening of thin metal shell structures using FRP composites. This paper presents a numerical study of the buckling behaviour of FRP strengthened thin cylindrical shells with an axisymmetric imperfection. The results show that the buckling strength of the shell under axial loading can be significantly increased by using only a small amount of FRP in the critical area of the imperfection. This outcome indicates that this technique is indeed very effective and economical for enhancing the buckling strength of thin shell structures, especially under conditions where a local defect causes the shell to fail the tolerance requirement.

ABSTRACT: Thin metallic shell structures such as silos and tanks are susceptible to buckling failure which is usually very sensitive to local imperfections. The strengthening of such thin shells has previously been rather difficult if not impossible. Welding additional metal plates to the existing structure is not easy and can be prohibitive for health and safety reasons if the structure contains materials like harmful chemicals, flammables, explosive liquids or gases. Welding also introduces imperfections and residual stresses which may reduce the buckling strength of the structure. The authors have recently proposed to strengthen such structures using externally bonded FRP. This paper presents a numerical study of the buckling behavior of cylindrical metal shells with a dent and strengthened with FRRP. The results show that the scheme is very effective and economical.

ABSTRACT: Thin metal cylindrical shell structures such as silos and tanks are susceptible to an elastic–plastic instability failure at the base boundary known as elephant's foot buckling, due to its characteristic deformed shape. This form of buckling occurs under high internal pressure accompanied by axial compression in the shell structure. This is a common failure mode for tanks under earthquake loading. Another common situation is in a silo where the silo wall is subjected to both normal pressures from the stored granular solid and vertical compressive forces developed from the friction between the stored solid and the silo wall. This paper presents a novel method of strengthening cylindrical shells against elephant's foot buckling in which a small amount of fibre-reinforced polymer (FRP) composite, used at a critical location, can effectively eliminate the problem and increase the buckling strength. The strengthened shell is analysed using linear elastic bending theory in this preliminary study. Within the scope of this research, the strengthening effect is shown to be sensitive to the thickness, height and location of the FRP sheet. The issue of optimal FRP strengthening to allow the shell to attain pure membrane-state deformation is examined in detail as strengthening with too much and too little FRP are both undesirable. Both pinned-based and fixed-based shells are examined and their responses are compared.

ABSTRACT: Silos and tanks are probably the commonest form of large engineering shell structure in service, but their placement on industrial sites and out of the public eye often leads them to be neglected by researchers and the public alike. The high rate of structural failure in these structures is a strong indication of the extensive range of issues that must be understood by the designer and the complexity of their behavior. This paper outlines some of the most critical aspects of the loading, structural behavior and failure modes of silos and tanks, and points in many places towards the need for additional research to permit better regulation of these very varied and complex structures.

ABSTRACT: The most serious loading condition for slender thin-walled metal silos has long been recognized to be the condition of discharge, with eccentric discharge causing more catastrophic failures than any other. Two key reasons for this high failure rate are the difficulties in characterizing the pressure distribution caused by eccentric solids flow, and in understanding the associated unsymmetrical stresses in the silo wall. Few studies have addressed either the linear elastic behavior of such a silo or its buckling failure under eccentric discharge. In this study, the eccentric discharge pressures are characterized using the new rules of the European Standard EN 1991-4 on Silos and Tanks. This novel description of unsymmetrical pressures permits a study of the structural behavior leading to buckling during eccentric discharge, including the critical effects of change of geometry and imperfection sensitivity, to be undertaken using geometrically and materially nonlinear computational analyses. The mechanics of the behavior are found to be quite complicated. A silo which is safe under axisymmetric loading is found to be susceptible to catastrophic stability failure under eccentric discharge.

ABSTRACT: Eccentric discharge in slender metal silos is known to be one of the most critical load conditions, responsible for many silo buckling disasters in the past. The high failure rate may be significantly attributed to difficulties in devising a suitable wall pressure representation for this condition. Where the flow of stored solids is eccentric and has partial contact with the wall in a slender silo, the solid exerts much lower pressures than the adjacent stationary solid. This pressure drop leads to very high local axial compression and causes buckling failure. Experimentally measured pressures indicate that a significant rise in pressure may occur just outside the flow channel, but its form and magnitude are not yet well understood because very detailed and expensive instrumentation is needed to obtain data that can define it. This paper explores the nonlinear structural behaviour and buckling of a slender metal silo with and without specific inclusion of an adjacent rise in pressure, to determine whether it is a necessary part of any design pressure representation. To assist this investigation, the mechanics of the nonlinear behaviour of a cylindrical silo under this load condition is explored using the analogy of a propped cantilever slice-beam. Advantage is taken of a particular load condition that leads, by chance, to buckling at the same load factor for both linear and geometrically nonlinear analyses. This special case permits the detrimental effect of wall flattening and the beneficial effect of the changing prebuckling stress pattern to be explored to give a deeper insight into the behaviour. The slice-beam analogy may also be generalised to describe the nonlinear behaviour of any thin-walled cylindrical shell under meridional strip-like loads acting on part of the circumference.

ABSTRACT: Modern procedures for the design of shell structures against buckling have their basis in analytical studies of axisymmetric shell geometries under the very simple load cases of uniform compression, external pressure and torsion. Studies of more complex but realistic stress states were based on prebuckling analyses using either membrane theory or linear bending theory because even these involved considerable mathematical complexity. As a result, only limited conclusions for practical design could be drawn and the effects of geometric nonlinearity could not be assessed. With recent advances in computing power and nonlinear finite element programs, it is now possible to undertake nonlinear analyses of complex load patterns that would have been very difficult to do only a decade or so ago.

ABSTRACT: Many problems in structural mechanics involve complex principal stress fields that are not orthogonal to the geometric axis of the structure. Such problems are often analysed with finite elements, but the quality of a finite element solution may be sensitive to the orientation of the mesh with respect to the principal axes of stress. This paper presents the outline of a procedure to generate well-structured inclined quadrilateral finite element meshes for the analysis of thin plate and shell structures. The procedure was developed using the commercial FE pre-processor ABAQUS CAE and the Python script language, though it may readily be applied in any pre-processor which supports an external scripting functionality. A set of mesh convergence studies using linear buckling analyses are presented on four benchmark problems with known analytical solutions to illustrate the effect of inclined meshes on the accuracy of the computed solution. These illustrations are intended to raise an awareness of the subtle but important relationship between mesh and stress field orientation.
and are presented for the benefit of practising finite element analysts in structural engineering.

ABSTRACT: This paper presents an initial study of the effects of an accidental eccentric flow channel that sometimes develops in the conical hopper of a metal storage silo. A simple assumed pressure regime is adopted, based on studies of eccentric discharge in cylindrical silos, and the structural actions are analysed using shell membrane theory. The results are verified against a finite element analysis. A set of equations is derived which give the complete membrane stress state in the hopper under such an unsymmetrical pressure regime. Under symmetrical loading, silo hoppers are subject to biaxial tension, with failure normally governed by material rupture due to tensile meridional membrane stresses. It is found that the eccentric flow channel leads to dramatically increased meridional membrane stresses at the transition. Compressive membrane stresses are also found near the hopper outlet and at the sides of the flow channel near the transition. A reasonably close correlation is found between the derived membrane theory equations in a right circular conical hopper and linear elastic finite element predictions.

ABSTRACT: The buckling strength of a thin cylindrical shell is important in many applications in civil engineering. On the one hand, current design rules are principally based on an empirical interpretation of test data and hence very simple loading conditions are applied. On the other hand, experimental and theoretical observations show significant stress non-uniformity and hence a deviation from the buckling strength expected under uniform load. Reliable quantification of this effect is still challengingly difficult. This paper explores a typical thin cylindrical silo shell under localized axial compression. Two different buckling phenomena are identified with corresponding, and distinct, buckling mode forms. The influence of geometric imperfections on the buckling strength of the shell is also considered. INTRODUCTION Cylindrical silo shells are subject to vertical stresses in their walls as a consequence of friction between the stored solid and the wall. Shell buckling under axial compression is normally the controlling design consideration especially for steel silos. The classical buckling strength (Lorenz, 1908; Timoshenko, 1910; Southwell, 1914) continues to be treated as a practical reference load for such shells. On the one hand, Janssen theory (1895) remains the dominant method of defining silo pressures for design. On the other hand, more recent experimental (Pieper, on silo loading show significant non-uniform deviations from the classical theory even under careful symmetrical filling. Unsymmetrical loads on silo walls lead to high local axial compression (Rotter, 1986a; Rotter, 1998). The buckling strength under an axial compression that acts over only a part of the circumference is significantly reduced, but has been scarcely explored at all (Rotter, 1986a; Rotter, 1986b; Ansourian, 1992; Rotter, 1997). A recent investigation by Cai et al. (2002) is the first known study to examine this problem systematically. The present paper details some of the results from their study.

ABSTRACT: This paper explores the results of full-scale bending tests of thick spiral welded steel tubes in the slenderness range of $d/t = 73.5$ to 101.5. The experimental investigations reveal unused bending capacities for such tubes compared to existent design rules and support the need for the development of improved and more efficient design recommendations. The results of the bending tests together with the investigations of the initial geometric quality of the specimens' surfaces suggest that the influence of spiral welding on the bearing behaviour is negligible in case of the investigated thick-walled specimens.

INTRODUCTION: Recent work in the field of semi-analytical methods used for the nonlinear analysis and design of stiffened plates with buckling problems have shown an important and alternative tool that provide an efficient and understandable response [1–4]. Nowadays two computational programs use the semi-analytical method to analyse the post-buckling behaviour of plates and to predict their ultimate strength. The computer program ALPS/ULSAP [5], which uses a semi-analytical method previously known as the incremental Galerkin method [6] and the computer program PULS [7] developed at Det Norske Veritas (DNV) and accepted as general buckling code for ship and offshore platform structures as part of the DNV specifications [8]. The existing semi-analytical models are restricted to stiffened plates supported by rigid transverse and longitudinal girders. This type of arrangement is typical in ship, aircraft, tanks and offshore platform structures where it is assumed that the analysed stiffened plate is simply supported and the in-plane displacements perpendicular to the edges are constrained to remain straight in all edges. Generally, in bottom flanges of steel box girder bridges there are no neighbouring panels in the longitudinal edges to provide this kind of constraint and it is more conservative to consider the longitudinal edges with fully free in-plane displacements that are characteristic of edges free from stresses. This paper presents a computational semi-analytical model for the post-buckling analysis and ultimate strength prediction of stiffened plates under longitudinal uniform compression. The possibility of considering fully free in-plane displacements at longitudinal edges (or unloaded edges) is the innovation of this model over existing models. Comparisons between the semi-analytical model and nonlinear finite element model results are presented.

ABSTRACT: A solution for the elastic and inelastic local buckling of flat rectangular plates with centerline boundary conditions subjected to non-uniform in-plane compression and shear stress is presented. The loaded edges are simply supported, the longitudinal edges may have any boundary conditions and the centerline is simply supported with a variable rotational stiffness. The Galerkin method, an effective method for solving differential equations, is applied to establish an eigenvalue problem. In order to obtain plate buckling coefficients, combined trigonometric and polynomial functions that satisfy the boundary conditions are used. The method is programmed, and several numerical examples including elastic and inelastic local buckling, are presented to illustrate the scope and efficacy of the procedure. The variation of buckling coefficients with aspect ratio is presented for various stress gradient ratios. The solution is applicable to stiffened plates and the flange of the I-shaped beams that are subjected to biaxial bending or combined flexure and torsion and shear stresses, and it is important to estimate the reduction in elastic buckling capacity due to stress gradient.

ABSTRACT: This paper outlines key aspects of the new European Standard on the Strength and Stability of Metal Shells EN 1993-1-6 with its extended commentary and expansion in the fifth edition of the European Recommendations on Shell Buckling. This European design standard is the first to be strongly oriented toward numerical analyses in design, with clear distinctions between different classes of both analysis and fabrication. It presents a different style of standard: Each limit state is defined in a separate chapter, but all shell geometries are treated and all analysis types are used within each chapter. The strength evaluation criteria differ according to the calculation that has been made. This new structure, with its new paradigm that permits generalization of the design procedure for all thin shells, geometries, load cases, boundary conditions, and qualities, represents a major step forward. It also offers the opportunity for future research studies of shell structures to be undertaken within a coherent conceptual framework that is completely general. The EN 1993-1-6 standard goes a long way toward bridging the gap between the computational engineering mechanics and structural engineering design communities. Unfortunately, this European standard EN 1993-1-6 has a complex and extensive background that cannot be stated within the document so the European Recommendations on Shell Stability, now published in its fifth edition, gives an extensive commentary, many expanded rules, and many additional geometries and load cases that are not formally presented within the standard itself. The development of both EN 1993-1-6 and the recommendations has been the work of the Eurocode shell structures development committee CEN/TC250/SC3/PT4 and the European Convention for Constructional Steelwork committee (ECCS) TWG 8.4. It is presented here by the convener of these two committees. This paper explains the reasoning behind several particular choices that have been taken in developing the standard, occasionally running counter to traditional views. It also identifies several tricky issues that have not been addressed well in the shell buckling literature but that have arisen through the attempts to achieve completely general rules and which need imaginative answers to ensure a fully consistent treatment of all systems. It is hoped that this paper will assist researchers and designers to understand the rules and recommendations and will encourage researchers to undertake and present their work in a manner that permits its rapid adoption into the new standardized design procedures.

ABSTRACT: Metal silos used to store granular solids often take the form of a cylindrical shell with an aspect ratio in the range 2<H/D<6. It has long been recognised that the most serious load case for all silos is probably the condition of eccentric discharge of its stored solid, but in circular metal silos this is especially true. More
failures have occurred under this condition than any other. This high failure rate is chiefly due to the complexity of the pressures exerted by an eccentrically discharging granular material, and the difficulty in understanding the pattern of stresses that develops in a shell wall under such unsymmetrical pressure regimes. The nonsymmetric behaviour of a shell structure under unsymmetrical pressures is not at all well described in the voluminous shell structures literature, and only a few studies have explored the mechanics leading to high local stresses which in turn lead to buckling failure under eccentric discharge. This study follows an earlier initial exploration by Sadowski and Rotter (2010) [2], in which buckling in a moderately slender perfect silo was explored. Here, the work is taken further to explore a very slender structure, and to investigate the imperfection sensitivity of this failure mode. The pressures caused by eccentric discharge are characterised using the new rules of the European Standard EN 1991-4 (2006) [1] that define the actions in silos and tanks. Using this new improved description of unsymmetrical eccentric discharge pressures, it is now possible to perform relatively realistic calculations relating to this common but complicated shell buckling condition. The shell buckling calculations described here employ a pressure distribution formulated with the assumption of a parallel-sided flow channel and are undertaken using geometrically and materially nonlinear analyses in accordance with the European Standard EN 1993-1-6 (2007) [25] on the strength and stability of shells. The paper explores the structural behaviour of a slender silo under eccentric discharge, leading to buckling and including the critical effects of changes of geometry and imperfection sensitivity.

ABSTRACT: The current European standards for the design of thin-walled metal silos require the designer to use a complex combination of rules covering many different aspects of loading, structural behaviour and strength. Each individual rule was often developed autonomously, usually with implicit and undocumented conservative assumptions. When combined, the overall factor of safety of a designed silo may be significantly different from that guaranteed by the standard, making it difficult to reproduce the design rules in a numerical calculation that does not include the same implicit assumptions. This paper explores the behaviour of five thin-walled cylindrical silos with stepwise-varying wall thickness and aspect ratios varying from very squat to very slender, all custom-designed for and analysed under the EN 1991–4 concentric discharge loading condition. The aspect ratio plays a deciding role in both the behaviour and design of silos, and it is important to ascertain that a finding that is valid for one is transferable to the others. The nonlinear finite element analyses reveal that the computed load factor exceeds the partial safety factor in design by a large factor over a wide range of aspect ratio, suggesting that the overall design process is particularly conservative. The reasons for these discrepancies are explored. This paper is the first of a pair. The second paper explores the behaviour of the same set of example silos under the EN 1991–4 eccentric discharge loads, with fundamentally different conclusions.

ABSTRACT: The phenomenon of eccentric discharge is widely recognised as the most dangerous condition for thin-walled metal silos and the cause of many catastrophic buckling failures. A realistic pressure model for this condition appears in a regulating standard for the first time in EN 1991-4 (2006) on Actions on Silos and Tanks. However the structural consequences of its application are currently largely unknown. The behaviour of a silo

ABSTRACT: The phenomenon of eccentric discharge is widely recognised as the most dangerous condition for thin-walled metal silos and the cause of many catastrophic buckling failures. A realistic pressure model for this condition appears in a regulating standard for the first time in EN 1991-4 (2006) on Actions on Silos and Tanks. However the structural consequences of its application are currently largely unknown. The behaviour of a silo

subjected to these pressures is certainly very dependent on the aspect ratio of the silo, the granular solid properties and the discharge channel geometry. This paper explores the behaviour of four thin-walled cylindrical silos with stepwise-varying wall thickness and aspect ratios varying from intermediate to very slender, subject to the codified EN 1991-4 eccentric discharge pressures. It is shown that a silo design that was found to be very safe under the EN 1991-4 concentric discharge pressures becomes very unsafe under eccentric discharge. Further, as it is known that the aspect ratio has an important effect on the flow pattern in discharging granular solids, and that slender silos exhibit very different flow patterns from squat silos, it is currently not certain whether a suitable range of aspect ratio over which the codified eccentric discharge model is to be applied has been prescribed in the standard. This paper is the second of a pair. In the first, the behaviour of a set of example silos under the EN 1991-4 concentric discharge condition was studied. The same example silos are studied here under eccentric discharge.

ABSTRACT: Large quantities of particulate solids and fluids are stored in cylindrical metal shell silos and tanks with a vertical axis. Such metal silos and tanks are often required to be elevated above ground level to permit trains, trucks or conveying systems to be placed beneath a hopper from which the solid or fluid is withdrawn. Elevated silos must be supported, and access requirements often mean that the supports must be local (either on columns or supported from an elevated floor system). The connection of a local support to an elevated cylindrical metal silo shell is a long-standing difficult problem in shell analysis, and most designs are based on simple ideas using past experiences of successes and failures. Smaller silo structures are often supported on local brackets attached to the side of the shell, but very few investigations of the behaviour or strength of such an arrangement have ever been made. This thesis presents a comprehensive investigation into the behaviour of a cylindrical steel shell that is discretely supported on several brackets, each rigidly connected to a stiff column or floor. The study has been conducted within the framework of the European Standard for Shell Structures (EN1993-1-6, 2006), which requires that the two reference strengths of the small displacement theory plastic collapse resistance and the linear bifurcation critical elastic resistance should both be evaluated to establish the context in which more sophisticated analyses are judged, and to provide a rapid means of producing reliable but simple design information. Therefore this thesis begins with a thorough investigation of the predictions of these two reference strengths for these structures, discovering the challenges inherent in this methodology and finally developing equations that can be used in hand calculations intended for the simple evaluation of the reference strengths for a wide variety of geometries. The influence of geometric nonlinearity is next explored, both with and without geometric imperfections. The results pose some interesting questions concerning the relative importance of geometric nonlinearity and geometric imperfections in shell buckling problems where the stress field is far from uniform. In the final part of the investigation, analyses are conducted that include both material and geometric nonlinearity with and without geometric imperfections. The results of these analyses are presented and analysed in the context of interaction capacity curves. Following this extensive parametric investigation using linear and nonlinear analyses of all kinds, design recommendations are formulated so that bracket supports of this type can be used on thin cylindrical shells of any thickness and with any bracket dimensions necessary to transmit the loads. Finally, proposals are made for key future research investigations.

ABSTRACT: Cylindrical shells of stepwise variable wall thickness are widely used for cylindrical containment structures, such as vertical-axis tanks and silos. The thickness is changed because the stress resultants are much larger at lower levels. The increase of internal pressure and axial compression in the shell is addressed by increasing the wall thickness. Each shell is built up from a number of individual strakes of constant thickness. The thickness of the wall increases progressively from top to bottom. Whilst the buckling behaviour of a uniform thickness cylinder under external pressure is well defined, that of a stepped wall cylinder is difficult to determine. In the European standard EN 1993-1-6 (2007) and Recommendations ECCS EDR5 (2008), stepped wall cylinders under circumferential compression are transformed, first into a three-stage cylinder and thence into an equivalent uniform thickness cylinder. This two-stage process leads to a complicated calculation that depends on a chart that requires interpolation and is not easy to use, where the mechanics is somewhat hidden, which cannot be programmed into a spreadsheet leading to difficulties in the practical design of silos and tanks. This paper introduces a new "weighted smeared wall method", which is proposed as a simpler method to deal with stepped-wall cylinders of short or medium length with any thickness variation. Buckling predictions are made for a wide range of geometries of silos and tanks (unanchored and anchored) using the new hand calculation method and compared both with accurate predictions from finite element calculations using ABAQUS and with the current Eurocode rules. The comparison shows that the weighted smeared wall method provides a close approximation to the external buckling strength of stepped wall cylinders for a wide range of short and medium-length shells, is easily programmed into a spreadsheet and is informative to the designer.

ABSTRACT: Cylindrical shells are widely used in civil engineering. Examples include cooling towers, pipelines, nuclear containment vessels, steel silos and tanks for storage of bulk solids and liquids, and pressure vessels. The loading condition for these shells is quite varied depending on the function of the shell. Axial compression, global bending, external or internal pressure and wind loading are some of the most common loading forms for realistic structures. The failure of these cylindrical shell structures is often controlled by elastic or elastic-plastic buckling failure. Yield failure may occur in thick cylinders in some situations. A cylindrical shell under different loading conditions may display quite different buckling behaviour. The objective of this thesis is to investigate the characteristics of different buckling behaviours of cylindrical shell structures under axial compression, global bending, uniform external pressure and wind pressure. Some challenging practical problems in the design of these shell structures are explored. This thesis is expected to have some far-reaching impacts in defining how to design cylindrical shell structures to give them adequate strength to resist extreme events. Many aspects will be based on the latest Eurocode (EN 1993-1-6, 2007) and Recommendations (ECCS EDR5, 2008). The results show both some strength and some weaknesses in the Eurocode in design of shell structures. New methods are proposed for some practical problems. Some new conclusions and suggestions are derived and are expected to provide some useful knowledge for the improvement of the Eurocode in cylindrical shell design in general.

ABSTRACT: The objective of this thesis is to broaden current knowledge of the strength and buckling/collapse of shells, with special reference to steel silo structures on discrete supports, and thus to provide design guidance of practical value for future silo design and construction and to develop new research aspects for further investigation. A linear elastic solution of the cylindrical shell bending equations is presented for local loadings, with special attention to local longitudinal distributed loadings. Algebraic expressions for the displacements and stresses induced by a rectangular patch of longitudinal load on a simply supported cylindrical shell are derived using double Fourier series. The solution of this problem is general, and therefore can be applied to cylindrical shells under local I loadings in any direction and with different boundary conditions. Linear elastic analyses of discretely supported perfect cylinders under axial compression are presented using the finite element method. The pre-buckling meridional membrane stress distribution above the support centreline is examined in detail, and is followed by investigations of the linear bifurcation behaviour of the cylinders. The effects on the stress distribution and the buckling strength of different loading patterns and different geometric configurations are extensively examined. Geometrically nonlinear elastic buckling analyses are also performed using large
deflection theory. Both perfect and imperfect cylinders are studied with various geometric configurations and under different loading conditions. The nonlinear elastic buckling behaviour, the buckling strength and the buckling configuration are thoroughly investigated for discretely supported cylinders. Further studies extend the work into the plastic range. Discretely supported cylinders obeying the von Mises yield criterion are analysed. Limit analyses of perfect cylinders are first conducted using small deflection theory. Geometrically nonlinear elastic-plastic collapse analyses of both perfect and imperfect cylinders are performed next. Studies of different loading conditions and parametric studies of varying geometries and material strengths are presented in both types of analysis. The nonlinear elastic-plastic behaviour of discretely supported cylinders is thus explored. A complete silo which consists of a cylindrical shell, a conical roof hopper and a conical discharge hopper is briefly examined, with the aim of exploring the applicability of the established cylinder model in the elastic buckling analysis of silo structures. Finally, the conclusions drawn from this research are summarised and recommendations are also made for further research on locally supported shells.

ABSTRACT: Steel silos are widely used as long-term or short-term containers for the storage of granular solids, of which a huge range are stored, from flour to iron ore pellets, coals, cement, crushed rocks, plastic pellets, chemical materials, sand, and concrete aggregates. The radius to thickness ratio for silos is in the range of 200 to 3000, so they fall into the category of thin shells, for which failure by buckling is the main concern and requires special attention in design. The primary aim of this thesis is to investigate the possible application of Fibre Reinforced Polymer (FRP) as a new repair and strengthening technique to increase the buckling capacity of thin metallic cylindrical shells. Extensive research has been conducted on the use of fibre reinforced polymer (FRP) composites to strengthen concrete, masonry and timber structures as well as metallic beams. However, all these studies were concerned with failure of the structure by material breakdown, rather than stability. As a result, this thesis marks a major departure in the potential exploitation of FRP in civil engineering structures. Many analyses of cylindrical shells are presented in the thesis. These are all focussed on strengthening the shell against different failure modes. Two loading conditions were explored: uniform internal pressure accompanied by axial load near a base boundary, and axial loads with geometric imperfections. For the latter, local imperfections are usually critical, and two categories of imperfection were studied in detail: an inward axisymmetric imperfection and a local dent imperfection. For the first loading condition, which leads to elephant’s foot buckling, an analytical method was used to derive general equations governing the linear elastic behaviour of a cylindrical shell that has been strengthened with FRP subject to internal pressure and axial compression. It was used to identify optimal application of the FRP. All the later studies were conducted using nonlinear finite element analysis (using the ABAQUS program) to obtain extensive predictions of many
conditions causing shell buckling and the strengthening effect of well-placed FRP. In all the cases studied in this thesis, it was shown that a small quantity of FRP composite, applied within a small zone, can provide a significant enhancement of the resistance to buckling failure of a thin metal cylinder. These calculations demonstrate that this new technique is of considerable practical value. However, it is clear that not all the relevant questions have been fully answered, so the author poses appropriate questions and makes suggestions for future work.

ABSTRACT: An isoparametric shell element has been developed capable of linear response to the imposed loads. The original formulation, which was written for static and dynamic analyses, was extended to embrace linear buckling problems. A variety of numerical examples were attempted in order to assess the adaptability of the element to different geometrical representations. Despite serious size limitations of the computer, the accuracy of the predicted buckling loads was found to be satisfactory.

-------Fatih Bazman, Monday, 17 August 2009 blog:
Shell Buckling Calculations
The buckling behaviour of shells is not widely known and simple procedures for analysis of buckling of shells are available only to a very limited extent in design codes. Although AWWA D100 considers the buckling effects in itself, API 650 doesn't investigate any buckling behaviour of shell structure. Storage tank designers must be consider the buckling behaviour due to self weight, vacuum load, wind load and seismic load effects on shell. At the present time, several papers or standards are available:
- Det Norske Veritas: DNV-RP-C202: Buckling Strength of Shells
- DIN 1880 Part 4: Structural Steelwork Analysis of Safety Against Buckling of Shells
- ASME Code Case N-284: Metal Containment Shell Buckling Design Methods, Miller C.D. 1991,
In my opinion, DIN 1880 Part 4 has more practical solutions instead of others.

“Stiffening of thin cylindrical silo shell against buckling loads, 12th International Conference on Machine Design and Production, September 2006, Kusadasi, Turkey
ABSTRACT: Buckling is one of the important criteria to be checked in silo design. Buckling behaviour of silos can be analyzed with finite element methods or analytical methods which are developed for cylindrical shells. In this study, buckling analysis of a silo which is also supporting another structure is analyzed with eigenvalue solution by using finite element method and one of these analytical methods. The results obtained by using these two methods are compared.

-------Glenn A. Hrinda, NASA Langley Research Center
ABSTRACT: Shell-buckling knockdown factors (SBKF) have been used in large cylindrical shell structures to account for uncertainty in buckling loads. As the diameter of the cylinder increases, achieving the manufacturing tolerances becomes increasingly more difficult. Knockdown factors account for manufacturing imperfections in the shell geometry by decreasing the allowable buckling load of the cylinder. In this paper, large-diameter (33 ft) cylinders are investigated by using various SBKF's. An investigation that is based on finite-element analysis (FEA) is used to develop design sensitivity relationships. Different manufacturing
imperfections are modeled into a perfect cylinder to investigate the effects of these imperfections on buckling. The analysis results may be applicable to large-diameter rockets, cylindrical tower structures, bulk storage tanks, and silos.

**Buckling Analysis of Shell Structures**

Predicting the buckling response of thin shells in structural simulations is difficult because most models do not include the physical characteristics of the problem that initiate instabilities. For shell structures, the character of the buckling and load levels that lead to instability are governed by the nonuniformities or imperfections in either the structure or loading. A methodology was developed to accurately predict the buckling response of the thin shell structures by incorporating either the measured imperfections in the structure and loading or accurate statistical approximations to the imperfections. This analysis approach has been applied successfully to a variety of buckling problems. One application is the analysis of dynamic pulse buckling of impulsively loaded thin cylindrical aluminum shells. The cosine distributed external impulsive loads drive the shell inward, producing compressive circumferential stresses and pulse buckling on the loaded side of the shell. These buckles produce strain concentrations that govern the eventual fracture of the structure. Thus, the buckling response needs to be correctly modeled to predict failure. A cross section of a dynamically pulse buckled thin cylindrical shell and the calculated response are shown in Figure 1. In the calculation, we used the measured imperfections in the cylinder shape to initiate the buckling. The buckling response can clearly be seen on the loaded (front) side of the cylinder and is accurately reproduced in the calculation. These modeling techniques have also been applied to other structural applications, including analysis of crash energy management structures for vehicles, static axial collapse of cylinders, and dynamic buckling of thick shells. One example application for thick shells is the buckling that occurs in explosively formed penetrators (EFPs), as shown in Figure 2. Understanding and modeling the processes that lead to dynamic plastic buckling in EFP liners allows the designer to control the buckling process to gain enhanced aerostability.

ABSTRACT: A finite difference solution is presented for elastic wave propagation in laminated composite hollow tubes under axial plane strain, subjected to a radially symmetric pressure pulse at the inner surface. The solution is applied to two-layered cross-ply and angle-ply AS4/3501-6 graphite/epoxy cylinders, and to homogeneous monoclinic cylinders. The effects of pulse time duration, stacking sequence, ply angle and stiffnesses on the resulting displacement, stresses (radial, hoop, axial and shear) and dynamic stress concentration factor are studied.

ABSTRACT: The dynamic plastic buckling of cylindrical shells (rings) subjected to general initial impulsive velocity and subjected to impulsive loading is studied based on the energy criterion. A simple analysis method is given and the formulas of critical mode numbers, n cr, and critical impulsive velocity, v cr, are obtained.

ABSTRACT: This paper is devoted to the derivation and the analysis of vibrations of shallow spherical shell subjected to large amplitude transverse displacement. The analog for thin shallow shells of von Karman’s theory for large deflection of plates is used. The validity range of the approximations is assessed by comparing the analytical modal analysis with a numerical solution. The specific case of a free edge is considered. The governing partial differential equations are expanded onto the natural modes of vibration of the shell. The problem is replaced by an infinite set of coupled second-order differential equations with quadratic and cubic non-linear terms. Analytical expressions of the non-linear coefficients are derived and a number of them are found to vanish, as a consequence of the symmetry of revolution of the structure. Then, for all the possible internal resonances, a number of rules are deduced, thus predicting the activation of the energy exchanges between the involved modes. Finally, a specific mode coupling due to a 1:1:2 internal resonance between two companion modes and an axisymmetric mode is studied.

“Non-linear modal interactions in free-edge thin spherical shells: measurements of a 1:1:2 internal resonance”, in Computational Fluid and Solid Mechanics, K.J. Bathe (Editor), Paper no. 120-221, 2005
ABSTRACT: This study is devoted to the experimental validation of a theoretical model of large amplitude vibrations of thin spherical shells described in Thomas et al.[1]. A specific mode coupling due to a 1:1:2 internal resonance between an axisymmetric mode and two companion asymmetric modes is especially addressed. The structure is forced with a sinusoidal signal of frequency close to the natural frequency of the axisymmetric mode. The experimental setup, which allows precise measurements of the vibration amplitudes of the three involved modes, is presented. Experimental resonance curves showing the amplitude of the modes as functions of the driving frequency are compared to the theoretical ones. A good qualitative agreement is obtained with the predictions given in the model. The quantitative discrepancies are discussed and an improvement of the model is proposed.

ABSTRACT: The aim of the present paper is to compare two different methods available for reducing the complicated dynamics exhibited by large amplitude, geometrically nonlinear vibrations of a thin shell. The two methods are: the proper orthogonal decomposition (POD), and an asymptotic approximation of the nonlinear normal modes (NNMs) of the system. The structure used to perform comparisons is a water-filled, simply supported circular cylindrical shell subjected to harmonic excitation in the spectral neighbourhood of the fundamental natural frequency. A reference solution is obtained by discretizing the partial differential equations (PDEs) of motion with a Galerkin expansion containing 16 eigenmodes. The POD model is built by using responses computed with the Galerkin model; the NNM model is built by using the discretized equations of motion obtained with the Galerkin method, and taking into account also the transformation of damping terms. Both the POD and NNMs allow to reduce significantly the dimension of the original Galerkin model. The computed nonlinear responses are compared in order to verify the accuracy and the limits of these two methods.

For vibration amplitudes equal to 1.5 times the shell thickness, the two methods give very close results to the original Galerkin model. By increasing the excitation and vibration amplitude, significant differences are observed and discussed. The response is investigated also for a fixed excitation frequency by using the excitation amplitude as bifurcation parameter for a wide range of variation. Bifurcation diagrams of Poincare maps obtained from direct time integration and calculation of the maximum Lyapunov exponent have been used to characterize the system.

Marco Amabili, “Reduced-order models for nonlinear vibrations, based on natural modes: the case of the circular cylindrical shells”, Philosophical Transactions of the Royal Society A, May 2013
DOI: 10.1098/rsta.2012.0474

ABSTRACT: Reduced-order models are essential to study nonlinear vibrations of structures and structural components. The natural mode discretization is based on a two-step analysis. In the first step, the natural modes of the structure are obtained. Because this is a linear analysis, the structure can be discretized with a very large number of degrees of freedom. Then, in the second step, a small number of these natural modes are used to discretize the nonlinear vibration problem with a huge reduction in the number of degrees of freedom. This study finds a recipe to select the natural modes that must be retained to study nonlinear vibrations of an angle-ply laminated circular cylindrical shell that the author has previously studied by using admissible functions defined on the whole structure, so that an accuracy analysis is performed. The higher-order shear deformation theory developed by Amabili and Reddy is used to model the shell.

ABSTRACT: The problem of a thin spherical linearly-elastic shell, perfectly bonded to an infinite linearly-elastic medium is considered. A constant axisymmetric stress field is applied at infinity in the matrix, and the displacement and stress fields in the shell and matrix are evaluated by means of harmonic potential functions. In order to examine the stability of this solution, the buckling problem of a shell which experiences this deformation is considered. Using Koiter’s nonlinear shallow shell theory, restricting buckling patterns to those which are axisymmetric, and using the Rayleigh–Ritz method by expanding the buckling patterns in an infinite series of Legendre functions, an eigenvalue problem for the coefficients in the infinite series is determined. This system is truncated and solved numerically in order to analyse the behaviour of the shell as it undergoes buckling, and to identify the critical buckling stress in two cases — namely where the shell is hollow and the stress at infinity is either uniaxial or radial.

Partial text from the given page:

shells are needed, especially for shells made of advanced composite materials. Shell-buckling design criteria have a history steeped in empiricism. From approximately 1930 to 1967, many shell-buckling experiments were conducted on metallic shells. Typically, the experiments yielded buckling loads that were substantially lower than the corresponding analytical predictions, which were based on simplified linear bifurcation analyses of geometrically perfect shells with nominal dimensions and idealized support conditions. The primary source of discrepancy between corresponding analytical predictions and experimental results is attributed to small deviations from the idealized geometry of a shell, known as initial geometric imperfections. Empirical design factors, known as "knockdown" factors, were determined from these test data and were to be used in conjunction with linear bifurcation analyses for simply supported shells to adjust or "knockdown" the unconservative analytical prediction. This approach to shell design remains prominent in industry practice, as evidenced by the extensive use of the NASA space vehicle design recommendations. Recent advancements in digital computers, high-fidelity structural analysis tools and testing technologies are enabling the development of a new shell buckling design philosophy, namely, analysis-based knockdown factors. Key enabling technology developments and their implementation in ongoing NASA Shell Buckling Knockdown Factor development activities are presented in this lecture. In addition, the development of a refined shell-buckling preliminary-design criteria that is based on high-fidelity nonlinear finite-element analyses that include the effects of a manufacturing-process-specific geometric imperfection signature is presented.

ABSTRACT: Validity of the assumptions relating the applicability of continuum shell theories to the global mechanical behavior of carbon nanotubes is examined. The present study focuses on providing a basis that can be used to qualitatively assess the appropriateness of continuum-shell models for nanotubes. To address the effect of nanotube structure on their deformation, all nanotube geometries are divided into four major classes that require distinct models. Criteria for the applicability of continuum models are presented. The key parameters that control the buckling strains and deformation modes of these classes of nanotubes are determined. In an analogy with continuum mechanics, mechanical laws of geometric similitude are presented. A parametric map is constructed for a variety of nanotube geometries as a guide for the applicability of different models. The continuum assumptions made in representing a nanotube as a homogeneous thin shell are analyzed to identify possible limitations of applying shell theories and using their bifurcation-buckling equations at the nano-scale.

ABSTRACT: The buckling behaviors of double-walled carbon nanotubes (DWCNTs) under torsion are investigated by using molecular dynamics (MD) simulations. The effect of length on the torsional buckling behaviors of DWCNTs is examined for the first time. The simulation results show that the DWCNTs experience gradual or simultaneous buckling deformations depending on their lengths. In addition, the effect of the inner tube in a DWCNT on its torsional buckling behavior is also examined. The presence of the inner tube triggers van der Waals (vdW) interactions between it and the outer tube and thus leads to a stiffening effect of the DWCNT against torsional deformation. Whether the ends of the inner tube are free or fixed and whether it is subject to a torque or not, the critical torque and the critical torsional angle of the outer tube are only marginally affected.

ABSTRACT: Carbon nanotubes (CNTs) have potential applications in various fields of science and engineering due to their extremely high elasticity, strength, and thermal and electrical conductivity. Owing to their hollow
and slender nature, these tubes are susceptible to buckling under a compressive axial load. As CNTs can undergo large, reversible post-buckling deformation, one may utilize this postbuckling response of CNT to manufacture mechanical energy storage devices at the nano-scale, or use it as a nano-knife or nano-pump. It is therefore important to understand the buckling behavior of CNTs under a compressive axial load. Experimental investigations on CNT buckling are very expensive and difficult to perform. As such, researchers often rely on molecular dynamics (MD) simulations, or continuum mechanics modeling to study their mechanical behaviors. In order to develop a good continuum mechanics model for buckling analysis of CNTs, one needs to possess adequate experimental or MD simulation data for its calibration. For “short” CNTs with small aspect ratios (B10), researchers have reported different critical buckling loads/strains for the same CNTs based on MD simulations. Moreover, existing MD simulation data are not sufficiently comprehensive to allow rigorous benchmarking of continuum-based models. This chapter presents extensive sets of MD critical buckling loads/strains for armchair single-walled CNT (SWCNTs) and double-walled CNTs (DWCNTs), with various aspect ratios less than 10. These results serve to address the discrepancies found in the existing MD simulations, as well as to offer a comprehensive database for the critical buckling loads/strains for various armchair SWCNTs and DWCNTs. The Adaptive Intermolecular Reactive Bond Order (AIREBO) potential was adopted for MD simulations. Based on the MD results, the Young’s modulus, Poisson’s ratio and thickness for an equivalent continuum cylindrical shell model of CNTs are calibrated. The equivalent continuum shell model may be used to calculate the buckling loads of CNTs, in-lieu of MD simulations.

ABSTRACT: An elastic double-shell model is presented for infinitesimal buckling of a double-walled carbon nanotube embedded in an elastic matrix under axial compression. The analysis is based on a Winkler model for the surrounding elastic medium and a simplified model for the van der Waals interaction between the inner and outer nanotubes. An explicit formula is derived for the critical axial strain, which indicates the effects of the surrounding elastic matrix combined with the intertube van der Waals forces. In particular, the present model predicts that the critical axial strain of the embedded double-walled nanotube is lower than that of an embedded single-walled nanotube under otherwise identical conditions. This implies that inserting an inner tube lowers the critical axial strain of an embedded single-walled carbon nanotube, although the total critical compressive force could be increased due to the increase in the cross-sectional area of the nanotube. The reduced critical axial strain is attributed to the intertube slips between the inner and outer tubes. This result indicates that embedded multi-walled carbon nanotubes could be even more susceptible to infinitesimal axial buckling than embedded single-walled carbon nanotubes.

ABSTRACT: This paper studies axially compressed buckling of an individual multiwall carbon nanotube subjected to an internal or external radial pressure. The emphasis is placed on new physical phenomena due to combined axial stress and radial pressure. According to the radius-to-thickness ratio, multiwall carbon nanotubes discussed here are classified into three types: thin, thick, and (almost) solid. The critical axial stress and the buckling mode are calculated for various radial pressures, with detailed comparison to the classic results of singlelayer elastic shells under combined loadings. It is shown that the buckling mode associated with the minimum axial stress is determined uniquely for multiwall carbon nanotubes under combined axial stress and radial pressure, while it is not unique under pure axial stress. In particular, a thin N-wall nanotube (defined by the radius-to-thickness ratio larger than 5) is shown to be approximately equivalent to a single layer elastic shell whose effective bending stiffness and thickness are N times the effective bending stiffness and thickness of singlewall carbon nanotubes. Based on this result, an approximate method is suggested to substitute a multiwall nanotube of many layers by a multilayer elastic shell of fewer layers with acceptable relative errors. Especially, the present results show that the predicted increase of the critical axial stress due to an internal radial pressure appears to be in qualitative agreement with some known results for filled singlewall carbon nanotubes obtained by molecular dynamics simulations.

ABSTRACT: This paper examines applicability and limitations of simplified models of elastic cylindrical shells for carbon nanotubes. The simplified models examined here include Donnell equations and simplified Flugge equations characterized by an uncoupled single equation for radial deflection. These simplified elastic shell equations are used to study static buckling and free vibration of carbon nanotubes, with detailed comparison to exact Flugge equations of cylindrical shells. It is shown that all three elastic shell models are in excellent agreement (with relative errors less than 5%) with recent molecular dynamics simulations for radial breathing vibration modes of carbon nanotubes, while reasonable agreements for various buckling problems have been reported previously for Donnell equations. For general cases of buckling and vibration, the results show that the simplified Flugge model, which retains mathematical simplicity of Donnell model, is consistently in better agreement with exact Flugge equations than Donnell model, and has a significantly enlarged range of applicability for carbon nanotubes. In particular, the simplified Flugge model is applicable for carbon nanotubes (with relative errors around 10% or less) in almost all cases of physical interest, including some important cases in which Donnell model results in much larger errors. These results are significant for further application of elastic shell models to carbon nanotubes because simplified shell models, characterized by a single uncoupled equation for radial deflection, are particularly useful for multiwall carbon nanotubes of large number of layers.

ABSTRACT: Based on a multiple-shell model, a comprehensive investigation has been performed on the effect of three dimensional factors, i.e., aspect ratio, the innermost radius, and the number of layers, on buckling behavior of multiwall carbon nanotubes (MWCNTs) under axial compression or radial pressure. In contrast to previous shell models, which use the single Donnell equation [Wang et al, ASME J. Appl. Mech. 71, 622 (2004)] and thus are only adequate for buckling of MWCNTs of relatively small aspect ratio (e.g., not larger than 10), the present shell model based on the simplified Flugge equation [Wang et al, ASME J. Appl. Mech. 71, 622 (2004)] allows for the study of buckling behavior of MWCNTs without any limitation on their aspect ratios. In addition, the pressure dependence of the interlayer van der Waals interaction coefficient (defined as the second derivative of the interlayer potential energy-interlayer spacing relation) has been considered for pressure-induced buckling of MWCNTs. The relevance of the present shell model for buckling of MWCNTs has been confirmed by the good agreement between the present shell model and available discrete models or experiments. Here, distinct buckling behaviors under axial compression or radial pressure are identified for long and short MWCNTs, separated by a certain critical value of aspect ratio. On the other hand, while the critical buckling load usually changes monotonically with the innermost radius an optimum value of the number of layers associated with the maximum critical buckling pressure is obtained for MWCNTs under radial pressure. In particular, the present shell model shows that the three dimensional factors effecting buckling of MWCNTs are generally interacting with, rather than being independent of, one another.

ABSTRACT: We report experimental observations of shell buckling instabilities in freestanding, vertically aligned multiwalled carbon nanotubes subjected to uniaxial compression. Highly ordered and uniform arrays of carbon nanotubes embedded in an alumina matrix were fabricated and subjected to uniaxial compression using a nanoindenter. The buckling load was found to be on the order of 2 _ºN for nanotubes with 25 nm outer radius, 13 nm inner radius, and heights of 50 and 100 nm. Good agreement was found between the experimental observations and the predictions of linear elastic shell buckling theory.

ABSTRACT: Although the mechanical behavior of carbon nanotubes has been studied extensively in recent years, very few experimental results exist on the shell buckling of nanotubes, despite its fundamental importance in nanotube mechanics and applications. Here we report an experimental technique in which individual multiwalled carbon nanotubes were axially compressed using a nanoindenter and the critical shell-buckling load was measured. The results are compared with predictions of existing continuum theories, which model multiwalled carbon nanotubes as a collection of single-walled shells, interacting through van der Waals forces. The theoretical models significantly underpredict the experimental buckling load.

ABSTRACT: In this article, we present recent progress in selected areas of carbon nanotube mechanics. First, we present the authors’ experimental work on shell buckling mechanics of multi-walled carbon nanotubes using nanoindentation. A comparison with existing elastic theories showed that the shell theories under-predict the buckling loads by as much as 50%. We then present an investigation of electromechanical coupling in carbon nanotubes by focusing on phonon frequency shifts as a result of charge injection. Raman spectroscopic measurements of the electromechanical couplings under varied but controlled charge injection conditions are analyzed, and the close agreement between the model results and the measured Raman peak shifts suggests that geometrical changes of charged carbon nanotubes previously observed or speculated in different experiments can indeed originate from the simple quantum effects described herein.

ABSTRACT: We have investigated the axial buckling of a multiwall nanotube by changing its number of layers. Young's moduli of nanotubes with different inner hollow diameters are estimated to be 0.77 TPa and 0.80 TPa from the Euler's buckling model, respectively. This good agreement implies that the Euler's buckling model is applicable to the analysis of the axial buckling behaviors of the nanotubes. The MD simulations for the buckling behaviors of the triple- and the double-walled nanotubes are also consistent with the continuum analysis. Consequently, the multi-shells composing multiwall nanotubes can be treated as a single shell with a thickness for whole shells.

ABSTRACT: Experiments were conducted in which multiwalled carbon nanotubes were subjected to uniaxial compression and shell-buckling loads were measured. A comparison with existing theoretical models shows that the predictions are about 40–50% smaller than the experimentally measured buckling loads. This is in contrast to the classical elastic shell studies in which the experimental values were always substantially lower than the predicted values due to imperfection sensitivity. It is proposed that the discrepancy between the predicted and measured value might be due to imperfections in the multiwalled nanotubes in the form of sp³ bonds between the tube walls, which introduce shear coupling between them. An analytical model is presented to estimate the effect of the shear coupling on the critical buckling strain, which shows that the contribution from shear coupling increases linearly with the effective shear modulus between the walls. Further, this
contribution increases with the number of walls; the increment from each additional wall progressively decreases.

ABSTRACT: Debonding of a single CNT (carbon nanotube) from the midway or one end of a CNT rope is studied in this paper. The analysis of buckling-driven debonding of an individual CNT is based on an elastic beam model, while the local debonding growth, stability and arrest are explained by the energy release rate criterion. The debonding from a preloaded CNT rope is driven by excess energy released from the unbuckled to the buckled state of an individual CNT. Some interesting debonding behaviors are displayed for varying dimensions, compression strain and van der Waals (vdW) adhesive energy. The growth of the debonding may be stable, unstable or unstable growth followed by a stable growth when an initial debonding CNT rope is loaded.

proximal probe tip that consists of an open, hydrogen-terminated, (10,10) carbon nanotubule. The simulations showed that upon indenting 1.8 Å, the tubule deforms but returns to its original shape upon retraction. The Young’s modulus of the tubule was determined using the predicted Euler buckling force and was found to be comparable to measured and calculated values. In a second series of simulations, an open (10, 10) nanotubule was heated to 4500 K and allowed to close. We find that at this temperature the resulting cap contains numerous imperfections, including some not mentioned previously in the literature.

ABSTRACT: Triangular lattices were assembled on spherical surfaces and caps via thermal stress engineering on core/shell microstructures. The lattices on a complete spherical surface, when the total number is small, contain uniquely fivefold disclinations, whereas scars consisting of pentamer-heptamer chains emerged when more vertices are available (>360). Disclination-free pattern were obtained on caps, revealing the defect management strategy in nature. All the experimental observations can be explained by numerical studies to Thomson’s problem [ J. J. Thomson, Philos. Mag. 7, 237 (1904) ]. These results can help understand the various patterns assembled on curved surfaces, and be of essential importance for the en masse fabrication of nanostructures on pliable substrates.

ABSTRACT: In this work the electromechanical buckling and postbuckling responses of a circular cylindrical shallow shell are analyzed. The cylindrical shell is subjected to a radial axi-symmetric electrostatic field that is generated by setting voltage difference between an exterior elastic thin shallow cylinder and an inner infinitely stiff solid cylinder. The nonlinear prebuckling state of the cylinder is considered in order to increase the accuracy of the analysis. The prebuckling, buckling and postbuckling states are solved by implementing the perturbation asymptotic approach. The critical electromechanical buckling voltage and the stability of the postbuckling states are solved for a wide range value of the geometrical parameters of the elastic shell, such as radius-thickness ratio, the radius-length ratio and the ratio between the radius of the interior stiff cylinder and the exterior cylindrical shell. The numerical results show that the initial electromechanical postbuckling of the shell is unstable for all the considered range of parameters.

ABSTRACT: Author(s):
We report atomistic studies of single-wall carbon nanotubes with very large aspect ratios subject to compressive loading. These long tubes display significantly different mechanical behavior than tubes with smaller aspect ratios. We distinguish three different classes of mechanical response to compressive loading. While the deformation mechanism is characterized by buckling of thin shells in nanotubes with small aspect ratios, it is replaced by a rod-like buckling mode above a critical aspect ratio, analogous to the Euler theory in continuum mechanics. For very large aspect ratios, a nanotube is found to behave like a flexible macromolecule which tends to fold due to vdW interactions between different parts of the carbon nanotube. This suggests a shell-rod-wire transition of the mechanical behavior of carbon nanotubes with increasing aspect ratios. While continuum mechanics concepts can be used to describe the first two types of deformation, statistical methods will be necessary to describe the dynamics of wire-like long tubes.

ABSTRACT: Control over the composition, shape, spatial location and/or geometrical configuration of semiconductor nanostructures is important for nearly all applications of these materials. Here we report a mechanical strategy for creating certain classes of three-dimensional shapes in nanoribbons that would be difficult to generate in other ways. This approach involves the combined use of lithographically patterned surface chemistry to provide spatial control over adhesion sites, and elastic deformations of a supporting substrate to induce well-controlled local displacements. We show that precisely engineered buckling geometries can be created in nanoribbons of GaAs and Si in this manner and that these configurations can be described quantitatively with analytical models of the mechanics. As one application example, we show that some of these structures provide a route to electronics (and optoelectronics) with extremely high levels of stretchability (up to ~100%), compressibility (up to ~25%) and bendability (with curvature radius down to ~5 mm).

ABSTRACT: We have studied the scaling of controlled nonlinear buckling processes in materials with dimensions in the molecular range (i.e., about 1 nm) through experimental and theoretical studies of buckling in individual single-wall carbon nanotubes on substrates of poly(dimethylsiloxane). The results show not only the ability to create and manipulate patterns of buckling at these molecular scales, but also, that analytical continuum mechanics theory can explain, quantitatively, all measurable aspects of this system. Inverse calculation applied to measurements of diameter-dependent buckling wavelengths yields accurate values of the Young's moduli of individual SWNTs. As an example of the value of this system beyond its use in this type of molecular scale metrology, we implement parallel arrays of buckled SWNTs as a class of mechanically stretchable conductor.

ABSTRACT: Local buckling can form microcorrugations in thin films on elastomeric substrates, to yield an effective type of mechanical stretchability in otherwise rigid, brittle materials, with many application possibilities. For large area films or relatively thin substrates, however, global Euler buckling, as opposed to local buckling, can be observed in experiments. This paper describes analytically the mechanics of local and global buckling of one-dimensional thin films or two-dimensional thin membranes on elastomeric substrates. The critical condition separating these two buckling modes is obtained analytically, and it agrees well with experiments and numerical simulations.

ABSTRACT: Based on the finite-deformation shell theory for carbon nanotubes established from the interatomic potential and the continuum model for van der Waals (vdW) interactions, we have studied the buckling of double-walled carbon nanotubes subjected to compression or torsion. Prior to buckling, the vdW interactions have essentially no effect on the deformation of the double-walled carbon nanotube. The critical
buckling strain of the double-wall carbon nanotubes is always between those for the inner wall and for the outer wall, which means that the vdW interaction decelerates buckling of one wall at the expenses of accelerating the buckle of the other wall.

ABSTRACT: This paper discusses the size dependence of the hardness with respect to the depth and the radius of the indenter for multiple walled carbon nanotubes. Results show a peculiar size influence on the hardness, which is explained via the shear resistance between the neighboring walls during the buckling of the multiwalled nanotubes.

ABSTRACT: We use Reddy's third order plate theory to study buckling and steady state vibrations of a simply supported functionally gradient isotropic polygonal plate resting on a Winkler–Pasternak elastic foundation and subjected to uniform in-plane hydrostatic loads. Young's modulus and the Poisson ratio for the material of the plate are assumed to vary only in the thickness direction. Effects of rotary inertia are considered. The problem of determining the critical buckling load or the vibration frequency of the plate is found to be analogous to that of ascertaining the frequency of a membrane clamped at the edges and whose shape coincides with that of the plate. The critical buckling load and the vibration frequency are shown to be positive. Some available results for plates symmetric about the mid-plane can be retrieved from the present analysis.

ABSTRACT: The dynamic buckling of thin isotropic thermoviscoplastic cylindrical shells compressed with a uniform axial velocity prescribed at the end faces is investigated analytically and numerically. In the first part of the paper, the stressed/deformed state of a shell is assumed to have buckled if infinitesimal perturbations superimposed upon it grow. Cubic algebraic equations are derived for both the initial growth rate of the perturbation and its wavenumber. The wavenumber corresponding to the maximum initial growth rate of a perturbation introduced at an axial strain of 0.1 is taken to determine the buckling mode. The computed buckling modes are found to match well with those listed in the available experimental data. A thermoviscoplastic constitutive relation is used to delineate the influence of material parameters on the buckling behavior. In the second part of the paper, the finite element method is used to analyze the collapse of an imperfect circular cylindrical tube with axial velocity prescribed at one of its flat end faces with the other end face kept fixed. The influence of initial randomly located imperfections on the buckling behavior is investigated and discussed.

ABSTRACT: Buckling of single-walled and multiwalled carbon nanotubes (SWNTs and MWNTs, respectively) due to axial compressive loads has been studied by molecular mechanics simulations, and results compared with those from the analysis of equivalent continuum structures using Euler buckling theory and the finite element method. It is found that a MWNT of large aspect ratio (length/diameter) buckles as a column with axial strain at buckling given reasonably well by the Euler buckling theory applied to the equivalent continuum structure. However, a MWNT of low aspect ratio buckles in shell wall buckling mode with the axial strain at buckling corresponding to the highest axial strain at buckling of one of its constituent SWNTs. A finite element model has been developed that simulates van der Waals forces by truss elements connecting nodes on adjacent walls of a MWNT; the axial strain at buckling from it is close to that obtained from the MM simulations but the two sets of mode shapes are different.

Buckling of a simply supported three-layer circular cylindrical shell under axial compressive load is studied. The inner and outer layers of the shell are comprised of the same homogeneous and isotropic material, and the middle layer is made of an isotropic functionally graded (FG) material whose Young's modulus varies either affinely or parabolically in the thickness direction from its value for the material of the inner layer to that of the outer layer. The solution is expressed in terms of trigonometric functions that identically satisfy displacement type boundary conditions at the edges. Buckling loads for different values of the geometric parameters and the variation in material parameters of the middle layer are computed. Numerical results show that buckling modes are symmetric in the circumferential coordinate, and the buckling load decreases with an increase in the radius to thickness ratio, and increases with an increase in the average value of Young's modulus of the middle layer. The increase in the length to radius ratio has no effect on the buckling load, and it increases the axial wave number of the buckled shapes.

ABSTRACT: We use molecular statics simulations with the embedded atom method potential to delineate yielding (material instability) and buckling (structural instability) in gold nanowires deformed axially in compression. It is found that both local (stacking faults) and global instabilities occur when the gold nanowire yields but only global instabilities occur when the nanowire buckles. Furthermore strong surface effects reorient the lattice structure which significantly increases Young’s modulus in the axial direction and cause a nanowire of relatively small slenderness ratio (e.g., 14) to buckle. Upon complete unloading of the nanowires, the average axial stress and the total potential energy revert to their values in the reference configuration for the nanowires that buckled but not for the one that yielded.

ABSTRACT: Analytical relations between the critical buckling load of a functionally graded material (FGM) Timoshenko beam and that of the corresponding homogeneous Euler–Bernoulli beam subjected to axial compressive load have been derived for clamped–clamped (C–C), simply supported–simply supported (S–S) and clamped–free (C–F) edges. However, no such relation is found for clamped–simply supported (C–S) beams. For C–S beams, the transcendental equation has been derived to find the critical buckling load for the FGM Timoshenko beam which is similar to that for a homogeneous Euler–Bernoulli beam. For the FGM beams Young’s modulus, E, and Poisson’s ratio, μ, are assumed to vary through the thickness. The significance of this work is that for the C–C, S–S and C–F FGM Timoshenko beams, the critical buckling load can be easily found from that of the corresponding homogeneous Euler–Bernoulli beam and two constants whose values depend
upon the through-the-thickness variations of E and m. For the C–S FGM Timoshenko beam the transcendental equation for the determination of the critical buckling load is similar to that for the corresponding homogeneous Euler–Bernoulli beam.

ABSTRACT: The solution of viscoplastic axisymmetrical buckling of a complete thin spherical shell subjected to radial pressure impulse is presented. Analytically, the problem is formulated as a superposition of small perturbations on the basic unperturbed motion. The amplitudes of perturbed motion are restricted to be so small that the homogeneous compressive deformation predominates over the local bending. This condition allows the constitutive equations to be linearized by the expansion into Taylor's series in the vicinity of unperturbed motion. As a result, a set of two linear partial differential equations of the fifth order is obtained for describing
the perturbed motion of the shell. The functional coefficients of these equations are determined by the solution for the unperturbed motion. The governing set of equations is solved using the series of Legendre's functions. As a result, for the time-dependent amplitudes in the series, the set of two ordinary equations with variable coefficients is arrived at. It turns out that certain harmonics grow very rapidly and cause the shell to exhibit a characteristic wrinkled shape which is characterized by a critical mode number. This property of the amplitudes is used to determine the threshold impulse that a shell can tolerate without excessive deformation. The influence of the meridional displacement on the magnitude of radial displacement, buckling mode and critical impulse is investigated. Also, the influence of the viscosity and the initial imperfections of the geometry and loading is shown. The numerical results for a steel shell are presented diagrammatically.

ABSTRACT: The paper develops a direct, intrinsic approach to the equilibrium equations of bodies coated by a thin film with a nonlinear shell like structure. The forms of the equations in the reference and actual configurations are considered. The equations are shown to coincide with those obtained by using coordinate systems on the film or on the thin shell.

ABSTRACT: The solution of viscoplastic buckling of a complete thin spherical shell subjected to impulse pressure is given. The nonlinear flow law is assumed and the influence of elevated temperature on the magnitude of displacements, buckling mode and threshold impulse is discussed. The special cases of bucking modes are also considered. The numerical results are presented diagrammatically for a steel shell loaded by a radial impulse.

ABSTRACT: Viscoplastic material behavior could influence the inelastic collapse and buckling loads of shell structures due to the strain rate dependence of the flow stress and through pre-buckling creep deformations and inelastic unloading. An examination of these effects is performed by incorporating the unified elastic-viscoplastic constitutive equations of Bodner-Parton into the BOSOR-5 computer program of Bushnell for the deformation and buckling of axisymmetric shells subjected to both pressure and thermal loadings. The combined computer program enables consideration of both time-dependent geometrical and material effects on the pre-buckled state and the instability condition. In particular, the procedure enables the determination of a bifurcation-type lower bound on the buckling load. A few numerical exercises were performed to illustrate the various effects, including that of temperature dependence of the viscoplastic properties.

ABSTRACT: The small deformation elastic-viscoplastic constitutive equations of Bodner-Partom are modified to model strong non-proportional loading paths such as experienced in corner turning tests and certain cases of inelastic buckling. An essential generalization is made to the flow rule, causing the magnitude and direction of plastic strain rate to become an explicit function of deviatoric total strain rate as well as of stress and hardening variables. With this and other modifications, the equations indicate some of the important characteristics of the response to abrupt changes in the loading direction. These are: (a) a reduced effective shear modulus; (b) a transient drop in the effective stress; and (c) a transient non-coaxiality of the plastic strain rate relative to the
deviatoric stress. Predictions of the modified theory compare reasonably well with experimental values for inelastic torsional buckling of axially compressed cruciform columns and for corner turning tests.

ABSTRACT: The buckling of structures of elastic-viscoplastic materials is a stability problem that does not admit a realistic bifurcation formulation in the classical manner. In the absence of imperfections and inertial effects, the standard bifurcation criterion leads only to elastic buckling since an instantaneous jump in strain rate would develop at the critical condition. However, an expression for the “short time” inelastic tangent modulus at the pre-buckling strain rate can be developed from an appropriate incremental constitutive theory and this can be used in the quasi-static bifurcation buckling condition appropriate to the structure and loading. Such a buckling value can be interpreted as a lower bound on the actual instability condition. For the case of structures with initial imperfections, the calculation of local inelastic tangent moduli at the current state should lead to close correspondence between bifurcation and instability. Under creep conditions, the procedure gives approximate creep buckling times for both perfect and initially imperfect structures. For situations where the buckling mode generates abrupt changes in the multiaxial stress state, modifications to the reference constitutive theory are required to properly represent the governing physics. In this manner, the procedure seems capable of indicating buckling values consistent with test results without relying on a “deformation” type plasticity theory.

ABSTRACT: Large deformation behavior and post-buckling modes of single-walled carbon nanotubes are studied numerically by using traditional continuum shell theory and eigenvalue buckling methodology with elasticity parameters obtained by atomistic methods incorporated. Comparison with molecular mechanics and an atomistic-based continuum membrane method shows that the continuum shell theory is convenient and efficient in predicting the post-buckling behavior of the nanotubes subjected to axial compression, torsion and...
bend loads, providing that the elasticity parameters of the tube are obtained from atomistic theory. Higher-order buckling modes, which are difficult to be obtained by molecular mechanics, have been analyzed as well.

ABSTRACT: Buckling of nanotubes has been studied using many methods such as molecular dynamics (MD), molecular mechanics, and continuum-based shell theories. In MD, motion of the individual atoms is tracked under applied temperature and pressure, ensuring a reliable estimate of the material response. The response thus simulated varies for individual nanotubes and is only as accurate as the force field used to model the atomic interactions. On the other hand, there exists a rich literature on the understanding of continuum mechanics-based shell theories. Based on the observations on the behavior of nanotubes, there have been a number of shell theory-based approaches to study the buckling of nanotubes. Although some of these methods yield a reasonable estimate of the buckling stress, investigation and comparison of buckled mode shapes obtained from continuum analysis and MD are sparse. Previous studies show that the direct application of shell theories to study nanotube buckling often leads to erroneous results. The present study reveals that a major source of this error can be attributed to the departure of the shape of the nanotube from a perfect cylindrical shell. Analogous to the shell buckling in the macro-scale, in this work, the nanotube is modeled as a thin-shell with initial imperfection. Then, a nonlinear buckling analysis is carried out using the Riks method. It is observed that this proposed approach yields significantly improved estimate of the buckling stress and mode shapes. It is also shown that the present method can account for the variation of buckling stress as a function of the temperature considered. Hence, this can prove to be a robust method for a continuum analysis of nanosystems taking in the effect of variation of temperature as well.

ABSTRACT: This exercise is intended to provide a direct correlation between the axial compressive buckling of elastic thin-walled cylinders and the response of a mechanical model that exhibits a peak load at large deformation. The model is similar, but more general, to those used by Budiansky and Hutchinson and by Kounadis and associates to illustrate dynamic buckling behavior of imperfection sensitive nonlinear systems. Here, an empirical relation between observed static shell buckling loads and the shell geometry is used to characterize the restraining spring parameter of the model. The resulting model indicates realistic imperfection sensitivity of the load-deflection relation and, as a good physical analogy, provides insight into the shell buckling mechanism. Specifically, from the perspective of the model, shell buckling is viewed as a local event governed by shallow arch-like behavior where the extent of the arch depends on the shell geometry. This implies that the specific geometry of local axial imperfections of the shell (out of straightness) might be more important than that of circumferential imperfections (out of roundness) for shell buckling under axial loading. Moreover, use of an imperfection slope factor rather than an imperfection displacement term might be more suitable for actual shells in some cases. In addition, the model analogy indicates that the buckling (peak) load also depends on the shell geometry and that the bifurcation load serves only as a reference value. A comparison is made to Koiter’s approximate formula for axially compressed isotropic shells.

ABSTRACT: The torsional buckling of a double-walled carbon nanotube embedded in an elastic medium is studied in this paper. The effects of surrounding elastic medium and van der Waals forces between the inner and outer nanotubes are taken into account. Using continuum mechanics, an elastic double-shell model is presented for the torsional buckling of a double-walled carbon nanotube. Based on the model, a condition is derived in terms of the buckling modes of the shell and the parameters describing the effect of van der Waals interaction and surrounding elastic medium. A simplified analysis is also carried out estimate the critical torque for torsional buckling of the double-walled carbon nanotube.

ABSTRACT: (cannot easily cut and paste)

ABSTRACT: In view of the fact that microtubules exhibit strong anisotropic elastic properties, an orthotropic elastic shell model for microtubules is developed to study buckling behavior of microtubules. The predicted critical pressure is found to agree well with recent unexplained experimental data on pressure-induced buckling of microtubules [Needleman et al., Phys. Rev. Lett. 93, 198104 (2004); Biophys. J. 89, 3410 (2005)] which are lower than that predicted by the isotropic shell model by four orders of magnitude. General buckling behavior of microtubules under axial compression or radial pressure is studied. The results show that the isotropic shell model greatly overestimates the buckling loads of microtubules, except columnlike axially compressed buckling of long microtubules (of length-to-diameter ratio larger than, say, 150). In particular, the present results also offer a plausible explanation for the length dependency of flexibility of microtubules reported in the literature.

ABSTRACT: This paper presents the research on the stability analysis of carbon nanotubes (CNTs) via elastic continuum beam and shell models. The estimation of the flexural stiffness of a single-walled nanotube (SWNT) via the elastic beam model is proposed based on the postulate analyzed and provided in the paper. The validation of the stiffness is conducted with the ab initio calculations of the vibration of a SWNT. Based on the stiffness proposed, the stability analysis of CNTs is further conducted and validated with the well-cited research results by Yakobson and his collaborators. In addition, more predictions of various buckling phenomena of carbon nanotubes by beam and shell models are provided and studied. Finally, the kink phenomenon in a SWNT under pure bending is discussed via the continuum model. It is hoped that this paper will pave the way toward a better understanding of the application of continuum models in the stability and dynamics analysis of carbon nanotubes.

ABSTRACT: Nonlocal elastic beam and shell models are developed and applied to investigate the small scale effect on buckling analysis of carbon nanotubes (CNTs) under compression. General and explicit solutions are derived and expressed in terms of the solutions via local or classical elastic models, in which the scale effect is not accounted, to reveal the small scale effect on CNTs buckling results. The dependence of the scale effect with respect to the length, radius, and buckling modes of CNTs is clearly established and observed from the universal solutions derived in the manuscript. It is clearly seen from the results that the buckling solutions for CNTs via local continuum mechanics are overestimated and hence the scale effect is indispensable in providing more accurate results for mechanical behaviors of CNTs via continuum mechanics.

ABSTRACT: Continuum mechanics models for the torsional buckling of carbon nanotubes (CNTs) are developed in the Letter. The applicability of these models is investigated for CNTs with different aspect ratios. In particular, molecular dynamics simulations are conducted to verify the feasibility of the models for moderately long CNTs.

ABSTRACT: The buckling of short double-walled carbon nanotubes subjected to compression is investigated through molecular dynamics in the paper. The inner wall is discovered to have helically aligned buckling mode while the outer wall is reported to have shell buckling mode with kinks. Such buckling modes are attributed to the interaction of the two walls via the van der Waals effect. In addition, a buckling strain higher than the buckling strains of two constituent inner and outer walls is found in the double-walled tube within a certain size range. The causes for such a phenomenon are analyzed and discussed.

ABSTRACT: The small-scale effect on the torsional buckling of multi-walled carbon nanotubes coupled with temperature change is investigated in this paper. A nonlocal multiple-shell model for the multi-walled carbon nanotubes surrounded an elastic medium under torsional and thermal loads is established, and then general solutions are obtained from the governing equations. The influence of the nonlocal effect on critical shear force and change in temperature is investigated. It is demonstrated that the critical shear force could be overestimated by the classical continuum theory and the nonlocal effect on critical buckling force decreases as the change in temperature increases at room or low temperature but increases as the change in temperature increases at higher temperature. Meanwhile, the effect of small size-scale is dependent on the buckling mode under different thermal environments. It is also shown that the innermost radius and the number of layer can affect the small-scale effect on critical change in temperature and buckling shear force. When the ratio of tube length and outmost radius are given, the critical shear force in each layer decreases and the nonlocal effect on the critical shear force becomes weaker as the innermost radius and the layer number increase.

ABSTRACT: Buckling and postbuckling analysis of single-walled carbon nanotubes (SWCNTs) with (n,n)- and (n,0)-helicity, when acted upon by the destabilizing loads of axial compression, torsion and external pressure, is presented by using molecular dynamics simulation. Based on the interatomic interactions given by Brenner and Lennard–Jones potentials, the molecular dynamics method is used to determine the postbuckling equilibrium paths as well as the variation of strain energy. Temperature changes and van der Waals interaction forces between the opposite walls of SWCNTs are both taken into account. Comprehensive numerical results for armchair (12,12)- and zigzag (21,0)-tubes are presented. The results reveal that the effect of van der Waals interactions on the postbuckling behavior of SWCNTs under axial compression can be negligible, while the additional van der Waals forces will affect the postbuckling equilibrium paths of SWCNTs under torsion and external pressure when the deformation of the tube is sufficiently large. The results also show that the temperature change has a significant effect on the postbuckling response of SWCNTs under axial compression, but it has a small effect in the loading case of torsion. In contrast, it only has a less effect on the postbuckling response of SWCNTs under external pressure.

ABSTRACT: In this paper, the buckling behavior and critical axial pressure of double-walled carbon nanotubes (DWCNTs) with surrounding elastic medium are investigated. A double-shell (circular cylindrical shell) model is presented and the effects of surrounding elastic medium on the outer tube and the van der Waals forces between two adjacent tubes are taken into account. The analysis and the numerical solution method are based on the classical theory of plates and shells and the Galerkin method. Equations are derived for the critical axial forces and pressures of DWCNTs; the critical axial forces and pressures are calculated for different axial half sine wavenumbers and circumferential sine wavenumbers and compared with those for single-walled carbon nanotubes (SWCNTs). Results indicate that the critical axial force of a DWCNT is higher than that of an SWCNT, but the critical axial pressure of a DWCNT is lower than the critical axial pressure of a SWCNT. Although the critical axial force of a DWCNT decreases as the axial half sine wavenumbers increase, it rises as the circumferential sine wavenumbers increase.

ABSTRACT: This paper studies the pure axially compressed buckling and combined loading effects of a cylindrical shell and an individual single-walled carbon nanotube (SWCNT). The results of finite element (FE)
simulations of SWCNT using the ANSYS software are presented, and are compared with the classical (local) and continuum (nonlocal) mechanical theories. Critical axial stress and deflections are calculated for all the cases. Two types of buckling are considered in this study, namely, the shell buckling which depends on the radius-to-thickness ratio, and the column buckling which is controlled by the length-to-diameter ratio.

ABSTRACT: The torsional and axially compressed buckling of an individual embedded multi-walled carbon nanotube (MWNTs) subjected to an internal and/or external radial pressure was investigated in this study. The emphasis is placed on new physical phenomena which are due to both the small length scale and the surrounding elastic medium. Multiwall carbon nanotubes which are considered in this study are classified into three categories based on the radius to thickness ratio, namely, thin, thick, and almost solid. Explicit formulas are derived for the van der Waals (vdW) interaction between any two layers of an MWNT based on the continuum cylindrical shell model. In most of the previous studies, the vdW interaction between two adjacent layers was considered only and the vdW interaction among other layers was neglected. Moreover, in these works, the vdW interaction coefficient was treated as a constant that was independent of the radii of the tubes. However, in the present model the vdW interaction coefficients are considered to be dependent on the change of interlayer spacing and the radii of the tubes. The effect of the small length scale is also considered in the present formulation. The results show that there is a unique buckling mode \((m,n)\) corresponding to the critical shear stress. This result is obviously different from what is expected for the pure axially compressed buckling of an individual multi-walled carbon nanotube.

ABSTRACT: This paper presents an assessment of continuum mechanics (beam and cylindrical shell) models in the prediction of critical buckling strains of axially loaded single-walled carbon nanotubes (SWCNTs). Molecular dynamics (MD) simulation results for SWCNTs with various aspect (length-to-diameter) ratios and diameters will be used as the reference solutions for this assessment exercise. From MD simulations, two distinct buckling modes are observed, i.e. the shell-type buckling mode, when the aspect ratios are small, and the beam-type mode, when the aspect ratios are large. For moderate aspect ratios, the SWCNTs buckle in a mixed beam–shell mode. Therefore one chooses either the beam or the shell model depending on the aspect ratio of the carbon nanotubes (CNTs). It will be shown herein that for SWCNTs with long aspect ratios, the local Euler beam results are comparable to MD simulation results carried out at room temperature. However, when the SWCNTs have moderate aspect ratios, it is necessary to use the more refined nonlocal beam theory or the Timoshenko beam model for a better prediction of the critical strain. For short SWCNTs with large diameters, the nonlocal shell model with the appropriate small length scale parameter can provide critical strains that are in good agreement with MD results. However, for short SWCNTs with small diameters, more work has to be done to refine the nonlocal cylindrical shell model for better prediction of critical strains.

ABSTRACT: The axially compressed buckling of a double-walled carbon nanotube surrounded by an elastic medium using the energy and the Rayleigh-Ritz methods is investigated in this paper. In this research, based on the elastic shell models at nano scale, the effects of the van der Waals forces between the inner and the outer tubes, the small scale and the surrounding elastic medium on the critical buckling load are considered. Normal stresses at the outer tube medium interface are also included in the current analysis. An expression is derived relating the external pressure to the buckling mode number, from which the critical pressure can be obtained. It is seen from the results that the critical pressure is dependent on the outer radius to thickness ratio, the material parameters of the surrounding elastic medium such as Young’s modulus and Poisson’s ratio. Moreover, it is shown that the critical pressure descend very quickly with increasing the half axial wave numbers.

ABSTRACT: (FMLs) subjected to low-velocity impact. The deflection to thickness (w/h) ratio has been identified through the governing equations of the plate that are solved using the first-order shear deformation theory as well as the Fourier series method. With the help of a two degrees-of-freedom system, consisting of springs-masses, and the Choi’s linearized Hertzian contact model the interaction between the impactor and the plate is modeled. Thirty-one experiments are conducted on samples of different layer sequences and volume fractions of Al plies in the composite Structures. A reliable fitness function in the form of a strict linear mathematical function constructed. Using an ordinary least square method, response regression coefficients estimated and a zero-one programming technique proposed to optimize the FML plate behavior subjected to any technological or cost restrictions. The results indicated that FML plate behavior is highly affected by layer sequences and volume fractions of Al plies. The results also showed that, embedding Al plies at outer layers of the structure significantly results in a better response of the structure under low-velocity impact, instead of embedding them in the middle or middle and outer layers of the structure.

ABSTRACT: We propose a method to estimate the natural frequencies of the multi-walled carbon nanotubes (MWCNTs) embedded in an elastic medium. Each of the nested tubes is treated as an individual bar interacting
with the adjacent nanotubes through the inter-tube Van der Waals forces. The effect of the elastic medium is introduced through an elastic model. The mathematical model is finally reduced to an eigen value problem and the eigen value problem is solved to arrive at the inter-tube resonances of the MWCNTs. Variation of the natural frequencies with different parameters are studied. The estimated results from the present method are compared with the literature and results are observed to be in close agreement.

ABSTRACT: The small-scale effect on the torsional buckling of a double-walled carbon nanotube (DWCNT) embedded on Winkler and Pasternak foundations is investigated in this study using the theory of nonlocal elasticity. The effects of the surrounding elastic medium, such as the spring constant of the Winkler type and the shear constant of the Pasternak type, as well as the van der Waals (vdW) forces between the inner and the outer nanotubes are taken into account. Finally, based on the theory of nonlocal elasticity and by employing the continuum models, an elastic double-shell model is presented for the nonlocal torsional buckling load of a DWCNT. It is seen from the results that the shear constant of the Pasternak type increases the nonlocal critical torsional buckling load, while the difference between the presence and the absence of the shear constant of the Pasternak type becomes large. It is shown that the nonlocal critical buckling load is lower than the local critical buckling load. Moreover, a simplified analysis is carried out to estimate the nonlocal critical torque for the torsional buckling of a DWCNT.

“Thermal buckling analysis of double-walled carbon nanotubes considering the small-scale length effect”,
Proceedings of the Institution of Mechanical Engineers, Part C: Journal of Mechanical Engineering Science,
ABSTRACT: In this article, the buckling analysis of a double-walled carbon nanotube (DWCNT) subjected to a
uniform internal pressure in a thermal field is investigated. The effects of the temperature change, the
surrounding elastic medium based on the Winkler model, and the van der Waals forces between the inner and
the outer tubes are considered using the continuum cylindrical shell model. The small-length scale effect is also
included in the present formulation. The results show that there is a unique buckling mode corresponding to
each critical buckling load. Moreover, it is shown that the non-local critical buckling load is lower than the local
critical buckling load. It is concluded that, at low temperatures, the critical buckling load for the infinitesimal
buckling of a DWCNT increases as the magnitude of temperature change increases whereas at high
temperatures, the critical buckling load decreases with the increasing of the temperature.

“Postbuckling Equilibrium Path of a Long Thin-Walled Cylindrical Shell (Single-Walled Carbon Nanotube)
January 2011, pp. 79-86
ABSTRACT: In this paper, an elastic shell model is presented for postbuckling prediction of a long thin-walled
cylindrical shell under axial compression. The Ritz method is applied to solve the governing equilibrium
equation of a cylindrical shell model based on the von-Karman type nonlinear differential equations. The
postbuckling equilibrium path is obtained using the energy method for a long thin-walled cylindrical shell.
Furthermore, the postbuckling relationship between the axial stress and end-shortening is investigated with
different geometric parameters. Also, this theory is used for postbuckling analysis of a single-walled carbon
nanotube without considering the small scale effects. Numerical results reveal that the single-walled carbon
nanotube under axial compression has an unstable postbuckling behavior.

ABSTRACT: Thermoelastic buckling behavior of thick rectangular plate made of functionally graded materials is investigated in this article. The material properties of the plate are assumed to vary continuously through the thickness of the plate according to a power-law distribution. Three types of thermal loading as uniform temperature raise, nonlinear and linear temperature distribution through the thickness of plate are considered. The coupled governing stability equations are derived based on the Reddy’s higher-order shear deformation plate theory using the energy method. The resulted stability equations are decoupled and solved analytically for the functionally graded rectangular plates with two opposite edges simply supported subjected to different types of thermal loading. A comparison of the present results with those available in the literature is carried out to establish the accuracy of the presented analytical method. The influences of power of functionally graded material, plate thickness, aspect ratio, thermal loading conditions and boundary conditions on the critical buckling temperature of aluminum/alumina functionally graded rectangular plates are investigated and discussed in detail. The critical buckling temperatures of thick functionally graded rectangular plates with various boundary conditions are reported for the first time and can be served as benchmark results for researchers to validate their numerical and analytical methods in the future.

ABSTRACT: In this paper, the dynamic stability of single- and double-walled carbon nanotubes (SWCNT and DWCNT) under dynamic axial loading is investigated using the continuum mechanics model and the minimum total energy method. The natural frequencies of the SWCNT and the critical dynamic axial load of the SWCNT and DWCNT are obtained using the Rayleigh-Ritz method. The effects of the elastic medium and the van der Waals forces between the two layers in the DWCNT are taken into account using the Winkler model and Lennard-Jones theory, respectively. The effect of the small length scale is also considered using the Eringen Model. The critical dynamic axial load is increased by inserting an inner carbon nanotube (CNT) into an isolated CNT embedded in an elastic medium.

ABSTRACT: This paper investigates the effect of partially filled foam core on the behavior of buckling in a thin-walled cylindrical shell. Previous studies have focused on 100% infill or simply used a fixed thickness of foam core. However, this may not be the optimum arrangement in terms of design. To further investigate this, a theoretical analysis is carried out using the Rayleigh–Ritz approximation, and a new formula is proposed to predict the critical buckling stress of an infill ranging from 0% up to 100% rigid. The proposed formula agrees well with works reported in the literature. It also shows that filling a foam core in a thin-walled cylindrical shell can enhance its resistance to buckling failure. Meanwhile, a simplified formula is provided to the practicing engineer. The paper concludes that an excessive increase in foam core thickness beyond 10% of outer radius is inefficient due to extra cost and weight.

ABSTRACT: Using principle of minimum total potential energy approach in conjunction with Rayleigh-Ritz method, the electro-thermo-mechanical axial buckling behavior of piezoelectric polymeric cylindrical shell reinforced with double-walled boron-nitride nanotube (DWBNNT) is investigated. Coupling between electrical and mechanical fields are considered according to a representative volume element (RVE)-based micromechanical model. This study indicates how buckling resistance of composite cylindrical shell may vary by applying thermal and electrical loads. Also, applying the reverse voltage or decreasing the temperature, increases the critical axial buckling load. This work showed that the piezoelectric BNNT enhances on the whole the buckling resistance of the composite cylindrical shell.

ABSTRACT: Using harmonic differential quadrature (HDQ) method, nonlinear vibrations and instability of a smart composite cylindrical shell made from piezoelectric polymer of polyvinylidene fluoride (PVDF) reinforced with boron nitride nanotubes (BNNTs) are investigated while clamped at both ends and subjected to combined electro-thermo-mechanical loads and conveying a viscous-fluid. The mathematical modeling of the cylindrical shell and the resulting nonlinear coupling governing equations between mechanical and electrical fields are derived using Hamilton’s principle based on the first-order shear deformation theory (FSDT) in conjunction with the Donnell's non-linear shallow shell theory. The governing equations are discretized via HDQ method, and solved to obtain the resonant frequencies and critical flow velocities associated with divergence and flutter instabilities as well as re-stabilization of the system. Results indicate that the internal moving fluid plays an important role in the instability of the cylindrical shell. Application of a smart material such as PVDF improves significantly the stability and vibration of the system.

ABSTRACT: Nonlinear vibration of embedded polymeric pipes reinforced with single-walled carbon nanotubes (SWCNTs) is investigated in the present work. The classical cylindrical shell theory is used for mathematical modeling of structure. The pipe is subjected to thermal and magnetic loads. The surrounding elastic foundation is simulated with spring constant of Winkler-type and shear constant of Pasternak-type. Mori-Tanaka model is applied in order to obtain the characteristics of the equivalent composite. Based on energy method and Hamilton's principal, the motion equations are derived and solved numerically for calculating the nonlinear frequency utilizing the differential quadrature method (DQM). The effects of different parameters such as volume percent of SWCNTs, geometrical parameters of shell and elastic foundation on the vibration of pipe are investigated. Results showed that with increasing the volume percent of SWCNTs in pipe, the frequency of structure increases.

ABSTRACT: In this paper, we apply the asymptotic analysis to thin piezoelectric shells in the framework of geometrically exact formulation. The formal mathematical approach used here is based neither on geometrical nor on mechanical assumptions and rigorously justifies the limiting constitutive nonlinear-two-dimensional equations. More precisely, we formally obtain two-dimensional membrane and flexural models written on the middle surface of the shell. We show that the coupling between the limit displacement field and the limit electric potential inherent to piezoelectricity appears in the membrane model but not in the flexural model. Finally, we suggest a “full” new model for piezoelectric shells using membrane and flexural effects.

PARTIAL INTRODUCTION: This paper aims at extending the range of applicability of the now classic equations of quasi-shallow shells. To this end, the condition of quasi-shallowness is replaced by the weaker assumption of slow variation of curvatures over the middle surface — an assumption first proposed by Duddeck [4] in the context of linear theory and then exploited by Łukasiewicz (see [5]) in a series of papers concerning both linear and nonlinear shell problems. We borrow from Duddeck his refined expression for membrane forces in terms of a strain function which, contrary to quasi-shallow shells, takes account of the Gaussian curvature.

The second of Duddeck's variables, the normal deflection of the midsurface, turns out to be unsuitable for the intended displacement-free theory and is not used. Instead, we express the bending strains through a strain function, finding the appropriate formula from Duddeck's stress function by noting a static-geometric analogy between membrane forces and bending strains. Compared with Koiter's strain function ("curvature function" in his terminology), our new formula is only slightly more complicated….

ABSTRACT: We study the Γ-limit of 3d nonlinear elasticity for shells of small, variable thickness, around an arbitrary smooth 2d surface.

INTRODUCTION: The following question receives large attention in the current literature on elasticity [1]: which theories of thin objects (rods, plates, shells) are predicted by the 3d nonlinear theory? For plates, this problem has been extensively studied through Γ-convergence; first by LeDret and Raoult [5], leading to a
rigorous derivation of the membrane theory, and later by Friesecke, James and Mueller [4], for the Kirchhoff, von Karman and linear theories. In this framework, much less has been done for shells. The membrane and the bending theories were obtained in [6] and [2], respectively. More recently, the generalized von Karman and linear theories have been rigorously introduced and justified by the authors in [7]. In this paper, we present these last new results, in an extended version for shells with variable thickness and mid-surface.

ABSTRACT: We discuss the limiting behavior (using the notion of Γ-limit) of the 3d nonlinear elasticity for thin shells around an arbitrary smooth 2d surface. In particular, under the assumption that the elastic energy of deformations scales like $h^4$, $h$ being the thickness of a shell, we derive a limiting theory which is a generalization of the von Kármán theory for plates.

Marta Lewicka (Dept. of Mathematics, University of Minnesota, Minneapolis), “A note on convergence of low energy critical points of nonlinear elasticity functionals, for thin shells of arbitrary geometry”, ESAIM: Control, Optimization and Calculus of Variations, Vol. 17, No. 2, pp 493-505, 2011, DOI: 10.1051/cocv/2010002
ABSTRACT: We prove that the critical points of the 3d nonlinear elasticity functional on shells of small thickness $h$ and around the mid-surface $S$ of arbitrary geometry, converge as $h \to 0$ to the critical points of the von Kármán functional on $S$, recently proposed in [Lewicka et al., Ann. Scuola Norm. Sup. Pisa Cl. Sci. (to appear)]. This result extends the statement in [Müller and Pakzad, Comm. Part. Differ. Equ.33 (2008) 1018–1032], derived for the case of plates when $S \subset \mathbb{R}^2$. The convergence holds provided the elastic energies of the 3d deformations scale like $h^4$ and the external body forces scale like $h^3$.

Herve Le Dret and Annie Raoult, “Variational convergence for nonlinear shell models with directors and related semicontinuity and relaxation results” (publisher and date not given in the pdf file; most recent citation is dated 1998)
ABSTRACT: We use a variational convergence method to study the consistency of various Cosserat hypotheses in shell theory with the limit nonlinear membrane model derived from three-dimensional elasticity. In the course of the analysis, we introduce a generalization of quasiconvexity that is suitable for problems of the calculus of variations with two vectorial unknowns, one of which appears through its gradient, the other one
through its value, in a weak $W^{1,p} \times L^p$ framework.

ABSTRACT: Nonlinear buckling response of a composite cylindrical shell made of polyvinylidene fluoride (PVDF), is investigated. A two-dimensional smart model surrounded by an elastic foundation subjected to combined electro-thermo-mechanical loading is considered. The nonlinear strain terms based on Donnell’s theory are taken into account using the first shear deformation theory. The Hamilton’s principle is employed to obtain coupled differential equations, containing displacement and electric potential terms. Harmonic differential quadrature method (HDQM) is applied to obtain the critical buckling load for clamped supported mechanical and free electric potential boundary conditions at both ends of the smart cylinder. Results indicate that the critical buckling load increases when piezoelectric effect is considered.

ABSTRACT: Nonlinear buckling of bonded double-walled boron nitride nanotubes (DWBNNTs) under combined electro-thermo–mechanical loadings based on the nonlocal piezoelectricity theory and Euler–Bernoulli beam (EBB) model is presented in this paper. Coupled DWBNNTs are embedded in an elastic medium that is simulated as a Pasternak foundation. Using the Lennard-Jones model, the van der Waals interaction between 2 layers of DWBNNTs is taken into account. Considering the von Kármán geometric nonlinearity, Hamilton’s principle, and charge equation, higher order governing equations are derived and solved by differential quadrature method (DQM). The detailed parametric study is conducted, focusing on the remarkable effects on the behavior of nonlinear buckling loads. The results indicated that the small-scale parameter, elastic medium, boundary conditions, electric potential, aspect ratio, and different vibration phases play an important role in the nonlinear buckling of smart elastically coupled systems. In addition, it is found that the trend of figures has good agreement with those of previous research. The results of this work could be used in the design and manufacture of nano/micro-electro–mechanical systems.

Sci. Tech., 68 (2008) 1489–1501, DOI: 10.1016/j.compscitech.2007.10.024
ABSTRACT: Unlike widely used carbon nanotubes, boron nitride nanotubes (BNNTs) have shown to possess stable semiconducting behavior and strong piezoelectricity. Such properties along with their outstanding mechanical properties and thermal conductivity, make BNNTs promising candidate reinforcement materials for a verity of applications especially nanoelectronic and nanophotonic devices. Motivated by these abilities, we aim to study the buckling behavior of BNNT-reinforced piezoelectric polymeric composites when subjected to combined electro-thermo-mechanical loadings. For this, the multi-walled structure of BNNT is considered as elastic media and a set of concentric cylindrical shells with van der Waals interaction between them. Using three-dimensional equilibrium equations, Donnell shell theory is utilized to show that the axially compressive resistance of BNNT varies with applying thermal and electrical loads. Also, a new equivalent spring constant model of piezoelectric matrix under electro-thermo-mechanical loadings is developed according to the concept of Whitney–Riley model. Results indicate that the support of piezoelectric matrix significantly enhances the buckling resistance of BNNT. Alternatively, the effect of BNNT piezoelectric property on the buckling behavior of composites is demonstrated. Furthermore, it is demonstrated that the supporting effect of elastic medium depends on the direction of applied voltage and thermal flow. More specifically, it is shown that applying direct and reverse voltages to BNNT changes the buckling loads for any axial and circumferential wavenumbers. Such capability could be uniquely utilized when designing BNNT-reinforced composites for structural vibration control applications.

Loghman (Department of Solid Mechanics, Faculty of Mechanical Engineering, University of Kashan, Kashan, Iran), “Influence of the Elastic Foundation on the Free Vibration and Buckling of Thin-Walled Piezoelectric-Based FGM Cylindrical Shells Under Combined Loadings”, Journal of Solid Mechanics, Vol. 6, No. 4 pp 347-365, 2014
ABSTRACT: In this paper, the influence of the elastic foundation on the free vibration and buckling of thin-walled piezoelectric-based functionally graded materials (FGM) cylindrical shells under combined loadings is investigated. The equations of motion are obtained by using the principle of Hamilton and Maxwell's equations
and the Navier's type solution used to solve these equations. Material properties are changed according to power law in the direction of thickness. In this study, the effects of Pasternak elastic foundation coefficients and also the effects of material distribution, geometrical ratios and loading conditions on the natural frequencies are studied. It is observed that by increasing Pasternak elastic medium coefficients, the natural frequencies of functionally graded piezoelectric materials (FGPM) cylindrical shell always increases. The mode shapes of FGPM cylindrical shell has been shown in this research and the results show that the distribution of the radial displacements is more significant than circumferential and longitudinal displacements.

ABSTRACT: By means of ping-pong balls, the dynamic buckling behaviours of thin-walled spherical shells under impact loading are studied both experimentally and numerically. First, the quasi-static tests were conducted on an MTS tester, in which the ball was compressed onto a PMMA plate. Apart from the force-displacement relationship, the evolution of the contact zone between the ball and the plate was obtained by a digital camera. In the impact tests, ping-pong balls were accelerated by an air-gun and then impinged onto a rigid plate with the velocity ranging 10-45 m/s. The local dynamic buckling processes of the ball were recorded by a high-speed digital camera, from which the impact duration, the maximum contact diameter, as well as the contact diameter at snap-through buckling under different impact velocities were obtained. It is found that with the same size of contact zone, the dynamic energy absorption of the ball is much larger than that in the quasi-static tests. To understand the dynamic effects in the impact process, numerical simulations were performed by using different material properties and different impact velocities. The comparison between the experimental and numerical results show that the kinetic energy absorption of the ball is induced by the strain-rate effect, local vibration of the ball and viscous-elastic effect, respectively.

ABSTRACT: This paper considers the elastic buckling of rectangular Mindlin plates that are subjected to partially distributed in-plane edge loadings. A numerical algorithm based on the radial point interpolation method (RPIM) is proposed for the solution of such plates. The pre-buckling stresses are first determined using the RPIM based on a two-dimensional (2-D) elastic plane stress problem. The buckling load intensity factors for rectangular plates that incorporate these predetermined pre-buckling stresses are then computed via the RPIM based on the Mindlin plate theory. Numerical examples of the plates with various boundaries and subjected to different partially distributed in-plane edge loadings are presented. Shear-locking of the buckling load is
studied. The results demonstrate the high accuracy of the proposed RPIM.

ABSTRACT: This paper employs the atomic-scale finite element method (AFEM) to study critical strain of axial buckling for carbon nanotubes (CNTs). Brenner et al. “second-generation” empirical potential is used to model covalent bonds among atoms. The computed energy curve and critical strain for (8, 0) single-walled CNT (SWNT) agree well with molecular dynamics simulations. Both local and global buckling are achieved, two corresponding buckling zones are obtained, and the global buckling behavior of SWNT with a larger aspect ratio approaches gradually to that of a column described by Euler's formula. For double-walled CNTs with smaller ratio of length to outer diameter, the local buckling behavior can be explained by conventional shell theory very well. AFEM is an efficient way to study buckling of CNTs.

ABSTRACT: Carbon nanotubes subject to large deformations reversibly switch into different morphological patterns. Each shape change corresponds to an abrupt release of energy and a singularity in the stress-strain curve. These transformations, simulated using a realistic many-body potential, are explained by a continuum shell model. With properly chosen parameters, the model provides a remarkably accurate “roadmap” of nanotube behavior beyond Hooke's law.

ABSTRACT: Graphene is an ultimate membrane that mixes both flexibility and mechanical strength, together with many other remarkable properties. A good knowledge of the elastic properties of graphene is prerequisite to any practical application of it in nanoscopic devices. Although this two-dimensional material is only one atom thick, continuous-medium elasticity can be applied as long as the deformations vary slowly on the atomic scale and provided suitable parameters are used. The present paper aims to be a critical review on this topic that does not assume a specific pre-knowledge of graphene physics. The basis for the paper is the classical Kirchhoff-Love plate theory. It demands a few parameters that can be addressed from many points of view and fitted to independent experimental data. The parameters can also be estimated by electronic structure calculations. Although coming from diverse backgrounds, most of the available data provide a rather coherent picture that gives a good degree of confidence in the classical description of graphene elasticity. The theory can than be used to estimate, e.g., the buckling limit of graphene bound to a substrate. It can also predict the size above which a scrolled graphene sheet will never spontaneously unroll in free space.

ABSTRACT: This paper presents the buckling analysis of functionally graded carbon nanotube-reinforced composite (FG-CNTRC) plates under various in-plane mechanical loads, using the element-free kp-Ritz method. The first-order shear deformation plate theory is applied and a set of mesh-free kernel particle functions are used to approximate two-dimensional displacement fields. Effective properties of materials of the plates reinforced by single-walled carbon nanotubes (SWCNTs) are estimated through a micromechanical model based on either the Eshelby–Mori–Tanaka approach or the extended rule of mixture. Comparison study and numerical simulations with various parameters are conducted to assess efficacy and accuracy of the present method for analysis of buckling of SWCNT-reinforced composite plates. Results demonstrate that the change of carbon nanotube volume fraction, plate width-to-thickness ratio, plate aspect ratio, loading condition and temperature have pronounced effects on buckling strength of CNTRC plates as well as the boundary condition. ABSTRACT: This paper investigates the transverse and torsional wave in single- and double-walled carbon nanotubes (SWCNTs and DWCNTs), focusing on the effect of carbon nanotube microstructure on wave dispersion. The SWCNTs and DWCNTs are modeled as nonlocal single and double elastic cylindrical shells. Molecular dynamics (MD) simulations indicate that the wave dispersion predicted by the nonlocal elastic cylindrical shell theory shows good agreement with that of the MD simulations in a wide frequency range up to the terahertz region. The nonlocal elastic shell theory provides a better prediction of the dispersion relationships than the classical shell theory when the wavenumber is large enough for the carbon nanotube microstructure to have a significant influence on the wave dispersion. The nonlocal shell models are required when the wavelengths are approximately less than 2.3x10^-9 and 0.95x10^-9 m for transverse wave in armchair (15,15) SWCNT and torsional wave in armchair (10,10) SWCNT, respectively. Moreover, an MD-based estimation of the scale coefficient ε0 for the nonlocal elastic cylindrical shell model is suggested. Due to the small-scale effects of SWCNTs and the interlayer van der Waals interaction of DWCNTs, the phase difference of the transverse wave in the inner and outer tube can be observed in MD simulations in wave propagation at high frequency. However, the van der Waals interaction has little effect on the phase difference of transverse wave.

Q. Wang (Department of Mechanical and Manufacturing Engineering, University of Manitoba, Winnipeg, Manitoba, Canada R3T 5V6), “Compressive buckling of carbon nanotubes containing polyethylene molecules”,

ABSTRACT: The instability of a carbon nanotube containing a polyethylene molecule subjected to compression is investigated using molecular dynamics. A decrease up to 35% in the buckling strain of the (6,6) and (10,10) carbon nanotube/polymer structures due to the attractive van der Waals interaction between the tube wall and the polymer molecule is reported. In particular, the decrease in the buckling strain of the (6,6) carbon nanotube/polymer structure is attributed to the initiation of two flattenings on the tube wall. Simulations show that the buckling strain of the structure is insensitive to the number of units of the polymer molecule.

ABSTRACT: The discovery of a buckling instability of a single-walled carbon nanotube wrapped by a polyethylene molecule subjected to compression is reported through molecular mechanics simulations. A decrease up to 44% in the buckling strain of the nano-structure owing to the van der Waals interaction between the two molecules is uncovered. A continuum model is developed to calculate both the interaction between the tube and the polymer and the decreased buckling strain of the structure by fitting the molecular mechanics results.

ABSTRACT: In this study, single-walled carbon nanotubes were generated in their perfect state as finite element models in the MSC.Marc software. The buckling behaviour and resonant frequency modes of the two limiting cases of carbon nanotubes, i.e. the armchair and zigzag models, were studied. The obtained results were compared with the classical analytical solutions related to a similar continuum structure of a hollow cylinder. The buckling behaviour of single-walled carbon nanotubes under cantilever boundary conditions proved to be almost identical to the prediction of the classical Euler equation. Furthermore, there was very good agreement between the analytical and finite element results of the studied single-walled carbon nanotubes; though the achieved value of the first mode of frequency, obtained from the finite element results, was more accurate than the higher modes.

ABSTRACT: The three-dimensional theory of stability of a carbon nanotube (CNT) in a polymer matrix is presented. The results are obtained on the basis of the three-dimensional linearized theory of stability of deformable bodies. Flexural and helical (torsional) buckling modes are considered. It is proved that the helical (torsional) buckling modes occur in a single CNT (the interaction of neighboring CNTs is neglected) and do not occur in nanocomposites (the interaction of neighboring CNTs is taken into account).

ABSTRACT: The results obtained in setting up a theory of stability of fibrous and laminated composites in the case where the plane ? is in an arbitrary position are analyzed. The plane ? is formed by the points of a buckling mode that have equal phases relative to the line of compression. This theory follows from the linearized three-dimensional theory of stability of deformable bodies and is used to determine the critical compressive load and the associated position of the plane ?. Numerical examples are presented. A brief historical sketch is given.

ABSTRACT: This paper reports the elastic buckling behavior of carbon nanotubes. Both axial compression and bending loading conditions are considered. The modeling work employs the molecular structural mechanics approach for individual nanotubes and considers van der Waals interaction in multi-walled nanotubes. The effects of nanotube diameter, aspect ratio, and tube chirality on the buckling force are investigated. Computational results indicate that the buckling force in axial compression is higher than that in bending, and the buckling forces for both compression and bending decrease with the increase in nanotube aspect ratio. The trends of variation of buckling forces with nanotube diameter are similar for single-walled and double-walled carbon nanotubes. Compared to a single-walled nanotube of the same inner diameter, the double-walled carbon nanotube shows a higher axial compressive buckling load, which mainly results from the increase of cross-sectional area, but no enhancement in bending load-bearing capacity. The buckling forces of nanotubes predicted by the continuum beam or column models are significantly different from those predicted by the atomistic model.

ABSTRACT: A meshfree method based on the reproducing kernel particle approximate is employed for the free vibration and buckling analyses of shear-deformable plates. In this approach, the first order Mindlin/Reissner plate theory (FSDT) is used, and the displacement shape functions are constructed using the reproducing kernel approximation satisfying the consistency condition. The essential boundary conditions are enforced by a transformation method. Numerical examples considering various aspect ratios, skew angles and boundary conditions are demonstrated to show the validity of the proposed method, and satisfactory results were obtained when comparisons are made with the exact and other available numerical results existing in the literature.

ABSTRACT: A new atomistic structural model is developed here for graphene sheets based on the stiffnesses from the REBO potential. Using this model, the flexural vibration natural frequencies and buckling loads of rectangular single-layer graphene sheets of different sizes, chiralities and boundary conditions are calculated. The newly developed atomistic structural model is verified by comparing the calculated fundamental natural frequencies for small-sized graphene sheets with those obtained from ab initio density functional theory (DFT) frequency analysis. The vibration and buckling analysis results are also compared with those of an earlier atomistic structural model based on the AMBER potential as well as the equivalent continuum model for graphene sheets. Through this study, it is observed that graphene sheets display very slight anisotropic characteristics in flexural vibration and buckling. Also, it is shown that the atomistic structural model cannot be replaced by a classical equivalent continuum model such as a plate model. Most significantly, we verify that the new atomistic structural model based on the REBO potential predicts more accurate natural frequencies and buckling loads for graphene sheets, which are considerably lower than those predicted by the earlier atomistic structural model based on the AMBER potential.

ABSTRACT: Explicit formulas are derived for the van der Waals (vdW) interaction between any two layers of a multi-walled carbon nanotube (CNT). Based on the derived formulas, an efficient algorithm is established for the buckling analysis of multi-walled CNTs, in which individual tubes are modeled as a continuum cylindrical shell. The explicit expressions are also derived for the buckling of double-walled CNTs. In previous studies by
Ru (J. Appl. Phys. 87 (2000b) 7227) and Wang et al. (Int. J. Solids Struct. 40 (2003) 3893), only the vdW interaction between adjacent two layers was considered and the vdW interaction between the other two layers was neglected. The vdW interaction coefficient was treated as a constant that was not dependent on the radii of the tubes. However, the formulas derived herein reveal that the vdW interaction coefficients are dependent on the change of interlayer spacing and the radii of the tubes. With the increase of radii, the coefficients approach constants, and the constants between two adjacent layers are about 10% higher than those reported by Wang et al. (Int. J. Solids. Struct. 40 (2003) 3893). In addition, the numerical results show that the vdW interaction will lead to a higher critical buckling load in multi-walled CNTs. The effect of the tube radius on the critical buckling load of a multi-walled CNT is also examined.

ABSTRACT: Buckling and postbuckling behaviors of multi-walled carbon nanotubes (MWCNTs) under a compressive force are studied. MWCNTs are modeled by Donnell’s shallow shell nonlinear theory with the allowance of van der Waals (vdW) interaction between the walls. It is shown herein that the buckling load decreases while the buckling strain increases as the innermost radius of MWCNT increases. For the postbuckling behavior, the shortening-load curves show an initial steep gradient that gradually level up when the radius of the innermost tube changes from a small value to a large value. However, the deflection-load curves are almost level for various radii of MWCNTs. In addition, the analytical results showed that the shortening-load curves are almost linear but the deflection-load curves are nonlinear and the stability of MWCNTs can be enhanced by adding tubes.

References listed at the end of the paper:
nm are proposed and optimized based on molecular dynamics simulation, in which the second-generation Tersoff-Brenner potential and Lennard-Jones (12-6) potential are used to characterize the intratube interatomic interaction and the intertube van der Waals (vdW) interaction, respectively. Then, a multishell continuum model that is combined with a refined vdW force model is used to carry out the buckling analysis of abnormal MWNTs (including two-, four-, and six-walled MWNTs) and to investigate the effect of the vdW interaction of abnormal MWNTs. The numerical results show that the effect of the vdW interaction is more significant for abnormal MWNTs than for normal MWNTs and that the vdW interaction of abnormal MWNTs cannot be neglected. The critical buckling strains of abnormal MWNTs are greatly enhanced compared with those of normal MWNTs, which suggests that abnormal MWNTs may be excellent candidates as enforced fibers of nanocomposites.

Abstract: This paper investigates size-effects in the torsional response of single walled carbon nanotubes (SWCNTs) by developing a modified nonlocal continuum shell model. The purpose is to facilitate the design of devices based on SWCNT torsion by providing a simple, accurate and efficient continuum model that can predict the corresponding buckling loads. To this end, Eringen’s equations of nonlocal elasticity are incorporated into the classical models for torsion of cylindrical shells given by Timoshenko and Donnell. In contrast to the classical models, the nonlocal model developed here predicts non-dimensional buckling torques that depend on the values of certain geometric parameters of the CNT, allowing for the inclusion of size-effects. Molecular dynamics simulations of torsional buckling are also performed and the results of which are compared with the classical and nonlocal models and used to extract consistent values of shell thickness and the nonlocal elasticity constant (e0). A thickness of 0.85 Å and nonlocal constant values of approximately 0.8 and 0.6 for armchair and zigzag nanotubes respectively are recommended for torsional analysis of SWCNTs using nonlocal shell models. The size-dependent nonlocal models together with molecular dynamics simulations show that classical shell models overestimate the critical buckling torque of SWCNTs and are not suitable for modeling of SWCNTs with diameters smaller than 1.5 nm.

Abstract
An analysis-based approach for developing shell-buckling design criteria for laminated-composite cylindrical shells that accurately accounts for the effects of initial geometric imperfections is presented. With this approach, measured initial geometric imperfection data from six graphite-epoxy shells are used to determine a manufacturing-process-specific imperfection signature for these shells. This imperfection signature is then used as input into nonlinear finite-element analyses. The imperfection signature represents a "first-approximation" mean imperfection shape that is suitable for developing preliminary-design data. Comparisons of test data and analytical results obtained by using several different imperfection shapes are presented for selected shells. Overall, the results indicate that the analysis-based approach presented for developing reliable preliminary-design criteria has the potential to provide improved, less conservative buckling-load estimates, and to reduce the weight and cost of developing buckling-resistant shell structures.

ABSTRACT: Description of a casting technique for fabricating high-quality plastic structural models, and review of results regarding the use of such specimens to parametrically study the effect of base ring stiffness on the critical buckling pressure of a ring-stiffened conical shell. The fabrication technique involves machining a metal mold to the desired configuration and vacuum-drawing the plastic material into the mold. A room-temperature curing translucent thermoset epoxy was the casting material selected. A shell of revolution computer program which employs a nonlinear axisymmetric prebuckling strain field to obtain a bifurcation buckling solution was used to guide the selection of configurations tested. The shell experimentally exhibited asymmetric collapse behavior, and the ultimate load was considerably higher than the analytical bifurcation prediction. The asymmetric buckling mode shape, however, initially appeared at a pressure near the analysis bifurcation solution.

J. G. Williams and R. C. Davis, “Buckling experiments on stiffened cast-epoxy conical shells A casting technique for manufacturing high-quality shell specimens with complex geometry is described and experimental and theoretical results are presented for a pressure-loaded ring-stiffened conical shell”, Experimental Mechanics, Vol. 15, No. 9, 1975, pp. 329-338, DOI: 10.1007/BF02318873
ABSTRACT: This paper describes a casting technique for fabricating high-quality plastic structural models and presents results on the use of such specimens to parametrically study the effect of base-ring stiffness on the critical buckling pressure of a ring-stiffened conical shell. The fabrication technique involves machining a metal mold to the desired configuration and vacuum drawing the plastic material into the mold. A room-temperature-
curing translucent thermoset epoxy was the casting material selected. The casting technique allows many high-quality specimens to be produced and each specimen is capable of being repeatedly tested without failure. The conical shell was modified for successive tests by machining the epoxy base-ring configuration to reduce its stiffness. A shell-of-revolution computer program which uses a nonlinear axisymmetric prebuckling strain field to obtain a bifurcation-buckling solution was used to guide the selection of configurations tested. The shell experimentally exhibited asymmetric collapse behavior and the ultimate load was considerably higher than the analytical bifurcation prediction. The asymmetric buckling-mode shape, however, initially appeared at a pressure near the analysis-bifurcation solution. Comparison of experimental and analytical prebuckling strains at pressure magnitudes below the initiation of asymmetric collapse showed good agreement.

ABSTRACT: A 3-m-diameter by 3-m-long corrugated cylindrical shell with external stiffening rings was tested to failure by buckling. The corrugation geometry for the graphite-epoxy composite cylinder wall was optimized to withstand a compressive load producing the relatively low maximum load intensity of 157.6 kN/m without buckling. The resulting mass per unit of shell-wall area, including stiffening rings and fasteners, was 1.96 kg/sq m. The cylinder-test load achievement of 101 percent of design ultimate demonstrates a substantial mass-saving potential over available data for corrugated aluminum shell designs. Future space missions will require low-mass structures to achieve maximum payloads. For such structures that must carry compression loads
without buckling, graphite-epoxy materials offer an attractive approach to providing the needed low-mass structural components. Preliminary design studies of lightly loaded shells, using minimum-mass structural-sizing codes, indicate that ring-stiffened graphite-epoxy corrugated shells can, like corrugated graphite epoxy panels offer a mass-saving potential of 20 to 40 percent over aluminum shell-wall design concepts. To evaluate the merits of a corrugated graphite-epoxy cylindrical shell and to develop a design data base for lightweight space structures, a program was initiated to design, fabricate, and test a 3-m-diameter by 3-m-long corrugated ring-stiffened graphite-epoxy cylinder. The preliminary design for the cylinder was generated using a minimum-mass structural-sizing code to carry an ultimate axial-compression loading intensity of 157.6 kN/m. The preliminary design for the shell was modified and verified by testing subcomponent specimens as described. The purpose of this paper is to present the results from the test of the cylinder.

Buckling analysis is carried out in compliance with the French design code RCC-MR. As per this, it is required to determine the critical buckling load multipliers for the various load combinations and ensure that these multipliers should be more than the minimum values specified…..For the theoretical buckling analysis, the computer codes available at Indira Gandhi Centre for Atomic Research such as CAST3M…..From citation given on the website, http://www.ebook2you.net/ebook/shell-buckling-pdf.php

ABSTRACT: Thin aluminum-alloy cylinders were tested under different combinations of torque and circumferentially varying axial thermal stress. The methods of application of the required loads and the measuring techniques employed are discussed. The buckling process is described and interaction curves are presented.

ABSTRACT: The stiffness coefficients of a laminated conical shell, orthotropic, or in some more general mode, are usually assumed to be constant. It is shown that due to the geometry of the conical surface, in connection with the filament winding process necessary to build the laminated conical shell, this can never be achieved. To calculate the varying stiffness coefficients of a laminated conical shell the geometry of the shell and the winding process needed to build the shell must be taken into account. A method to calculate those stiffness coefficients is proposed. The geodesic paths, which are the practical ways to position the fibers, are especially examined. Of course stiffeners can also be placed on these paths. However, other paths are also examined. Stiffeners, for example, can be placed on these paths for optimization purposes. The stiffness coefficients of a laminated conical shell vary always and are functions of the coordinates of the shell. It is shown that by proper filament winding process these functions can be made to be functions of the longitudinal coordinate only.

ABSTRACT: A finite element model is presented for analyzing the strength and stability of sandwich shells of arbitrary configuration with an adhesion failure zone between the core and one of the facings. The model is based on the assumptions that both facings are laminated Timoshenko-type composite shells, only transverse shear stresses in the core and normal stresses in the thickness direction have nonzero values, a free slip in the tangential plane in the adhesion failure zone and unilateral contact along the normal are possible, and the prebuckling state in the stability problem is linear. Biquadratic nine-node approximations for all functions and numerical integration were used. The displacements and rotation angles of the normals toward the facings as well as stresses in the core are taken as global degrees of freedom. The algebraic problem is solved using a special step-by-step procedure of determining the contact area in the scaling zone and employing unilateral constraints for some of the unknowns. Numerical examples are also given.

ABSTRACT: This paper presents computational models for simulating the behaviour of reinforced concrete structures which exhibit a combination of geometric and material nonlinearity. The nonlinear finite element model is described and methods are presented for the solution of the nonlinear equilibrium equations using arc-length procedures. In order to examine the performance of the finite element model and the solution procedures, examples are presented which involve material and geometric nonlinearity with snap-through and/or snap-back behaviour.

ABSTRACT: We propose a method for investigation of the stability of shells under the action of forces and thermal factors that is based on relations of the geometrically nonlinear theory of elasticity and the moment scheme of finite elements. For the case of uniformly heated restrained cylinders, we demonstrate the efficiency of the method and the validity of the results obtained. We analyze the distinctive features of deformation of the investigated class of shells.

ABSTRACT: Submersible structures consist merely of simple and double curvature thin-walled shells. For this kind of structure, collapse occurs due to the combined nonlinear action of buckling and plasticity of material. Load-carrying capacity may then be assessed mainly by two approaches: experimental investigations and step-by-step numerical procedures. In nonlinear analyses, the results obtained are influenced by the magnitude of the load increment adopted. Solution procedures are then required in order to choose adequate parameters for material failure description as well as elastic nonlinearity. The aim of this paper is to carry out a suitable numerical procedure whose reliability does not depend on the finite-element code adopted.

ABSTRACT: Experiments are carried out into the deformation and stability of a reinforced conical shell in local loading with concentrated forces applied to the ring of the larger base, in both longitudinal and transverse directions. The dependence of the distribution of strains in the shell and critical loads on the number of forces and the conicity node (24 shells were tested) were obtained. Strains in the tested shells were calculated. Comparison of the calculated and experimental results shows that they are in satisfactory agreement.

ABSTRACT: The survey is devoted to problems on the stability and load-carrying capacity of imperfect shells in a nonhomogeneous stress-strain state. Methods recently developed at the Institute of Mechanics (Kiev, Ukraine) are briefly described. The approaches proposed are based on the generalized Euler criterion. Special attention is focused on numerical methods. The stability and load-carrying capacity of shells with symmetric and asymmetric, local and regular imperfections are considered. The data presented are compared with the well-known theoretical results and experimental data. At the end of the review, an analytical method (of reduced stiffness) is presented for predicting the lower bounds of sensitivity to imperfection in elastic buckling of longitudinally compressed stiffened shells with a nearly cylindrical shape.

ABSTRACT: A procedure is proposed whereby critical loads for elastic near-cylindrical shells are determined with the use of equations in terms of displacements. An analytical expression has been derived for the assessment of critical stresses in momentless smooth shells. A contribution of individual components of the total potential energy of such shells to stabilization or destabilization of the strain state is analyzed graphically. Dimensionless critical stresses are assessed with respect to classical ones as determined for ideal cylindrical shells. The data obtained are compared with the known experimental results.

ABSTRACT: The paper outlines a numerical method for stability analysis of cylindrical shells with initial imperfections. We solve a nonlinear buckling problem for a cylindrical shell with variable wall thickness under surface pressure. The imperfections of the shell are modeled as the first buckling mode. A probabilistic approach is used to determine the reliability against buckling of the cylindrical shell with the probability density of initial imperfections represented by uniform distribution, triangular distribution, or Gaussian distribution.

A. Kadir Yavuz and S. Leigh Phoenix (Cornell University), “Buckling stability of adhesively bonded composite

ABSTRACT: A mathematical model is developed for buckling stability of an adhesively bonded composite conical shell system consisting of carbon fiber in a polyimide (PI) matrix. The conical shell is modeled by two orthotropic layers bonded together with a PI adhesive. In-plane compressive and external surface pressure loads are applied. The adhesive layer is modeled by mechanical linear normal and shear springs. The Galerkin method is applied to analyze the buckling stability of the structure as an eigenvalue problem to give critical buckling loads and corresponding mode shapes. Parametric studies are performed to show effects of system parameters on buckling stability of the system.

ABSTRACT: A Donnell type theory is developed for finite deflection of closely stiffened truncated laminated composite conical shells under arbitrary loads by using the variational calculus and smeared-stiffener theory. The most general bending-stretching coupling and the effect of eccentricity of stiffeners are considered. The equilibrium equations, boundary conditions and the equation of compatibility are derived. The new equations of the mixed-type of stiffened laminated composite conical shells are obtained in terms of the transverse deflection and stress function. The simplified equations are also given for some commonly encountered cases.

References listed at the end of the paper:

ABSTRACT: In this paper, based on the mixed-type theory developed by the same authors[11], a theoretical analysis is presented for the stability of laminated composite circular conical shells under external pressure. The
formulas for critical external pressure are obtained by using the potential energy variation principle. Very good agreement is shown between the theoretical prediction of critical external pressure and the experimental data. Finally, the influence of some parameters on critical external pressure is discussed numerically. The mixed-type theory developed by the same authors[1] and the results obtained in this paper are very useful in aerospace engineering design.

ABSTRACT: The results of FEM calculations of stability of thin–walled spherical shells are presented. A static and dynamic stability analysis was conducted. Hemispherical shells and spherical caps with various dilation angles, subjected to external pressure, were considered. For each shell calculated, various boundary conditions of support were analyzed: joint, fixed and elastically fixed support. In the calculations, an axisymmetric and random discretization of the model was accounted for. As a result of the calculations conducted for static loads, values of upper critical pressures and buckling modes of the shells were obtained. The results were presented for various shell thicknesses. The FEM solutions were compared to the available results obtained with analytical and numerical methods, showing a good conformity. Dynamic calculations were conducted for a triangular pulse load. On the basis of the Budiansky–Roth dynamic criterion of stability loss, values of upper dynamic critical pressures were obtained. Shell buckling modes were determined as well.

ABSTRACT: The paper deals with an analysis of the dynamic response of the isotropic conical shell subjected to rectangular or triangular pulse loading. This problem was solved with the Bubnov–Galerkin analytical–numerical method, using a two–parameter function of deflection. In the equations of dynamic equilibrium, an orthotropic material was taken into consideration. Moreover, pressure loading and compression force were included. The solution results were compared with the finite element method, using ANSYS 11.

References listed at the end of the paper:

ABSTRACT: The thin conical and spherical shell structures subjected to pulse loading were considered. The influence of shell geometrical parameters and pulse loading parameters such as its amplitude, direction and duration on the dynamic response was analyzed. The calculations were conducted for two material models: linearly elastic and elastic plastic. To solve the problem of dynamic response of shell structures the ANSYS software based on finite element method was employed.

INTRODUCTION: A thin plate or thin-walled constructions are used in the sports industry, automotive, aerospace and civil engineering. As an example of such structural elements snowboard, skis, poles may be mentioned, as well as all kinds of crane girders, structural components of automobiles (car body sheathing or all longitudinal members), aircraft fuselages and wings, supporting structures of the walls and roofs of large halls and warehouses. All the above structures, as well as many others which can be regarded as a thin, exhaust carrying capacity not by exceeding the allowable stresses but by the stability loss. Therefore, not only critical load but also the postbuckling behaviour of thin-walled structures subjected to static and dynamic load is essential knowledge for designers. The use of more accurate mathematical models allows to explore the phenomena occurring after the loss of stability and to describe more precisely their behaviour. Engineers and designers need guidelines to construct as well as quick and easy software to use for analyse the behaviour of thin-walled structures. Therefore, the author of this chapter decided to explore this issue, propose a mathematical model and the method of analysis of orthotropic thin-walled structures subjected to static and dynamic load.

ABSTRACT: The subject of this monograph is a study of buckling and postbuckling behaviour of thin plates and thin-walled structures with flat walls, subjected to static and dynamic load.

ABSTRACT: The finite element method is used here to validate the analytical–numerical method presented in Chapter 3 [See the previous entry]. The basic assumption and the used equations for thin plates in both the methods (ANM—the analytical–numerical method, FEM—the finite element method) are identical, but the way of solution is different. To apply a program based on the finite element method as a numerical experiment, confirming or verifying the theoretical analysis or the analysis based on the analytical–numerical method, it is important to create an appropriate model. A properly chosen finite element type, a rational mesh density and appropriate boundary conditions play a significant role in obtaining the calculation results close to the reality. ABSTRACT: Dynamic stability, or better, dynamic buckling (sometimes referred to as a dynamic response) means a loss of stability of the structure subjected to pulse load. Especially, it can act along the axis of the column or in the plane of the plate. It should be mentioned that for the ideal uniformy compressed structures (without any geometrical imperfection) the critical buckling amplitude of pulse loading leads to infinity. Therefore, the dynamic buckling can be analysed only for structures with initial geometrical imperfections. In such a case, the critical value of dynamic load does not have a bifurcation character, thus it has to be determined on the basis of the assumed criterion. Some the most popular and some new criterion allowing to determine dynamic buckling is presented in this chapter.

**ABSTRACT:** The results of the dynamic buckling analysis of girders subjected to torsion are presented in this chapter. All the results of numerical calculations to be discussed further were obtained with finite element method commercial software. Girders with square cross-sections and different lengths were considered. A little attention is paid to thin-walled structures with flat wall subjected to bending or torsion. It was therefore decided to fill this gap by conducting an analysis of thin-walled girders with closed cross-section and behaviour of such structures subjected to torsion impulse of finite duration.

ABSTRACT: The aim of this paper is the analysis of strain–rate sensitivity in dynamic stability of thin–walled isotropic columns of closed rectangular cross–section, subjected to in–plane pulse loading of finite duration. The analysis is performed with the FE Method application. The full Lagrange strain tensor is assumed and various material characteristics are applied. The First Shear Deformation Theory displacement field is employed for the solution as well as the viscoplasticity constitutive model for material behavior under high strain rate loading. In the performed analysis the strain–rate effect influence on the dynamic buckling load is examined and also the initial imperfections of walls, pulse shape and pulse duration. The applications of some dynamic criteria are compared as well.

distributed (UD) and functionally graded (FG) reinforcements, are considered. The material properties of FG-CNTRC beam are assumed to be graded in the thickness direction. The SWCNTs are assumed aligned, straight and with a uniform layout. Exact solutions are presented to study the thermal buckling behavior of beams made of a symmetric single-walled carbon nanotube reinforced composite with surface-bonded piezoelectric layers. The critical temperature load is obtained for the nonlinear problem. The effects of the applied actuator voltage, temperature, beam geometry, boundary conditions, and volume fractions of carbon nanotubes on the buckling of piezoelectric CNTRC beams are investigated.

ABSTRACT: During the past few decades, a number of conical tanks have collapsed in various locations around the globe. Previous studies attributed the reason of collapse to inadequate thickness of the conical vessel especially at the bottom part. Most of the previous studies focused on studying the stability of conical tanks under the effect of only hydrostatic pressure. The current study focuses on studying the combined effect of wind loading and hydrostatic pressure on the stability of conical tanks. The study is conducted numerically, using a three-dimensional finite element model that is developed in-house. The critical imperfection shapes leading to minimum buckling capacity of conical shells under wind load alone, and under the combined effect of wind load and hydrostatic pressure, are determined. The study shows that a non-axisymmetric imperfection shape leads to minimum buckling capacity of empty conical tanks subjected to wind loads, while an axisymmetric distribution is noticed in the case of conical tanks under the combined effect of wind loads and hydrostatic pressure. In addition, the current study assesses the adequacy of an existing design procedure, which accounts for hydrostatic pressure, when the combination of hydrostatic pressure and wind load is considered. ABSTRACT: This article deals with the loss of stability of the experimental model of the conical shell subjected to an external pressure. Experiment with real specimens is based on the numerical analysis, which it was performed in (3). The problem is limited to a case of the simply supported conical shell. The main task is to verify the numerical analysis results and the method of the preparation of the experimental models. Fully nonlinear analysis of the conical shells GMNA is performed in a computer program COSMOS/M based on the Finite Element method (FEM).

Petr Tomek (Department of Mechanics, Materials and Machine Parts, University of Pardubice, Czech Republic), “Influence of the initial imperfections on the strength and stability of thin-walled structures”, Ph.D. Dissertation, 2012

PARTIAL SUMMARY: Doctoral dissertation focuses on the influence of initial geometric imperfections on the loss of stability spherical caps stiffened by circumferential ring. Investigated area is limited to simply supported spherical caps with the final stiffness in the radial direction. The described problem is mostly solved by numerical analyses in the environment of program COSMOS/M [5] and CosmosWorks [6]. Verification of the results of numerical analysis performing the experiment is currently still ongoing. Preparation of experiments and the development of the test equipment are described in the doctoral dissertation. First tests of the loss of stability test specimens were performed on the test equipment. [To date] results of the experiments [have been] used to modify test equipment and method of production of test specimens.

ABSTRACT: Based on the Von Karman large deflection theory of shallow shell, the problem of nonlinear stability of symmetrically FGM shallow conical shells under the action of mechanical and thermal loads is investigated. The nonlinear governing equation under the united action of mechanical and thermal loads of FGM shallow conical shells whose physical parameters change with the power rate is derived and solved by the modified iteration method. The nonlinear characteristic relation of load, deflection and temperature is obtained. The extremum buckling principle is employed to determine the critical buckling load. The influences of gradient constants, geometric parameters and temperature differences on buckling are discussed as well.

ABSTRACT: An experimental study of repeated buckling of shear panels, which represents the first phase of a more comprehensive program is presented. Two similar typical Wagner beams were tested under cyclic loading not exceeding 70% of the predicted ultimate static load, one tested as a cantilever and one loaded symmetrically at three points. The aim of these pilot tests was better understanding of the physical phenomena and evaluation of the experimental methods for future tests. The appropriate location and precautions for use of strain gages to measure the stress concentrations at the edges of the diagonal of tension were determined, and the suitability of the shadow moire technique for deflection measurements was ascertained. It was found that cyclic loading at a fairly high load level causes significant structural changes in the shear panels that affect the failure of the beam.

ABSTRACT: A method has been developed for analysis of the vibration and buckling of preloaded stiffened cylindrical panels with different boundary conditions along the straight edges, including elastic restraints. In the analysis linear, “smeared” stiffener, Flügge type theory is used. A computer program VIBUPAL has been developed. The method has been verified by comparison with results available for limited cases and very good agreement has been obtained.

ABSTRACT: The measurement of initial geometric imperfections of stringer-stiffened cylindrical shells on a laboratory scale is reviewed and recent results are presented. Buckling loads are predicted by the multimode analysis and are compared with experimental results. The concept and purpose of an international imperfection data bank is outlined and the activity of the Technion branch is described. An evaluation of the characteristics of shells from their measured imperfection record is attempted.

ABSTRACT: Analytical studies with the ADINA computer code were performed to determine the Dynamic Load Amplification Factor (DLF) of metal beams and plates subjected to axial in-plane impact compression loading. The results were compared with experimental ones and those yielded by self developed finite differences programs. The influences of initial geometric imperfections, as well as duration of loading on the DLF were evaluated. As anticipated, the DLFs were usually higher than unity. However, in a few cases, in the presence of certain magnitudes of initial geometric imperfection and for loading durations close to the first natural period in bending, DLFs smaller than unity were observed.

ABSTRACT: The recent developments in shell buckling experiments are surveyed and related to a review of the progress in the seventies. Model fabrication, imperfection measurements, boundary conditions, nondestructive testing, combined loading, postbuckling behavior, composite shells and other aspects of shell buckling tests are discussed. The motivation for experiments and the conclusions drawn in the previous review are reassessed.

ABSTRACT: The vibration-correlation technique, VCT for definition of real boundary conditions, and the method of repeated buckling were employed for nondestructive generation of improved interaction curves for buckling of stringer-stiffened circular-cylindrical shells subjected to a combined axial compression and external-pressure state of loading. Thirteen shells were tested, five on clamped boundary conditions and eight on nominal simple supports. The study also included an assessment of the influence of the order of loading on the behavior of the shells before and at buckling as a result of the nonlinear interaction. It has been shown that the VCT and repeated buckling approach are feasible for closely stiffened shells and are adequate tools for the derivation of more realistic buckling interaction curves. It appears that the sequence of loading, constant axial compression first and then increasing the external pressure until buckling occurs, or the reverse order of loading, does not influence the buckling loads.

ABSTRACT: The role of experiments in buckling and postbuckling studies of structures is examined. The essential elements of the experimental approach are discussed for a simple buckling test — a column under axial compression — and typical modern techniques are enumerated. The theory of modeling and its applications are summarized. The problems of buckling and postbuckling experiments for plates and shells are then discussed in detail, with emphasis on comparison with theoretical results and recent developments like initial imperfection measurements, definition of boundary condition and nondestructive methods.

ABSTRACT: The present experimental study aims at providing better inputs for improvement of the buckling load predictions of stiffened cylindrical shells subjected to combined loading. The work focuses on two main factors which considerably affect the combined buckling load of stiffened shells, namely initial geometric imperfections and boundary conditions. Six shells with nominal simple supports were tested under various combinations of combined loading. The Vibration Correlation Technique (VCT) is employed to define the real boundary conditions. The initial geometric imperfections of the integrally stiffened shells are measured in the present experiments in situ and are used as inputs to a multimode analysis which yields the appropriate “knockdown” factor for various combinations of axial compression and external pressure. Thus when employing the repeated buckling method for obtaining interaction curves, each point on the curve is adjusted (using the multimode analysis) for the measured degradation of the shell and this results in improved interaction curves and reduced experimental scatter. The measured geometrical imperfections of the preloaded shells can also serve as a contribution to International Imperfection Data Bank for future studies on the correlation between the manufacturing method of the shell and its geometric imperfections.

I. Patlashenko and T. Weller (Faculty of Aerospace Engineering, Technion-Israel Institute of Technology, Haifa 32000, Israel), “Cubic B-spline collocation method for nonlinear static analysis of panels under mechanical and...

ABSTRACT: This study presents the cubic B-spline collocation method for solution of one- and two-dimensional nonlinear boundary problems, describing the behavior of panels subjected to mechanical and thermal loadings. Snap-through of panels under pressure loading, and nonlinear thermally-induced response of panels are considered. Available results, yielded by other solution methods, were compared with those obtained by the proposed method. The accuracy, as well as efficiency of the present approach are verified.

ABSTRACT: The application of the spline collocation method, using the cubic B-splines technique, was extended to solve two-dimensional problems, and employed to determine the pre- and postbuckling behavior of laminated panels subjected to mechanical and heating induced loadings. Transverse shear deformation effects were included in the analysis. The accuracy of the method was validated and its efficiency and adequacy to solve problems, concerned with moderate and thin-walled (which may experience “shear-locking”) shell type structures under the above types of loadings, were shown. Examples, demonstrating the capability of the method to satisfactorily provide the buckling loads and postbuckling branches of multilayered panels under axial, pressure and uniform heating type loadings, are presented.

ABSTRACT: The buckling and postbuckling behaviors of perfect and imperfect antisymmetrically angle-ply laminated composite plates under uniaxial compression have been studied by perturbation technique which takes deflection as its perturbation parameter.

In this paper, the effects of in-plane boundary conditions, angles, total number of layers and initial geometric imperfection on the postbuckling behavior of laminated plates have been discussed.

Recent developments in shell buckling experiments are reviewed and related to earlier investigations. The motivation for buckling experiments on shells in the era of the digital computer, analysed by the author in two previous reviews, is re-examined and evaluated. The historical development of shell buckling tests is briefly traced and the interaction of theory, experiments and numerical studies in developing better understanding of buckling and postbuckling phenomena is emphasized. Some significant measurement problems are briefly discussed. The role of initial imperfections and their measurement is outlined, as well as the effect of boundary conditions. Nondestructive test methods for shell buckling are briefly mentioned. Finally, areas of shell buckling experimentation that deserve attention in coming years are enumerated.

ABSTRACT: The development of techniques for measuring geometric imperfections is traced from the sixties to the present day. First, the early laboratory experiments that initiated the concepts and developed the basic techniques are outlined. Imperfection measurements of large and full-scale shells are then considered, including those performed in industry. Modern, more sophisticated, semi-automated measurement techniques as well as imperfection data banks are discussed. Finally, a design methodology which includes the correlation of realistic imperfections with manufacturing techniques is outlined, and ways are indicated of inclusion of the relevant imperfection data into design methods.

Josef Singer, Haim Abramovich and Tanchum Weller (Faculty of Aerospace Engineering, Technion – Israel Institute of Technology, Haifa 32000, Israel), “The prerequisites for an advanced design methodology in shells prone to buckling”, in New approaches to structural mechanics, shells, and biological structures, edited by

ABSTRACT: The performance goals of future aerospace vehicles will require an unprecedented degree of structural efficiency, which can be obtained by an advanced design methodology, often called “high-fidelity analysis”. Such a methodology combines accumulated geometrical, material and loading imperfections and boundary-condition data with the available computer codes. The prerequisite for a successful application of such a high fidelity analysis to shell type structures is the existence of data banks of measured imperfections and data on the effective boundary conditions. These data banks have to be not only extensive, but also well correlated with the relevant manufacturing processes, loading conditions and practical end fixtures. The experimental work on stiffened metal shells that produced the available data banks is briefly reviewed and their present limitations are emphasized. The urgent need for coordinated extensive international efforts by industry and research laboratories to measure imperfections and effective boundary conditions, and correlate them with experimental buckling loads as well as fabrication processes, is emphasized. Nondestructive vibration correlation techniques are also briefly discussed as a means for determining the effective boundary conditions. Finally, assuming that the necessary prerequisites will become available, the consecutive stages of the advanced design methodology are outlined.

ABSTRACT: The present experimental study aims at providing better inputs for improvement of the buckling load predictions of stiffened cylindrical shells subjected to combined loading. The work focuses on two main factors which considerably affect the combined buckling load of stiffened shells, namely geometric imperfections and boundary conditions. Six shells with nominal simple supports were tested under various combinations of axial compression and external pressure. The vibration correlation technique is employed to define the real boundary conditions. The geometric imperfections of the integrally stiffened shells are measured in the present experiments in situ and are used as inputs to a multimode analysis which yields the corresponding “knockdown” factor for various combinations of loading. Thus, when employing the repeated buckling procedure for obtaining interaction curves, each point on the curve is adjusted (using the multimode analysis) for the measured “new” surface of the shell and this results in more realistic interaction curves. The geometrical imperfections of the preloaded shells can also serve as an input to the International Imperfection Data Bank for future studies on the correlation between the manufacturing method of the shell and their geometric imperfections.

ABSTRACT: The dynamic buckling of cylindrical stringer stiffened shells was investigated both numerically and experimentally. A new criterion to define the numerical “dynamic” buckling load was developed yielding consistent results. The ADINA finite element code was applied to simulate the static and dynamic buckling loads of the shells. It was shown numerically that when the period of the applied loading (half-wave sine)
equals half the lowest natural period of the shell, there is a slight drop in the dynamic load amplification factor (DLF). The DLF is defined, as the ratio of the dynamic buckling to the static buckling of the shell. This factor drops below unity, when the ratio of the given sound speed in solids, c, to the velocity developed axially due to the applied dynamic loading, approaches unity. It means that, for this particular loading period, the dynamic buckling load would be lower than the static one. It was shown numerically that the shape of the loading period, half-wave sine, a shape encountered during the tests, as well as the initial geometric imperfections have a great influence on the dynamic buckling of the shells. The relatively simple test set-up design to cause a shell to buckle dynamically did not fulfill our expectations. Although, the process leading to eventually the dynamic buckling of the shell worked properly, still no test results were obtained to form a sound experimental database for this phenomenon. Based on the numerical predictions, correct guidelines were formulated for better test procedures to be applied in future tests, which will be reported in due time.

PARTIAL ABSTRACT: Stiffened shells, and in particular stiffened circular cylindrical shells, are usually very efficient structures that have many applications in civil, aerospace, marine, petrochemical and mechanical engineering...

ABSTRACT: This paper provides a novel approach to the geometrically nonlinear analysis of shells by deriving the geometric stiffness matrix by load perturbing the linear equilibrium equations in their finite element formulation. Rotations are considered as finite, and rigid body motion is elegantly removed to result in pure elastic deformations that enable stress retrieval via linear constitutive relations. Simple three-noded triangular elements that have proven successful in linear analysis will thus transform to powerful nonlinear elements.

ABSTRACT: The aim of this paper is to present the buckling analysis of a laboratory tested composite panel under axial compression by means of a simple shell finite element that is developed and presented herein. The tests were performed in the Aircraft Structure Laboratory of the Faculty of Aerospace Engineering at the Technion. Buckling is achieved via incremental geometrically nonlinear analysis and monitoring of the tangent stiffness matrix at each increment. The performance of the finite element is further validated by solving a complex multi-snap example from the literature.
ABSTRACT: This paper is concerned with the development of the geometric stiffness matrix of thick shell finite elements for geometrically nonlinear analysis of the Newton type. A linear shell element that is comprised of the constant stress triangular membrane element and the triangular discrete Kirchhoff Mindlin theory (DKMT) plate element is ‘upgraded’ to become a geometrically nonlinear thick shell finite element. Perturbation methods are used to derive the geometric stiffness matrix from the gradient, in global coordinates, of the nodal force vector when stresses are kept fixed. The present approach follows earlier works associated with trusses, space frames and thin shells. It has the advantage of explicitness and clear physical insight. A special procedure, tailored to triangular elements is used to isolate pure rotations to enable stress recovery via linear elastic constitutive relations. Several examples are solved. The results compare well with those available in the literature.

ABSTRACT: The present study deals with "dynamic buckling", where a composite cylindrical shell, which is subjected to an axial impact load, loses its stability once its lateral transient behaviour becomes unbounded in response to the applied impulsive load. Under this type of loading, a structure may survive suddenly applied loads, the amplitudes of which may exceed by many times its static buckling capacity before reaching its critical conditions, provided the loading duration is short enough. Hence, the load intensity is loading duration dependent, where the prescribed loading amplitude determines its maximum safe time of application. In the case under consideration, triggering of "dynamic buckling" is only possible in presence of relatively small lateral initial geometric imperfections, or lateral coupled deformations stemming from the cylinder skin constitutive relations. Instability in these cases results from continuous amplification of either the imperfections or the coupled deformations once they exceed permissible critical arbitrarily prescribed values of stress/strains or deformations. Therefore, definition of "dynamic buckling" is arbitrary and consequently there is no unique criterion as yet for determination of "dynamic buckling", nor guidelines for design of dynamic buckling resistant structures exist. A criterion that lends itself to a rational definition of "dynamic buckling" has been proposed by Budiansky and Hutchinson. It defines simplified means for determination of the critical dynamic loading, and in essence is analogous to ones employed in the definition of static buckling load of an imperfect structure. Thus, it provides means for comparison between static and dynamic buckling loads corresponding to a given structure; however the analogy is incomplete since in the dynamic case the loading and the structural response are time dependent. In light of the above discussion wide range parametric numerical studies have been undertaken in the present study to assess the influence of shell wall configuration and its initial geometrical imperfections on the dynamic buckling capacity and behaviour of thin walled composite shells, as well as on the loading duration of the shell, which in turn also affects the critical load capacity. In performing
these evaluations the Budiansky and Hutchinson criterion has been adopted for determination of the shell critical dynamic load. Cylindrical structures are very sensitive to the presence of initial geometric imperfections. The effect of identical imperfections on dynamic buckling is compared with their influence on static buckling. For this purpose, initial geometric imperfections, the shapes of which correspond to the first static buckling mode of the perfect shell have been employed. The amplitude of this mode is treated as a free parameter in this assessment. Previous theoretical and experimental studies on dynamic buckling of beams and plates have indeed demonstrated that the shorter the duration $n$ of loading, the higher the resistance to dynamic buckling of these structural elements, and significantly higher than the respectively static buckling load, i.e. there exists a dynamic load amplification factor, D.L.F. However, in the neighbourhood of loading durations corresponding to the period of the first natural bending vibration D.L.F.'s smaller than one have been observed, namely the dynamic buckling load is smaller than the static one. Consequently, special attention is given in the present study to the buckling behaviour of cylinders subjected to axial impacts of duration in this particular range.

ABSTRACT: The effective width method that is widely applied for the analysis of isotropic planar stringer-stiffened panels has been extended to laminated composite stringer-stiffened circular cylindrical panels. The approach was modified and adapted to handle curved composite structures. Panels stiffened by blade type stiffeners, J-form stiffeners and T-form stiffeners were considered in the present study. Bending buckling of the stiffeners, their torsional buckling, combined bending and torsion buckling and local buckling of the stringers were accounted for in the investigation. Using the proposed extended effective width method, a MATLAB based software code TEW1 was developed and implemented. To validate this code, predictions obtained by it were compared with experimental results and with finite element calculations. Good agreement between the present proposed method, experiments and finite element simulations was found, thus yielding an efficient, simple to apply and fast engineering code to be used in design and optimization stages.

ABSTRACT: The performances of the air transport sector as a whole have almost reached a stage of leveling off. New breakthrough design concepts and technologies are needed to introduce a new era of air flight. Air transport demands are predicted to double in the next 10 – 15 years and triple in 20 years time. Involved with it, both the European and American aeronautical industries expect an operating cost reduction of 20% in the mean period followed by a further reduction of 50% in the long run [1]. These extreme expectations can be understood and realized based on the actual and future design scenarios of basic aeronautical structures – a laminated composite stringer stiffened panel presented in Figure 1, where the axial compression load vs. end shortening behaviors of such a structure is depicted. This schematic figure summarizes the vision of the COCOMAT consortium [1-2], namely improved material exploitation of laminated composite airframe structures by accurate simulation of postbuckling and collapse. It is only natural to attempt achieving the above expectations by narrowing the large conservative gap traditionally accepted between the ultimate and the collapse load capacities, thus, yielding the future design scenario as depicted in Fig.1. To realize this target, it is necessary to develop the appropriate tools to be able to
correctly predict the behavior of a laminated composite stringer stiffened shell in the deep postbuckling region, at the collapse load, which is characterized by separation between the skin and the stringers, delaminations, crack propagations and matrix failure, as well as to understand its behavior under repeated buckling. During its normal service life, a fuselage, which is composed of many curved laminated composite stringer stiffened panels, may experience a few hundreds of buckling-postbuckling cycles. Although it is well recognized that CFRP stiffened structures are capable of withstanding very deep post-buckling, yielding collapse loads equal to three - four times their buckling load (see for example typical Refs. [4-6]), there exists scarce knowledge in the literature about the effects of repeated buckling on the global behavior of the panels composing such fuselages. The data found in the literature is dealing with simple structures and loadings [7-8]. Very few results are available (for example [9, 20]) on how repeated buckling under combined loading influences the non-linear behavior of aluminum cylindrical shells and CFRP aeronautical panels and their collapse modes, and on how far into the post-buckling region it is possible to increase loading without loosing structural safety.

Therefore, in light of the above, it is the aim of the present manuscript, to contribute to the basic understanding and knowledge of the above topic, by summarizing the experimental and numerical results that were experienced and obtained within the COCOMAT consortium, during the years 2003-2008.

with composite webs bonded to an aluminum alloy frame, whereas the axial compression specimens were “I” and “J” stiffened cocured composite panels. The test results demonstrate that composite stiffened panels are less fatigue sensitive than comparable metal ones. In the shear panels repeated buckling, even when causing extensive damage, does not reduce the residual strength by more than 20 percent. For the axial compression panels no reduction in residual strength was observed. Safe design of stiffened Graphite/Epoxy panels well beyond their initial buckling is therefore feasible. This can lead to more efficient structures.

ABSTRACT: It is well known [1] that non-closely stiffened panels can have considerable postbuckling reserve strength, enabling them to carry loads significantly in excess of their initial buckling load. If appropriately designed, their load carrying capacity will even appreciably exceed that corresponding to an equivalent weight unstiffened shell (i.e. a shell of identical radius and thicker skin and which is also more sensitive to geometrical imperfections). In these shells, initial buckling of their panels takes place in a local mode, i.e. skin buckling between stiffeners, and not in an overall mode, i.e., an Euler or wide column mode. The design of aerospace structures places great emphasis on exploiting the behavior and on mass minimization of such panels to reduce lifecycle costs. An optimum (minimum mass) design approach based on initial buckling, stress or strain, and stiffness constraints, typically yields an idealized structural configuration characterized by almost equal critical loads for local and overall buckling. This, of course, results in little postbuckling strength capacity and susceptibility to premature failure. However, an alternative optimum design approach can be imposed to achieve lower mass designs for a given loading by requiring the initial local buckling to occur considerably below the design load and allowing for the response characteristics known to exist in postbuckled panels [2] i.e. capability to carry loads higher than their initial buckling load. To meet the requirements of low structurally weight, advanced lightweight laminated composite elements are increasingly being introduced into new designs of modern aerospace structures for enhancing both their structural efficiency and performance. In recognition of the numerous advantages that composites offer, there is a steady growth in replacement of metallic components by composite ones in marine structures, ground transportation, robotics, sports and other fields of engineering. Many theoretical and experimental studies have been performed on buckling and postbuckling behavior of flat stiffened composite panels (see for example Refs.3-8). Recently, a wide body of description and detailed data on buckling and postbuckling tests has been compiled [9] (see chaps.12-14). However, studies on cylindrical composite shells and curved stiffened composite panels are still quite scarce (see for example Refs.10-15). Most of them have been discussed in detail in Ref. 9 (see chap. 14). In light of the above discussion, it has been suggested that permitting postbuckling to take place under ultimate load of fuselage structures, i.e. alleviation of design constraints, may provide a means for meeting the objectives for the design of next generation aircraft, where the demand is reduction of weight without prejudice to cost and structural life (see paper Vision 2020 of the European Community). This approach has been undertaken in an experimental study (Improved P0stbuckling SImulation for Design of Fibre COmposite Stiffened Fuselage Structures - POSICOSS project) as a part of an ongoing effort on design of low cost low weight airborne structures initiated by the 5th European Initiative Program. It was aimed at supporting the development of improved, fast and reliable procedures for analysis and simulation of postbuckling behavior of fiber composite stiffened panel of future generation fuselage structures and their design. Within the POSICOSS project, the Technion performed a long test series, on curved laminated composite stringer stiffened panels under axial compression, shear load introduced by torsion and combined axial compression and shear. The buckling and
postbuckling behavior of these panels was recorded till their final collapse. The first part of this test series, dealing with panels PSC1-PSC9 was summarized in Ref. 16. The results of the tests with panels BOX1-BOX4, which deal with two identical panels, combined together by two flat non-stiffened aluminum panels, to form a torsion box,….

PARTIAL ABSTRACT: Experimental results on the behavior of nine single panels and of four torsion boxes, each comprising of two stringer-stiffened cylindrical graphite-epoxy composite panels are presented. These were tested under axial compression, torsion, and combined loading. The buckling and postbuckling behavior of these single panels and torsion boxes demonstrated consistent results. Prior to performing the buckling tests, the initial geometric imperfections of the panels and boxes were scanned and recorded. The tests were complemented by finite element calculations, which were performed for each panel and box…

ABSTRACT: Carbon nanotube (CNT)-reinforced polymer composites have attracted great attention due to their exceptionally high strength. Their high strength can be affected by the presence of defects in the nanotubes used as reinforcements in practical nanocomposites. In this article, a new three-phase molecular structural mechanics/finite element (MSM/FE) multiscale model is used to study the effect of CNT vacancy defects on the stability of single-wall (SW) CNT-polymer composites. The nanotube is modeled at the atomistic scale using MSM, whereas the interphase layer and polymer matrix are analyzed by the FE method. The nanotube and polymer matrix are assumed to be bonded by van der Waals interactions based on the Lennard-Jones potential. Here, two of the most commonly used buckling regimes of CNTs, called column and shell buckling, are considered. To study the stability of the nanocomposites, the buckling onset strain is calculated for perfect and defected CNTs in the polymer nanocomposites. The results reveal that the presence of vacancy defects causes a decrease in the axial buckling strain of SWCNT-polymer composites. Meanwhile, this decrease is much more noticeable in the case of the column buckling mode. Also, it is shown that decreasing the CNT diameter causes a reduction in the onset buckling strain of defected nanocomposites. Finally, the role of the interphase layer on the stability behavior of these nanocomposites is discussed. It is concluded that the existence of a more compact layer than the polymer chains coated on the nanotube can enhance drastically the buckling behavior of these nanocomposites (about 35%).

ABSTRACT: The mechanical stability of conductive, single-walled carbon nanotubes (SWCNTs) under applied electric field and compressive loading is investigated. The distribution of electric charges on the nanotube surface is determined by employing a method based on the classical electrostatic theory. For mechanical stability analysis, a hybrid atomistic-structural element is proposed, which takes into account the nonlinear features of the stability. Nonlinear stability analysis based on an iterative solution procedure is used to determine the buckling force. The coupling between electrical and mechanical models is accomplished by adding Coulomb interactions to the mechanical model. The results show that in the presence of uniform axial electric fields, stability of SWCNTs under compressive axial loading increases. Also, the effects of CNT geometry on the mechanical stability in the presence of electric fields are studied and the dependence of the increase in the stability of the nanotube on length and diameter is shown.

M. Jabbarzadeh, R. Naghdabadi and M. Tahani, “Corotational Lagrangian formulation for elastic and elastic-plastic large deformation analysis using FEM”, Archive of SID, 2006

ABSTRACT: In this paper a corotational Lagrangian finite element method is presented to analyze the geometric and material nonlinearity problems using degenerated shell and solid elements. The formulation is based on the updated Lagrangian conjugate stress and strain tensors with the linear and nonlinear terms to eliminate the approximation of the Cauchy stress in the finite element formulation. Linear work hardening and the Prandtl-Reuss flow rule along with the von-Mises yield criterion are used to model material nonlinearity. To investigate the accuracy and computational efficiency of the formulation some examples in the elastic and elastic-plastic regime are presented. Also, the results obtained from this method are compared with those available using other corotational finite element formulations. (in Arabic)

DOI: 10.1007/s11431-012-4995-2

ABSTRACT: Based on the consistent symmetrizable equilibrated (CSE) corotational formulation, a linear triangular flat thin shell element with 3 nodes and 18° of freedom, constructed by combination of the optimal membrane element and discrete Kirchhoff triangle (DKT) bending plate element, was extended to the geometric nonlinear analysis of thin shells with large rotation and small strain. Through derivation of the consistent tangent stiffness matrix and internal force vector, the corotational nonlinear finite element equations were established. The nonlinear equations were solved by using the Newton-Raphson iteration algorithm combined with an automatic load controlled technology. Three typical case studies, i.e., the slit annular thin plate, top opened hemispherical shell and cylindrical shell, validated the accuracy of the formulation established in this paper.

ABSTRACT: On the basis of the finite element corotational formulation for geometric nonlinear static analysis of thin shells with large rotation and small strain established before and from the generalized-α time integration algorithm, the energy conserving and decaying algorithms for corotational formulation nonlinear dynamic response analysis of thin shells are established in this paper. Responses are solved by means of a predictor-corrector procedure. In the case of ignoring the structural damping, the conserving or decaying total energy of structure and the controllable numerical damping for high frequency responses can ensure the numerical stability of the algorithm. The inertial parts are linearly interpolated directly in the fixed global coordinate system by using the element nodal displacement in the global coordinate system for obtaining the constant mass matrix, while the elastic parts adopt the corotational formulation. Hence, the whole formulation obtained in this paper is element independent. Through three typical numerical examples, the performances of the algorithm in this paper were compared with those of the classical Newmark and HHT-α algorithms to indicate that the algorithm in this paper could accurately solve nonlinear dynamic responses of thin shells with large displacements and large rotations.
ABSTRACT: The nonlinear static and dynamic response of circular and annular plates under electrostatic, thermal, and combined loading is investigated. The main motivation for the study of these phenomena is providing fundamental insights into the mechanics of micro-electro-mechanical-systems (MEMS). MEMS devices are usually miniaturization of the corresponding macro-scale devices. The basic mechanics of the components of many MEMS devices can be modeled using conventional structural theories. Some of the most used and actively researched MEMS devices - namely pressure sensors and micropumps - use circular or annular diaphragms as principle components. The actuation and sensing principles of these devices are usually electrostatic in nature. Most MEMS devices are required to operate under wide environmental conditions, thus, a study of thermal effects on the performance of these devices is a major design consideration. There exists a wide arsenal of analytic, semi-analytic, and numerical tools for nonlinear analysis of continuous systems. The present work uses different tools for the analysis of different types of problems. The selection of the analysis tools is guided by two principles. The first consideration is that the analysis should reveal the fundamental mechanics and dynamics of the problem rather than simply generating numerical data. The second consideration is numerical efficiency. Guided by the same principles, the basic structural model adopted in this work is the von-Karman plate model. This model captures the basic nonlinear phenomena in the plate with minimal complexity in the equations of motion, thus providing a balance between simplicity and accuracy. We address a wide array of problems for a variety of loading and boundary conditions. We start by analyzing annular plates under static electrostatic loading including the variation of the plate natural frequencies with the applied voltage. We also analyze parametric resonances in plates subjected to sinusoidally varying thermal loads. We investigate the prebuckling and postbuckling static thermal response and the corresponding variation of the natural frequencies. Finally, we close by investigating the problem of a circular plate under a combination of thermal and electrostatic loading. The results of this investigation demonstrate the importance of including nonlinear phenomena in the modeling of MEMS devices both for correct quantitative predictions and for qualitative description of operations.

In this paper, eight sets of popularly employed benchmark problems are identified and their deflection curves. In most, if not all, of the previous work on finite element formulation and nonlinear solution procedures, results of geometric nonlinear benchmark problems of shells are presented in the form of load-deflection curves. In this paper, eight sets of popularly employed benchmark problems are identified and their...
detailed reference solutions are obtained and tabulated. It is hoped that these solutions will form a convenient basis for subsequent comparison and that the tedious yet inaccurate task of reconstructing data points by graphical measurement of previously reported load-deflection curves can be avoided. Moreover, the relative convergent difficulty of the problems are revealed by the number of load increments and the total number of iterations required by an automatic load incrementation scheme for attaining the converged solutions under the maximum loads.

ChaoRong Li, Xiaona Zhang and Zexian Cao (Institute of Physics, Chinese Academy of Sciences, Post Office Box 603, 100080 Beijing, China), “Triangular and Fibonacci Number Patterns Driven by Stress on Core/Shell
ABSTRACT: Fibonacci number patterns and triangular patterns with intrinsic defects occur frequently on nonplanar surfaces in nature, particularly in plants. By controlling the geometry and the stress upon cooling, these patterns can be reproduced on the surface of microstructures about 10 micrometers in diameter. Spherules of the Ag core/SiOx shell structure, possessing markedly uniform size and shape, self-assembled into the Fibonacci number patterns (5 by 8 and 13 by 21) or the triangular pattern, depending on the geometry of the primary supporting surface. Under proper geometrical constraints, the patterns developed through self-assembly in order to minimize the total strain energy. This demonstrates that highly ordered microstructures can be prepared simultaneously across large areas by stress engineering.

ABSTRACT: We use numerical simulations to show how noninteracting hard particles binding to a deformable elastic shell may self-assemble into a variety of linear patterns. This is a result of the nontrivial elastic response to deformations of shells. The morphology of the patterns can be controlled by the mechanical properties of the surface, and can be fine-tuned by varying the binding energy of the particles. We also repeat our calculations for a fully flexible chain and find that the chain conformations follow patterns similar to those formed by the nanoparticles under analogous conditions. We propose a simple way of understanding and sorting the different structures and relate it to the underlying shape transition of the shell. Finally, we discuss the implications of our results.

ABSTRACT: The current study reports the use of buckling structures as a measure of film elasticity on physisorbed, solid-supported polymer-tethered lipid monolayers consisting of phospholipids and poly(ethylene glycol) (PEG) lipopolymers. These monolayer systems, built using the Langmuir–Blodgett (LB) technique, exhibit buckles over a wide range of lipopolymer concentrations. Systematic quantitative analysis of the buckling structures using epifluorescence microscopy and atomic force microscopy reveals that increased lipopolymer concentrations are associated with higher area fractions of buckling regions. Quantitative analyses of buckling profiles show, furthermore, that enhanced lipopolymer concentrations lead to increased buckling widths without notably altering buckling amplitude. On the basis of these experimentally determined buckling parameters, we are able to derive a metric between elastic properties and buckling structures in the polymer-tethered lipid monolayer system. This is achieved by combining mean-field calculations of elastic properties of polymer-tethered lipid membranes with buckling theory of an Euler column. Our findings are significant because they provide new insight into the fascinating materials properties of polymer-lipid supramolecular assemblies and represent a tool for the characterization of elastic properties in complex biomembrane-mimicking film architectures with buckling structures.

ABSTRACT: Many natural fruits and vegetables adopt an approximately spheroidal shape and are characterized by their distinct undulating topologies. We demonstrate that various global pattern features can be reproduced by anisotropic stress-driven buckles on spheroidal core/shell systems, which implies that the relevant mechanical forces might provide a template underpinning the topological conformation in some fruits and plants. Three dimensionless parameters, the ratio of effective size/thickness, the ratio of equatorial/polar radii, and the ratio of core/shell moduli, primarily govern the initiation and formation of the patterns. A distinct morphological feature occurs only when these parameters fall within certain ranges: In a prolate spheroid, reticular buckles take over longitudinal ridged patterns when one or more parameters become large. Our results demonstrate that some universal features of fruit/vegetable patterns (e.g., those observed in Korean melons, silk gourds, ribbed pumpkins, striped cavern tomatoes, and cantaloupes, etc.) may be related to the spontaneous buckling from mechanical perspectives, although the more complex biological or biochemical processes are involved at deep levels.

ABSTRACT: A thin metal film vapor deposited on thick elastomer substrate develops an equi-biaxial compressive stress state when the system is cooled due to the large thermal expansion mismatch between the elastomer and the metal. At a critical stress, the film undergoes buckling into a family of modes with short wavelengths characteristic of a thin plate on a compliant elastic foundation. As the system is further cooled, a highly ordered herringbone pattern has been observed to develop. Here it is shown that the herringbone mode constitutes a minimum energy configuration among a limited set of competing modes.

ABSTRACT: The wrinkling of a stiff thin film bonded on a soft elastic layer and subjected to an applied or residual compressive stress is investigated in the present paper. A three-dimensional theoretical model is presented to predict the buckling and postbuckling behavior of the film. We obtained the analytical solutions for the critical buckling condition and the postbuckling morphology of the film. The effects of the thicknesses and elastic properties of the film and the soft layer on the characteristic wrinkling wavelength are examined. It is found that the critical wrinkling condition of the thin film is sensitive to the compressibility and thickness of the soft layer, and its wrinkling amplitude depends on the magnitude of the applied or residual in-plane stress. The bonding condition between the soft layer and the rigid substrate has a considerable influence on the buckling of the thin film, and the relative sliding at the interface tends to destabilize the system.

“Thermal buckling analysis in InSb focal plane arrays detector”, Journal of Mechanical Science and Technology, Vol. 27, No. 6, pp 1809-1813, June 2013

ABSTRACT: When exploring the buckling mechanism in indium antimonide (InSb) detector, the global square checkerboard buckling pattern reappears in finite element simulation results. The contributions from the three layered materials to the deformations along the Z-direction are systematically analyzed. Analysis of results shows that the buckling deformation originated from the thermal difference between silicon readout integrated circuits (silicon-ROIC) and the intermediate layer directly above. Furthermore, the buckling pattern is determined by indium bumps array. After passing through the 10 μm intermediate layer, the deformation amplitude is significantly reduced from 2.23 μm to 0.24 μm. Afterwards, passing upward through the 10 μm InSb chip, the maximal deformation is further decreased to 0.09 μm.

ABSTRACT: The English-language dictionary defines wrinkles as “small furrows, ridges, or creases on a normally smooth surface, caused by crumpling, folding, or shrinking”. In this paper we review the scientific aspects of wrinkling and the related phenomenon of buckling. Specifically, we discuss how and why
wrinkles/buckles form in various materials. We also describe several examples from everyday life, which demonstrate that wrinkling or buckling is indeed a commonplace phenomenon that spans a multitude of length scales. We will emphasize that wrinkling is not always a frustrating feature (e.g., wrinkles in human skin), as it can help to assemble new structures, understand important physical phenomena, and even assist in characterizing chief material properties.

References listed at the end of the paper:

We have measured the multi-scale wrinkling that occurs along the edge of torn plastic sheets. The plastic deformations induced by tearing define a new metric on the sheet, which then relaxes elastically. The resultant patterns of wrinkles correspond to a superposition of waves of different wavelengths. Measurements of the variation of the pattern as a function of the distance from the edge reveal a set of transitions, each of which adds a new mode to the cascade. The wavelengths \( \lambda \) in the cascade depend on both a geometrical length scale, \( L_{\text{geo}} \), given by the metric near the
sheet’s margin, and the sheet thickness $t$: $\lambda \propto t^{0.3}L^{0.7}$. This scaling implies vanishingly short geo
wavelengths in the limit $t \to 0$. A possible geometrical origin of this behavior is discussed. Finally, we show that
our measurement and analysis techniques are applicable to the study of some wavy patterns of leaves.
Measurements of metric properties of leaves indicate that some leaves form waves through a spontaneous
wrinkling like that in the plastic sheets, rather than through an explicit three-dimensional construction.

[18] In power spectra of profiles $z(x,y)$, such as in Fig. 3(b), peaks corresponding to higher modes appear less and less well defined.
These modes are not periodic with respect to the lab’s x coordinate but are periodic modulations of the curved base-line formed by the
longer wavelengths, on which they are superimposed. Therefore, we obtain the amplitude of a given mode $A_n$, by comparing two
profiles: The first - the “base line” - is the surface profile at a given y that consists of modes of lower order than $n$ (obtained by
filtering all $i \geq n$ modes out of $z(x)$). The second is the same profile with the nth mode (obtained by filtering out all $i > n$ modes). The
root mean square of distances between the two curves (measured perpendicularly to the local tangent to the “base line”) gives the
amplitude when divided by $\sqrt{2}$.

nanotube/graphene junctions using finite element modeling”, “The European Physical Journal Applied Physics,
Vol. 76, 20402, 2016, DOI: 10.1051/epjap/2016160173

ABSTRACT: Current study concerns the vibrational behavior of single-walled carbon nanotube/graphene
junctions using the finite element method. The effects of different parameters including nanotube and graphene
geometry/boundary conditions on the vibrations of nanotube/graphene junction are investigated. Two types of
junctions are considered. In the first type, the nanotube is connected to one side of graphene, while in the
second type, both sides of the graphene are connected to nanotubes. It is shown that increasing the height-to-
length ratio of graphene results in decreasing the fundamental natural frequency of the junctions. When the
boundary conditions are imposed on the graphene, increasing the radius of carbon nanotube leads to decreasing
the frequency. Moreover, the frequencies of the second type models are larger than those of the first type.

ABSTRACT: Wafer-scale strained bilayer graphene is demonstrated by employing a silicon nitride (Si$_3$N$_4$) stressor layer. Different magnitudes of compressive stress up to 840 MPa were engineered by adjusting the Si$_3$N$_4$ deposition recipes, and different strain conditions were analyzed using Raman spectroscopy. The strained graphene displayed significant G peak shifts and G peak splitting with 16.2 cm$^{-1}$ and 23.0 cm$^{-1}$ of the G band and two-dimensional band shift, which corresponds to 0.26% of strain. Raman mapping of large regions of the graphene films found that the largest shifts/splitting occurred near the bilayer regions of the graphene films. The significance of our approach lies in the fact that it can be performed in a conventional microfabrication process, i.e., the plasma enhanced chemical vapor deposition system, and thus easily implemented for large scale production.

Qiming Wang and Xuanhe Zhao, “A three-dimensional phase diagram of growth-induced surface instabilities”, Scientific Reports, Vol. 5, 8887, March 2015, DOI: 10.1038/srep08887
ABSTRACT: A variety of fascinating morphological patterns arise on surfaces of growing, developing or aging tissues, organs and microorganism colonies. These patterns can be classified into creases, wrinkles, folds, period-doubles, ridges and delaminated-buckles according to their distinctive topographical characteristics. One universal mechanism for the pattern formation has been long believed to be the mismatch strains between biological layers with different expanding or shrinking rates, which induce mechanical instabilities. However, a general model that accounts for the formation and evolution of these various surface-instability patterns still does not exist. Here, we take biological structures at their current states as thermodynamic systems, treat each
instability pattern as a thermodynamic phase, and construct a unified phase diagram that can quantitatively predict various types of growth-induced surface instabilities. We further validate the phase diagram with our experiments on surface instabilities induced by mismatch strains as well as the reported data on growth-induced instabilities in various biological systems. The predicted wavelengths and amplitudes of various instability patterns match well with our experimental data. It is expected that the unified phase diagram will not only advance the understanding of biological morphogenesis, but also significantly facilitate the design of new materials and structures by rationally harnessing surface instabilities.

ABSTRACT: A large number of authors in the past have concluded that the flow theory of plasticity tends to overestimate significantly the buckling load for many problems of plates and shells in the plastic range, while the deformation theory generally provides much more accurate predictions and is consequently used in practical applications. Following previous numerical studies by the same authors focused on axially compressed cylinders, the present work presents an analytical investigation which comprises the broader and different case of nonproportional loading. The analytical results are discussed and compared with experimental and numerical findings and the reason for the apparent discrepancy on the basis of the so-called “buckling paradox” appears once again to lie in the overconstrained kinematics on the basis of the analytical and numerical approaches present in the literature.
ABSTRACT: Here, we study hierarchy of graphene wrinkles induced by thermal strain engineering and demonstrate that the wrinkling hierarchy can be accounted for by the wrinklon theory. We derive an equation $\lambda = (ky)^{0.5}$, explaining evolution of wrinkling wavelength $\lambda$ with the distance to the edge $y$ observed in our experiment by considering both bending energy and stretching energy of the graphene flakes. The prefactor $k$ in the equation is determined to be about 55nm. Our experimental result indicates that the classical membrane behavior of graphene persists down to about 100nm of the wrinkling wavelength.

ABSTRACT: Wrinkling is a ubiquitous phenomenon in two-dimensional membranes. In particular, in the large-scale growth of graphene on metallic substrates, high densities of wrinkles are commonly observed. Despite their prevalence and potential impact on large-scale graphene electronics, relatively little is known about their structural morphology and electronic properties. Surveying the graphene landscape using atomic force microscopy, we found that wrinkles reach a certain maximum height before folding over. Calculations of the energetics explain the morphological transition and indicate that the tall ripples are collapsed into narrow standing wrinkles by van der Waals forces, analogous to large-diameter nanotubes. Quantum transport calculations show that conductance through these “collapsedwrinkle” structures is limited mainly by a density-of-states bottleneck and by interlayer tunneling across the collapsed bilayer region. Also through systematic measurements across large numbers of devices with wide “foldedwrinkles”, we find a distinct anisotropy in their electrical resistivity, consistent with our transport simulations. These results highlight the coupling between morphology and electronic properties, which has important practical implications for large-scale high-speed graphene electronics.

ABSTRACT: In a soft elastic film compressed on a stiff substrate, creases nucleate at preexisting defects and grow across the surface of the film like channels. Both nucleation and growth are resisted by the surface energy, which we demonstrate by studying creases for elastomers immersed in several environments—air, water, and an aqueous surfactant solution. Measurement of the position where crease channeling is arrested on a gradient thickness film provides a uniquely characterized strain that quantitatively reveals the influence of surface energy, unlike the strain for nucleation, which is highly variable due to the sensitivity to defects. We find that these experimental data agree well with the prediction of a scaling analysis.

ABSTRACT: Soft tissues growing under constraint often form creases. We adopt the model of growth that factors the deformation gradient into a growth tensor and an elastic deformation tensor, and show that the critical conditions for the onset of creases take a remarkably simple form. The critical conditions are illustrated with tubes of tissues growing either inside a rigid shell or outside a rigid core. By comparing the critical conditions for the onset of wrinkles, we show that the creases are the preferred type of instability. Furthermore, deep creases in a tube are simulated by using the finite-element method, and the number of creases in the tube is estimated by minimizing the free energy.

ABSTRACT: As the thinnest atomic membrane, graphene presents an opportunity to combine geometry, elasticity, and electronics at the limits of their validity. We describe the transport and electronic structure in the neighborhood of conical singularities, the elementary excitations of the ubiquitous wrinkled and crumpled graphene. We use a combination of atomistic mechanical simulations, analytical geometry, and transport calculations in curved graphene, and exact diagonalization of the electronic spectrum to calculate the effects of geometry on electronic structure, transport, and mobility in suspended samples, and how the geometry-generated pseudomagnetic and pseudoelectric fields might disrupt Landau quantization.

ABSTRACT: In this paper, the shear wrinkles of a rectangular membrane under the pretension were analyzed firstly. A critical shear distance was then obtained based on the tension field theory. An expression between the wavelength and the amplitude of the membrane wrinkles were developed using the Von Karman large deflection formula. The simulation flow of the membrane wrinkles were also established using the nonlinear post-buckling analytical method. The results indicated that the wrinkle was firstly generated on both sides of the membrane and then extended to the center. The wrinkle amplitude increased with the shear distance increases. The wrinkle formation and expansion were effectively resisted by increasing the initial pretension. Buckling mode of the shear membrane was unstable in the post-buckling process and the secondary buckling phenomenon was obviously observed. The theoretical and numerical results were compared to verify the rationality of the theoretical and simulation results.

ABSTRACT: We report the critical effects the deformational stress from the elastic nature of a confined polymer layer has during the relaxation process on the buckling of thin metal-polymer bilayer systems (less than 100 nm) even above the temperature at which the polymer is in the liquid flow region. In contrast with what is generally believed, the dispersion force does not play a significant role in the buckling. We also find that the final wrinkled waves take on the shape of wormlike islands. The coarsening leading to the island structure is driven by the growth in amplitude of the dominant wave at the expense of less dominant ones.

References listed at the end of the paper:

[14] Equation (2) is valid for initial perturbation of the film or \( h_0 = \alpha x \). The normal component contributing to the stress is given by \( \tau_{xx} \sin^2 \theta \cos^2 \theta x \alpha_\sigma \sin \theta \sigma_0 \), where \( \tan \theta_0 = \alpha / 0 \).

ABSTRACT: Wrinkles occur due to a mechanical instability when sufficient strain is applied to an incompressible thin film attached to a deformable substrate. For wrinkles made with a polymer film supported on a soft elastomer, the amplitude is directly proportional to the wavelength and the square root of the applied strain. This dependence has been confirmed with ideal substrates where the global strain is homogeneously distributed, but the influence of strain inhomogeneity has not been considered previously. We use the contact line wrinkling technique to prepare polystyrene thin films with periodic regions of different wrinkle amplitudes, hence strains, on soft substrates. We find that an inhomogeneously strained surface approaches amplitude homogeneity globally upon the application of sufficiently large strains. We derive relationships to describe this process, providing fundamental knowledge of the wrinkling mechanism.
ABSTRACT: Wrinkling of spherical surfaces represents a promising pathway for the formation of complex hierarchical structures and patterns. Using a swelling-based approach, we demonstrate the relationship between applied compressive stress, radius of curvature, and wrinkle pattern morphology. Surface features with spherical curvature are fabricated on poly(dimethylsiloxane) elastomers and a stiff surface oxide layer is generated using UV–ozone treatment. Swelling of this surface layer with ethanol vapor results in the formation of periodic wrinkles on the spherical caps. The radius of curvature is found to influence the critical wrinkling stress of the system, allowing cap size to independently dictate wrinkle morphology from non-wrinkled caps at small radii, through hexagonal dimple and long ridge structures as the cap radius increases. A similar transition is observed at constant radius by varying the UV–ozone treatment time, which affects the oxide film thickness and composition. The influence of curvature on the critical wrinkling stress is confirmed by modulating the atmospheric concentration of ethanol, and measuring the applied stress for the lowest concentration for which wrinkling occurs.

ABSTRACT: Wrinkled surfaces are ubiquitous in Nature and can be used in a large range of applications such as improved adhesives, microfluidic patterns, or as metrology instruments. Despite wide-ranging applications, existing methods do not permit local pattern control since all existing methods impose extensive compressive strains. In this article, we describe a new process that exploits the local deformation of a soft substrate as it stretches to form an adhesive interface with a thin polymer film. The wrinkle pattern is effectively a measurement of the strain-field created during the adhesion process, which shows a strong dependence on the speed of attachment. We develop simple scaling arguments to describe this velocity dependence and a critical velocity above which wrinkles do not form. Notably, our approach allows us to define the surface pattern “wrinkle-by-wrinkle”, thus permitting the creation of single wrinkles. Intricate patterns on laterally extensive length scales can also be produced by exploiting the shape of the contact line between the film and the substrate. This level of control—the placement of single features of prescribed trajectory—which is not present in any other method of thin film wrinkling, is absolutely necessary for any realistic, scalable application.

ABSTRACT: Osmotically-driven surface buckling is a simple method for introducing controlled micro- and nano-scale topography onto material surfaces. To achieve a fundamental understanding of the buckling process and a library of the equilibrium and kinetically-trapped structures that can be attained, we observe the growth processes of a buckling silicate plate rigidly attached to an elastomeric substrate. The primary variable is the lateral extent of the silicate plate which is shown to dictate the location of buckle initiation, and thus the resulting morphology of the final buckled structure. We present a model to qualitatively describe the radial stress profile within the plate, based on both the diffusion-controlled local osmotic stress and the ability of the plate to transfer this stress to the relatively unconfined region surrounding it. These results and insights provide lessons for controlling the order and arrangement of buckled microstructures.

ABSTRACT: Surface buckling instabilities, particularly wrinkles, are spontaneously occurring surface patterns that can cover large areas and have the potential to modify the adhesion of surfaces in a systematic manner; however, the impact of these wrinkled features is not understood quantitatively. We utilize a novel fabrication process to form aligned wrinkles from polystyrene and polydimethylsiloxane and quantify their adhesion using contact adhesion tests. Wrinkle amplitudes range from 0.3 μm to 11.4 μm and wavelengths range from 6.2 μm to 74.0 μm, and these two parameters are tuned independently. The maximum separation force of a flat cylindrical probe from a wrinkled surface depends non-linearly on the wrinkle geometry, as described by both amplitude and wavelength. Additionally, results are presented for a set of adhesion experiments conducted on single, macroscopic cylinders using small circular flat probes to mimic the contact of individual wrinkles. A simple scaling is presented that incorporates geometric parameters, testing geometry and materials properties to predict the separation force. This relationship is shown to be in good agreement with the experimental data.

ABSTRACT: Wrinkles and strain localized features are observed in many natural systems and are useful surface patterns for a wide range of applications, including optical gratings and microfluidic devices. However, the transition from sinusoidal wrinkles to more complex strain localized features, such as delaminations or folds, is not well understood. In this paper, we investigate the onset of wrinkling and strain localizations in a model system of a glassy polymer film attached to a surface of an elastomeric substrate. We show that careful measurement of feature amplitude as a function of applied strain allows not only the determination of wrinkle, fold, or delamination onset but also allows clear distinction between each type of feature. We observe that amplitude increases discontinuously as delamination occurs; whereas, the amplitude for a fold deviates gradually compared to the amplitude for a nearby wrinkle as a function of applied strain. The folds observed in these experiments have an outward morphology from the surface, in contrast to folds that form into the plane for a film floating on a liquid substrate. A deformation mode map is presented, where the measured critical strain for localization is compared for films with thickness ranging from 5 nm to 180 nm.

ABSTRACT: In this study, geometrically non-linear shell element post-buckling analysis was performed to study the wrinkling behavior of creased square membranes under corner loads. To instigate the out-of-plane wrinkle deformation, the finite element meshes were seeded with semi-random geometrical imperfection, and "STATIC,STABILIZE" option was used to stabilize the solution procedure. A pristine membrane and creased membranes with various initial deployment angles were considered. The local and global wrinkle formation was studied as increasing the ratio of corner loads. The effect of load level and the development of separate wrinkles along the crease line were also discussed.

ABSTRACT: In this paper, geometrically non-linear post-buckling analyses were performed to study the effect of sheet thickness on the crease-wrinkle interaction. A square sheet configuration with a single transverse crease was modeled using thin shell elements. The analysis proceeded by initially providing a realistic deployed state of a creased membrane sheet. Then an uneven corner loading was applied to introduce wrinkling. The effects of the induced anisotropy from the crease on the fine-scale detail of the wrinkle evolution, as a function of sheet thickness, loading, and crease deployment angle were systematically investigated.

ABSTRACT: The present paper provides insight into the crease-wrinkle interaction through a numerical analysis of a square sheet configuration, i.e., a thin membrane with small but finite bending stiffness (induced here by the crease). The analysis proceeds by initially providing a realistic deployed state of a creased membrane sheet. Then an uneven corner loading is applied to introduce wrinkling. The effects of the induced anisotropy from the crease on the fine-scale detail of the wrinkle evolution, as a function of crease orientation, loading, and crease deployment angle are presented. Then a brief study is performed by replacing selected crease cases with a seam. The results of the study have ramifications for the surface topology, global static shape, and dynamic response of large, lightly-loaded membranes in gossamer spacecraft.

ABSTRACT: Within the frame work of the three-dimensional linearized theory of stability of deformable bodies (LTTSDB), the near-surface buckling instability of a system consisting of a half-plane (substrate), a viscoelastic bond layer, and an elastic covering layer is suggested. The equations of the LTTSDB are obtained from the three-dimensional geometrically non linear equations of viscoelasticity theory by using the boundary-form perturbation technique. By employing the Laplace transform, a method for solving the problem is developed. It is supposed that the covering layer has an insignificant initial imperfection. The stability of the system is considered lost if the imperfection starts to increase and grows indefinitely. Numerical results for the critical compressive force and the critical time are presented.

ABSTRACT: The delamination buckling problem for a rectangular plate made of an orthotropic composite material is studied. The plate contains a band crack whose faces have an initial infinitesimal imperfection. The subsequent development of this imperfection due to an external compressive load acting along the crack is studied through the use of the three-dimensional geometrically nonlinear field equations of elasticity theory for anisotropic bodies. A criterion of initial imperfection is used in determining the critical forces. The corresponding boundary-value problems are solved by employing the boundary-form perturbation technique and the FEM. Numerical results for the critical force are presented.

ABSTRACT: This paper describes the spontaneous formation of patterns of aligned buckles in a thin film of gold deposited on the surface of an elastomer [poly(dimethylsiloxane), PDMS]. The surface of the elastomer is patterned photochemically into areas differing in stiffness and coefficient of thermal expansion. The gold is deposited while the surface of the patterned elastomer is warm (T > 100 °C). On cooling, shrinkage in the elastomer places the gold film under compressive stress. The buckles relieve this compressive stress. The distribution of stresses and buckle patterns is described during the pre- and postbuckling regimes using solutions from calculations describing a model comprising a thin stiff plate resting on a thick elastic foundation.

(7) A footnote.
ABSTRACT: Upon cooling, a thin metal film deposited on compliant elastomer substrate undergoes equibiaxial compression and begins to buckle at a critical stress. As further cooling occurs, a highly ordered herringbone pattern self-assembles. The preference for the herringbone pattern over other potential modes is demonstrated based on minimum energy arguments. Control of the pre-buckling in-plane stress components may be one way to influence the pattern formation, possibly giving rise to a family of unbalanced herringbone modes that links one-dimensional modes with the balanced herringbone mode.

ABSTRACT: An analysis of the stability of squeezing flows between flat plates (consolidation flows) of viscous liquids reinforced by continuous fibres is presented. The ideal linear fibre-reinforced fluid model is used to model the composite as an incompressible Newtonian fluid reinforced with inextensible fibres. The development of small fibre wrinkles initially present in the preimpregnated plies is analysed using linear stability theory. It is shown that when the flows are lubricated by resin rich layers, two perturbation modes are possible. In the first mode, the wrinkles are of the same form throughout the thickness of the sample while in the second mode they vary linearly with distance from the platens. In both cases the stability depends on the normal components of the applied stress. If the only traction acting in addition to hydrostatic pressure is that due to the squeezing force then the first perturbation mode is stable. This prediction is in agreement with experimental results.

ABSTRACT: Wrinkling that occurs in the stamping of tapered square cups and stepped rectangular cups is investigated. A common characteristic of these two types of wrinkling is that the wrinkles are found at the draw wall that is relatively unsupported. In the stamping of a tapered square cup, the effect of process parameters, such as the die gap and blank-holder force, on the occurrence of wrinkling is examined using finite-element simulations. The simulation results show that the larger the die gap, the more severe is the wrinkling, and such wrinkling cannot be suppressed by increasing the blank-holder force. In the analysis of wrinkling that occurred in the stamping of a stepped rectangular cup, an actual production part that has a similar type of geometry was examined. The wrinkles found at the draw wall are attributed to the unbalanced stretching of the sheet metal between the punch head and the step edge. An optimum die design for the purpose of eliminating the wrinkles is determined using finite-element analysis. The good agreement between the simulation results and those observed in the wrinkle-free production part validates the accuracy of the finite-element analysis, and demonstrates the advantage of using finite-element analysis for stamping die design.

ABSTRACT: The clearances between tube and various dies have a significant and complicated influence on the onset of wrinkling during the rotary draw bending process. To study the effect of clearance on wrinkling, a 3D finite element (FE) model of the process for thin-walled rectangular aluminum alloy tube has been built using the explicit code ABAQUS/Explicit and validated by comparing the experiment. Then, simulation and analysis of the process have been carried out based on the model. The influence laws of clearances between tube and various dies on wrinkling have been studied and the reasonable combination of clearances obtained using the combination method of 3D FE simulation and orthogonal experimental design. The results show that with the increase of tube mandrel clearance, \( \Delta c_m \), and tube bending die clearance, \( \Delta c_b \), the wrinkling wave number decreases rapidly, whereas the wrinkling wave height increases sharply. The effects of tube wiper die clearance, \( \Delta c_w \), and tube pressure die clearance, \( \Delta c_p \), on wrinkling are not significant. The reasonable combination of clearances is \( \Delta c_m = 0.15 \text{ mm}, \Delta c_b = 0 \text{ mm}, \Delta c_w = 0 \text{ mm}, \) and \( \Delta c_p = 0 \text{ mm}. \) These achievements are helpful to the design and optimization of the process.

ABSTRACT: An investigation into material wrinkling failure mechanics of conventional metal spinning and the effects of process parameters and material properties are presented in this paper. By developing finite element (FE) models using the Box-Behnken design of experiments, the effects of six key process and material parameters on the start of material wrinkling have been investigated. These key factors include roller feed per pass, feed rate, blank thickness, tool path profile, material Young’s modulus, yield stress and strain hardening exponent. The results of FE simulation are validated by comparing the modelled roller tool forces and spun part end shape with those measured during a spinning experiment. From FE simulations, large residual stresses in the form of bending moments are found to be present in the flange of the blank, induced by the roller contact. It is found that material wrinkling failure begins when a plastic hinge is formed between the roller and the edge of the blank. It is found that both roller feed per pass and feed rate produce the most significant effect on the initiation of wrinkling failure, as they increase the bending stresses causing a plastic hinge to form more rapidly, thus wrinkling to occur more quickly.
ABSTRACT: A new model is proposed to accurately predict the wrinkling and collapse loads of a membrane inflated beam. In this model, the pressure effects are considered and a modified factor is introduced to obtain an accurate prediction. The former is achieved by modifying the pressure-related structural parameters based on elastic small strain considerations, and the modified factor is determined by our test data. Compared with previous models and our test data, the present model, named as shell-membrane model, can accurately predict the wrinkling and collapse loads of membrane inflated beams.

ABSTRACT: The burning of a sheet of cellulose-based material, such as paper or cloth, involves uneven shrinkage which causes wrinkling. We simulate this geometrically complicated phenomenon by modeling the effects of heat transfer, shrinkage and partial ablation on a thin shell. A strain-limitation technique is applied to a two-layer structure of springs arranged as a body-centered square. Although this structure is over-constrained, convergence can be achieved using a new successive fast projection method. We also remesh the shells.
dynamically to deal with the topological changes that occur as regions burn away.

ABSTRACT: Various geometric sizes and helical types (i.e., armchair, zigzag, and chiral) of single-walled carbon nanotubes (CNTs) are considered in molecular dynamics simulations in order to systematically examine the length-to-radius ratio and chirality effects on the buckling mechanism. The buckling strain is getting smaller as the CNT becomes slender for most nanotubes, which implies that the slender nanotubes have lower buckling resistance regardless of the radius of the CNTs. The applicability of the continuum buckling theory, which has been well developed for thin tubes, on predicting the buckling strain of the CNT is also examined. In general, the corresponding buckling strain and buckling type predicted by the continuum buckling theory could agree reasonably well with simulation results except at the transition region due to the competition of two buckling mechanisms.

PARTIAL INTRODUCTION: Since Iijima reported MWCNTs in 1991, CNTs have captured the intensive attention of researchers worldwide due to the combination of their expected structural perfection, small size, low density, high stiffness, high strength, and excellent electronic properties. CNTs have been widely adopted as microscopic probing tips (Dai et al., 1996; Hafner et al., 2001), nanocomposites reinforcements (Bower et al., 1998; Jin et al., 1998), nanotweezers (Kim & Lieber, 1999), and nanoactuators (Baughman et al., 1999; Fennimore et al., 2003) due to their slender and high aspect ratio structures. Meanwhile, nanotubes are also highly susceptible to buckling under compression, which is a structural instability. Once the buckling of CNTs occurs, the load-carrying capability would suddenly reduce and lead to possible catastrophic failure of the nanotubes, which significantly limit the loading strengths of the probing tips and compressive strengths of nanocomposite structures. Even the physical properties such as conductance of carbon nanotube can be influenced by the occurrence of buckling (Postma et al., 2001). Hence, it is crucial to understand the mechanism of nanotube buckling and even predict the onset of buckling in order to improve the nanotube applications. A review of the relevant literature shows that significant studies have employed both experimental (Falvo et al., 1997; Iijima et al., 1996; Thostenson & Chou, 2004; Waters et al., 2004) and theoretical (Ru, 2000; Yakobson & Avouris, 2001) approaches to investigate the bucking behaviors of CNTs.

ABSTRACT: We carry out systematic molecular mechanics (MM) analyses to study the effect of the displacement increment on the critical buckling strain of single-walled carbon nanotubes (SWCNTs) under axial compression. The SWCNT geometric parameters, such as the tube length, diameter, and chirality, are varied in the numerical studies. The results show that the critical buckling strain of the SWCNTs deduced from the atomistic analyses is highly sensitive to the displacement increment used in the numerical simulation, and such an effect is more obvious for tubes with smaller diameters. Therefore, a reasonable compressive displacement increment should be selected in the atomistic simulations in order to obtain the intrinsic values of the critical buckling strain, which is suggested in this paper. The studies in this paper may be used to explain the contradicting results of the critical compressive buckling strains computed by other MM analyses in the literature.

ABSTRACT: The bending buckling behaviors of single-walled carbon nanotubes (SWCNTs) are systematically investigated by using both molecular dynamics (MD) simulation and finite element method (FEM), to analyze the relationships between critical bending buckling curvature, critical buckling strain and nanotube geometry parameters (e.g., tube diameter, length and chirality). The postbuckling shape of SWCNT and the effect of loading boundary conditions are also discussed. The comparison between MD and FEM simulations shows that the continuum shell model provides some useful insights into the bending buckling mechanisms, yet it cannot quantitatively reproduce the bending buckling behavior of SWCNTs, since the continuum model does not account for the geometrical imperfections in the atomic system that are critical to the onset of buckling. Improvements of continuum models are suggested based on the findings.

ABSTRACT: During the general (conventional) molecular mechanics (GMM) simulation of the buckling of single-walled carbon nanotubes (SWCNTs), the load is displacement controlled and the calculated critical buckling strain is very sensitive to the specific displacement increment and convergence threshold chosen in molecular dynamics (MD) simulations, which may have led to the contradictory and diverged results in the previous studies. In this paper, a targeted-molecular mechanics (TMM) simulation method is proposed to study the buckling behavior of SWCNTs under axial compression, bending, and torsion. Comparing with the GMM method, the TMM technique is independent of the displacement increment and thus the solution is converged. The critical buckling strain computed from the TMM is higher than that from the GMM under axial compression and torsion, and the TMM results are similar to the GMM results upon bending. The TMM result
approaches to the intrinsic critical buckling strain of a perfect tube; in addition, the TMM significantly reduces
the computational cost and thus may be more efficient to study larger systems with atomistic simulations.

P. Waters and A.A. Volinsky (Department of Mechanical Engineering, University of South Florida, 4202 E
Fowler Ave ENB118, Tampa, FL, 33620, USA), “Stress and moisture effects on thin film buckling

ABSTRACT: Deposition processes control the properties of thin films; they can also introduce high residual
stresses, which can be relieved by delamination and fracture. Tungsten films with high 1–2 GPa compressive
residual stresses were sputter deposited on top of thin (below 100 nm) copper and diamond-like carbon (DLC)
films. Highly stressed films store large amounts of strain energy. When the strain energy release rate exceeds
the films’ interfacial toughness, delamination occurs. Compressive residual stresses cause film buckling and
debonding, forming open channels. Profiles of the buckling delaminations were used to calculate the films’
interfacial toughness and then were compared to the adhesion results obtained from the superlayer indentation
test. Tests were conducted in both dry and wet environments and a significant drop in film adhesion, up to 100
times was noticed due to the presence of moisture at the film/substrate interface.

ABSTRACT: As instrument technology is needed for rapid determination of the smaller, thinner and lighter specimens, more stringent demands are related to thin films such as micro-electro-mechanical systems (MEMS), dielectric coatings and electronic packaging. Therefore, the requirement for testing platforms for rapidly determine the mechanical properties of thin films is increasing. Buckling of a film/substrate system could offer a variety of applications, ranging from stretchable electronics to micro-nanoscale metrology. In this paper, a fatigue-loading device has been designed to make the cyclic loading available for investigating the cumulative propagation of thin film buckling. The straight side buckling of thin compressed titanium film with the thickness of 50 nm deposited on organic glass substrates is investigated by using an optical microscope. The cumulative buckling propagation under the cyclic loading of a sequence of peak compression with the frequency 1 Hz is recorded by CCD camera. The buckling extension lengths are calculated by digital image measurement technology.

ABSTRACT: We investigated the possibility of controlling thin film buckling patterns by varying the substrate curvature and the stress induced therein upon cooling. The numerical and experimental studies are based on a spherical Ag core/SiO2 shell system. For Ag substrates with a relatively larger curvature, the dentlike triangular buckling pattern comes out when the film nominal stress exceeds a critical value. With increasing film stress and/or substrate radius, the labyrinthlike buckling pattern takes over. Both the buckling wavelength and the critical stress increase with the substrate radius.

ABSTRACT: Wrinkling is a common everyday occurrence. Over the last decade wrinkling in thin films has become an interesting topic. Nearly all studies to date have focused on the underlying physics or how the wrinkles can be used for a specific application. With more and more devices being created from stacked materials, a need for ways to prevent buckling has arisen. In this article we highlight the prevention of wrinkling in nanoscale thin films.

ABSTRACT: Self-assembled buckling patterns of thin films on compliant substrates have been subjected to extensive studies and shown great promise in micro-fabrication. However, most previous studies were limited to planar substrates, and the study of buckling of films on curved substrates has not received sufficient attention. With the constraining effect from various types of substrate curvature, numerous new types of buckling morphologies may emerge which not only enable true three-dimensional (3D) fabrication of microstructures and microdevices, but also have important implications for the morphogenesis of quite a few natural and biological systems. We review the scientific aspects of elastic buckling of thin films on several representative curved substrates, emphasizing the critical effect of substrate curvature, its interaction with other material/system parameters, ways to control the buckles based on mechanical and physical principles, and bridge them with prospective applications in biology, biomedical engineering, and small-scale fabrication.

ABSTRACT: Space-saving design is a requirement that is encountered in biological systems and the development of modern technological devices alike. Many living organisms dynamically pack their polymer chains, filaments or membranes inside deformable vesicles or soft tissue-like cell walls, chorions and buds.
Surprisingly little is known about morphogenesis due to growth in flexible confinements—perhaps owing to the daunting complexity lying in the nonlinear feedback between packed material and expandable cavity. Here we show by experiments and simulations how geometric and material properties lead to a plethora of morphologies when elastic filaments are growing far beyond the equilibrium size of a flexible thin sheet they are confined in. Depending on friction, sheet flexibility and thickness, we identify four distinct morphological phases emerging from bifurcation and present the corresponding phase diagram. Four order parameters quantifying the transitions between these phases are proposed.

ABSTRACT: A method to simulate orthotropic behaviour in thin shell finite elements is proposed. The approach is based on the transformation of shape function derivatives, resulting in a new orthogonal basis aligned to a specified preferred direction for all elements. This transformation is carried out solely in the undeformed state leaving minimal additional impact on the computational effort expended to simulate orthotropic materials compared to isotropic, resulting in a straightforward and highly efficient implementation. This method is implemented for rotation-free triangular shells using the finite element framework built on the Kirchhoff–Love theory employing subdivision surfaces. The accuracy of this approach is demonstrated using the deformation of a pinched hemispherical shell (with a 18-degree hole) standard benchmark. To showcase the efficiency of this implementation, the wrinkling of orthotropic sheets under shear displacement is analyzed. It is found that orthotropic subdivision shells are able to capture the wrinkling behavior of sheets accurately for coarse meshes without the use of an additional wrinkling model.

ABSTRACT: The details of development of the stiffness matrix for a doubly curved quadrilateral element suited for static and dynamic analysis of laminated anisotropic thin shells of revolution are reported. Expressing the assumed displacement state over the middle surface of the shell as products of one-dimensional first order Hermite polynomials, it is possible to ensure that the displacement state for the assembled set of such elements,
is geometrically admissible. Monotonic convergence of total potential energy is therefore possible as the modelling is successively refined. Systematic evaluation of performance of the element is conducted, considering various examples for which analytical or other solutions are available.

ABSTRACT: Laminated composite sandwich panels are extensively used in many engineering industries. Stability studies are needed to achieve good structural performance with minimum weight. The work presented in this paper deals with the prediction of elastic buckling loads for composite sandwich rectangular panels with a grid core subjected to axial compression. Kirchhoff-Love assumptions are used and each of the edges is considered to be clamped (C) or simply supported(S). The given panel is idealised as a homogeneous orthotropic plate whose equivalent properties are determined based on the given parameters of the panel. The boundary conditions considered are SCSC, CSCS, SCSS, CSSS, CCCS, CCCS and CCSC. Critical buckling loads are obtained using conventional orthotropic plate theory. A large class of $0^\circ/90^\circ/45^\circ/-45^\circ$ lamination schemes leading to quadridirectional, tridirectional and bidirectional T300/N5208 sandwich panels is examined and merit listed from buckling point of view. Results indicate that by proper choice of lamination scheme, very significant increases in buckling loads compared to quasi isotropic case can be obtained when $a/b < 1$ (the lower the value of $a/b$, the higher the gain) and for $a/b > 2$, the corresponding gains are smaller. For $a/b > 3$, having more $45^\circ$ layers is found to be more advantageous from buckling point of view, whereas for $a/b < 0.75$ having more $0^\circ$ layers is more advantageous.

ABSTRACT: Instability of laminated curved composite beams made of repeated sublaminate construction is studied using finite element method. In repeated sublaminate construction, a full laminate is obtained by repeating a basic sublaminate which has a smaller number of plies. This paper deals with the determination of optimum lay-up for buckling by ranking of such composite curved beams (which may be solid or sandwich). For this purpose, use is made of a two-noded, 16 degrees of freedom curved composite beam finite element. The displacements $u$, $v$, $w$ of the element reference axis are expressed in terms of one-dimensional first-order Hermite interpolation polynomials, and line member assumptions are invoked in formulation of the elastic stiffness matrix and geometric stiffness matrix. The nonlinear expressions for the strains, occurring in beams subjected to axial, flexural and torsional loads, are incorporated in a general instability analysis. The computer program developed has been used, after extensive checking for correctness, to obtain optimum orientation scheme of the plies in the sublaminate so as to achieve maximum buckling load for typical curved solid/sandwich composite beams.

ABSTRACT: Fibre-reinforced composite cylindrical panels are a typical subcomponent used in various aerospace structures. Buckling is one of the important modes of failure of such a panel. Repeated sublaminate
construction is often used in practice to reduce manufacturing errors and to produce more damage-tolerant laminates. In this type of construction, the full laminate is obtained by repeating the basic sublaminate, which has a smaller number of plies. This paper deals with the determination of optimum lay-up for buckling by ranking of such fibre-reinforced plastic composite cylindrical panels (which may be solid, sandwich or stiffened) using the finite element method. The particularized form of a four-noded, 48-dof doubly curved quadrilateral laminated anisotropic thin shell finite element is used. The core/stiffener can be a corrugated composite sheet or a regular grid. The computer program developed has been used, after extensive checking for correctness, to obtain the optimum orientation scheme of the plies in the sublaminate so as to achieve maximum buckling load for typical composite cylindrical panels.

ABSTRACT: Buckling of discretely stiffened composite cylindrical panels made of repeated sublaminate construction is studied using a finite element method. In repeated sublaminate construction, a full laminate is obtained by repeating a basic sublaminate, which has a smaller number of plies. This paper deals with the determination of the optimum lay-up for buckling by ranking of such stiffened (longitudinal and hoop) composite cylindrical panels. For this purpose we use the particularized form of a four-noded, 48 degrees of freedom doubly curved quadrilateral thin shell finite element together with a fully compatible two-noded, 16 degrees of freedom composite stiffener element. The computer program developed has been used, after extensive checking for correctness, to obtain an optimum orientation scheme of the plies in the sublaminate so as to achieve maximum buckling load for a specified thickness of typical stiffened composite cylindrical panels.

ABSTRACT: The buckling of plain and discretely stiffened composite axisymmetric shell panels/shells made of repeated sublaminate construction is studied using the finite element method. In repeated sublaminate construction, a full laminate is obtained by repeating a basic sublaminate, which has a smaller number of plies. The optimum design for buckling is obtained by determining the layup sequence of the plies in the sublaminate by ranking, so as to achieve maximum buckling load for a specified thickness. For this purpose, a four-noded 48-dof quadrilateral composite thin shell element, together with fully compatible two-noded 16-dof composite meridional and parallel circle stiffener elements are used.

ABSTRACT: Fibre-reinforced composites are used in many engineering structures with cylindrical panels being a typical component. Buckling is one of the important modes of failure of such a panel. The work presented in this paper deals with optimizing the orientation of plies in a simply supported composite cylindrical panel so as to achieve maximum buckling load. The panel is assumed to be composed of a repeated sublaminate construction. In this type of construction the basic sublaminate has a smaller number of plies, for example, 8, 6, 4 or 2, and the full panel is obtained by repeating the basic sublaminate. Such a construction is used to avoid
manufacturing errors and to produce damage-tolerant panels resulting from maximum splicing of plies. The buckling loads have been found using an energy method, and optimization of ply orientations in the basic sublaminate is achieved by using the ranking technique proposed by Tsai. The following configurations are considered in the paper: (i) solid laminated panel, (ii) sandwich panel, and (iii) stiffened panel. The sandwich or stiffened panel may have sinusoidally corrugated sheet, hat-type corrugated sheet or regular grid as core or stiffener respectively. The computer program developed was first checked for accuracy by comparing with results available in the literature for isotropic and orthotropic cylindrical panels. Then it was used to optimize the ply orientation in the sublaminate for any specified geometry, material, loading and boundary conditions. It was found that significant gains in buckling loads can be had by choosing the optimum lay-up scheme and that quasi-isotropic lay-up in many cases is far from the optimum.

ABSTRACT: Linear bifurcation buckling of FRP axisymmetric shells with fully compatible FRP meridional and hoop stiffeners is studied using the finite element method. Eccentricity of the stiffeners is taken into account. The composite shell and the stiffener are assumed to be made of a repeated sublaminate construction. This type of construction is used in industry to reduce manufacturing errors and to produce more damage-tolerant laminates. In this type of construction, the sublaminate consists of smaller number of plies and the required thickness of the laminate is obtained by repeating the sublaminate many times. This paper deals with the determination of the optimum lay-up scheme in the sublaminate of a composite axisymmetric shell with composite stiffener elements so as to achieve maximum buckling load for a given geometry, loading and boundary conditions using the finite element method. A four-noded, 48-DOF doubly curved quadrilateral laminated anisotropic thin shell finite element with fully compatible two-noded, 16-DOF meridional stiffener elements (MSE) and parallel circle stiffener elements (PCSE) is used. The buckling loads computed for several cases of shells (solid/stiffened) of positive and negative Gaussian curvatures with different applied loads and boundary conditions compare well with existing results in the literature. Subsequently the computer program has been used to find the optimum lay-up scheme of the plies in the sublaminate so as to achieve maximum buckling load for typical composite solid/stiffened shells.

ABSTRACT: The buckling of plain and discretely stiffened composite axisymmetric shell panels/shells made of repeated sublaminate construction is studied using the finite element method. In repeated sublaminate construction, a full laminate is obtained by repeating a basic sublaminate, which has a smaller number of plies. The optimum design for buckling is obtained by determining the layup sequence of the plies in the sublaminate by ranking, so as to achieve maximum buckling load for a specified thickness. For this purpose, a four-noded 48-dof quadrilateral composite thin shell element, together with fully compatible two-noded 16-dof composite meridional and parallel circle stiffener elements are used.

Sijl, Jeroen and Rozendal, Timo and Overvelde, Marlies and Garbin, Valeria and Dollet, Benjamin and Jong, Nico de and Lohse, Detlef and Versluis, Michel (2009) “Shell buckling increases the nonlinear dynamics of
ultrasound contrast agents at low acoustic pressures”. Journal of the Acoustical Society of America, 125 (4). p. 2680. ISSN 0001-4966

PARTIAL ABSTRACT: The key feature of ultrasound contrast agents in distinguishing blood pool and tissue echoes is based on the nonlinear behavior of the bubbles. Here we investigate the nonlinear properties of the shell which lead to an increased nonlinear bubble response, especially at low acoustic pressures. The microbubbles were studied in free space away from the wall using the Brandaris camera coupled to an optical tweezers setup. The microbubble spectroscopy method (Van der Meer et al., JASA, 121, 648, 2007) was employed to characterize BR-14 microbubbles (Bracco, Geneva). For increasing applied pressures the bubble resonance curves become asymmetrical and the frequency of maximum response decreases, up to 50% at a pressure of 25 kPa. It was found that the skewing of the nonlinear resonance curve is the origin of the so-called thresholding behavior below resonance. Traditional bubble models account for a purely elastic shell predict linear behavior, whereas the shell buckling model by Marmottant et al. . . .

ABSTRACT: Contrast-enhanced ultrasound imaging relies on the nonlinear scattering of microbubbles suspended in an ultrasound contrast agent. The bubble dynamics is described by a Rayleigh-Plesset-type equation, and the success of harmonic imaging using contrast agents has always been attributed to the nonlinear behavior predicted by this equation. A surfactant layer of phospholipids stabilizes the microbubbles and it has always been assumed that the visco-elastic properties of the coating lead to an increased stiffness and additional damping of the radial dynamics, hence to a reduction of the nonlinear response of the bubbles. Here we show that the coating material in fact leads to an increased nonlinear bubble response even at low acoustic pressures where the traditional models for coated as well as uncoated bubbles would only predict linear behavior. For a selection of bubbles we show a pronounced skewness of the resonance curve for increasing pressures to be the origin of the ‘threshold’ behavior, where it appears as if the bubbles are activated only at elevated pressures. Another set of bubbles shows a ‘compression-only’ behavior, where the bubbles are observed to efficiently compress, while their expansion is highly reduced. Moreover, the majority of these bubbles display a very strong subharmonic response. The shell-buckling model by Marmottant et al. accounts for buckling and rupture of the shell and captures all of the above cases for a unique set of the shell parameters, the relevant parameter being the phospholipid concentration at the bubble interface.

ABSTRACT: Subharmonic behavior of coated microbubbles can greatly enhance the contrast in ultrasound imaging. The threshold driving pressure above which subharmonic oscillations are initiated can be calculated from a linearized Rayleigh-Plesset type equation. Earlier experimental studies on a suspension of phospholipid-coated microbubbles showed a lower threshold than predicted from traditional elastic shell models. Here we present an experimental study of the subharmonic behavior of individual BR-14 microbubbles (Bracco Research) with initial radii between 1.6 and 4.8 micro-m. The subharmonic behavior was studied as a function of the amplitude and the frequency of the driving pressure pulse. The radial response of the microbubbles was recorded with the Brandaris ultrahigh-speed camera, while the resulting acoustic response was measured with a calibrated transducer. It is shown that the threshold pressure is minimum near a driving frequency equal to half the resonance frequency of the bubble, as expected. We found a threshold pressure as low as 10 kPa for certain bubble sizes, which can be explained by the shell buckling model proposed by [Marmottant et al., JASA (2005)]. We show that the origin of subharmonic behavior is a result of the discontinuous transition within the bubble shell from the elastic state to the tensionless buckling state.

“Buckling resistance of solid shell bubbles under ultrasound”, Journal of the Acoustical Society of America,
Vol. 129, No. 3, pp. 1231-1239, March 2011, DOI: 10.1121/1.3543943
ABSTRACT: Thin solid shell contrast agents bubbles are expected to undergo different volume oscillating
behaviors when the acoustic power is increased: small oscillations when the shell remains spherical, and large
oscillations when the shell buckles. Contrary to bubbles covered with thin lipidic monolayers that buckle as
soon as compressed: the solid shell bubbles resist compression, making the buckling transition abrupt.
Numerical simulations that explicitly incorporate a shell bending modulus give the critical buckling pressure
and post-buckling shape, and show the appearance of a finite number of wrinkles. These findings are
incorporated in a model based on the concept of effective surface tension. This model compares favorably to
experiments when adjusting two main parameters: the buckling tension and the rupture shell tension. The
buckling tension provides a direct estimation of the acoustic pressure threshold at which buckling occurs.

S. J. Britvec (Institute for Mechanics, University of Bundeswehr, Munich, Germany), “Static and dynamic
buckling of complex hyperstatic pin-connected elastic systems”, in Stability and Optimization of Flexible Space
Structures, pp 157-271, 1995
ABSTRACT: In this chapter we consider hyperstatic lattices composed of three-dimensional space elements
such as tetrahedrons, octahedrons, combinations of cubes and tetrahedrons etc., in which each element is made
of light flexible members joined together by hinged or quasi-hinged (hinge-like) connectors at the nodes. By
giving these members appropriate lengths, the lattice may be shaped into any curved three dimensional array of
space elements, as demonstrated in Fig. 3.1.1. Curved three-dimensional arrays of space elements constitute
shell-type geometrical configurations. Lattices and, in general, structures of this type are called reticulated shells.

“The geometrically nonlinear stability analysis of the composite reticulated spherical shell”, Spatial Structures, 1996-01, doi: CNKI:SUN:KJJG.0.1996.01.000

ABSTRACT: The geometrically nonlinear stability analysis of the composite reticulated spherical shell is studied in this paper by nonlinear finite element method of composite structure. The tangent stiffness matrices of spaal bea

spatial element and "discrete Kirchhoff" shell element are derived, and the nonlinear load-deflection response of the structure is analyzed by the cylindrical arc-length method. Finally taking a composite reticulated spherical shell with 40m span as an example, the load-deflection response, deflection shapes and critical load are studied in details. The comparison of computed results of composite reticulated spherical shell with those of spherical ribbed shell, plain shell and reticulated shell is also studied. Some useful conclusions are obtained.

doi: 10.1061/40513(279)99

ABSTRACT: This paper was based on the design of Space City, Science & Technology City of Shanghai (STCS). The Space City, the shape of which looks like an ovum, is a single-layered reticulated shell, so the buckling problem should be paid attention to. In this paper, Some nonlinear buckling analyses on two arrangements of the structure were used to solve the puzzle of engineers on the stable problems existing in the structure system of STCS. And the results were used to direct the design and construction.

ABSTRACT: Contrary to the usual procedure, a desired state of stress is assumed and that corresponding
funicular shells shape is obtained. The reticulated domes that are developed from these equivalent shells are called Funicular domes. For shallow shells the governing equation is a Poisson's equation and for deep shells the governing equation is a nonlinear partial differential equation. The Boundary Integral Element method is used to obtain the shape of the funicular reticulated domes. Nonlinear analysis is carried out to investigate the snap through buckling and load deformation response. Numerical examples are solved using the program "NLA" developed.

ABSTRACT: The constitutive model of laminated veneer lumber dealing with the creep and suitable for FE modeling was developed, based on the year-long tension and compression tests of laminated veneer lumber. The constitutive model was incorporated into the commercial FE software ABAQUS by developing a user-defined subroutine UMAT. FE models to predict the long-term behaviour of reticulated laminated veneer lumber shells, buckling in particular, were developed. Buckling analysis of single layer reticulated laminated veneer lumber shells with three-directional mesh was conducted. The interdependent relationship between the creep buckling load and the buckling time of the shells was revealed through the analysis, and the safety load against buckling during service life of the shells was defined.

ABSTRACT: This paper aims to achieve analysis and experiment results that relate to mechanics capability and structural parameter of a special saddle shell of revolution. Theoretically speaking, the saddle shell of revolution consists of a toroidal shell and a spherical shell. The shells simultaneous equations can be solved with harmonious terms. Where, the fundamental equations can be solved by asymptotic exponential perturbation method. The equations of special solution can be solved by Hovozhilovs special solution. This new idea is from a study of some existing solutions of the toroidal shell. The results have been proved by compared with some experimental results. The experiments aims to study the effect caused by change of material parameter, or by change of different geometric dimensions of the saddle shell, which include the change of thickness, the change of radius of shell, and the change of ribs. Finally, the accepted product of the saddle shell were reinforced by a toroidal rib has been submitted.

ABSTRACT: This paper describes the features of the JET shell element, a new thin shell curved finite element, based on Marguerre's theory. The element is quadrilateral with corner nodes only; each node has six degrees of freedom, i.e. three translations and three rotations. We emphasize here the physical aspects rather than the equations and give an explanation of the element, choice, difficulties encountered and their solutions, the resulting element and its capabilities, through various examples in linear, nonlinear and instability analysis.

ABSTRACT: The single-layer latticed cylindrical shell is one of the most widely adopted space-framed structures. In this paper, free vibration properties and dynamic response to horizontal and vertical seismic waves of single-layer latticed cylindrical shells are analyzed by the finite element method using ANSYS software. In the numerical study, where hundreds of cases were analyzed, the parameters considered included rise-span ratio, length-span ratio, surface load and member section size. Moreover, to better define the actual behavior of single-layer latticed shells, the study is focused on the dynamic stress response to both axial forces and bending moments. Based on the numerical results, the effects of the parameters considered on the stresses are discussed and a modified seismic force coefficient method is suggested. In addition, some advice based on these research results is presented to help in the future design of such structures.

ABSTRACT: To analysis progressive collapse behavior of single-layer reticulated shell under severe earthquake, based on spatial fiber beam element failure criteria, a simulation method on progressive collapse of shell is presented, which account of mechanical properties of components after buckling and damage accumulation effect of combine hardening material. And a computation program is developed correspondingly. At last the method and program proves to be applicable by an example.

PARTIAL ABSTRACT: According to the responses of the single-layer reticulated shell under dynamic loads, this study discusses the relationship between the failure model and the corresponding dynamic load parameters…

DOI: 10.1109/RSETE.2011.5964359

ABSTRACT: The collapse model and state judgment of reticulated shell structures is one of the research focuses of spatial structures. With structure double nonlinearity and material failure strain taken into account and based on LS-DYNA software, the collapse processes of three typical reticulated shell structures are simulated in this paper. And different states are defined in the dynamic collapse processes, including dynamic local buckling, dynamic overall buckling and dynamic whole collapse. By the simulation results, collapse model of reticulated shell structures is proposed, and a reference for space structures design and construction is provided.

ABSTRACT: This paper presents the study on failure mechanism of single-layer saddle-curve reticulated shells subjected to severe earthquake. Failure mode of single-layer saddle-curve reticulated shells is illustrated with the consideration of material damage accumulation. The effects of different parameters on failure characteristics of single-layer saddle-curve reticulated shells are discussed. The influence of substructure upon failure behaviors of single-layer saddle-curve reticulated shells is particularly investigated. It is observed that dynamic strength failure is the failure mode of single-layer saddle-curve reticulated shells. The substructure has great influence on failure characteristics of single-layer saddle-curve reticulated shells subjected to the severe earthquake.

ABSTRACT: The purpose of this study is to determine the buckling load of both continuous spherical shells and reticulated spherical shells using the continuum analogy method empirically and numerically. During the non-linear analysis, a post-buckling plateau and the appearance of a dimple in the shell wall identified the buckling load. By applying the theorem of work and energy to the dimple, an empirical formula to predict the buckling load of thin spherical shells was derived then extended to single-layer reticulated shells. It was observed that the buckling load is proportional to the thickness raised to exponential 2.5. Several finite element modeling and simulations using ABAQUS were conducted to validate the results.

**ABSTRACT:** Nonlinear behavior of single-layer squarely-reticulated shallow spherical shells with geometrical imperfections subjected to a central concentrated (joint) load has been studied in this paper. Using the asymptotic iteration method, an analytical characteristic relationship between the non-dimensional load and central deflection is obtained. The resulting asymptotic solution can be used readily to perform the analysis of parameters and predict the buckling critical load. Meanwhile, numerical examples are presented and effects of imperfection factor and boundary conditions on buckling of the structures are discussed. Comparisons with data based on the finite element method show good exactness of the resulting solution.

ABSTRACT: The nonlinear dynamical equations are established by using the method of quasi-shells for three-dimensional shallow spherical shells with circular bottom. Displacement mode that meets the boundary conditions of fixed edges is given by using the method of the separate variable. A nonlinear forced vibration equation containing the second and the third order is derived by using the method of Galerkin. The stability of the equilibrium point is studied by using the Floquet exponent.

ABSTRACT: The single-layer spherical reticulated shell is the structure which is sensitive to imperfections. The initial imperfections reducing structural stability included initial curvature and residual stress of element and installation deviation of nodes. The stress-strain curve concerning the residual stress was got by model CRC, the influence of initial curvature was got by the half-sinusoid and the programs about them were programmed by ANSYS secondary exploitation. Then the stochastic imperfections method about installation deviation of nodes was advanced, meanwhile, a new method was put forward for stability of the single-layer spherical reticulated shell. Comparing with the consistent imperfect buckling analysis method, the precision of the new method was higher. So the new method is better to the stability analysis of single-layer spherical reticulated shell.

ABSTRACT: Based on mechanical characteristics of the single layer latticed shell member, two buckling types of structural compression members are summarized. The pre-buckling and post-buckling mechanical behaviors of the member are simulated by different calculating model, and the member calculating model are founded by which the likely buckle-straighten processes of the member and the form-disappear processes of the plastic hinge can be simulated. Numerical computing results indicate that based on the member calculating model presented in this paper, the changes of member mechanical behaviors and the consequent complex changes of structural bearing capacity in the seismic dynamic responses process of single layer latticed shell can be calculate accurately, and the refined simulation of the full-range dynamic response process for single layer latticed shell subject to dynamic excitation are realized.

ABSTRACT: The collapse processes of three typical long-span reticulated shell structures were simulated using nonlinear dynamic finite element analysis under strong seismic excitations. The plastic kinematic hardening model, which considers failure strain, was adopted for simulating steel. Both geometric and contact nonlinearities were considered in this study. The three failure states—i.e., dynamic local buckling, dynamic overall buckling, and whole collapse—were identified in accordance with the analysis results. Taking the Schwedler reticulated shell structure as an example, seismic waves were applied to the structure in three directions. The critical loads were obtained by the incremental dynamic analysis method (IDAM), and some critical state indices were obtained according to the dynamic responses. The results showed that all the critical indices need to be considered simultaneously in order to judge the dynamic collapse states.

ABSTRACT: Thin spherical shells usually fail due to buckling. An empirical equation to predict their buckling load is derived based on the theorem of work done and energy released in the inversion of a section of a shell and nonlinear finite element (FE) modeling done using ABAQUS to determine their post-buckling behavior. It is observed that the initial buckling is sensitive to initial geometrical imperfections but the post-buckling load is little influenced. Therefore, the post-buckling load is used to predict a more realistic load as compared to classical buckling theory prediction.

ABSTRACT: The critical load of structures sensitive to initial imperfections may be considerably less than the classical buckling load. A method to evaluate the critical load of reticulated shells with rigid joints based on Koiter's general post-buckling theory is introduced. The use of generalized strain-displacement relationships and vector algebra leads to a polynomial representation of the static, buckling and post-buckling equation. As a result, the numerical solution is simplified and consists of solution of systems of linear equations and an eigenvalue problem. The slope of the post-buckling curve is obtained by the aid of which the critical load is computed.

ABSTRACT: In order to produce efficient, reliable design and to avoid unexpected catastrophic failure of structures, the engineer must understand the behaviour of buckling of large span reticulated shell structures. The function and the feature of the Code DDJTJQ, which is a computer program for static and buckling analysis of complex structures using finite element method, and the Code PPTJQ, which is a pre-post processing of DDJTJQ, are briefly introduced. The system has been implemented on microcomputers. An engineering structure, whose thin plate, thin shell and beam are important components, with 2965 degrees of freedom and 655 max. semi-bendwidth is analyzed. The numerical results of global buckling of reticulated shell structure of Jinan Zoo which was designed by Jinan Architectural Designing and Research Institute are given.

ABSTRACT: The influence of eccentric discharge of stored solids in squat silos has been highly valued by many researchers. However, calculation method of lateral pressure under eccentric flowing still needs to be deeply studied. In particular, the lateral pressure distribution on vertical wall could not be accurately recognized mainly because of its asymmetry. In order to build mechanical model of lateral pressure, flow channel and flow pattern of stored solids in squat silo are studied. In this passage, based on Janssen's theory, the method for calculating lateral static pressure in squat silos after eccentric discharge is proposed. Calculative formulae are deduced for each of three possible cases. This method is also focusing on unsymmetrical distribution characteristic of silo wall normal pressure. Finite element model is used to analysis and compare the results of lateral pressure and the numerical results illustrate the practicability of the theoretical method.

ABSTRACT: The final form of tubular nanofibres produced by the co-electrospinning of two solutions (core/shell) is largely determined by the kinetics governing the buckling phenomenon. The buckling mechanism involves the evaporation of the core solution through a solidified shell resulting in a pressure difference across the fibre shell. Buckling can take place when the pressure drop across the fibre shell exceeds a critical value. In this work the physical conditions leading to fibre buckling are analysed from a kinetic point of view. A time interval, $\Delta t$, during which buckling may occur, is introduced as a single criterion determining the buckling probability. Different core/shell systems were spun by varying the surface tension, viscosity, flow rate, electric field and the diffusion coefficient of the core solvent through the fibre shell. The imaged as-spun nanofibres were analysed statistically to determine the buckling probability, and the corresponding $\Delta t$ values were calculated using the values of the spinning parameters. The obtained data were fitted with an exponential distribution function which afforded determination of the characteristic time to buckling, $t_b$. The results provide a means of predicting the buckling of tubular nanofibres. In particular, one can conclude that the dominant parameter determining the final form of the as-spun tubular nanofibres is the diffusion coefficient of the core solvent through the fibre shell.

ABSTRACT: This paper presents a formulation for analysis of thin elastic membranes using a rotation-free shell element within an explicit time integration strategy. The applications presented are isotropic/anisotropic rectangular membranes under shear forces and fabric drapes falling over a pedestal. Results are compared with other numerical results existing in the literature.

ABSTRACT: The implementation of equilibrium and compatibility conditions along discontinuities in the geometry of thin shells is considered for finite element displacement formulations in which the displacements and their first derivatives are specified as generalised coordinates. A method is proposed in which the transformations of generalised coordinates affect only the element stiffness matrix. Applied to the solution of a
rotationally symmetric shell with discontinuities in the geometric curvature the method is shown to eliminate the numerical disturbances that can otherwise occur in the solution.

ABSTRACT: The elastic stability of shells or shell-like structures under two independent load parameters is considered. One of the loads is associated to a limit point form of buckling, whereas the second is a bifurcation. A simple one degree of freedom mechanical system is first investigated, for which an analytical solution is possible. Next, a cylindrical shell under the combined action of axial load and localised lateral pressure is studied via a non linear, two-dimensional, finite element discretization. It is shown that both problems display the same general behaviour, with a stability boundary in the load space which is convex towards the region of stability. The results show the need of performing a full non-linear analysis to evaluate the stability boundary for the class of interaction problems considered.

ABSTRACT: A study is presented of the elastic buckling of pressurized complex shells of revolution which are formed by the intersection of cylindrical with spherical or conical shells. The studies are based on the general theory of elastic stability using an asymptotic approximation to the secondary path. An axisymmetric finite element is used for the discretization of the shell. First, the behaviour of the individual components is presented for simply supported and clamped boundary conditions. Next, the complex shells are investigated in terms of the buckling load, the meridional and circumferential shape of the buckling mode, and the initial characteristics of the post-buckling path. The results show that the bifurcation loads of complex shells are lower than those of the individual components; but the post-critical path does not decrease as severely as in the isolated shells.

ABSTRACT: Dynamic instability of simple one-degree-of-freedom systems is studied under two loading parameters: lambda1, associated to a static load, and lambda2, which represents a dynamic load. Two models are considered which correspond to quadratic and cubic non-linearities. The static buckling response of the system shows unstable post-buckling behaviour (bifurcation for lambda2 and limit point for lambda2). Three forms of dynamic load lambda2 are studied: a step, a rectangular and an impulsive loading. The results are represented in terms of interaction curves, which show the relation between the parameters that lead to a critical state. An equivalent problem is also studied to allow for a generalization of the results to arbitrary dynamic
loads of finite duration.

Luis A. Godoy, Genock Portela, Eduardo M. Sosa, Luis E. Suarez, Juan C. Virella, and Raúl Zapata (Department of Civil Engineering and Surveying University of Puerto Rico, Mayaguez, PR 00681-9041, Puerto Rico), “Damage due to buckling in aboveground storage tanks” (publisher not given, date not given in the pdf file. Most recent citation is dated 2001) ABSTRACT: The damage due to buckling in thin-walled, short cylindrical aboveground tanks is discussed in this paper. Various sources of buckling are considered, including wind, earthquake, support settlement and vacuum during emptying of the tank. In all cases the tanks were modeled using finite elements, and the results include the buckling load and associated buckling mode, and the postbuckling equilibrium path. The results have been obtained using the computer packages ABAQUS and ALGOR. Experiments on flexible small-scale tanks with settlement of the supports on a sector of the foundation were conducted. Also, wind tunnel tests were carried out on rigid tanks with and without a roof to evaluate the pressure distribution due to wind. References listed at the end of the paper:

ABSTRACT: The main equations for the equilibrium, stability and critical state analysis of discrete elastic systems are presented following the works of Thompson, but in such a way that the original set of generalized coordinates and loads are preserved in the Total Potential Energy. This introduces differences in the resulting equations in bifurcation analysis but does not introduce any new feature regarding the physics of the problem. The new formulation is approximated by means of a standard finite element approach based on interpolation of displacements, in which the derivatives of the potential energy are approximated. The terms retained are those of moderately large rotation theory. The energy analysis is finally related to the more conventional finite element notation in terms of stiffness matrices, and it is shown how in such a way it can be included in present day codes.

ABSTRACT: The general theory developed in Part 1 of this paper for the finite element stability analysis of structural systems, using perturbation expansions in the vicinity of a critical point, is applied here to the analysis of shells of revolution. The discretization of the shell is performed by means of a semianalytical approximation, and the matrices required for the evaluation of critical points and postcritical equilibrium paths are obtained. Two cases are presented: bifurcation in axisymmetric and in asymmetric buckling modes. The derivatives required for an imperfection analysis are also obtained. A technique of switching between two paths using continuation methods is also discussed, in which the switch is performed using derivatives of the perturbation expansion. Results are presented for bifurcation in axisymmetric and in non-axisymmetric modes, and compared with known solutions or with results from changing the path using continuation methods; good correlation is shown. For structures displaying unstable bifurcation, the influence of load and geometric imperfections is evaluated.

ABSTRACT: The equations that define the load equivalent to an imperfection in the geometry (in the form of a deviation from the as-designed midsurface) of a thin shallow shell are considered. The present formulation defines initial displacements and an initial strain field in order to model the imperfection. It is assumed that deviations involve only initial displacements in the out-of-plane direction. Nonlinear terms in displacements due to the loads are neglected. The complete displacement field is introduced into the equilibrium equations to isolate the equivalent load. It is shown that the complete equivalent load obtained in this way differs from the simplified one employed in the literature due to the presence of nonlinear terms in the initial displacements. (The simplified load is the product of the membrane stress resultants multiplied by the error in geometric curvature of the shell.) An example illustrates the differences of stress resultants obtained from these linear and nonlinear approximations.

ABSTRACT: This paper presents a convenient formulation for the stability analysis of structures using the finite element method. The main assumptions are linear elasticity, a linear fundamental path, and the existence of distinct critical loads (i.e. no coupling between buckling modes occurs). The formulation developed is known as W-formulation, in which the energy is written in terms of a sliding set of incremental coordinates measured with respect to the fundamental path. In the presentation developed here, the only ingredients required to carry out the analysis are the strain-displacement and the constitutive matrices at the element level. The present formulation is compared with the so called V-formulation, in which the displacements refer to the unloaded state. It is shown that under the present assumptions of linear fundamental path, the advantages of the V-formulation are lost and both approaches are similar. An example of a circular plate under in-plane loading
illustrates the procedures. Part II of this paper deals with the application to the post buckling analysis of plate assemblies made of composite materials.

ABSTRACT: In a companion paper the authors presented a convenient formulation for the stability analysis of structures using the finite element method. The main assumptions are linear elasticity, a linear fundamental path and the existence of distinct critical loads. The formulation developed is known as the W-formulation, where the energy is written in terms of a sliding set of incremental coordinates measured with respect to the fundamental path. In the present paper a number of applications of finite elements for post-buckling analysis on composite plate assemblies are presented. Thin-walled composite plates, I-beams, angle sections, and a specially designed box-beam with flanges (unicolumn) are studied in post-buckling when axially loaded. The results are in good agreement with previous studies. Moreover, a parametric study involving critical buckling load and geometry is presented for the case of the unicolumn.

ABSTRACT: An analytical approximate model, leading to a closed form solution, is presented to account for buckling mode interaction in composite I section columns. Three buckling modes are considered in the analysis: a global mode (Euler mode about the weak axis); a primary local mode (rotation of the flanges and bending of the web); and a secondary local mode (bending of the flanges), which are modeled using analytical functions and four degrees of freedom. The fundamental state is shown to be linear and the three critical states for the isolated modes are found to be stable symmetric bifurcations. Mode interaction analysis in terms of the amplitudes of first order fields is carried out, for the first time, for prismatic sections of composite material. The tertiary (coupled) path involves coupling between the two local modes and it describes the sensitivity to imperfections of the buckling behavior of the composite column. A salient feature of the model presented is the closed form of the resulting solution, which enables the designer to easily perform parametric studies. Also, this is the first buckling mode interaction study for thin-walled composite columns. Numerical examples are presented to validate the results and to show the influence of the geometry and properties of the composite on the interaction phenomenon.

ABSTRACT: The dynamic instability of discrete, elastic, multiple degree of freedom (d.o.f.) systems under a combination of static and step loads is studied. Conservative, autonomous and holonomic systems are considered, in which the associated static response is a bifurcation under one load parameter, and a limit point under the second parameter. A review of different criteria and algorithms obtained from them for the computation of dynamic buckling loads is first presented, followed by a procedure derived from previous investigations on one d.o.f. systems. The different procedures are applied to a two d.o.f. problem under axial and lateral load, with quadratic and cubic non-linearities. The response in time shows that the system oscillates about the static equilibrium position before dynamic buckling is reached, with the kinetic energy tending to zero as assumed in the static (energy) procedures of stability.

ABSTRACT: First-ply failure (FPF) of composite thin-walled columns and frames is investigated in the buckled structure. Elastic behavior is assumed during the pre-buckling and buckling states, and along part of the post-buckling equilibrium path. The Tsai-Hill criterion is employed to identify failure of one ply at one specific location. The technique of analysis is based on evaluation of the post-buckling elastic path, and using FPF as a constraint in the analysis. The structure is modeled using a few degrees of freedom to include local and/or overall buckling modes. The theoretical results are compared with experimental bounds and show good agreement for local buckling of isolated columns. There are no experimental results for frames in the literature, but theoretical results are presented for a simple case with asymmetric bifurcation.

ABSTRACT: Pultruded composite structural members with open or closed thin-walled sections are being extensively used as columns for structural applications where buckling is the main consideration in the design. In this paper, global buckling is investigated and critical loads are experimentally determined for various fiber reinforced composite I-beams of long column length. Southwell's method is used to determine the critical buckling load about strong and weak axes. The experimentally determined buckling load is compared with theoretical predictions. A number of observations about testing methodology and data reduction techniques are presented.

References listed at the end of the paper:

ABSTRACT: Column buckling is a major design concern for pultruded composite columns. Interaction between the local (flange) and global (Euler) buckling modes occurs in intermediate length thin-walled columns
with near coincident buckling loads. The interaction of more than one buckling mode induce an unstable tertiary post-buckling path, causing imperfection sensitivity and premature failure. In this work, the existence of buckling-mode interaction is experimentally verified for intermediate length pultruded wide-flange columns subjected to uniaxial compression. Characterization of the interaction mode is done using both conventional testing techniques and the shadow moiré optical technique, allowing for non-contact, full field measurement of the buckling modes.

Luis A. Godoy and Sandra Lopez-Bobonis (Department of Civil Engineering, University of Puerto Rico, Mayagüez, PR 00681-9041, Puerto Rico), “On the collapse of a reinforced concrete digester tank”, (publisher and date not given in the pdf file. Most recent citation is dated 1999.)

ABSTRACT: The investigation following the collapse of a large reinforced concrete dome, which was part of a digester tank, is presented. The shell was constructed in 1987, and had construction errors related to the location of the single layer of reinforcement, which were discovered as a consequence of the collapse. The shell collapsed without the occurrence of any natural hazard. It is believed that a high internal pressure developed on the day of the collapse because of a problem with a valve, which allowed the discharge of large quantities of sewage inside the tank and filled the structure completely. A finite element analysis of the structure shows the stress levels in the structure, and support the hypothesis of a failure mechanism which coupled the construction errors with the internal pressure. Finally, the strengthening of the shell with externally bonded fiber composite sheets is described as a possibility to improve the safety of other tanks in similar situations.

ABSTRACT: This paper reports theoretical studies on the design sensitivity of problems with geometrically
non-linear behavior leading to buckling and post-buckling of thin-walled structural members. For the class of problems considered, buckling occurs in the form of a stable bifurcation, and it is assumed that changes in the design parameters do not break the bifurcation behavior. The specific focus of the research is the first yield or first failure of the material as part of the sensitivity study of equilibrium states along the post-critical path. The investigation employs a discrete model of a structure in terms of generalized coordinates (suitable for finite element analysis) and a single load parameter; and perturbation techniques to classify the critical state and to approximate the post-critical path. The problem of material behavior is modeled by means of constraints on the post-critical path, based on a yield criterion. For simplicity, the presentation uses the von Mises yield criterion, but other more complex criteria, such as those employed in composite materials (first-ply failure) can also be represented. Two forms of the constraints are formulated, and the problem of sensitivity with respect to changes in a design parameter is discussed. A simple example of a circular plate is presented to illustrate the use of the formulation for the sensitivity with respect to a single design parameter.

Luis A. Godoy and Genock Portela (University of Puerto Rico, Mayaguez Campus, Department of Civil Engineering), “A review of wind-tunnel results of pressures on tank models”, (publisher and date not given in the pdf file; latest reference is 2001)

GENERAL OVERVIEW: The Caribbean Islands are heavily exposed to hurricanes due its geographical location in the Atlantic and Caribbean Seas. Damage due to wind pressure of tanks used for storage different liquids have been observed and studied by different authors (Flores and Godoy (1998), Godoy and Mendez (2001)). Some of the cases studied were found in St. Croix, St. Thomas, and Puerto Rico during Hugo (1989), Marilyn (1995), and Georges (1998), respectively. Studies of wind pressures have taken place since early in the 20th century. During this era, air flow effects were investigated by different authors (H. L. Dryden et. al., 1930). A common problem is the variation of wind pressures depending on tank geometry. Both external wall pressure, as external roof pressure distribution is strongly dependent of the tank geometry. Detailed studies concerning to wind loads on cylinders include wind tunnel tests performed by Maher (1966) to dome-cone and dome-cylinder tanks. The height of hemisphere and spherical dome roofs mounted on cylinders with base diameters of 12 in. or 24 in., was changed to account variation of wind on the roof and wall of the shell. Pressures were measured both in the meridian and parallel axes of the cylinders and different pressure patterns were developed. Purdy et. al. (1967), studied wind pressure distributions on flat-top cylinders. The aspect ratio (h/D) was varied from short (tanks) to long (silos) cylinders to quantify the dimensional effects in pressure distribution. The cylinder diameters were 12 and 24 in., and the heights were increased from 6 in. Numerical approximations were developed based in Fourier cosines series on the surface of the flat roof diameter and along the parallel and meridian axes of the shell. More recent studies concerning to pressure variations around the shells were accomplished by Esslinger et.al. (1971), Gretler (1978), Gorenc (1986), Greiner (1998), and Pircher (1998). Studies based on wind distribution on conical roof tanks were accomplished by Sabransky et.al (1986), and MacDonald et.al (1988). Variations in aspect ratios were considered in the experimental tests and the authors give contours of different pressure coefficients found at different tank sections.

ABSTRACT: Shell buckling problems belong to the class of geometrically nonlinear behavior, and may be coupled with material nonlinearity of the shell. There are many general-purpose finite element programs that perform geometric and material nonlinear analysis of shells; however, this does not mean that a user can feed data and collect reliable results without a full understanding of the physics of the problem. This paper discusses the theories involved in the explanation and classification of phenomena, and in the prediction of results. Next, those approaches are considered in the practical analysis of one shell form, namely thin-walled steel tanks used to store oil. Results have been obtained with the general-purpose package ABAQUS, and they tend to show that their interpretation requires the use of Koiter’s theory in order to make sense of what is obtained. Some thoughts on possible ways to implement Croll’s lower bound reduced energy approach in practice are given.

ABSTRACT: An experimental/computational strategy is used in this paper to evaluate the buckling behavior of steel tanks with a dome roof under exposure to wind. First, wind tunnel experiments using small scale rigid models were carried out, from which pressure distributions due to wind on the cylindrical part and on the roof were obtained. Second, a computational model of the structure (using the pressures obtained in the experiments) was used to evaluate buckling loads and modes and to study the imperfection sensitivity of the tanks. The computational tools used were bifurcation buckling analysis (eigenvalue analysis) and geometrical nonlinear analysis (step-by-step incremental analysis). Geometric imperfections and changes in the buckling results due to reductions in the thickness were also included in the study to investigate reductions in the buckling strength of the shell. For the geometries considered, the results show low imperfection sensitivity of the tanks and buckling
loads associated with wind speeds 45% higher than those specified by the ASCE 7-02 standard.

ABSTRACT: We investigate dynamic buckling of aboveground steel tanks with conical roofs and anchored to the foundation, subjected to horizontal components of real earthquake records. The study attempts to estimate the critical horizontal peak ground acceleration (Critical PGA), which induces elastic buckling at the top of the cylindrical shell, for the impulsive hydrodynamic response of the tank–liquid system. Finite elements models of three cone roof tanks with height to diameter ratios (H/D) of 0.40, 0.63 and 0.95 and with a liquid level of 90% of the height of the cylinder were used in this study. The tank models were subjected to accelerograms recorded during the 1986 El Salvador and 1966 Parkfield earthquakes, and dynamic buckling computations (including material and geometric non-linearity) were carried out using the finite element package ABAQUS. For the El Salvador accelerogram, the critical PGA for buckling at the top of the cylindrical shell decreased with the H/D ratio of the tank, while similar critical PGAs regardless of the H/D ratio were obtained for the tanks subjected to the Parkfield accelerogram. The elastic buckling at the top occurred as a critical state for the medium height and tallest models regardless of the accelerogram considered, because plasticity was reached for a PGA larger than the critical PGA. For the shortest model (H/D=0.40), depending on the accelerogram considered, plasticity was reached at the shell before buckling at the top of the shell.

ABSTRACT: Ground-supported steel tanks experienced extensive damage in past earthquakes. The failure of tanks in earthquakes may cause severe environmental damage and economic losses. This study deals with the evaluation of the elastic buckling of above-ground steel tanks anchored to the foundation due to seismic shaking. The proposed nonlinear static procedure is based on the capacity spectrum method (CSM) utilized for the seismic evaluation of buildings. Different from the standard CSM, the results are not the base shear and the maximum displacement of a characteristic point of the structure but the minimum value of the horizontal peak ground acceleration (PGA) that produces buckling in the tank shell. Three detailed finite element models of tank-liquid systems with height to diameter ratios H/D of 0.40, 0.63, and 0.95 are used to verify the methodology. The 1997 UBC design spectrum and response spectra of records of the 1986 El Salvador and 1966 Parkfield earthquakes are used as seismic demand. The estimates of the PGA for the occurrence of first elastic buckling obtained with the proposed nonlinear static procedure were quite accurate compared with those calculated with more elaborate dynamic buckling studies. For all the cases considered, the proposed methodology yielded slightly smaller values of the critical PGA for the first elastic buckling compared to the dynamic buckling results.

“Challenges in the computation of lower-bound buckling loads for tanks under wind pressures”, Thin-Walled
ABSTRACT: This paper reports on the implementation of a lower-bound approach for the buckling of imperfection-sensitive shells using general purpose finite element codes. The stability of cylindrical steel tanks under wind pressure is evaluated for two tank configurations: conical roof tanks and open top tanks. For both tank configurations, several geometric relations are considered in order to find the variation of the knock-down factor as the geometry changes. The reduced energy method is implemented to compute a lower-bound for critical wind pressures and the results are compared with the static non-linear analysis carried out on the same models. An alternative way to implement the reduced energy method is presented to improve the results obtained with the proposed methodology.

ABSTRACT: Shell structures are usually designed by considering their final shape and configuration, so that it is assumed that stability during the construction will be satisfied without further thought. However, evidence from recent collapses of metal tanks under moderate winds shows that this is a matter that requires special attention. This paper reports analytical studies of tanks for the oil industry that failed during their construction in the Argentinean Patagonia under moderate winds. The cylindrical part of the tanks was set up in place with point welding, but the roof was not yet in place at the time of collapse. To understand the mechanism of failure, static, geometrically nonlinear finite element modeling of the tanks was carried out, in which the shell was represented as close as possible to the actual conditions during the construction stage at which it failed. The results show that for the wind velocities prevalent at the time of collapse, an explanation of the failure mechanism can only be achieved by taking into account several special features of the structure under construction, i.e. the localized nature of welding and the influence of the incomplete junction with the bottom plate.

“Reduced Stiffness Buckling Analysis of Aboveground Storage Tanks with Thickness Changes”, Advances in Structural Engineering Vol. 14 No. 3 2011, pp. 475-487
ABSTRACT: The Reduced Stiffness Analysis (RSA) to compute lower bounds to buckling loads of shells has been employed by a number of researchers as a simple way to evaluate the buckling capacity of shells that display unstable behavior and imperfection-sensitivity. It allows the use of simple eigenvalue analysis, without having to perform incremental nonlinear analysis, and is based on the physical behavior of the shell which recognizes that a significant contribution to the stability of a shell under lateral pressure is provided by its membrane stiffness. Unstable post-critical behavior is associated with the loss of this stabilizing membrane
contribution. Past use of the approach has been mainly restricted to cases of uniform shell thickness and uniform pressures in the circumferential direction, in which case analytical solutions are possible. Recent applications by the authors and other researchers have shown ways to compute the lower bounds using finite element analysis, for which a modified eigenvalue analysis is constructed by neglecting the membrane contributions to the matrix containing the initial stresses. This paper illustrates the application of the methodology to cases of pressure loaded shells with thickness changes in the meridional direction. A semi-analytical finite element code has been employed for the buckling analysis when uniform pressures act on aboveground steel tanks. The tanks are representative of those constructed for the oil industry, with diameter to thickness ratios of the order of 3000, and height to diameter ratios lower than one.

ABSTRACT: This paper reviews the research on the theory of elastic stability published at the end of the 19th century, with emphasis on the work by G. H. Bryan in Cambridge. The state of the studies on structural stability previous to Bryan is reviewed, and two lines of work are identified: one is a general stability of rigid bodies and the other is a collection of case studies of elastic stability. Bryan's theory is discussed next, presenting his arguments based on first energy principles, which led him to strong conclusions. The importance of the word “general” and the idea of having solved the problem in each case are explained. The impact of the contributions made by Bryan, together with the critiques that this generated, is also discussed.

ABSTRACT: Advances in computational methods to model the nonlinear elastic behavior of shell structures have generated new computer capabilities to solve complex industrial problems. Shell buckling involves a number of specific features not present in other structural forms, such as imperfection-sensitivity, load-sensitivity, mode interaction, and exchange of energy contributions along a nonlinear equilibrium path. However, rather than using increasingly complex tools, it is also desirable to have methods in which the physics of the problem is taken into account to set theoretically loaded models, which can be solved using simpler computational tools. The authors have recently investigated one such strategy, known as Reduced Stiffness Method, in which selected energy components are eroded as a consequence of mode interaction and imperfection-sensitivity. This physical interpretation allows the formulation as an eigenvalue problem, in which the critical loads are lower bounds to experiments or to nonlinear incremental analysis. This paper considers the computational implementation of a reduced stiffness approach to the buckling of axisymmetric shell structures under wind loads. The structural configurations of interest in this work are cylindrical storage tanks with a roof (either flat or conical roof), in which case the thickness is decreased from the bottom to the top of the cylindrical part. A reduced stiffness approach has been implemented in a finite element code for shells of revolution, in which stabilizing membrane components are eliminated on the assumption that they will be eroded due to imperfection-sensitivity and mode interaction. Several strategies are considered depending on the zone of the shell in which elimination of membrane components is made. The code is employed to estimate buckling loads and modes in tanks with various roof configurations. It is shown that there are two aspects that influence the results: first, the existence of zones with different stiffness in the structure, and second, a load with a circumferential variation. The present results are compared with geometrically nonlinear analysis including shape imperfections and with experimental results. The results indicate that a reduction in meridional and torsional membrane components applied on a zone of the shell leads to good results in terms of limit point loads and modes.

ABSTRACT: This paper reports the computational results of an investigation of oil storage tanks with the shape of an open cylindrical shell under thermal loads induced by fire. Interest in this problem has arisen as a consequence of a catastrophic fire that affected an oil storage facility in Puerto Rico in 2009 that caused the failure of 21 large tanks. To identify patterns of deformations that could be expected under various fire conditions, computer modeling has been carried out for one tank geometry. It is assumed that fire occurs outside the tank and induces an increasing temperature field affecting part of the external surface in the circumferential direction. The nonlinear shell response is modeled using finite elements under thermal loads and self-weight. The nonlinear behavior is computed to identify thermal buckling of the shell as a limit point. The response is initially computed for empty tanks, and the influence of various factors is investigated, including the liquid stored, a temperature gradient across the thickness, the circumferential zone affected by fire, and the shell thickness. The results for open tanks show that the location of large out-of-plane displacements attributable to thermal buckling coincides with the heated zone. The importance of thermal gradients in the thickness to the buckling load and mode are shown.

ABSTRACT: The strategy of Reduced Stiffness (or Reduced Energy) Analysis, in which selected energy components are eliminated to account for mode interaction and imperfection-sensitivity in a simplified way, was developed by Croll and co-workers since the early 1980s. This physical interpretation allows the formulation as an eigenvalue problem, in which the eigenvalue (critical load) is a lower bound to experiments and to nonlinear incremental analysis. This paper considers the computational implementation of both reduced stiffness and reduced energy approaches to the buckling of shell structures by means of perturbation techniques and penalty parameter methods. The structural configurations of interest in this work are cylindrical shells with or without a roof. The reduced stiffness approach has been implemented in a special purpose finite element code for shells of revolution, whereas the reduced energy methodology was implemented in a general purpose finite element code. The present results are compared with geometrically nonlinear analysis including geometric imperfections. Achievements and difficulties in extending the methodologies to complex problems in engineering practice are highlighted.

ABSTRACT: Buckling pressures were measured by collapsing thirteen 4000-gallon steel underground storage tanks using water to generate external pressure. These tanks were built using the minimum shell thickness specified in Underwriter Laboratories Standards UL-58 and UL-1746, reduced wall thickness. The effects on buckling pressure of shell thickness and shell-to-shell weld geometry were measured, as was the effect of internal stiffeners. These buckling pressures were compared with calculated values using standard formulas available in the literature. A predeformation force was applied to the bottom of the test tanks to induce uniform failure modes. A tank “stiffness” was determined from these measurements and correlated with buckling pressure. Measurements were also made on single-wall tanks with a surface coating of fiberglass reinforced plastic and on double-wall steel tanks.

ABSTRACT: In many practical problems, e.g., storage bins, oil tanks, missile shells, launch vehicles, etc., cylindrical shells are subjected to unsymmetrical lateral external load. These shells are usually made of thin sheets of metal; therefore, in many instances these structures have failed due to buckling. In this paper, the stability of cylindrical shells under the action of wind load is investigated. Often these shells are constructed of corrugated steel sheets; therefore, the shells are analyzed by considering the material as orthotropic. This analysis can also be used for other orthotropic materials. The principle of minimum potential energy in conjunction with Ritz’s approach is used. The buckling loads, as well as the buckling configurations, are obtained for short cylinders made of corrugated steel sheets subjected to wind pressure. The present study is made on cylindrical shells of various dimensions, which are simply supported at the base and are open or closed at the top. For practical use, buckling load curves for these shells are given for different length-to-radius and radius-to-thickness ratios.

Zhou Fang, Zhi Ping Chen, Chu Lin Lu, Ming Zeng, “Effect of Weld on Axial Buckling of Cylindrical Shells”, Advanced Materials Research (Volumes 139 - 141), pp 171-175, October 2010, DOI: 10.4028/www.scientific.net/AMR.139-141.171

ABSTRACT: Large oil storage tank (oil tank for short) shells are vulnerable to buckling damage when suffering the seismic loads. Numerical simulation analysis was taken to estimate the effects of the weld form, number and their location to axial buckling stress of cylindrical shells, considering not only the characteristic of welding
processes, but also the effects probably caused by magnitude of residual stress and deformation on elephant foot buckling to oil tanks. It is revealed that the existence of circumferential welds had obvious negative effect on axial buckling critical stress compared with the structure without welds, while the effects of weld number and location were not as much; longitudinal welds had no visible effect on axial buckling critical stress; controlling the residual stress and deformation range caused by circumferential welds should be the key point during the tanks welding process.

ABSTRACT: Based on two international well accepted design standards, Eurocode 8 Part 4—Tanks, Silos and Pipelines and API Standard 650—Seismic Design of Storage Tanks, the structural response of seismically excited vertical circular cylindrical tanks is analysed from a novel perspective. The common basic assumption, adopted from Haroun-Housner and Veletsos, that a circular cylindrical tank containing liquid behaves like a cantilever beam without deformation of its cross-section is obsolete. Instead the authors consider the shell modal forms in order to generate a refined model. Emphasis is laid on the analysis of the fundamental frequencies for the tank-liquid-system. They are calculated by a new method, based on Galerkin’s approximations for cylindrical shells. As the results differ significantly from those calculated by the proposed formulae in both EC8 and API Standard 650, the new results are compared with tank failures during recent earthquakes. This comparison is astonishing. It can be seen from recent examples of tank damage that most failures are caused by resonance effects, which are taken into account neither in EC8 nor in API Standard 650. And, therefore, we take into account a high safety risk. This leads to the conclusion that the basic assumptions for current design provisions are no longer tenable under the present knowledge of shell theory and shell design, and, therefore should be reconsidered.

ABSTRACT: The earthquake response behaviour of a cylindrical wine storage tank similar to many that were damaged in Livermore, California during the January 1980 earthquake was studied on the University of California shaking table. Tests of the 9.5 ft diameter by 20 ft high tank, with simulated earthquake accelerations up to 0.95 g, induced buckling patterns similar to those observed after the actual earthquake. Observed peak axial compression stresses in the test tank wall were substantially higher than those assumed in typical design standards, demonstrating the need for further study of the buckling problem in tanks free to uplift during earthquake excitation.

ABSTRACT: The magnitude M = 6.5 Coalinga earthquake of 2 May 1983 caused intense ground shaking throughout the epicentral region. Unanchored cylindrical ground supported tanks located at six sites within this oil producing area were damaged; damages included elephant's foot buckling at the base of three moderate sized tanks, joint rupture and top shell buckling in one large old rivetted tank, bottom plate rupture of a relatively new welded tank and damage to the floating roofs of 11 tanks. Also oil spilled over the top of many tanks and secondary damages occurred in pipe connections, ladders, etc. In this paper an estimate is made of the intensity of ground motion at each of the tank sites, based on strong motion records made during the main shock and the strongest aftershock. Then response parameters specified by current codes are correlated with the damages observed at each tank site. Based on this comparison, it is concluded that current U.S. practice under-estimates the sloshing response of tanks with floating roofs and does not adequately address the uplifting mechanism of unanchored ground supported tanks.

ABSTRACT: The bulging observed on the wall of a ground supported cylindrical storage tank, located at the Chiba Experimental Station of the University of Tokyo, is investigated. This damage is correlated with a ground motion recording obtained very near the tank base during a moderately strong earthquake that occurred on September 25, 1980 not far from the Chiba Experimental Station. From this correlation the importance of the horizontal excitation in amplitude and direction is clearly established. In addition, good agreement can be seen between the predicted tank wall earthquake performance, derived by an empirical approach proposed by the first author, and the shell deformation observed at the Chiba Experimental Station.

ABSTRACT: This paper details the damage sustained by a number of wine tanks during the San Juan, Argentina, 1977 earthquake. The available ground motion information is used to compare the actual tank performance with that predicted. Two of the tanks examined were located quite near the two accelerographs that recorded the ground motion in the city of San Juan for the main shock. An empirical attenuation formula which describes the intensity of the shaking was derived for this earthquake and used in a quantitative evaluation of the performance of a number of other tanks. By correlating and comparing the observed performance of the anchors and what was predicted we see the predictions are upheld by the actual damage. When the anchoring
system failed during the earthquake the tanks were rendered effectively unanchored. Consequently, the state of stress that results from their base uplift was then examined in conjunction with the tank wall stability approach proposed by the author, and seen to give results consistent with the observed tank wall performance.

ABSTRACT: Generally, we increase the cross sectional area of circular transverse frames or decrease the overall buckling length for increasing the critical buckling load of the ring-stiffened cylindrical shells. However, it is of no use to a large submarine. The curve r-p and formula are presented here, which determines whether the result of ordinary calculated methods is correct or not, estimates the maximum buckling load, determines the thickness of the shell, decides the reinforcements of the structure. There is only one curve. Therefore it is convenient to use. The curve has been checked by both model experiment and exact solution.

INTRODUCTION: The dynamic analysis of a cylindrical shell experiencing elastic deformation that is comparable to its wall thickness cannot be described within the framework of the linear theory. The same is applied if the liquid free-surface amplitude is relatively large. In both cases, nonlinear analysis should be carried out. The presence of nonlinearities may result in nonlinear resonance conditions that cause complex response characteristics. One of the main difficulties in nonlinear problems of shell–liquid systems is that the boundary conditions are essentially nonlinear. This is in addition to the fact that the strain state of an elastic shell and the shape of the liquid free surface are not known a priori. The treatment of the nonlinear interaction of a liquid–shell system is a nonclassical boundary-value problem and relies on mechanics of deformable solids, fluid dynamics, and nonlinear mechanics. With reference to nonlinear vibrations of cylindrical shells in vacuo, the literature is very rich and reports some controversies regarding the influence of nonlinearities on the shell dynamic behavior. The main results have been reviewed by Vol'mir (1972, 1979), Leissa (1973), Evensen (1974), Kubenko, et al. (1984), Amiro and Prokopenko (1997), and Amabili, et al. (1998b). Some attempts have been made to reconcile the reported discrepancies (see, e.g., Dowell, 1998, Evensen, 1999, and Amabili, et al. 1999c). It is believed that Reissner (1955) made the first attempt to study the influence of large-amplitude vibration for simply supported shells.

H. Moghaddam and S. Sangi (Faculty of Civil Engineering, Sharif University of Technology, Tehran, Iran), “Elephant’s Foot Buckling of Cylindrical Steel Storage Tanks Subjected to Earthquake Excitation”, 6th National Congress on Civil Engineering, April 26-27, 2011, Semnan University, Semnan, Iran
ABSTRACT: Thin metal cylindrical shell structures such as silos and tanks are susceptible to an elastic–plastic instability failure at the base boundary known as elephant’s foot buckling, due to its characteristic deformed shape. This form of buckling occurs under high internal pressure accompanied by axial compression in the shell structure. This work concerns with Theoretical studies on elephant's foot buckle failure of ground-supported, cylindrical liquid storage tanks under horizontal excitation. The buckling loads are obtained from finite elements models and codes and are compared. Theoretical nonlinear seismic analyses are carried out using ANSYS package. Studies are conducted on 13 models of cone roof tanks with height to diameter ratios (H/D)
between 1 and 2, and a liquid level of 85% of the height of the cylinder with and without axial constraint at the point diametrically opposite the loading. The results are compared to which of the codes API 650, NZSEE guidelines and Eurocode 8. The comparisons of analytical buckling loads and those obtained by the codes reveal the following. Tanks designed by the codes API650 and Eurocode 8 tend to be unsafe due to elastic-plastic buckling occurrence of the shell. However, NZSEE guidelines have a near coherence to the analysis results. It is also obtained from the results that constraints at the base of the tank reduces sloshing height while cause the buckling capacity to rise up.

Badawi (Department of Civil Engineering, University of California, Irvine, California, USA), “Seismic Behavior of Unanchored Ground-Based Cylindrical Tanks”, Proceedings of Ninth World Conference on Earthquake Engineering, August 2-9, 1988, Tokyo-Kyoto, Japan (Vol. VI)

SUMMARY: A review of the methods of seismic analysis of unanchored liquid storage tanks is presented along with an outline of an ongoing study to model the complex response mechanism of these structures. The study includes: 1. nonlinear static and dynamic analyses of the tank’s base plate under uplifting forces considering the nonlinear contact with the foundation and the underlying soil, the large deformation, and the inelastic response; 2. an analysis of the large-amplitude motion of the liquid and the corresponding hydrodynamic pressures; and 3. an analysis of the coupled response of the liquid, the shell, and the base plate under moderate to severe earthquake motions.

ABSTRACT: Local uplift of the tank wall is perhaps the most important characteristic of the seismic behaviour of unanchored liquid storage tanks made out of steel. Such uplift is necessary, because unanchored tanks rely primarily on the weight of the liquid resting on an uplifted portion of the base plate to balance the overturning moments that occur during strong shaking. A simplified method of analysis for static lateral loads is developed, based on the assumption that the restraining action of the base plate can be modelled with equivalent, non-linear
springs. This assumption, together with a Fourier decomposition of the displacements, simplifies the problem to the extent that it can be solved on a personal computer. The solutions are compared with those from experiments and those from current U.S. design analysis methods.

ABSTRACT: The diamond - modes of collapse are studied with finite element methods. Both linear and nonlinear analyses are performed on the buckling of a cylindrical shell under axial compression. Among the postbuckling shapes of the cylindrical shell, a number of diamond modes (cos(Ntheta); N = 0, 14, 18, 10, 24 and 28) are found to be possible. The analysis is compared to those conducted by Maewal and Nachbar, Crisfield, and Yoshida et al. Agreement is established in conceiving the deformed shape with circumferential number of 14 as the stable postbuckling mode of the cylindrical shell. The transition from the axisymmetric mode to a diamond mode of collapse is shown to be an instantaneous process triggered in the proximity of the critical state by a small perturbation of the load increment.

ABSTRACT: A Galerkin Finite Element formulation for the dynamic stability analysis of liquid-filled shells is given in this paper. The coupling among the axial and circumferential modes is investigated. The dynamic stability characteristics of two liquid-filled storage tanks subjected to vertical, horizontal and rocking seismic excitations are presented. It is shown that a tall tank tends to buckle at distinct frequencies; and for cos theta-type ground excitation, cos 2theta, cos 3theta and cos 4theta are the dominant modes of failure. On the other hand, in a broad tank, buckling regions overlap each other. In particular, for cos theta-type ground excitation, the dominant buckling modes are cos 6theta to cos 9theta, and also cos 12theta to cos 14theta.

ABSTRACT: The matrix equation of motion for liquid-filled shells with a particular reference to the influence of ground excitation are derived through a Galerkin/finite element discretization procedure. The modal coupling among the various combinations of axial and circumferential modes are identified. The equations for the dynamic buckling analysis of liquid-filled shells are presented. The buckling criteria of liquid-filled shells subjected to horizontal ground excitation are established. A comparison to available experimental results gives strikingly good agreement. The importance of modal interaction in the axial as well as circumferential directions is also demonstrated. This provides guidelines for a better understanding of dynamic buckling of liquid-filled shells.

S. Li, W. Hao and W. K. Liu (Department of Mechanical Engineering, Northwestern University, 2145 Sheridan
ABSTRACT: In this paper, meshfree simulations of large deformation of thin shell structures is presented. It has been shown that the window function based meshfree interpolants can be used to construct highly smoothed (high order “manifold”) shape functions for three-dimensional (3-D) meshfree discretization/interpolation, which can be used to simulate large deformation of thin shell structures while avoiding ill-conditioning as well as stiffening in numerical computations. The main advantage of such 3-D meshfree continuum approach is its simplicity in both formulation and implementation as compared to shell theory approach, or degenerated continuum approach. Moreover, it is believed that the accuracy of the computation may increase because of using 3-D exact formulation. Possible mechanism to relieve shear/volumetric locking due to the meshfree interpolation is discussed. Several examples have been computed by using a meshfree, explicit, total Lagrangian formulation. Towards to developing a self-contact algorithm, a novel meshfree contact algorithm is proposed in the end.

ABSTRACT: Sheet buckling, a form of instability, is one of the major considerations in the design of part shape, die geometry and processing parameters of sheet metal forming. In this study, an adaptive enrichment meshfree method is developed to capture wrinkling and post-buckling behavior in sheet metal forming. A three-dimensional meshfree continuum approach is applied to the large deformation of plate/shell structures. A stress-based wrinkling predictor is used to predict the onset of buckling within effective compressive regions. Enrichment particles with a proper enrichment function are inserted/deleted in those regions to capture the buckling mode and therefore post-buckling behavior. For verification of the simulation results, a high-resolution wedge strip test is designed to study the onset and post-buckling behavior of a sheet under different boundary conditions.

ABSTRACT: Numerical simulation of sheet metal forming processes is overviewed in this work. Accurate and efficient elements, material modelling and contact procedures are three major considerations for a reliable numerical analysis of plastic forming processes. Two new quadrilaterals with reduced integration scheme are introduced for shell analysis in order to improve computational efficiency without sacrificing accuracy: the first one is formulated for plane stress condition and the second designed to include through-thickness effects with the consideration of the normal stress along thickness direction. Barlat’s yield criterion, which was reported to be adequate to model anisotropy of aluminum alloy sheets, is used together with a multi-stage return mapping method to account for plastic anisotropy of the rolled sheet. A brief revision of contact algorithms is included, specially the computational aspects related to their numerical implementation within sheet metal forming context. Various examples are given to demonstrate the accuracy and robustness of the proposed formulations.

ABSTRACT: To determine the relationship between dynamic instability phenomenon of liquid storage tanks and excitation parameters, from fluid-solid coupling equations with displacement-pressure form, the dynamic stability equations were established for liquid storage tanks under harmonic ground acceleration, in which the fluid-solid coupling effect was considered with added mass matrix and the shell stress change was considered with period-varying geometric stiffening matrix. After order reduction by modal truncation method, above equations were then solved based on Floquet theory to recursively search for the dynamic instability boundary described by the excitation parameters. The Chiba test models were analyzed by the proposed Floquet method, and the analysis results were reexamined based on B-R criterion. The results show that, the dynamic instability boundaries obtained by the Floquet method were consistent with Chiba test results, and agreed well with the estimates of B-R method. Floquet method can obviously improve the computational efficiency of dynamic instability boundary and eliminates the influence of half-wave assumption of shell vibration modes.

Hou Chao-sheng and Zhou Wei-yi (School of Civil Engineering, Tianjin University, Tianjin 300072, China), “Nonlinear stability of revolutionary shells with arbitrary variable thickness subjected to axisymmetric distributed line load” Journal of Tianjin University, 2007-07

ABSTRACT: To simplify the complexity of calculating the large deflection of a plate or shell with variable thickness under the action of distributed line load, the solutions of nonlinear stability of revolutionary shells with variable thickness are obtained using the point collocation method with the cubic B-spline function as a trial function. Under the action of distributed line load, upper and lower critical loads of conical shells, spherical shells or quartic polynomial shells with linearly or polynomially variable thickness are obtained. Most solutions are compared with those obtained by other methods (including the finite elements method). As the rise of a spherical shell with uniform thickness reaches 6052 times its thickness, upper critical load of the shell subjected to distributed line load remains convergent. The program written by the spline collection method are accurate and universal.

ABSTRACT: We examine the axisymmetric buckling of a generalized Kirchhoff cylindrical shell under an axial wrench. If the shell is non-linear elastic, we provide a boundary value problem amenable to the bifurcation theory of Poincaré. Using this theory we prove a non-uniqueness theorem and obtain the critical loads and critical states. In the hyperelastic case, by exploiting the variational character of the problem, a global existence and non-uniqueness theorem is also proved.

SUMMARY: The dynamic stability of thin, laminated cylindrical shells under combined static and periodic axial forces is studied here using three common thin shell theories, namely Donnell's, Love's and Flügge's shell theories. A normal-mode expansion of the equations of motion yields a system of Mathieu-Hill equations the stability of which is examined using Bolotin's method. The present study examines and compares the effects of the use of the various shell theories on the dynamic stability analysis.

ABSTRACT: Metal silo walls are often constructed from isotropic plates, and the controlling design condition is buckling under axial compression. It has long been recognised that this buckling strength is highly sensitive to imperfections in the cylindrical shell, but most attention has been paid to geometric imperfections and imperfect boundary conditions. Imperfections in the form of residual stresses have only rarely been investigated, and the challenges facing a rigorous treatment of them have often not been faced. This paper adopts a rigorous treatment technique to investigate residual stresses and their effect on the axial compression buckling strength under elastic conditions. It achieves this by considering consistent stress and displacement fields arising from local geometrical incompatibilities, and adopting their consequent geometric imperfections. The calculations of the strength of imperfect shells with residual stresses are compared with corresponding calculations for the same imperfections but with the residual stresses ‘annealed’ out of the analysis. The results show that consistent residual stresses generally appear to strengthen a thin shell relative to the corresponding strength with only geometric imperfections present.

J.M.F.G. Holst, J.M. Rotter, M. Gillie and M. Munch (School of Civil and Environmental Engineering, University of Edinburgh, Edinburgh, EH9 3JN, UK), “Failure Criteria for Shells on Local Brackets”, Chapter in

ABSTRACT: Several criteria are given in design standards for determining the failure load of cylindrical shell structures. When the loading is nonuniform, a nonlinear finite element analysis is required to capture fully the deformation characteristics of the shell and to obtain a true estimate of the failure load. However, even if a fully nonlinear analysis is performed, the determination of the strength of the shell is not always easily achievable. Several different forms of nonlinear load-deformation behaviour are found. The adequacy of existing design guidelines for obtaining an estimate of the design strength is examined. For certain types of behaviour alternative methods are suggested that may provide a more definitive measure. The numerical results are based on silos supported locally on brackets. The results are, however, more widely applicable to shells under a general set of loads. The bracket-supported silo is used in the calculations as it provides a good example of a simple design, but with a relatively complex pattern of deformations leading to a highly nonuniform stress state.

ABSTRACT: This paper presents theoretical descriptions of the key phenomena that govern the behaviour of composite framed structures in fire. These descriptions have been developed in parallel with large scale computational work undertaken as a part of a research project (The DETR-PIT Project, Behaviour of steel framed structures under fire conditions) to model the full-scale fire tests on a composite steel framed structure at Cardington (UK). Behaviour of composite structures in fire has long been understood to be dominated by the effects of strength loss caused by thermal degradation, and that large deflections and runaway resulting from the action of imposed loading on a ‘weakened’ structure. Thus ‘strength’ and ‘loads’ are quite generally believed to be the key factors determining structural response (fundamentally no different from ambient behaviour). The new understanding produced from the aforementioned project is that, composite framed structures of the type tested at Cardington possess enormous reserves of strength through adopting large displacement configurations. Furthermore, it is the thermally induced forces and displacements, and not material degradation that govern the structural response in fire. Degradation (such as steel yielding and buckling) can even be helpful in developing
the large displacement load carrying modes safely. This, of course, is only true until just before failure when material degradation and loads begin to dominate the behaviour once again. However, because no clear failures of composite structures such as the Cardington frame have been seen, it is not clear how far these structures are from failure in a given fire. This paper attempts to lay down some of the most important and fundamental principles that govern the behaviour of composite frame structures in fire in a simple and comprehensible manner. This is based upon the analysis of the response of single structural elements under a combination of thermal actions and end restraints representing the surrounding structure.

ABSTRACT: The buckling strength of a thin cylindrical shell is important in many applications in civil engineering. On the one hand, current design rules are principally based on an empirical interpretation of test data and hence very simple loading conditions are applied. On the other hand, experimental and theoretical observations show significant stress non-uniformity and hence a deviation from the buckling strength expected under uniform load. Reliable quantification of this effect is still challengingly difficult.

This paper explores a typical thin cylindrical silo shell under localized axial compression. Two different buckling phenomena are identified with corresponding, and distinct, buckling mode forms. The influence of geometric imperfections on the buckling strength of the shell is also considered.

PARTIAL INTRODUCTION: Storage containers are frequently constructed at ports in coastal regions or on reclaimed land where large settlements arise due to poor soil conditions. Uneven settlement beneath a ground-supported tank may occur, leading to several possible failure modes. The commonest causes are the use of non-uniform fill beneath the vessel and the construction of only part of the vessel on ground that has been consolidated by the earlier presence of a tank…. Each failure mode is closely related to a different component of the total settlement. Although the description given in the following outline review is mostly in terms of tank structures, it is equally applicable to all forms of cylindrical metal shells with the axis vertical…If buckling occurs in the tank wall, is it potentially catastrophic or only unsightly…

ABSTRACT: The design of cylindrical metal silos and tanks is often controlled by considerations of buckling under axial compression. Whilst the effects of geometric imperfections on the buckling strength have been extensively explored, few studies have explored the effects of defects in the boundary conditions and the effects of residual stresses have received even less attention. This paper investigates the initiation and development of imperfections caused by local differential settlement at the supported base and their effect on the elastic buckling of a thin cylindrical shell under axial compression. The shells were treated as initially perfect with perfect support, but developing geometric imperfections and residual stresses as a consequence of local displacement at the supported edge and with residual stresses consistent with the induced geometric imperfections. The results raise interesting questions concerning the criteria of failure and appropriate tolerance measurements for constructed cylindrical shells.
ABSTRACT: Thin cylindrical shells used in civil engineering applications are often susceptible to failure by elastic buckling. Most information on shell buckling relates to simple and uniform load cases, but most practical load cases involve stresses that vary very significantly throughout the structure. The buckling strength of an imperfect shell under relatively uniform stresses is much lower than that under locally high stresses, so design proposals have often suggested that designers use the uniform buckling stress strength even for local stresses. However, this leads to enormous overdesign, and many knowledgeable designers use their own very simple rules of thumb to produce safe but unverifiable designs. Unfortunately, very few scientific studies of shell buckling under locally elevated stresses have ever been undertaken. The most critical case is that of a locally axially compressed cylinder. This paper explores the buckling strength of an elastic cylinder in which a locally high, axial membrane stress state is produced far from the boundaries (which can elevate the buckling strength further) and adjacent to a serious geometric imperfection. Care is taken to ensure that there is relatively little influence from local bending phenomena, so that the stress state can mimic that produced by much more complex load cases. The study includes explorations of different geometries, different localisation of the loading and different imperfection amplitudes. The results show an interesting distinction between narrower and wider zones of elevated stresses. The study is a necessary precursor to the development of a complete design rule for the buckling strength under local axial compression.

“Buckling of Thin Cylindrical Shells Under Locally Elevated Compressive Stresses”, Journal of Pressure Vessel Technology, Bol. 133, No. 1, 011204 (11 pages), December 2010
ABSTRACT: Thin cylindrical shells used in engineering applications are often susceptible to failure by elastic buckling. Most experimental and theoretical research on shell buckling relates only to simple and relatively uniform stress states, but many practical load cases involve stresses that vary significantly throughout the structure. The buckling strength of an imperfect shell under relatively uniform compressive stresses is often much lower than that under locally high stresses, so the lack of information and the need for conservatism have led standards and guides to indicate that the designer should use the buckling stress for a uniform stress state even when the peak stress is rather local. However, this concept leads to the use of much thicker walls than is necessary to resist buckling, so many knowledgeable designers use very simple ideas to produce safe but unverified designs. Unfortunately, very few scientific studies of shell buckling under locally elevated compressive stresses have ever been undertaken. The most critical case is that of the cylinder in which locally high axial compressive stresses develop extending over an area that may be comparable with the characteristic size of a buckle. This paper explores the buckling strength of an elastic cylinder in which a locally high axial membrane stress state is produced far from the boundaries (which can elevate the buckling strength further) and adjacent to a serious geometric imperfection. Care is taken to ensure that the stress state is as simple as possible, with local bending and the effects of internal pressurization eliminated. The study includes explorations of different geometries, different localizations of the loading, and different imperfection amplitudes. The results show an interesting distinction between narrower and wider zones of elevated stresses. The study is a necessary precursor to the development of a complete design rule for shell buckling strength under conditions of locally varying axial compressive stress.

ABSTRACT: The strength of metal cylinders is well known to be highly sensitive to the presence of imperfections. Attention has long been focused on geometric imperfections, but some recent studies have examined the effect of including the residual stress state relating to the formation of these imperfections in assessing the buckling strength of the shell. This paper looks first at how the imposition of a local geometrical incompatibility on a long narrow circumferential region of the shell surface leads to the formation of dimple imperfections and how these, in turn, affect the buckling strength of the shell. As an example, a case study of a thin cylindrical steel tank is presented, where lack of fit and weld shrinkage have caused local dimpling of the shell. Some results are presented from an analysis of this tank, which successfully uses several of the procedures applied in studying the fundamental cases of misfits.

ABSTRACT: The general theory of an elastic Cosserat surface due to Green and Naghdi, along with some kinematic results from the theory of superposed small deformations on a large deformation of an elastic Cosserat surface, are applied to study axisymmetric buckling of a cylindrical elastic shell under axial compression. An eigencondition is determined for a sinusoidal buckling mode in an infinitely long shell which illustrates the dependence of the buckling load on the pre-buckling deformation and on shear deformation in the superposed buckling deformation.

ABSTRACT: Relying on the concept of a Cosserat continuum, the reduction of the three-dimensional equations of a shell body to two-dimensions is carried out in a direct manner by considering the Cosserat continuum to be a two-dimensional surface. By that, a non-linear shell theory, including transverse shear strains, with exact description of the kinematical fields is derived. The strain measures are taken to be the first and the second Cosserat deformation tensors allowing for an explicit use of a three parametric rotation tensor. Thus, inplane rotations, also called drilling degrees of freedom, are included in a natural way. The structure of the configuration space is discussed and two possible definitions of it are given equipped once with a Killing metric and once with an Euclidean one. A partially mixed variational principle is proposed on the base of which an efficient hybrid finite-element formulation, which does not exhibit locking phenomena, is developed. Various numerical examples of shell deformations at finite rotations, with excellent element performance, are presented.

Carlo Sansour (Technische Hochschule Darmstadt, Fachgebiet Maschinenelemente und Akustik, Magdalenenstr. 4, 64289, Darmstadt, Germany), “Large strain deformations of elastic shells constitutive
ABSTRACT: This paper is concerned with the constitutive modelling of large elastic strains with applications to shells. The shell theory itself is characterized by seven degrees of freedom and enjoys the following features: (1) it circumvents the use of a rotation tensor preserving the Euclidean structure of the configuration space and (2) it is capable to the application of a three-dimensional constitutive law. In addition, an elastic finite strain constitutive law is developed which: (1) covers the whole range of deformation experimentally given by Treloar and (2) is formulated in terms of invariants avoiding the use of principal stretches. The second feature means that the model is generalizable to anisotropic material behaviour, and that it allows for straightforward computations of the tangent operator making the whole theory well suited for large strain computations. In addition to the four-node and nine-node displacement-based finite elements, an enhanced strain finite element is examined. Its efficiency is compared with that of displacement-based element formulations. Different examples of large strain shell deformations are presented. It is shown that the application of the enhanced strain concept in the nonlinear constitutive range limits severely the stability of computation.

“A Shell Theory with Scale Effects, Higher Order Gradients, and Meshfree Computations”, Chapter in Recent Developments and Innovative Applications in Computational Mechanics, pp 107-114, 2011, DOI: 10.1007/978-3-642-17484-1_13

ABSTRACT: In recent times, scale effects have been given great attention due to the fact that they characterise the material behaviour at lower scales. The later being considered an important area of research in material sciences and engineering. Many applications, however, are concerned with so-called thin domains (e.g. thin films, nano tubes) which makes it more effective to run the computations via a shell theory. Hence the motivation to develop a shell theory which includes in a natural way scale effects. This is done by extending and modifying previous 3-d generalized formulations of the authors [5] to accommodate for the shell. Applications are discussed for the buckling of thin shells at small scales.

P. Wriggers (T. H. Darmstadt, Darmstadt, Germany), “Continuum mechanics, nonlinear finite element

ABSTRACT: This three lectures course will give a modern concept of finite-element-analysis in nonlinear solid mechanics using material (Lagrangian) and spatial (Eulerian) coordinates. Elastic response of solids is treated as an essential example for the geometrically and material nonlinear behavior. Furthermore a brief introduction in stability analysis and the associated numerical algorithms will be given. A main feature of these lectures is the derivation of consistent linearizations of the weak form of equilibrium within the same order of magnitude, taking also into account the material laws in order to get Newton-type iterative algorithms with quadratic convergence. The lectures are intended to introduce into effective discretizations and algorithms based on a well founded mechanical and mathematical analysis.

DOI: 10.1002/nme.1620371503

ABSTRACT: A numerical time-integration scheme for the dynamics of non-linear elastic shells is presented that simultaneously and independent of the time-step size inherits exactly the conservation laws of total linear, total angular momentum as well as total energy. The proposed technique generalizes to non-linear shells recent work of the authors on non-linear elastodynamics and is ideally suited for long-term/large-scale simulations. The algorithm is second-order accurate and can be immediately extended with no modification to a fourth-order accurate scheme. The property of exact energy conservation induces a strong notion of non-linear numerical stability which manifests itself in actual simulations. The superior performance of the proposed scheme method relative to conventional time-integrators is demonstrated in numerical simulations exhibiting large strains coupled with a large overall rigid motion. These numerical experiments show that symplectic schemes often regarded as unconditionally stable, such as the mid-point rule, can exhibit a dramatic blow-up in finite time while the present method remains perfectly stable.

ABSTRACT: Investigation of nonlinear static and dynamic response of solids and structures requires knowledge about the stability behaviour. In general we have to detect singular points (e.g. limit or bifurcation points) or the global loss of stability and furthermore one has to be able to follow nonlinear solution paths. ABSTRACT: This paper presents a general formulation of thin incompressible membranes and investigates the behavior of soft biotissues using the finite element method. In particular the underlying hyperelastic model is chosen to examine the highly non-linear constitutive relation of blood vessels which are considered to be perfectly elastic, homogeneous and (nearly) incompressible. First, the stress-deformation relation and the elastic tangent moduli are derived in a very general material setting which is subsequently specified for blood vessels in terms of Green-Lagrangian strains. Based on the principle of virtual work the finite element equations are provided and briefly discussed. Consistent linearization of the weak form of equilibrium and the external pressure term ensures a quadratic convergence rate of the iterative solution procedure. On the computational side of this work an effort was undertaken to show a novel approach on the investigation of soft tissue biomechanics. Representative numerical analyses of problems in vascular mechanics are discussed that show isochoric finite deformations (large rotations and large strains). In particular, a numerical simulation of the interaction between an inflated balloon catheter and a plaque deposit on the wall of a blood vessel is presented.

ABSTRACT: Author's own experimental and theoretical researches on buckling of shells of revolution are summarized with special emphasis on the conceptual approach behind them. Effect of the biaxial stress states is depicted in form of interaction diagrams. Design formulas based on these concepts and computations carried out for reinforced concrete hyperboloidal cooling tower shells allow the erection of very large and thin cooling towers which meanwhile have reached the 200m limit in height.

E.L. Jansen (Faculty of Aerospace Engineering, Delft University of Technology, Kluysterweg 1, HS 2629, Delft, Netherlands), “Non-stationary flexural vibration behaviour of a cylindrical shell”, International Journal of
ABSTRACT: An analytical/numerical method involving a small number of generalized coordinates is presented for the analysis of the non-linear vibration and dynamic stability behaviour of imperfect anisotropic cylindrical shells. The small amplitude vibration mode is characterized by \( m \) axial half-waves and \( n \) circumferential full waves. The radial excitation is assumed to have the same spatial distribution as the small amplitude vibration mode. For large excitations, a coupled mode response can occur, consisting of the directly excited “driven mode” and the so-called “companion mode”. The latter has the same spatial form as the driven mode, but is circumferentially 90 degrees out-of-phase. Donnell-type governing equations are used and classical laminate theory is employed. The assumed modes approximately satisfy “simply supported” boundary conditions. A formulation is used which can account for a possible skewedness of the asymmetric modes. Certain axisymmetric modes which are essential for a satisfactory description of the non-linear behaviour are also included in the assumed deflection function. The effect of axial and torsional inertia, including the inertia effect of a ring or disk at the loaded end of the shell, can be taken into account approximately. Viscous modal damping is included in the analysis. The shell is statically loaded by axial compression, radial pressure, and torsion. A two-mode imperfection model, consisting of an axisymmetric and an asymmetric mode, is used. The static state response is assumed to be affine to the given imperfection. In order to find approximate solutions for the dynamic state equations, Hamilton's principle is applied to derive a set of modal amplitude equations. The dynamic response is obtained via numerical time integration of the set of non-linear ordinary differential equations. The coupled mode non-linear vibration behaviour of an axially loaded isotropic shell is simulated using this approach. Non-stationary vibrations, where the response drifts between single mode and different types of coupled mode solutions, are observed in a small frequency region near resonance.

ABSTRACT: We present in this paper a simple finite element implementation of Koiter’s perturbation analysis for initial post-buckling of general shell structures. The calculation of post-buckling curvature coefficients shows converge problems when careless finite element implementation of Koiter’s analysis is carried out. Instead of using special formulations, we show that reasonably accurate results can be obtained by extending an existing linear triangular shell element with a nonlinear strain contribution derived from simple linear displacement shape functions. The resulting constant strains alleviate locking phenomena in the calculation of the post-buckling coefficients. Numerical results are shown to validate the proposed approach.

ABSTRACT: Analytical–numerical models to analyse the flexural vibration behaviour of anisotropic cylindrical shells are presented. The two models (denoted as Level-1 and Level-2 Analysis) have different levels of complexity and can be used to study the influence of important parameters, such as geometric imperfections, static loading, and boundary conditions. A specific anisotropic shell is used in the calculations in this paper. The influence of the imperfection shape and amplitude on the natural frequency is investigated for this shell via both the Level-1 and the Level-2 Analysis. Imperfections with the shape of the “lowest vibration mode” give a decrease of the natural frequency with increasing imperfection amplitude. The results of the Level-2 Analysis for the effect of imperfections on the natural frequency are in reasonable agreement with Finite Element calculations.

ABSTRACT: In this paper a multi-mode finite element implementation of Koiter’s initial post-buckling theory with the inclusion of the pre-buckling nonlinearity is presented. Using this implementation a multi-mode initial post-buckling analysis of an axially loaded composite cylindrical shell has been carried out with a small number of representative modes. The implementation has been done in a general purpose finite element code. Results are compared with results from semi-analytical perturbation analysis and from finite element based fully nonlinear analysis.

ABSTRACT: This paper presents a finite element formulation of Koiter's initial post-buckling theory using a multi-mode approach. Initial post-buckling theory provides direct information about the imperfection sensitivity of a structure under compressive loading, and is also the basis of a nonlinear reduced order model. The objective of the present work is to illustrate the capability of the implementation for buckling analysis of shell structures including modal interaction. A coupled mode initial post-buckling analysis for a composite cylindrical shell under axial compression, including the effect of a nonlinear pre-buckling state, has been carried out using a small number of representative modes. For small imperfection amplitudes the limit-point buckling loads obtained with the reduced order model compare reasonably well with full model nonlinear analysis, illustrating that a fast prediction of the coupled mode response of imperfect shells is possible using the approach proposed.

ABSTRACT: A finite element formulation of a reduction method for dynamic stability analysis of imperfection-sensitive shell structures is presented. The reduction method makes use of a perturbation approach, initially developed for static buckling and later extended to dynamic buckling analysis. The single mode dynamic buckling analysis and its extension to parametric excitation analysis are described. The approach is available within a general purpose finite element code. Characteristic results for the parametric excitation analysis of a composite cylindrical shell are shown.

ABSTRACT: In this paper a finite element formulation of a reduction method for dynamic buckling analysis of imperfection-sensitive shell structures is presented. The reduction method makes use of a perturbation approach, initially developed for static buckling and later extended to dynamic buckling analysis. The implementation of a single-mode dynamic buckling analysis in a general purpose finite element code is described. The effectiveness of the approach is illustrated by application to the dynamic buckling of composite cylindrical shells under axial and radial step loads. Results of the reduction method are compared with results available in the literature. The results are also compared with full model finite element explicit dynamic analysis, and a reasonable agreement is obtained.

“The direct prediction of buckling loads of shells under axial compression using VCT – Towards an upgraded approach”, 29th Congress of the International Council of the Aeronautical Sciences, St. Petersburg, Russia, September 7-12, 2014

ABSTRACT: The availability of a Vibration Correlation Technique (VCT) for nondestructive determination of buckling loads of cylindrical shells has obvious advantages. Earlier, a semi-empirical VCT approach has been developed and applied successfully for the prediction of the buckling load of closely stiffened aluminum shells. In the present paper, a possibility to support and improve the estimates of this semi-empirical VCT approach by means of the application of analysis tools is proposed. Two semi-analytical models with different levels of complexity will be used for this purpose. In the two approaches employed, both the nonlinear effect of the static state and the nonlinear effect of the geometric imperfections are represented. These two methods form the basis of an extension of the existing semi-empirical Vibration Correlation Technique for shells, to a VCT in which vibration measurements and analysis tools are combined. In this paper, the capability of the analysis tools which can be used to improve the VCT is illustrated.

“Mode-reduction applied to initial post-buckling behavior”, Chapter in DIANA Computational Mechanics ’94, pp 287-296, 1994

ABSTRACT: This paper presents a perturbation approach for analyzing the (initial) post-buckling behavior of elastic structures. In this perturbation a small number of buckling modes is taken into account. This approach results in a potential energy function which is defined in terms of amplitudes of the selected modes. The post-buckling displacement field is solved from the reduced set of equilibrium equations where the unknowns are the amplitudes of the Euler modes which are selected for the asymptotic expansion. To perform this technique the segment PERTUR in module *EULER is designed in DIANA 6.0. The theory of this segment and two calculating examples are demonstrated.

ABSTRACT: The objective of this paper is to predict the buckling pressure of a composite cylindrical shell using buckling formulas (ASME 2007, NASA SP 8007) and finite element analysis. The model in this study uses a stacking angle of [0/90]12t and USN 125 composite material. All specimens were made using a prepreg method. First, finite element analysis was conducted, and the results were verified through comparison with the hydrostatic pressure buckling experiment results. Second, the values obtained from the buckling formula and the buckling pressure values obtained from the finite element analysis were compared as the stacking angle was changed in increments from to . The linear and nonlinear results of the finite element analysis were consistent with the results of the experiment, with a safety factor of 0.85-1. Based on the above result, the ASME 2007 formula, a simplified version of the NASA SP-8007 formula, is regarded as a buckling formula that provides a reliable safety factor.

ABSTRACT: The non-linear dynamic behavior of suddenly loaded composite shells is the subject of this research. The objective of the research is two-fold: (1) to characterize the apparently random physical behavior sometimes observed in the finite element analysis as either numerical instability, chaotic behavior, or both; and (2) to develop criteria for choosing time steps for the finite element model, referred to as DSHELL. This displacement based finite element code is capable of dynamic analysis of plates, arches, and cylindrical shells undergoing large displacements and moderately large rotations during deformation. DSHELL uses a 36-DOF isoparametric shell element to obtain numerical results. A simplified shell model (MSHELL) is developed to provide a shell analog that requires much less computer time to run than the full-up finite element model. The results of the investigations using this simplified model are then applied toward understanding behavior seen in the finite element code. The simplified model and the composite shell exhibit chaotic behavior after collapse. For loads not sufficient to cause collapse, the composite shell experiences oscillations at the panel edges of a type associated with near-chaotic behavior. Significant in-plane oscillations (parametric resonances) are exhibited by the suddenly-loaded composite shell. Extensive use of the Fast Fourier Transform (FFT) is made to investigate behavior of the MSHELL and DSHELL models in the frequency domain. The composite shell is compared to an isotropic shell of identical physical dimensions and static collapse strength, showing the primary effect of isotropy to be increased flexibility in all displacement directions. A method is developed using MSHELL for choosing appropriate time steps for analyses using DSHELL. References listed at the end of the thesis.

ABSTRACT: The Implicit Corotational Method or simply ICM is a powerful tool for defining geometrically nonlinear structural models. Its main feature is the possibility of obtaining nonlinear models starting from linear ones in an easy and automatic fashion. This has great potential because the literature is full of linear theories while, conversely, satisfactory nonlinear models are not widely available. (text omitted) Our aim is to show that the ICM, by decoupling the kinematical coherency from the elastic response, can make a useful contribution to
this also allow us to directly recover the results provided by the tradition. The method is based on the polar decomposition theorem and the corotational description of motion, which is directly applied at the continuum level. (text omitted) The theoretical features of the ICM are presented and its main items are discussed referring to some implementations to planar and spatial beam and thin plate models. (text omitted) The FEM implementation is provided for both nonlinear 3D beam and plate models. For the beam model (based on Saint Venant theory) the assumptions about the rotation parameters and the details on handling finite rotations are given clearly. The accuracy of some finite elements that differ for the interpolation laws assumed for the kinematics and statics fields and for the interpolations strategy is pointed out. For the plate model (based on Kirchoff hypothesis) the proposed finite element is implemented in asymptotic FEM code. A large amount of numerical analysis is performed, also comparing beam and plate based solutions. The good agreement between them shows the accuracy and capability of the proposed approach for numerical implementations.

ABSTRACT: In our previous paper the implicit corotational method (ICM) was presented as a general procedure for recovering objective nonlinear models fully reusing the information obtained by the corresponding linear theories. The present work deals with the implementation of the ICM as a numerical tool for the finite element analysis of nonlinear structures using either a path-following or an asymptotic approach. Different aspects of the FEM modeling are discussed in detail, including the numerical handling of finite rotations, interpolation strategies, and equation formats. Two mixed finite elements are presented, suitable for nonlinear analysis: a three-dimensional beam element, based on interpolation of both the kinematic and static fields, and a rotation-free thin-plate element, based on a biquadratic spline interpolation of the displacement and piece-wise constant interpolation of stress. Both are frame invariant and free from nonlinear locking. A numerical investigation has been performed, comparing beam and plate solutions in the case of thin-walled beams. The good agreement between the recovered results and the available theoretical solutions and/or numerical benchmarks clearly shows the correctness and robustness of the proposed approach as a general strategy for numerical implementations.

ABSTRACT: We investigate a geometrically exact membrane model with respect to its capabilities in describing buckling and wrinkling. The concept is distinct from traditional ones by the introduction of an artificial viscosity related to an adjusted orthonormal frame (rotations). In this way our model is able to capture the detailed geometry of wrinkling while the balance of force equations remains elliptic throughout. The movement of rotations is given by a local evolution equation. We discuss the consistent linearization of the model and the local update of rotations. Numerical examples are presented, which demonstrate the effectiveness of the new model for predicting wrinkles in membranes undergoing large deformation.

“Implicit Corotational Method: analysis of slender panels assemblages”, (no publisher or date given. Most recent reference is dated 2009)
ABSTRACT: In some recent works, it has been shown that the Implicit Corotational Method (or simply ICM) is a powerful and consolidated approach for recovering nonlinear models starting from the corresponding linear ones both in the cases of continuum and discrete problems (see [1, 2, 3]). The method is based on the polar decomposition theorem and the corotational description of motion, which is directly applied at the continuum level. By referring to the linear stress solution as Biot tensor in corotational frame and using a mixed variational formulation, we obtain an automated way of using the information gained by the linear model in the nonlinear context. Since linearized model are always available it is easy to obtain, by this way, the corresponding nonlinear models in a form convenient for numerical implementations. A similar picture holds when the approach is directly applied to the finite element discretization. In this case, starting from a linear finite element, the methods give the corresponding nonlinear, frame indifferent, finite element interpolation. As good and accurate is the linear finite element as good will be the corresponding nonlinear one. On the other hand, in the last years high-performance plate finite elements, based on hybrid stress formulation and which exhibit a good behavior in the linear/elastic context, have been developed (see [4, 5, 6] and references therein) showing that they are in general simple, stable, locking–free. On the contrary, the developments of so good finite elements for the geometrically nonlinear case is in general more difficult. The idea of the present work is then to reuse these finite elements in a nonlinear context using the ICM. For this purpose, the format of the element has been rearranged to be suitable for ICM implementation and a specialized corotational algebra for the plate model has been developed [7]. The implementations are carried out in both contexts of path–following and asymptotic approaches, extending the FE codes KASP and RASP already available and aimed at asymptotic and path–following analysis, respectively, of slender panels assemblages (see [8] and related references).

References listed at the end of the paper:
This paper shows that the FEM implementation of Koiter's asymptotic method [W.T. Koiter, On the stability of elastic equilibrium, 1970, Ph.D. Thesis, Delft, 1945. English transl. NASA TT-F10, 883, 1967, AFFDL-TR70-25] outlined by Casciaro et al. [Finite element asymptotic analysis of slender elastic structures: a simple approach, Int. J. Num. Meth. Eng. 35 (1992) 1397–1426] provides accurate and reliable results in the critical and post-critical analysis of non-linear elastic structures. Care, however, does have to be taken in implementing (apparently) minor details to avoid locking effects which adversely affect accuracy and which can destroy the method reliability. As the effects related to the finite element interpolation have been discussed before this paper focuses on the non-linear locking due to the use, implicit in the method, of finite distance extrapolations. Within this scope, it is shown that perturbation algorithms based on compatible formulations can imply a strong critical and post-critical locking when analysing structures characterized by high stiffness ratios in the presence of moderate pre-critical rotations. On the contrary, perturbation algorithms based on independent extrapolations of displacements and stresses furnish reliable results in excellent agreement with those provided by step-by-step analysis, at a small fraction of its computational cost.

ABSTRACT: Finite element asymptotic post-buckling analysis, being based on fourth-order expansions of the strain energy, requires that nonlinear structural modeling be accurate to same order, at least with respect to the rigid motions of the elements. A corotational description is proposed here as a general tool to satisfy this requirement of objectivity, by referring each element to a local frame which moves (rotates) with the element, so filtering its rigid motion. In this description nonlinearity of the problem derives essentially from the change of reference, from the global fixed frame to the local one, the strain energy being governed by their relative rotations. In finite kinematics, this noticeably complicates the algebra for obtaining exact expressions of its variations. Quite simple, basic expressions for the first four corotational derivatives of the strain energy are provided, allowing the set up of a fourth-order accurate asymptotic analysis starting from standard finite elements based on linear or simplified nonlinear local modelings. The formulation is implemented for the analysis of 3D beam assemblages and several numerical results are presented and discussed showing the effectiveness and robustness of the proposed approach in reproducing the nonlinear equilibrium path in both cases of monomodal and coupled multimodal buckling.

ABSTRACT: A path-following non-linear elastic analysis for structures composed of assemblages of flat slender elastic panels is presented. The proposed path-following method employs FEM technology and a
kinematical model to analyse these structures using a Koiter asymptotic approach. As a result it is possible to verify the accuracy achieved by the asymptotic method. The proposed mixed path-following formulation is both efficient and robust with regards to the locking extrapolation phenomenon that strongly affects compatible formulations. The use of an HC finite element makes it possible to avoid the problem of the finite rotations in the space, maintaining a high degree of continuity and making the numeric formulation simple and efficient.

Giovanni Garcea, Antonio Madeo, Giuseppe Zagari, Emira Lanari (Dipartimento di modellistica per l’ingegneria, University of Calabria, Italy), “Implicit Corotational Method: FEM implementation”, ECSM 2009, Lisbon, Portugal

ABSTRACT: The Implicit Corotational Method (ICM) is a powerful and consolidated approach for recovering objective and suitable for FEM implementation nonlinear models fully reusing the corresponding linear ones [1, 2]. An appropriate stress/strain (Biot) representation for the description of the nonlinear elastic continuum, the use of corotational algebra for splitting the body motion into rigid and deformative parts and some assumptions on the reinterpretation of linear theory in the nonlinear context, constitute the basis of the ICM. An important feature of the method is the possibility of obtaining a tool that allow an easy FEM implementation. Different kinds of interpolation strategies (Total and Updated Lagrangian, Corotational) are used within the approach. A standard format and an automated way of implementing the nonlinear models into the FEM context based on the use of algebraic manipulator and aimed at path-following or asymptotic analyses have been developed [3]. The FEM implementation is provided for 3D beam and plate models recovered using ICM. For the 3D beam model, based on Saint Venant theory [2], the assumptions about the rotation parameters and the details on handling finite rotations are given clearly. The accuracy of some mixed finite elements that differ for the interpolation laws assumed for the kinematics and statics fields and for the interpolations strategy is pointed out. For the thin plate model, based on Kirchoff hypothesis [1], the proposed finite element is implemented as specialized one in asymptotic FEM code (see [7]). A numerical investigation has been performed, also comparing beam and plate based solutions in the case of thin–walled beams. The good agreement between the recovered results with the theoretical ones and the numerical benchmarks, shows clearly the correctness and capability of the proposed approach for numerical implementations.

“Finite rotation shell elements for nonlinear statics and dynamics”, European Congress on Computational Methods in Applied Sciences and Engineering (ECCOMAS 2000), Barcelona, 11-14 September, 2000

ABSTRACT: In this work we consider geometrically exact shell model subjected to finite rotations. We present some developments on handling constrained finite rotations that are of direct use in nonlinear static and dynamic finite element analysis of smooth shells. Relationships between different preferred parametrizations of constrained finite rotations are first given in a form of commutative diagrams. Incremental rotation vector for smooth shells is presented as the most suitable parameter for the standard incremental solution strategy as well as for the construction of the time-stepping schemes. An appropriate consideration is given to construct the corresponding Newmark implicit time stepping schemes for constrained rotations.

ABSTRACT: A simple non-linear stress resultant shell finite element is presented. The underlying shell theory is developed from the three-dimensional continuum theory via standard assumptions on the displacement field. A model for thin shells is obtained by approximating terms describing the shell kinematics is consistently linearized, leading to the Newton-Raphson numerical procedure, which preserves quadratic rate of asymptotic convergence. A range of linear and non-linear tests is provided and compared with available solutions to illustrate the approach.

ABSTRACT: This paper suggests a strategy for the imperfection sensitivity analysis of elastic thin-walled structures with notable residual stresses. The analysis is carried out by means of a Koiter's perturbation approach. The concept of imperfection, traditionally associated with geometric and load factors, is extended in this paper to the residual stresses. The strategy is implemented in a FEM code. A comparison of the obtained results allows a discussion on the accuracy and the influence of the different coefficients connected to the asymptotic analysis of the residual stresses.

ABSTRACT: This paper provides a review of recent research advances and trends in the area of stability of unstiffened circular cylindrical shells subjected to general non-uniform axial compressive stresses. Only the more important and interesting aspects of the research, judged from a personal viewpoint, are discussed. They can be crudely classified into four categories: (1) shells subjected to non-uniform loads; (2) shells on discrete supports; (3) shells with intended cutouts/holes; and (4) shells with non-uniform settlements.

cutouts/holes; and (4) shells with non-uniform settlements.

ABSTRACT: This paper presents a finite element study of the non-linear buckling behaviour of column-supported steel cylinders. Both perfect and imperfect shells are examined. High compressive stresses develop in the vicinity of the column support and these can lead to buckling of the shell at a load much lower than that for a uniformly supported shell. Imperfections are shown to play an important role in reducing the buckling load even when the structure is supported on a small number of columns.

ABSTRACT: The static buckling of a cylindrical shell of a four-lobed cross section of variable thickness subjected to non-uniform circumferentially compressive loads is investigated based on the thin-shell theory. Modal displacements of the shell can be described by trigonometric functions, and Fourier's approach is used to separate the variables. The governing equations of the shell are reduced to eight first-order differential equations with variable coefficients in the circumferential coordinate, and by using the transfer matrix of the shell, these equations can be written in a matrix differential equation. The transfer matrix is derived from the nonlinear differential equations of the cylindrical shells by introducing the trigonometric series in the longitudinal direction and applying a numerical integration in the circumferential direction. The transfer matrix approach is used to get the critical buckling loads and the buckling deformations for symmetrical and antisymmetrical shells. Computed results indicate the sensitivity of the critical loads and corresponding buckling modes to the thickness variation of cross section and the radius variation at lobed corners of the shell.

ABSTRACT: The objective of this paper is to study the elastic buckling characteristics of an axially loaded cylindrical shell of a three lobed cross section of variable thickness subjected to combined compression and bending loads based on the thin-shell theory and using the computational transfer matrix method. Modal displacements of the shell can be described by trigonometric functions and Fourier’s approach is used to separate the variables. The governing equations of the shell are reduced to eight first-order differential equations with variable coefficients in the circumferential coordinate, and by using the transfer matrix of the shell, these equations can be written in a matrix differential equation. The transfer matrix is derived from the non-linear differential equations of the cylindrical shells by introducing the trigonometric function in the longitudinal direction and applying a numerical integration in the circumferential direction. The computational transfer matrix method is used to get the critical buckling loads and the buckling deformations for symmetrical and antisymmetrical buckling-modes. Computed results indicate the sensitivity of the critical loads and corresponding buckling modes to the thickness variation of cross-section and the radius variation at lobed corners of the shell.

ABSTRACT: This paper presents the transfer matrix analysis of nonlinear dynamic response of stiffened thin shells in resonance regions of vibration. Considered is the interaction of geometric and physical nonlinearities. Direct time integration procedures to solve the equations of motion are used. Corresponding incremental transfer matrices are formulated in an updated Lagrangian reference mesh. Illustrative numerical example is presented, showing the influence of studied nonlinear interactions in resulting dynamic response of thin shells.

ABSTRACT: The present paper is concerned with the nonlinear finite solution of the postbuckling instability behaviour of thin shell structures in resonance regions of vibration. The development of reliable and efficient techniques for handling the dynamic postbuckling behaviour is emphasized. An illustrative solution associated with the postbuckling resonance response of thin shells is presented.

ABSTRACT: Some research results of failure behaviour of carbon fiber composites are presented. The solution of material instability on the basis of fiber kinking theory is adopted for the treatment of the failure process. The micromechanical modeling adopting the FETM-approach is used for a numerical analysis of the problem. Some numerical and experimental results with an actual application are submitted in order to demonstrate the efficiency of the approaches suggested.

ABSTRACT: In this paper, the Flügge's shell theory is modeled and the transfer matrix approach is used to investigate the elastic buckling behaviour of a cylindrical shell with a four lobed cross section with reduced thickness over part of its circumference under axial compressive loads. Modal displacements of the shell can be described by trigonometric functions and Fourier's approach is used to separate the variables. The buckling equations of the shell are reduced to eight first-order differential equations in the circumferential coordinate, and by using the transfer matrix of the shell, these equations can be written in a matrix differential equation. The transfer matrix is derived from the differential equations of the cylindrical shells by introducing the trigonometric functions in the longitudinal direction and applying a numerical integration in the circumferential direction. The method is used to get the critical buckling loads and the buckling deformations for symmetrical and antisymmetrical shells. Computed results indicate the sensitivity of the buckling loads and the corresponding buckling deformations to the geometry of the non-uniformity of the shell, and also to the radius of curvature at the lobed corners.

ABSTRACT: On the basis of the thin-shell theory and on the use of the transfer matrix approach, this paper presents the vibrational response and buckling analysis of three-lobed cross-section cylindrical shells, with circumferentially varying thickness, subjected to uniform axial membrane loads. A Fourier approach is used to separate the variables, and the governing equations of the shell are formulated in terms of eight first-order differential equations in the circumferential coordinate, and by using the transfer matrix of the shell, these equations are written in a matrix differential equation. The transfer matrix is derived from the non-linear differential equations of the cylindrical shells with variable thickness by introducing the trigonometric series in the longitudinal direction and applying a numerical integration in the circumferential direction. The natural frequencies and critical loads beside the mode shapes are calculated numerically in terms of the transfer matrix elements for the symmetrical and antisymmetrical vibration modes. The influences of the thickness variation of crosssection and radius variation at lobed corners of the shell on the natural frequencies, mode shapes and critical loads are examined.

“Computational buckling of a three-lobed cross section cylindrical shell with variable thickness under combined compression and bending loads”, International Journal of Mechanical Engineering Research and Development (IJMERD), Vol. 3, No. 1, pp. 11-27, January-March 2013, ISSN 2248-9347(print), ISSN 2248-9355(Online)

ABSTRACT: The objective of this paper is to study the elastic buckling characteristics of an axially loaded cylindrical shell of a three-lobed cross section of variable thickness subjected to combined compression and bending loads based on the thin-shell theory and using the computational transfer matrix method. Modal displacements of the shell can be described by trigonometric functions and Fourier’s approach is used to separate the variables. The governing equations of the shell are reduced to eight first-order differential equations with variable coefficients in the circumferential coordinate, and by using the transfer matrix of the shell. These equations can be written in a matrix differential equation. The transfer matrix is derived from the non-linear differential equations of the cylindrical shells by introducing the trigonometric function in the longitudinal direction and applying a numerical integration in the circumferential direction. The computational transfer matrix method is used to get the critical buckling loads and the corresponding buckling deformations for symmetrical and antisymmetrical buckling modes. Computed results indicate the sensitivity of the critical loads and corresponding buckling modes to the thickness variation of cross-section and the radius variation at lobed corners of the shell.

ABSTRACT: In this paper, the framework of the Flügge's shell theory, the transfer matrix approach and the Romberg integration method has been employed to investigate the buckling analysis of radial loaded oval cylindrical shell with parabolically varying thickness along of its circumference. Trigonometric functions are used to form the modal displacements of the shell and Fourier's approach is used to separate the variables. The mathematical analysis is formulated to overcome the difficulties related to mode coupling of variable curvature and thickness of the shell. Using the transfer matrix of the shell, the buckling equations of the shell are reduced to eight first-order differential equations in the circumferential coordinate and rewritten in a matrix form and solved numerically. The proposed model is adopted to get the critical buckling loads and the corresponding buckling deformations for the symmetrical and antisymmetrical modes of buckling. The influences of the shell geometry, orthotropic parameters, ovality parameter, and thickness ratio on the buckling parameters and the bending deformations are presented for different type-modes of buckling.

ABSTRACT: For the first time, a new cross-section profile and efficient method are developed for the vibration analysis of isotropic and orthotropic cylindrical shells having circumferentially varying profile of a cardioid cross-section expressed as an arbitrary function, under thermal gradient effect. The governing equations of orthotropic cylindrical shells with varying thermal gradient around its circumference are derived as a boundary-value problem and solved numerically as an initial-value problem, based on the framework of Flügge's shell theory, transfer matrix approach and Romberg integration method. As a semi-analytical procedure, the trigonometric functions are used with Fourier's approach to approximate the solution in the longitudinal
direction and also to reduce the two-dimensional problem to one-dimensional one. The thermal gradient is assumed to arise due to the variation of Young's moduli and shear modulus, along the circumferential direction of the shell. The results are obtained to indicate the effects of cardioid cross-section on the natural frequencies and corresponding mode shapes in the thermal environment as well as the sensitivity of the vibration behavior to the thermal gradient ratio and the orthotropy of the shell is also investigated for different types of vibration modes. In general, close agreement between the obtained results and those of other researchers has been found.

Mousa Khalifa Ahmed (Dept. of Mathematics, Faculty of science at Qena, South Valley University, Egypt), “How the thermal gradient affects the vibration behavior of a spinning orthotropic oval cylindrical shell”, International Journal of Applied Mechanics, Vol. 7, No. 4, August 2015

ABSTRACT: Based on the framework of Flügge's shell theory, transfer matrix approach and Romberg integration method, we investigated how the thermal gradient affects the vibration behavior of rotating isotropic and orthotropic oval cylindrical shells. The governing equations of orthotropic oval cylindrical shells, under parabolically varying thermal gradient around its circumference, with consideration of the effects of initial hoop tension and centrifugal forces due to the rotation are derived, and they are put in a matrix differential equation as a boundary-value problem. As a semianalytic solution, the trigonometric functions are used with Fourier's approach to approximate the solution in the longitudinal direction, and also to reduce the two-dimensional problem in to an one-dimensional one. Using the transfer matrix approach, the equations can be written in a matrix differential equation of first-order and solved numerically as an initial-value problem. The proposed model is applied to get the natural frequencies and vibratory displacement of the symmetrical and antisymmetrical vibration modes. The sensitivity of the vibration behavior to the rotational speed, the thermal gradient, the ovality and orthotropy of the shell is studied for different type-modes of vibration. The present method is found to be accurate when compared with the results available in the literature.

ABSTRACT:
Recently, nano devices have been developed which use Carbon Nanotubes (CNTs) as structural elements. To define the range of applicability of CNTs in such devices, it is important to investigate failure modes such as the axial buckling limit. Classical continuum models are inaccurate as they are unable to account for the size-effects in such devices. In this work, a modified nonlocal continuum shell model for the axial buckling of CNTs is proposed and compared with a nonlocal model for torsional buckling. This is done through modifying classical continuum models by incorporating basic concepts from nonlocal elasticity. Furthermore, molecular dynamics (MD) simulations are performed on a range of nanotubes with different diameters. Compared to classical models, the modified nonlocal models provide a much better fit to MD simulation results. Using MD simulation results for axial buckling, values of the nonlocal constant and shell thickness are calculated.

ABSTRACT: The development of a new approach based on the energy principle is presented to study the free vibration of shallow conical shells. In the numerical procedure, a set of orthogonally generated and kinematically oriented shape functions, which satisfies the geometric boundary conditions at the outset, is proposed to overcome the mathematical complexity in expressing the geometry and variable surface curvature of these shells. To establish the accuracy of this method, convergence and comparison studies have been carried out. In this study, the effects of various shell parameters on the fundamental and higher mode frequencies are investigated. It is found that monotonic increases in the fundamental nondimensional frequency parameter occurs when the cone vertex angle or base subtended angle is increased independently for the cantilever conical shell. The fundamental frequency parameter also becomes higher for the fully clamped conical shell with higher panel-length to cone-length (a/s) ratio. A set of first published vibration mode shapes is also presented.

ABSTRACT: A mesh-free radial basis function (RBF) method is employed for the buckling analysis of non-uniformly loaded thick plates. The field variables are approximated using a set of scattered nodes in the problem domain. The number of nodes and nodal distribution in the problem domain can be easily changed without a complex procedure for desired computational accuracy. The shape functions possess the ‘partition of unity’ properties. Based on the two-dimensional (2D) plane stress problem, a variational form of the static system of equations is formulated in terms of displacements, and is discretised. The initial (i.e., pre-buckling) stresses are obtained by solving the discrete system of equations. Based on the first-order shear deformation plate theory, a variational form of the plate problem with previously obtained initial stresses is established and discretised as the eigenvalue equation. The buckling loads of circular, trapezoidal and skew plates are presented. The present results have good convergence and are in good agreement with the finite element solutions. The present mesh-free radial basis function method is effective for the buckling analysis of non-uniformly loaded plates.

ABSTRACT: Buckling behavior of single-walled and multiwalled carbon nanotubes is studied under axial compression in this work. Brenner’s “second generation” empirical potential is used to describe the many-body
short-range interatomic interactions for single-walled carbon nanotubes, while the Lennard Jones model for the van der Waals potential is added for multiwalled carbon nanotubes. Single-, two-, three-, and four-walled nanotubes are considered in the simulations in order to examine the effects of the number of layers on the structural properties of the multiwalled nanotubes. Results indicate that there exists an optimum diameter for single-walled nanotubes at which the buckling load reaches its maximum value. The buckling load increases rapidly with the increase of the diameter up to the optimum diameter. A further increment beyond this diameter results in a slow decline in buckling load until a steady value is reached. The effects of layers on the buckling load of multiwalled nanotubes are also examined.

ABSTRACT: This paper presents thermal buckling and post-buckling analyses for moderately thick laminated rectangular plates that contain functionally graded materials (FGMs) and subjected to a uniform temperature change. The theoretical formulation employs the first-order shear deformation theory and accounts for the effect of temperature-dependent thermoelastic properties of the constituent materials and initial geometric imperfection. The principle of minimum total potential energy, the differential quadrature method, and iterative algorithms are used to obtain critical buckling temperatures and the post-buckling temperature-deflection curves. The results are presented for both symmetrically and unsymmetrically laminated plates with ceramic/metal functionally graded layers, showing the effects of temperature-dependent properties, layup scheme, material composition, initial imperfection, geometric parameters, and boundary conditions on buckling temperature and thermal post-buckling behavior.

ABSTRACT: The material properties of functionally graded materials (FGMs) possess inherent randomness due to their complicated fabrication process, in which the total control of various design parameters is often impossible. The present work investigates the effect of this randomness on the elastic buckling of FGM rectangular plates which are resting on an elastic foundation and subjected to uniform in-plane edge compressions. The interaction between the plate and foundation is included in the formulation with a two-parameter Pasternak model. The elastic material properties (including the Young’s modulus and Poisson’s ratio of each constituent material) and the foundation stiffness parameters are modeled as independent random variables. First-order shear deformation plate theory and a mean-centered first-order perturbation procedure are
used to examine the stochastic characteristics of the buckling load. Typical results are presented for plates with aluminum/zirconia two-phase functionally graded material to show the influence of variation in material constants and foundation stiffness parameters, volume fraction index, edge in-plane forces, side-to-thickness ratio, and plate aspect ratio on the second-order statistics of buckling loads.

“Thermo-mechanical post-buckling of FGM cylindrical panels with temperature-dependent properties”

ABSTRACT: This paper presents thermo-mechanical post-buckling analysis of cylindrical panels that are made of functionally graded materials (FGMs) with temperature-dependent thermo-elastic properties that are graded in the direction of thickness according to a simple power law distribution in terms of the volume fractions of the constituents. The panel is initially stressed by an axial load, and is then subjected to a uniform temperature change. The theoretical formulations are based on the classical shell theory with von-Kármán–Donnell-type nonlinearity. The effect of initial geometric imperfection is also included. A differential quadrature (DQ) based semi-analytical method combined with an iteration process is employed to predict the critical buckling load (where it is applicable) and to trace the post-buckling equilibrium path of FGM cylindrical panels under thermo-mechanical loading. Numerical results are presented for panels with silicon nitride and nickel as the ceramic and metal constituents. The effects of temperature-dependent properties, volume fraction index, axial load, initial imperfection, panel geometry and boundary conditions on the thermo-mechanical post-buckling behavior are evaluated in detail through parametric studies.

ABSTRACT: This paper presents a mesh-free Galerkin method for the free vibration and stability analyses of stiffened plates via the first-order shear deformable theory (FSDT). The model of a stiffened plate is formed by (1) regarding the plate and the stiffener separately, (2) imposing displacement compatible conditions between the plate and the stiffener so that displacement fields of the stiffener can be expressed in terms of the mid-surface displacement of the plate, and (3) superimposing the strain energy of plate and stiffener. Because there are no meshes used in this method, the stiffeners can be placed anywhere on the plate and need not be placed along the mesh lines. Several numerical examples are computed by this method to show its accuracy and convergence. The present results demonstrate good agreement with the existing solutions given by other researchers and the ANSYS. Influences of support size and order of the complete basis functions on the numerical accuracy are also investigated.

ABSTRACT: A Ritz method based on kernel particle approximation for the field variables is proposed for the postbuckling analysis of laminated composite plates. The first-order shear deformation plate theory (FSDT) is employed to model the plate flexure. The Ritz method is used to obtain the discretized non-linear equations. A geometrically non-linear analysis is used to trace the postbuckling paths of the plate. Typical numerical examples including isotropic plates, and cross-ply and angle-ply laminated composite plates have been solved using the proposed method. The results are in close agreement with the series solution as well as previous finite element results available in the literature.

“Geometrically nonlinear analysis of cylindrical shells using the element-free kp-Ritz method”, Engineering Analysis with Boundary Elements, Vol. 31, No. 9, September 2007, pp. 783–792,
doi:10.1016/j.enganabound.2007.01.003

ABSTRACT: In this paper, the geometrically nonlinear analysis of cylindrical shells is carried out using the element-free kp-Ritz method. The first-order shear deformation shell theory, which can cater for both thin and relatively thick shells, is utilized in the present study. Meshfree kernel particle functions are employed to
approximate the two-dimensional displacement field. The nonlinear equilibrium equations are formulated by applying the Ritz procedure to the energy functional of shells. The Newton–Raphson method and the arc length technique are used to determine the load–displacement path. To validate the accuracy and stability of this method, convergence studies based on the support size and number of nodes were performed. Comparisons were also made with the existing results available in the open literature, and good agreement is obtained.

ABSTRACT: The bending buckling of single-walled carbon nanotubes (SWCNTs) is studied in the theoretical scheme of the higher order gradient continuum. The deformation of the underlying lattice vectors is approximated with an extended Cauchy–Born rule in which the effect of the second order deformation gradient is considered, and the continuum constitutive responses are determined by minimizing the energy of the representative cell. A mesh-free method is developed to implement the numerical modeling of SWCNTs, and their bending buckling behavior is numerically simulated with the developed method. The results are compared with those obtained with a full atomistic simulation, and it is revealed that the developed mesh-free method can accurately exhibit the bending deformation of SWCNTs. Different types of carbon nanotubes (CNTs) are studied, and the buckling mechanism is investigated.

ABSTRACT: This paper employs the atomic-scale finite element method to study bending buckling of single-walled carbon nanotubes (SWNTs). As the bending angle increases, kinks will appear and the morphology of the SWNT will change abruptly. The (15, 0) SWNT changes into a one-kinked structure, and finally contains two kinks; while the (10, 0) SWNT changes into a one-kinked structure, then into a two-kinked one, and finally contains three kinks. Strain energy grows initially as a quadratic function of bending angle, then increases gradually slowly, and finally changes approximately linearly. The energy releases suddenly at morphology bifurcations and the amount depends on degree of morphology change. The simulation shows that the appearance of kinks associated with the large deformation nearby reduces the slope of the strain energy curve in the post-buckling stages and hence increases the flexibility of the SWNTs.

ABSTRACT: In this paper, the linearly conforming radial point interpolation method is extended for geometric nonlinear analysis of plates and cylindrical shells. The Sander’s nonlinear shell theory is utilized and the arc-length technique is implemented in conjunction with the modified Newton–Raphson method to solve the nonlinear equilibrium equations. The radial and polynomial basis functions are employed to construct the shape functions with Delta function property using a set of arbitrarily distributed nodes in local support domains. Besides the conventional nodal integration, a stabilized conforming nodal integration is applied to restore the deformability and to improve the accuracy of solutions. Small rotations and deformations, as well as finite strains, are assumed for the present formulation. Comparisons of present solutions are made with the results reported in the literature and good agreements are obtained. The numerical examples have demonstrated that the present approach, combined with arc-length method, is quite effective in tracing the load-deflection paths of snap-through and snap-back phenomena in shell problems.

ABSTRACT: The buckling response of functionally graded ceramic-metal cylindrical shell panels under axial compression and thermal load is presented here. The formulation is based on the first-order shear deformation shell theory and element-free kp-Ritz method. The material properties of shell panels are assumed to vary through their thickness direction according to a power-law distribution of the volume fraction of constituents. Approximations of the displacement field are expressed in terms of a set of mesh-free kernel particle functions. A stabilized conforming nodal integration approach is employed to estimate the bending stiffness, and the shear and membrane terms are evaluated using a direct nodal integration technique to eliminate membrane and shear locking for very thin shells. The mechanical and thermal buckling responses of functionally graded shell panels are investigated, and the influences of the volume fraction exponent, boundary conditions, and temperature distribution on their buckling strengths are also examined.

References listed at the end of the paper:

ABSTRACT: This paper presents a mechanical and thermal buckling analysis of metal and ceramic functionally graded conical shell panels using the element-free kp-Ritz method. The formulation is based on the first-order shear deformation shell theory, which accounts for the transverse shear strains and rotary inertia, and mesh-free kernel particle functions are employed to approximate the two-dimensional displacement fields. The effective material properties of the functionally graded conical shell panels are assumed to be smooth and continuous through their thickness direction, and are determined according to a power-law distribution of the volume fractions of their constituents. Convergence studies are performed in terms of the number of nodes, and comparisons between the current solutions and those reported in the literature are provided to verify the accuracy of the proposed method. Three types of functionally graded conical shell panels, Al/ZrO2, SUS304/Si3N4, and Al2O3/Ti6Al4V are selected for study, and the effects of the volume fraction, boundary condition, semi-vertex angle, length-to-thickness ratio, and temperature-dependent material properties on the buckling strength are discussed in detail.
ABSTRACT: Stability problems for cylindrical shells under various loading modes were considered in numerous papers. A detailed analysis of such problems can be found, e.g., in the monograph [1]. We refer to the solutions presented in this monograph as classical. For long cylindrical shells in axial compression, one of the buckling modes is the purely beam flexural mode similar to the classical buckling mode of a straight rod. It is well known that it can be studied by using the nonlinear or linearized equations of the membrane theory of shells. In [2], it was shown that, on the basis of such equations constructed starting from the noncontradictory version of geometrically nonlinear elasticity relations in the quadratic approximation [3], under the separate action of the axial compression, external pressure, and torsion, there are also previously unknown nonclassical buckling modes, most of which are shear ones.

In the present paper, we show that the use of the above equations for cylindrical shells under compression and external pressure with simultaneous pure torsion or bending permits revealing the earlier unknown torsional, beam flexural, and beam torsional-flexural buckling modes, which are nonclassical, just as those found in [2]. The second of these buckling modes is realized when axially compressing forces are formed in the shell with simultaneous torsion, and the third of them is realized under compression combined with pure bending. It was found that, earlier than the classical buckling modes, the torsional buckling modes can be realized for relatively short shells with small shear rigidity in the tangent plane, while the second and third buckling modes can be realized for relatively long shells.

ABSTRACT: (cannot cut and paste)

K. T. Hautala Consulting KORTES Ltd., Finland, 2003 The Steel Construction Institute, “Buckling Reduction Factors for Stainless Steel Shell Structures”

ABSTRACT: The material behaviour of stainless steel strongly differs from that of mild steel beyond the proportional limit. Consequently, the buckling behaviour of mild steel structures and stainless steel structures will differ from each other in so far as for any given stainless steel structure of medium slenderness, i.e. belonging to the ‘elastic-plastic’ region, the buckling capacity is lower than for a comparable mild steel structure of identical shape and area. This paper shows numerical buckling reduction factors for stainless steel shell structures. Firstly some buckling strength curves of European standards are numerically reproduced using simple substitute imperfections. Proposals are then made for modification of standards in order to include stainless steels. Preliminary new proposals are made for modelling of material behaviour of stainless steels and buckling design of shell structures under meridional compression.

ABSTRACT: In the construction of chimneys and tubular masts adjacent cylindrical shells often have to be built with different radii according to the global bending moment or operational requirements. With a steep conical shell in between a cylinder-cone-cylinder intersection is built. This paper reports on a numerical study on the buckling stability of these structures. Unstiffened and ring-stiffened structures are considered, where the rings are attached to the edges of the cone or set off into the adjacent cylindrical shells. It is shown that the critical load of the entire structure remains under the critical load of a straight cylinder, even if heavy stiffeners are used and local buckling is relevant.

ABSTRACT: The assessment of imperfections is most important for determining the load-bearing capacity of a thin-walled shell structure. Different ways of modelling imperfections are discussed in this paper and steel silo shells are used as an application. Buckling tests were performed on different types of model shell - standard quality and high quality with reduced heat input during welding. For the numerical studies two different approaches were used as well: an axisymmetric approach with substitute geometric imperfections and an FEM approach, where the nodal coordinates were derived from surveying the specimen. It was found that there is considerable gain in the buckling strength due to the presence of the granular solid. The larger the initial imperfections in the shell the greater the gain in strength compared to the empty cylinder. The modelling of the unevenness of the edges with uneven dead loading is also discussed.

ABSTRACT: The stress distribution in thinwalled shell structures with concentrated edge loads was investigated by means of FEA. Using the concept of effective width an 'angle of load spread' can be defined under which the load spreads from the loaded edge into the shell. Due to the usual constraints along the bottom, there is a non-critical zone along the edge, where no buckles will develop. If the stress peak remains limited to a small non-critical strip above the support it cannot trigger buckling and can be excluded from further considerations as well. Using this information the critical locus can be determined where the first buckle will form. The format of the stability check is according to German Standard DIN 18800 part 4. Because the effects of the concentrated edge loads are followed explicitly in the model, the empirical knock-down factor does not need to account for uneven edge load distribution. Therefore it is suggested, to increase K2 by a factor of 1.67. For plastic buckling special advice is given.

ABSTRACT: This paper reports on wind loaded shell structures. The description of the wind pressure distribution around the shell circumference is discussed. Five different structural models to determine the relevant axial membrane stresses of wind loaded shells are presented. An example is presented for which the axial membrane stress distributions are calculated according to the given models. The results are compared and discussed.

ABSTRACT: Thin walled short cantilever cylinders, such as supply-air-chimneys, silos or tanks, develop a shell-type distribution of membrane forces when subjected to natural wind. A structural analysis by hand involves a Fourier decomposition of the circumferential wind pressure distribution and a separate calculation for each harmonic, using an appropriate shell theory. With this classical method simple boundary conditions at the bottom edge of the shell, such as ‘pinned’ or ‘clamped’, can be modelled only. The use of a finite element code – if available – gives possibility to account for more realistic conditions at the bottom of the structure, such as
elastic flanges and anchors or unilateral contact. In designing silos, tanks or chimneys however, as often encountered by the authors, structural engineers use beam theory to determine stress resultants and anchor forces, may this be due to lack of time or due to ignorance. Those who determine ‘real’ anchor forces obtain dimensions, which they feel to be inadequate and which are so much in excess of beam-theory-anchors that there should be much more failures with ‘beam-designed-anchors’. In the present paper some evidence on this apparent contradiction is given and a practical design approach is suggested.

ABSTRACT: Commercial FEA packages became increasingly wide spread in design offices. Being general purpose software, these packages may easily be used to model a tank or a silo by an engineer, who might not be sufficiently experienced to do proper strength and stability checks by hand. Thus, the authors see very often FEA-based design, which does not meet the state of the art. This was the motivation for the present article. Based on the needs of practical design of a steel or aluminium tank or silo, rules are given for the application of the finite element method. These include general considerations about deriving a structural model. As well, hints are given as to when a hand calculation (DBF = design by formulae) could be less time consuming than a FEA. For practical application of FEA, issues are covered like modelling and meshing of the global structure, modelling of imperfections, material properties, welds and loads. The specific needs of documentation for shell structures is discussed, i. e. splitting the obtained stresses in membrane and bending and in meridional and circumferential parts. Finally, three examples of industrial applications are described shortly.

ABSTRACT: Open cylindrical steel tanks for the storage of liquids tend to be rather thin-walled because they are primarily designed for the circumferential tensile stresses from hydrostatic internal pressure. It is desirable to take advantage of the postbuckling strength of the thin cylindrical wall when designing the empty tank against wind load. The theoretical external pressure carrying behaviour of edge-stiffened thin-walled cantilever shells is discussed with regard to both bifurcation and postbuckling phenomena. For experimental verification, a series of postbuckling tests on cylindrical PVC and steel specimens with large radius/thickness ratio (r/t=2500) under internal underpressure and under a “wind-like” load arrangement has been carried out. Based on the numerical and experimental results, recommendations are put forward for an economic postbuckling strength design strategy. They are compared with existing design rules in tank codes.

ABSTRACT: The state-of-the-art of available knowledge about the stability design of steel shell structures is discussed. Specific stress is put on the various approaches to a numerically based stability design. The European Prestandard ENV 1993-1-6 (the “Shell Eurocode”) is briefly described.

ABSTRACT: Tubular structural components are used in a large variety of civil engineering structures, e.g. for off-shore platforms, chimneys, pipelines, bridge arches or wind turbine towers. They are often subjected to combined loading inducing membrane compressive stress states which – in case they are not thick-walled – implies the danger of loss of local structural stability (shell buckling). However, existing design codes show significant shortcomings for interactive shell buckling. Therefore, a comprehensive experimental and numerical study on cylindrical shells has been performed which leads to an improved design proposal for interactive buckling under combined loading.

ABSTRACT: Circular cylindrical shells made of steel are used in a large variety of civil engineering structures, e.g. in off-shore platforms, chimneys, silos, tanks, pipelines, bridge arches or wind turbine towers. They are often subjected to combined loading inducing membrane compressive and/or shear stress states which endanger the local structural stability (shell buckling). A comprehensive experimental and numerical investigation of cylindrical shells under combined loading has been performed which yielded a deeper insight into the real buckling behaviour under combined loading. Beyond that, it provided rules how to simulate numerically the realistic buckling behaviour by means of substitute geometric imperfections. A comparison with existing design codes for interactive shell buckling reveals significant shortcomings. A proposal for improved design rules is put forward.

H. Schmidt and Th. A. Winterstetter, “Cylindrical shells under combined loading: Axial compression, external
PARTIAL INTRODUCTION: Circular cylindrical shells made of steel are used in a variety of engineering structures, for example, tanks, chimneys, offshore platforms, pipelines, silos or wind turbine towers. The design against tensile hoop stresses (containments) or against tubular bending stresses (tower-type structures) often results in very thin shell walls which implies the danger of failure by instability due to compressive and/or shear forces (shell buckling). The behavior of cylindrical shells under each of the fundamental loads of axial compression, external pressure and pure torsion…. is well understood. However, in almost all cases the actions on the structure do not induce such a simple fundamental membrane stress state, but a combination of them, including membrane stress variations in axial and circumferential direction and stress peaks at different locations….

ABSTRACT: A subsea pipeline laid onto a flat seabed will buckle laterally from a combination of pressure and temperature due to the pipeline’s ‘out-of-straightness’. The pipeline will tend to buckle laterally due to horizontal imperfections associated with the pipeline laying process, and the horizontal frictional restraint force is less than the pipeline submerged weight. The lateral buckling may take place as a dynamic ‘snap’ if the out-of-straightness, or imperfection, in the pipeline length is small. The pipeline ‘snap’ will result in dynamic motion. Seabed soil friction factors, in both axial and lateral directions, are also parameters which govern the lateral buckling, beside the size of the initial out-of-straightness. All of these parameters will influence the lateral buckling, and under which conditions dynamic buckling behaviour can occur. This paper investigates the influence of these different parameters and their effect on the onset of dynamic buckling.

ABSTRACT: A study on the free vibration and linear buckling analyses of thick plates is described in this article. In order to determine the natural frequencies and buckling loads of plates, a plate element is developed by using isogeometric approach. The Non-uniform B-spline surface (NURBS) is used to represent both plate geometry and the unknown displacement field of plate. All terms required in isogeometric formulation are consistently derived by NURBS definition. The capability of the present plate element is demonstrated by using several numerical examples. From numerical results, it is found to be that the present isogeometric element can predict accurate natural frequencies and buckling loads of plates.

ABSTRACT: In standard stability investigations of structures applying the finite element method usually the bifurcation and snap-through points – so-called stability points – are detected. However, for practical design purposes not only the stable state of equilibrium itself is significant but also the robustness of the state against finite perturbations in contrast to infinitesimal perturbations. The sensitivity measure, which quantifies this robustness, can be investigated by introducing perturbations at certain load levels and considering the perturbed motion. Some sensitivity studies are performed for simple stability problems as well as for realistic structures (cylindrical shells) under different loading conditions. Further scalar parameters based on Liapunov Characteristic Exponents are developed to allow a better judgment of the motion after introducing perturbations and a more efficient analysis of the complex response (see Ewert/Schweizerhof[7]).

ABSTRACT: In standard stability investigations of structures applying the finite element method usually bifurcation and snap-through loads – so-called singular or stability points – are detected, see e.g. [4],[6],[7]. It is well-known that for complex structures like cylindrical shells these loads depend strongly on the geometrical and other imperfections, see [8],[9],[10]. It has been shown in [1] that the singular points and the corresponding modes vary significantly for small deviations of the approximated geometry using different ansatz-functions. Furthermore investigations in [1] have shown that the converging behavior for imperfect structures is non-monotone. Particular limitations exist for the stability analysis of shell structures which involve contact between parts or with surrounding objects. In the end it could be followed that stability points and the corresponding loading determined numerically by static stability analysis are often of limited use for design purposes. In contrast to the loading obtained for singular points the so-called post-buckling loads, which are the stable equilibrium states in the post-buckling region, are rather independent of geometrical imperfections and of approximation order, see [1]. Therefore it is advantageous to use post-buckling loads for design purposes instead of loads obtained for singular points. Since the applicability of static analyses in the computation of post-buckling paths like proposed e.g. in [5] is rather limited, it is favorable to model the complete loading and deformation behavior by a time dependent process, see [3], [2], [11], [12]. The major advantage of a purely transient analysis is the complete simulation of the buckling process as it happens in reality. This is possible with moderate numerical effort, since the matrices used in the solution are usually better conditioned compared to pure static analysis. In addition, this allows to take the changing boundary conditions as found in contact situations properly into account. For practical design purposes not only the equilibrium state itself is significant but also the ”robustness” of such states against finite perturbations in contrast to infinitesimal perturbations. In the case of systems with many equilibrium states at a defined load level finite perturbations can transfer the mechanical system from a stable equilibrium state to another equilibrium state or in some cases even to an unbounded motion initiating buckling. Then a sensitivity measure can be defined as the reciprocal value of the minimum perturbation energy, necessary for this transfer S = 1/Wper,min, see [2]. In the present paper stability and sensitivity studies are performed for simple stability problems (beams) and finally for rather general shell structures involving geometrical imperfections and in particular contact.

ABSTRACT: The nonlinear response of an aircraft panel due to acoustic and thermal loading is computationally expensive using traditional finite element methods. This has lead to the use of several reduced-order modal model development methods for such systems. In this paper, we first provide a historical review of the nonlinear phenomenon associated with the post-buckling response due to thermal-acoustic loading with specific emphasis on snap-through response. Next, a parametric space investigation is presented to study the effect of thermal gradient and/or preload on the post-buckling dynamic behavior of a clamped-clamped beam system. This paper studies a single mode approximation of the clamped-clamped beam. These reduced order models are based on the implicit condensation method. First the parametric space investigation is conducted to identify the stability of the periodic solutions for both models. The effect of harmonic excitation is presented in terms of the bifurcation diagram with specific focus on the effect of initial pre-load parameter. Finally, some conclusions about the response to multi-frequency excitation are presented in terms of the numerical bifurcation diagrams.

ABSTRACT: Linear stability of the cylindrical shell with the strong cover filled by the soft core is investigated. Such structures are usually elements of the vehicle bumpers. They are used for dissipating the crash energy. The analysis is focused on finding the most waved buckling form due to the parameters of the structure. An analytical approach is employed in this investigation instead of a numerical one. The standard Lagrangian energy algorithm is expressed in Mathematica formalism.

ABSTRACT: The present paper discusses a method to estimate the elasto-plastic buckling loads of two-way
grid shells. The method first applies the concept of shell analogy to derive linear buckling loads in a mathematical form, second calculates the generalized slenderness of buckling of members using linear buckling loads, and finally estimates the elasto-plastic buckling loads based on the concept of column strength curves in terms of generalized slenderness. In the mathematical form for linear buckling loads, the in-plane shear rigidity is reconfirmed to be the most important together with the out-of-plane bending rigidities. The buckling strength in elasto-plastic region, based on the present method, is compared with those obtained by elasto-plastic nonlinear analysis and verified very accurate. Nonlinear analysis and verified very accurate.

ABSTRACT: In general, the stiffened plates consisting of steel plate elements are unavoidably accompanied by initial imperfections such as residual stresses and initial deflections, which have considerable effects on their ultimate strength. Therefore, it is needed for designing them to develop more rational method taking the ultimate strength influenced by initial imperfections into account rather than the conventional design method being on the basis of the linear elastic buckling theory. From this point of view, this study aims to evaluate rigorously the ultimate strength of orthogonally stiffened plate with initial imperfections under uniaxial in-plane compression. The elasto-plastic finite element method is applied to attain this purpose. By a happy combination of modal analytical technique and conventional finite element method, much reduction of the degree of freedom can be expected to be realized herewith. Some numerical calculations are performed by means of this rigorous method to examine the exactness of the analysis. Moreover, the numerical results are compared with the experimental ones.

Abstract: The present paper aims to propose a method to evaluate elasto-plastic buckling strength of two-way grid shells, using mathematical formulas for linear buckling derived based on the continuum shell analogy. The paper is organised from two principal points of view. In the first discussion, we derive two formulas for linear buckling of two-way grid shells by substituting the equivalent continuum rigidity into the buckling formulas for orthotropic shells. The applicability of the formulas is verified using several structural examples by comparison with the other proposed formulas and FEM results. In the second discussion, based on the concept of column buckling, an effective approach to estimate elasto-plastic buckling strength of two-way grid shells is demonstrated. In the estimation procedure, the buckling formulas derived in the first discussion are effectively applied to obtain the generalised slenderness.

ABSTRACT: A study of the free vibration of finite cylinders with elliptical cross section under external
pressure is presented. The buckling pressure is obtained as a special case in the free vibration analysis. The elliptical cross section is considered to be composed of two circular arcs, and the equations of a circular cylindrical shell are applied. Numerical examples are presented to examine the effect of out-of-roundness on the natural frequencies and the buckling pressure.

ABSTRACT: The vibration of cylindrical shells subjected to initial stresses is studied on the basis of a shell theory including shear deformation and rotatory inertia. The original equation system with five unknowns is reduced to one in three unknowns. An analysis is carried out for cylindrical shells with simply supported ends and the effects of initial stresses as well as shear deformation and rotatory inertia on the frequencies and the buckling forces are examined, and results are compared with those obtained by using classical thin shell theory. Results for initially unstressed shells are compared with those obtained by using the Mirsky-Herrmann theory.

Kaoru Shirakawa and Tohru Tamada, “Vibration and Buckling of Cylindrical Shell under External Pressure”, ABSTRACT: The vibration problems of finite cylindrical shells under external pressure are studied based on the equations developed by Flugge. The buckling pressure is obtained as a special case in the vibration analysis. Numerical results are presented for nine different sets of boundary conditions, and their effects on the characteristics of vibration and buckling are examined with regard to the mode shapes and the geometrical parameters of cylindrical shells.

principal shortcoming in the analysis. The problem has been simplified by applying axial tensile load and external press to simple cylindrical shell specimen and observing the buckling load for various nonproportional load-paths. Results are compared to numerical predictions (BOSOR5) using classical type plasticity models such as [...] deformation and [...] incremental theory. Significant discrepancy was found attributed to inadequate modeling of the nonlinear material behavior. The effects of geometrical imperfections and large deflections were found to insignificant, thereby leading to an idea [...] of the discrepancy between test and theory is due to a use of inadequate plastic model. The introduction of the Southwell plot into elastic shell buckling problem reduced the already minor effects of geometric imperfections. The Christoffersen-Hutchinson corner theory model was introduced into BOSOR5 in its simplest form as presented by Poh-Sang Lam. Results obtained with this model, which allows corners to form on an initially smooth yield surface, displayed better agreement with experimental data. However, increased computational time and problems related to abrupt changes in load-path at the corner are a major concern at this present time.

ABSTRACT: The predictions for plastic buckling of shells are significantly affected by the plasticity model employed, in particular in the case of nonproportional loading. A series of experiments on plastic buckling of cylindrical aluminum alloy shells under biaxial loading (external pressure and axial tension), with well-defined loading and boundary conditions, was therefore carried out to provide experimental data for evaluation of the suitability of different, plasticity models. In the experiments, initial imperfections and their growth under load were measured and special attention was paid to buckling detection and load path control. The Southwell plot was applied with success to smooth the results. The results show that axial tension decreases resistance to buckling under external pressure in the plastic region due to Isqosofteningrsquo of the material behavior. Comparison with numerical calculations using J2 deformation and incremental theories indicate that both theories do not predict correctly plastic buckling under nonproportional loading.

ABSTRACT: Buckling of elastic-plastic cylindrical shells axially struck with a mass is discussed. The effect of stress wave fronts travelling along the shell is taken into account. This allows us to cast some more light on the mechanism of progressive buckling. Only axisymmetric buckling modes are considered. The analysis is based on the Kirchhoff-Love hypotheses. As a constitutive law, the rate independent elasto-plastic relations with linear strain hardening and von Mises yield condition are adopted. A method for calculating bifurcation times and buckling modes is presented. Numerical examples are given.

ABSTRACT: The buckling phenomena of the subducting lithosphere due to the sphericity or the earth are studied by a nonlinear finite element method, and the results are compared with the buckling experiments by Yamaoka et al. (1986b). The subduction or the lithosphere is modeled by a hemispherical shell squeezed at its circumferential edge. For simplicity, two parameters are employed in scaling the subducting lithosphere. One is the thickness or the lithosphere and the other is the length or its deformable portion (i.e., the length of the descending slab). Uniform inward load is applied to the free circumferential edge or the deformable portion. At the opposite edge (i.e., at the trench), built-in boundary condition is imposed; no displacements and no rotations are allowed. Investigations are made mainly on the following three subjects: (I) How do the two parameters control the wavelength of buckling? The results show that shorter waves are associated with thinner and shorter shells. The irregularities such as tears or seamounts do not alter the buckling wavelength very much. (2) How do shells deform in their postbuckling state. Sharp cusps pointing outward appear in the postbuckling undulation without any irregularities in shell property and in applied load. The shape or the cuspidal undulation is quite similar to that of the actual subducting lithosphere. (3) Can buckling take place in the subducting lithosphere under likely conditions in the earth? The examination is made with respect to the buckling load, the shell deflection, and the buckling wavelength. The results strongly suggest that the arcuate shapes of subduction zones are in fact generated by buckling or the subducting lithosphere.

ABSTRACT: The lithospheric plate is a spherical shell rather than a plane plate. A spherical shell must buckle when it is bent inward. We examined the possibility of lithospheric buckling upon subduction. The lithosphere with its subducted portion is simulated by a hemispherical elastic shell bent inward at its circumferential edge by a uniform radial load. The buoyancy force acting on the lithosphere seaward of the trench is simulated by
clamping the shell along a parallel. The deformable portion between the loaded and clamped edges corresponds to the subducting slab of lithosphere. Buckling analyses were made using the techniques of a linear stability analysis and a finite element method. The wavelength of buckling depends on the thickness of the shell and the length of its deformable portion: a longer wavelength is associated with a thicker shell and a longer deformable portion. By scaling the shell thickness and the length of the deformable portion to the elastic thickness of lithosphere and the length of subducting slab, respectively, the wavelength of buckling can be compared favourably to the length of one unit of arcuate trench in a chain-like continuation of island arcs. The load to be applied for initiation of buckling is called the critical load: a lower critical load is associated with a thinner shell with a longer deformable portion. The excess weight of subducting slab provides a load large enough to initiate lithospheric buckling at a relatively early stage of subduction. Radial displacement of the circumferential edge at the critical state is an order of magnitude smaller than the depth of the leading edge of the Wadati-Benioff zone, indicating that most of the present subducting lithospheres are under a postbuckling state. Undulation of the shell in the postbuckling state is not purely sinusoidal but a successive continuation of arcs with cusps in between, invoking the continuation of arcuate deep-sea trenches with cusps at their junctions. The cuspathe feature of island arc chains is thus a natural consequence of lithospheric buckling and does not require any such irregularities as seamounts colliding with a trench. Collision of seamounts, however, can aid buckling greatly if they are aligned along a trench at an interval not very different from the inherent buckling wavelength.

ABSTRACT: We investigated the buckling response of a faulted elastic plate under horizontal compression using the finite element technique to better understand the effect of faults on the elastic behavior of a plate. We studied the effect of changes in fault spacing, depth and dip on the effective Young's modulus, buckling stress and wavelength. Our model consists of a thick elastic plate whose entire upper surface is cut by evenly spaced faults. We impose either an initial sinusoidal deformation with a fixed wavelength or a random deformation to the grid. A fault is represented as a free surface with no resolved shear stress and is allowed to slip in a specified direction using the method of ‘slippery nodes’. With the assumption of free slip on the faults, our model results represent an end member case in which the buckling wavelength and buckling stress are minimized by the presence of the faults.

In our models, fault depth was varied from 0 to 75% of the plate thickness. As strain increases, the grid deforms by antisymmetric flexural folding and the initial imposed wavelength of deformation is modified such that the new buckling wavelength emerges. Our results show that the effective Young's modulus is a decreasing function of fault depth and an increasing function of fault spacing. In addition, buckling of the plate occurs at a lower stress for greater fault depths. Buckling wavelength is independent of the initial deformation wavelength however, it is modified by the presence of faults. For a plate with closely spaced faults extending through at least 75% of the plate, buckling occurs at a wavelength one half as large as that for a continuous plate. Buckling stress is not independent of the initial deformation wavelength, rather it increases slightly with increasing difference between the initial deformation wavelength and the buckling wavelength.

Analytical models that approximate or ignore the effect of faulting can have large errors in calculation of the buckling stress. More importantly, modeling the observed wavelength of deformation in a faulted region with analytical solutions for continuous plates may result in a significant underestimate of elastic thickness. Fault dip
does not strongly affect either the effective Young's modulus or the buckling wavelength. Thus, the buckling response should be the same for a plate cut by a low angle fault or a high angle fault.

ABSTRACT: Numerical methods for the computation of singular points of nonlinear equations \( G(u, \lambda, \mu) = 0 \) are discussed, where \( \lambda \) and \( \mu \) are real parameters. Simple and double limit points are treated in some detail and numerical algorithms are presented and applied to elastic shell stability problems. The case of simple symmetry breaking bifurcation points is also treated with applications to nonsymmetric bifurcation from axisymmetric states of deformation of shells of revolution.

ABSTRACT: The ‘static-geometric analogy’ in thin shell structures is a formal correspondence between equilibrium equations on the one hand and geometric compatibility equations on the other. It is well known as a fact, but no satisfactory explanation of its basis has been given. The paper gives an explanation for the analogy, within the framework of shallow-shell theory. The explanation is facilitated by two innovations: (i) separation of the shell surface conceptually into separate stretching (S) and bending (B) surfaces; (ii) use of change of Gaussian curvature as a prime variable. Various limitations of the analogy are pointed out, and a scheme for numerical calculation which embodies the most useful features of the analogy is outlined.

ABSTRACT: The classical buckling of a thin-walled circular cylindrical shell which is subjected simultaneously to uniform bending moment and internal pressure is investigated in an approximate fashion by assuming an appropriate eigenmode and obtaining a “best-fit” solution of the resulting equations. In this way, explicit formulae are derived for critical loading combinations and for the characteristics of the modal form. These formulae agree reasonably well with a wide range of numerical data previously obtained by Seide and Weingarten. A feature of the scheme is that it is feasible to interpret the results in physical terms, and to envisage the roles of bending, twisting and stretching in the critical solution.

ABSTRACT: This paper discusses in a general way some aspects of the theory of shell structures, and the nature of the theory itself. It emphasises the importance of the interaction between bending and stretching effects in shells, and shows that the “two surface” model of shells provides a useful way of investigating this interaction at both the conceptual and the computational level. A cylindrical shell under various simple kinds of loading demonstrates how the key dimensionless groups emerge from this type of analysis.
Some fresh light is thrown on the famous controversy between Love and Rayleigh on the vibration of simple shells. Various problems which arise in the numerical computation of shell structures are discussed. The paper concludes with some general remarks.

ABSTRACT: This paper commemorates the publication in 1888 of A.E.H. Love’s paper on thin elastic shells. It discusses Love’s relationship with Rayleigh and others, and assesses the historical significance of the work.

ABSTRACT: It is well known that the buckling load of a thin cylindrical shell under axial compression depends significantly on the initial imperfection of the specimen. In this paper we focus attention on the effect of imperfections in the form of a particular kind of damage on the load-carrying capacity of a thin cylindrical shell. The study is an experimental one. The specimens used were steel drinks cans having a radius/thickness ratio of about 350. The damage was introduced by pressing in an indentation by hand and then pushing it out again: this left two locally damaged regions in the shell; and the level of damage could be characterised by the width of the initial indentation. The specimens were tested under eccentric axial compression. Careful visual observations were made of the behaviour of the shells in the damaged regions. In general, as the load increased a small dimple near the damaged zone grew in size, and turned gradually into a diamond shape. When the width of such a dent reached 25 mm, the can collapsed catastrophically. The nominal stress level in the region of the dent at buckling was around 0.24 of the classical buckling stress, whereas the buckling stress level for undamaged cans was 0.5±0.1 of the classical value.

ABSTRACT: Simple experiments on self-weight buckling of thin, open-top, fixed-base, small-scale silicone rubber cylindrical shells are presented in this article. The buckling heights were found to be proportional to thickness raised to the power of approximately 1.5, compared to 1.0 as in the classical theory. A non-linear finite-element analysis of self-weight buckling showed that there is a ‘post-buckling plateau’ load corresponding to the experimental buckling loads. Moreover, the results of the present experiments showed very little ‘scatter’ in the buckling heights, compared to the large scatter in the experimental data from the literature on the buckling of thin cylindrical shells under axial compressive load (which also have buckling stress proportional to thickness raised to the power of approximately 1.5), although there were measurable imperfections in terms of thickness variations. These observations somehow defy the accepted hypothesis of ‘imperfection-sensitivity’ in shell buckling. The most obvious explanation of the difference is that the open-topped shells of the present study are statically determinate, whereas the usual closed-ended shells of tests reported in the literature are statically indeterminate; the possibility of high initial stresses may explain the scatter in the experimental observations in the literature.

ABSTRACT: The widely accepted theory of buckling of thin cylindrical shells under axial compressive loading emphasises the sensitivity of the buckling load to the presence of initial imperfections. These imperfections are conventionally taken to be minor geometric perturbations of a shell which is initially stress-free. The original aim of the present study was to investigate the effect on the buckling load of imperfections in the form of local initial stress, which are probably more typical of practice than purely geometric ones. Experiments were performed on a vertical “melinex” cylinder of diameter about 0.9 m and height about 0.7 m, with radius/thickness ratio about 1800. The upper and lower edges of the cylinder were clamped to end discs by means of circumferential belts, an arrangement that allowed states of self-stress to be introduced to the shell readily by means of local “uplift” at the base. The upper disc was made sufficiently heavy to buckle the shell, and it was supported by a vertical central rod under screw control. Many buckling tests were performed. Surprisingly, the buckling loads were generally at the upper end of the range of fractions of the classical buckling load that have been found in many previous experimental studies. Even when the local uplift at the base caused a local “dimple” to be formed before the shell was loaded, the buckling load was relatively high. A surface-scanning apparatus allowed the geometric form of the shell to be monitored, and the progress of such a dimple to be followed; and it was found that a dimple generally grew in size and migrated in a stable fashion up the shell as the load increased, until a point was reached when unstable buckling occurred. These unexpected and paradoxical features of the behaviour of the experimental shell may be attributed to the particular boundary conditions of the shell, which provide in effect statically determinate support conditions. This study raises some new issues in the field of shell buckling, both for the understanding of buckling phenomena and for the rational design of shells by engineers against buckling.

ABSTRACT: The classical theory of buckling of axially loaded thin cylindrical shells predicts that the buckling stress is directly proportional to the thickness $t$, other things being equal. But empirical data show clearly that the buckling stress is actually proportional to $t^{1.5}$, other things being equal. As is well known, there is wide scatter in the buckling-stress data, going from one half to twice the mean value for a given ratio $R/t$. Current theories of shell buckling explain the low buckling stress—in comparison with the classical—and the experimental scatter in terms of “imperfection-sensitive”, non-linear behaviour. But those theories always take the classical analysis of an ideal, perfect shell as their point of reference. Our present principal aim is to explain the observed $t^{1.5}$ law. So far as we know, no previous attack has been made on this particular aspect of thin-shell buckling. Our work is thus breaking new ground, and we shall deliberately avoid taking the classical analysis as our starting point. We first point out that experiments on self-weight buckling of open-topped cylindrical shells agree well with the mean experimental data mentioned above; and then we associate those results with a well-defined post-buckling “plateau” in load/deflection space, that is revealed by finite-element studies. This plateau is linked with the appearance of a characteristic “dimple” of a mainly inextensional character in the deformed shell wall. A somewhat similar post-buckling dimple is also found by quite separate finite-element studies when a thin cylindrical shell is loaded axially at an edge by a localised force; and it turns out that such a dimple grows under a more-or-less constant force that is proportional to $t^{2.5}$, other things being equal. This 2.5-power law can be explained by analogy with the inversion of a thin spherical shell by an inward-directed force. Thus, the deformation of such a shell is generally inextensional except for a narrow “knuckle” or boundary layer in which the combined local elastic energy of bending and stretching is proportional to $t^{2.5}$, other things being equal. Similarly, the modes of deformation in the post-buckling dimples in a cylindrical shell are practically independent of thickness, except in the highly deformed boundary-layer regions which separate the inextensionally distorted portions of the shell. These ideas lead in turn to an explanation of the $t^{1.5}$ law for the post-buckling stress of open-topped cylindrical shells loaded by their own weight. We attribute the absence of experimental scatter in the self-weight buckling of open-topped cylindrical shells to the statical determinacy of the situation, which allows a post-buckling dimple to grow at a well-defined “plateau load”. Conversely, the large experimental scatter in tests on cylinders with closed ends may be attributed to the lack of statical determinacy there. Our paper contains several arguments that are not mathematically water-tight, in contrast to many reports in the field of mechanics of structures. We plead that the problem which we have tackled is so difficult that the only way forward is one of “over-simplification”. We hope that our work will be judged not with respect to its absence of mathematical precision, but by the light which it sheds upon the problem under investigation.

ABSTRACT: Lattice structures are often made in the form of thin-walled cylindrical shells reinforced with helical and circumferential ribs. In this research, an integrated equivalent stiffness model is developed to describe such a structure. The structure is defined by the following independent design variables: thickness of the lattice layer, angle of helical ribs, spacing of helical ribs, thicknesses of ribs, thickness of the skin, angle-ply of the skin. Method of Moving Asymptotes (MMA) is used to model a cylindrical lattice shell with external laminated skin. Compression axial force and global and local buckling of the shell are considered. Solution methodology is described. A numerical example of optimization of the design variables to provide the minimum value of the shell mass and to satisfy the following constraint: acting compression axial force should not cause the general buckling of the shell neither the local buckling of the helical ribs, is given. The proposed model
allows analysis of the lattice structures and is not based on the finite element method which is still of little use for overall design due to model complexity and the inability to easily changes rib geometry (angle, spacing).

ABSTRACT: This paper simulates dynamic responses of single-layer elliptical paraboloid latticed shells under impact based on rate-dependent isotropic hardening material model, master-slave contact point searching method and penalty function method. Node displacement and structural energy are analyzed under impact of freely falling with certain initial height. The dynamic buckling of plasticity is judged according to the dynamic responses. The effects of all kinds of parameters (such as span, rise-to-span ratio and cross-sectional areas of members etc.) are analyzed on the structural dynamic buckling. The results show that the displacements of characteristic nodes, stain energy and total energy of the structure increase all of a sudden. The vertical stiffness of the latticed shells strengthens and critical momentums are enhanced with rise-to-span ratio's aggrandizement, and cross-sectional areas of members increasing. Supporting condition has a slight effect on critical loads and the latticed shells are sensitive highly to initial geometric imperfection.

ABSTRACT: Many papers which treat the dynamic instability of shell structures under step load have been published, but there are few papers which deal with dynamic buckling under a load with periodic characteristics, especially considering damping. Dynamic buckling behavior under periodic excitation is different from that of step excitation. In this paper, the damping influence on dynamic buckling for shell-like shallow trusses is numerically investigated under up-and-down excitation, that is, step, sinusoidal and seismic excitations, and compared with the static critical load. The results show that, considering the damping, dynamic buckling loads become higher than the case of no damping, and the indirect snapping responds more sensitively than the direct snapping by the damping effect, except in the vicinity of the main resonance region.

SYNOPSIS: An iterative approach is suggested to calculate the critical loads of single-layer shallow domes with initial stochastic geometrical imperfections. The tangent stiffness matrix of an element with a small initial curvature is also presented in this paper.

T. Nishimura , K. Morisako and S. Ishida, “Numerical analysis of rotational buckling in gusset plate type joints
of timber lattice dome under several loading conditions”, Journal of the International Association for Shell and Spatial Structures (J. IASS), Vol. 39, No. 2, April 1998

ABSTRACT: Numerical study of critical behaviors of a timber lattice dome with steel gusset plate type joints under several loading conditions is conducted using the spatial beam-column FEM developed by the authors. The good accuracy of this numerical method is verified by the simulation of the full-scale physical test of the timber lattice dome in EXPO’90 Osaka, in which the rotational buckling of the node joint composed of six steel gusset plates has previously been observed. The numerical data of strain in one of the steel plates suggest that the rotational buckling was induced by lateral elastic buckling of plates. Under the loading conditions adopted here, the initial critical behavior of the lattice dome was neither overall snap-through of the dome nor buckling of individual wooden members but was invariably the rotational buckling of the node joints.

PARTIAL ABSTRACT: This paper concentrates on the mathematical modeling of nonlinear mechanics of thin-walled structures in view of associated finite element formulations. This means that we will primarily focus on formulations for structural models as prerequisite for derivation of finite elements, rather than specific ‘elementology’. The main emphasis is put on shells, including the special case of flat plates, turning into shells anyway in the nonlinear regime. The derivations are kept as general as possible, including thick and layered shells (laminated or sandwich structures), as well as anisotropic and inhomogeneous materials from the outset. Throughout Section 4.4, we will specify the corresponding restrictions and assumptions to obtain the classical 5-parameter shell formulation predominantly used for standard shell problems in the context of finite element analysis. In most part of the text, we restrict ourselves to static problems within the framework of geometrically nonlinear elasticity, neglecting time dependence and inertia effects. The extension into the materially nonlinear area is a straightforward procedure. It is believed that this does not mean a too strong restriction in view of the underlying motivation. It is a well cultivated tradition to let review articles start with the remark that a complete overview of existing methods and appropriate literature is utterly impossible. The multitude of existing concepts, methods, and implementations, as well as scientific papers, text books, and yet other review articles would effectively prohibit an exhaustive overview…

ABSTRACT: The purpose of this study is to investigate the characteristics of the connector having an influence on the elasto-plastic buckling load of ball-jointed single layer latticed domes. As analytic model, domes are composed of tubular member elements, balls and joints. The joint system of members in the single layer latticed domes has an influence on buckling load. Generally, the joint is assumed to be pin or rigid joint for the simplification of analysis. But the mero system that is used mostly for the spatial structures has intermediate properties between pin joint and rigid joint. Several studies based on the property of this semi-rigid joint are
"Experiment and elasto-plastic buckling analysis of ball-jointed single layer reticulated domes" by Suzuki, "Elasto-plastic buckling loads of latticed shells with elastic springs at both ends of members" by Kato and "Loading test and elasto-plastic buckling analysis of a single layer latticed dome" by Ueki and so on.

ABSTRACT: Single layer latticed domes are lightweight and elegant structures that provide cost-effective solutions to cover the large areas without intermediate supports. The topological design of these structures present difficulty due to the fact that the number of joints and members as well as the height of the dome keeps on changing during the design process. This makes it necessary to automate the numbering of joints and members and the computation of the coordinates of joints in the dome. On the other hand the total number of joints and members in a dome is function of the total number of rings exist in the dome. Currently no study is available that covers the topological design of dome structures that give the optimum number of rings, the optimum height of crown and the tubular cross-sectional designations for the dome members under the given general external loading. The algorithm presented in this study carries out the optimum topological design of single layer lattice domes. The serviceability and strength requirements are considered in the design problem as specified in BS5950. The algorithm takes into account the nonlinear response of the dome due to effect of axial forces on the flexural stiffness of members. The optimum solution of the design problem is obtained using coupled genetic algorithm. Having the total number of rings and the height of crown as design variables provides the possibility of having a dome with different topology for each individual in the population. It is shown in the design example considered that the optimum number of joints, members and the optimum height of a geodesic dome under a given external loading can be determined without designer’s interference.

ABSTRACT: The purpose of this paper is to analyze a squared lattice cylindrical shell under compressive axial load and to optimize the geometric parameters to achieve the maximum buckling load. Also a comparison between buckling loads of a squared lattice cylinder and a solid hollow cylinder with equal weight, length and outer diameter is performed to reveal the superior performance of the squared lattice cylindrical shells. A cylindrical lattice shell includes circumferential and longitudinal rods with geometric parameters such as cross-section areas of the rods, distances and angles between them. In this study, the governing differential equation for buckling load which can be presumed as a criterion for designing lattice structures with a specific weight is derived and is used as an objective function in genetic algorithm (GA) method to calculate the optimum geometric parameters of the shell. The optimum parameters were modelled in finite element method (FEM) in order to verify the buckling loads obtained from GA. In another effort, the FEM was applied to analyze the solid hollow cylinders. The results demonstrate relatively close agreement between the buckling loads obtained from GA and FEM for such shells. It was also shown that latticed cylinders have better performance to carry compressive axial loads than the equivalent solid hollow cylinders with equal weights, lengths and outer diameters. The studies reported in this paper have been carried out for a single squared lattice shell without using two-side skins. However, using skins can give better performance in carrying compressive axial loads. The results in this paper show that this type of effective, economical lightweight and functional structures could
be applied as inter-stages, inter-tanks, aircraft fuselage, rocket motor cases, pressure vessels and other elements of civil engineering structures in order to have greater strength and lower weight. Squared lattice cylindrical shell with optimum geometric design could provide the chance for eliminating the stiffeners of shells in aerospace structures in order to decrease the weight and increase the load-bearing capacity.

ABSTRACT: In this paper, the buckling analysis of a multilayered composite cylindrical shell which volume fraction of its fiber varies according to power law in longitudinal direction, due to applied compressive axial load is studied. Rule of mixture model and reverse of that are employed to represent elastic properties of this fiber reinforced functionally graded composite. Strain displacement relations employed are based on Reissner-Naghd-Berry’s shell theory. The displacement finite element model of the equilibrium equations is derived by employing weak form formulation. The Lagrangian shape function for in-plane displacements and Hermitian shape function for displacement in normal direction to the surface of mid-plane are used. Then, finite element code is written in MATLAB based on stated method to obtain the critical axial buckling load. Numerical results show that despite having the same layout and average volume fraction of fibers, the critical axial buckling load of functionally graded composite cylindrical shell is more than that of traditional composite in which the volume fraction of its fiber is constant throughout the shell.

ABSTRACT: This paper presents the formulation and numerical buckling analysis of a circular cylindrical composite shell comprising of fibers made of functionally graded material (FGM). The material properties of the fibers vary through the shell length according to a power-law distribution of the volume fraction. That is the fiber material properties vary from the metal on the one end to the ceramic up to the middle of the shell then from the ceramic to the metal towards the other end of the shell. Based on the first order shear deformation theory (FSDT) the governing equations of the shells are derived. Then to determine the buckling load of the composite shell over simply supported edges these equations are solved using the generalized differential quadrature method. The obtained results for an isotropic shell are compared with those given in the literature. Very good agreement is seen. Then, the effects of geometric parameters and FG power index are also investigated on the magnitude of the buckling load through number of examples. The study of the obtained results shows that any decrease in the value of FG power index will lead to a better buckling behavior of the composite shell.

ABSTRACT: Thin-walled tube bending is an advanced technology for producing precision bent tube parts in aerospace, aviation and automobiles, etc. With increasing demands of bending tubes with a larger tube diameter and a smaller bending radius, wrinkling instability is a critical issue to be solved urgently for improving the bending limit and forming quality in this process. In this study, by using the energy principle, combined with analytical and finite element (FE) numerical methods, an energy-based wrinkling prediction model for thin-walled tube bending is developed. A segment shell model is proposed to consider the critical wrinkling region, which captures the deformation features of the tube bending process. The dissipation energy created by the reaction forces at the tube–dies interface for restraining the compressive instability is also included in the prediction model, which can be numerically calculated via FE simulation. The validation of the model is performed and its physical significance is evaluated from various aspects. Then the plastic wrinkling behaviors in thin-walled tube bending are addressed. From the energy viewpoint, the effect of the basic parameters including the geometrical and material parameters on the onset of wrinkling is identified. In particular, the influence of multi-tools constraints such as clearance and friction at various interfaces on the wrinkling instability is obtained. The study provides instructive understanding of the plastic wrinkling instability and the model may be suitable for the wrinkling prediction of a doubly-curved shell in the complex forming process with contact conditions.

PREFACE: This document is described as the 5th Edition of the ECCS European Recommendations for the Buckling of Steel Shells. It is the successor to the 4th Edition, published in 1988, which was very different in style, format and content, though some of the regulatory requirements of the 4th Edition are here retained in the 5th Edition. In the 20 years since the publication of the 4th Edition in 1988, much has changed in the field of metal shell buckling. Extensive research has been undertaken, much new knowledge has been developed, and powerful computational modelling has transformed the field, though much design is still conducted by hand calculation. These changes are reflected in this 5th Edition.

ABSTRACT: In this study sandwich-walled cylindrical shells with aluminum pyramidal truss core of constant curvature suitable for functional applications were fabricated employing an interlocking fabrication technique for the metallic core. The skins were made of carbon-fiber reinforced composites and co-cured with the metallic truss core. Thereafter, axial compression tests on some representative samples were carried out to investigate the failure modes of these structures and compared with an analytical failure map developed to account for Euler buckling, shell buckling, local buckling between reinforcements and face-crushing. The experimental data closely matched the analytically predicted behavior of the cylinders. In particular, it was found that local buckling and face crushing modes can exist together and are the most important modes of failure of the fabricated structure. In addition, a study on the bending response of semi-cylindrical samples is also presented using a combination of analytical modeling, three-point bending experiments and finite element (FE) based simulations. The aluminum pyramidal cores of these samples were also constructed using the novel interlocking method before curing them with composite face sheets to fabricate the final structure. A theoretical model was developed to analyze the experiments and develop failure criteria. Three failure modes: i) Face wrinkling, ii) Face crushing, and iii) Debonding between face sheet and truss cores, were considered and theoretical relationships for predicting the collapse load associated with each mode were developed. The experiments were carried out on two sets of specimens with differing face sheet thickness which clearly indicated the important role played by core debonding in determining the peak load of the structure. Localized buckling instabilities were also reported for samples with thinner face sheets. The role of debonding in determining strength was further highlighted by a comparison with FE simulations with suppressed debonding. This study highlighted the superior structural performance and failure properties of these structures thus demonstrating their suitability for their integration into the next generation of ultralight multifunctional systems.

ABSTRACT: Axial compression of aluminium spherical shells of $R/t$ values ranging from 25 to 43 was performed under central loading. Quasi-static tests were conducted on an INSTRON machine (model 1197) of 50 T capacity. Spherical shells were tested to identify their modes of collapse and to study the associated energy absorption capacity. In experiments all the spherical shells were found to collapse due to formation of an axisymmetric inward dimple associated with a rolling plastic hinge. A Finite Element computational model of development of the axisymmetric mode of collapse is also presented. Experimental and computed results of the deformed shapes and their corresponding load–compression and energy–compression curves were presented and compared to validate the computational model. The computed variations of the different strains and stresses were also studied. On the basis of the computational results mechanics of the development of the axisymmetric inward dimple mode of collapse has been presented, analysed and discussed.

ABSTRACT: Experimental investigations and numerical simulations are performed in order to numerically predict the buckling behaviour of thin composite laminated specimens. Experiments are aimed at two objectives: the first is to completely characterize the carbon/epoxy material under simple loading configurations, the second is to test this material in buckling and post-buckling situations. The data collected with the first campaign of experiments are used to obtain the strength parameters required to define a damage model based on the failure theory by Tsai-Wu. This model is implemented in a Finite Element (FE) code and numerical simulations of buckling are executed for unidirectional and cross-ply laminates; results are in good agreement with experiments both in terms of determination of the critical loads and prediction of failure during post-buckling.

ABSTRACT:

ABSTRACT: Buckling is a critical phenomenon in structural failure. Buckling is the failure of structures under compression load. Also buckling strength of structures depends on many parameters like supports, linear materials, composite or nonlinear material etc. Also buckling behavior is influenced by thermal loads and imperfections. Analyzing all these conditions is difficult task. So few parameters are considered for the present work. Due to the advances in the Finite element techniques, analysis of these problems is possible which is difficult in earlier days. Formulae’s are available based on experimental techniques for linear range and not available for nonlinear range. So these problems are solved by the advances in computer technology with Finite element techniques in the nonlinear domain. In the present work both cylindrical and elliptical members are considered for buckling strength. Initially both the members are created using Ansys top down approach. Scaling options are used to built the elliptical members. The structure is divided to ease map meshing. Initially one end constrained and other free condition is considered for analysis. The structure is fine meshed to get better results. Both Shell63 in elastic range and shell43 in plastic range are used for analysis. The elliptical results are compared with theoretical results to check Finite element validity. The results are very close and analysis is extended for circular members. The stresses and loads are very high with linear analysis. But the stresses and loads are considerably reduced with nonlinear analysis. The effect of thickness on buckling load and stresses are plotted. The buckling load is increasing with increase in thickness. The hinged boundary

conditions shows higher buckling strength compared to the initial boundary conditions for both elliptical and cylindrical members. The problem executed in the time domain also indicates the stresses reaching to the yield point and converging towards the critical loads. All results are represented with necessary graphical and pictorial plots.

ABSTRACT: The buckling of imperfect composite cylinders under concentric and eccentric compression is investigated experimentally and numerically, with particular attention given to the imperfection sensitivity of the shells. A series of glass-fiber-reinforced plastic cylinders have been tested under different load eccentricities to validate the corresponding nonlinear numerical analyses performed in this study. A good agreement between the experimental and numerical results was achieved through use of the ABAQUS/Explicit finite-element code and the introduction of initial imperfections. Both the experimental and the numerical results show that the knockdown factor increases as the loading eccentricity grows.

ABSTRACT: This experimental and numerical study focuses on the buckling problem of cylindrical composite shells under pulse loads. Series of experiments have been performed to determine buckling loads of the laminated cylinders under different axial loading rates. Numerical models of the tested specimens have been elaborated and good agreement between experimental and numerical results has been achieved. The numerical models have been used to study the buckling behavior of the cylinders at loading rates much higher than could be achieved experimentally. Additionally, the influence of imperfections on dynamic buckling behavior of the laminated shells has been studied numerically.

ABSTRACT: This thesis is focused on the investigation of the changes in the buckling behaviour of various composite shells due to dynamic, rapid loading. Currently, the structural design procedures of lightweight structures incorporate assumption of the loads as quasistatic, while maintaining reliability by applying conservative safety coefficients. Different investigations show that in various cases of dynamic loading the buckling loads can be both higher and lower than the static buckling load. Therefore, correct consideration of the load dynamics in the design procedure would lead to safer and more efficient structures. A reliable, experimentally validated analysis approach is required in order to benefit from the weight-saving potential of dynamically loaded composite structures, while maintaining the reliability. However, only few experimental investigations on dynamic buckling of composite structures have been performed because of the complexity of such experiments. In present thesis, the dynamic buckling of composite shells has been investigated experimentally and numerically, and an appropriate experimentally validated modelling approach has been proposed. Chapter 1 gives review of the accumulated knowledge in dynamic buckling of thin-walled structures. The key pioneering research has been reviewed along with the publications describing the current state-of-the-art in the field. It has been revealed that surprisingly few experimental studies have been attempted in dynamic buckling of composite shells, with most researchers resorting to the analytical and numerical investigations only. Chapter 2 contains the relevant information about the experimental and numerical methods used within this thesis. The experimental investigations have been performed on cylindrical composite shells using hydraulically actuated loading frames and a drop tower. The main numerical tool used in this thesis is the ABAQUS/Explicit finite element software. Chapter 3 describes the static buckling behaviour of the selected specimens as a reference for the comparison with the dynamic buckling behaviour. The imperfection sensitivity of the cylindrical shells has been addressed by measuring the geometrical imperfections of the specimens and
using this data in the numerical analyses. Chapter 4 contains the results of experimental and numerical investigations of dynamic buckling of composite cylinders. Gradually and suddenly applied loads, as well as half-sine shaped pulse loads have been considered and the influence of the load parameters on the buckling behaviour of the shells has been revealed. Chapter 5 expands the research to stiffened curved composite panels. The results have been obtained for various loading patterns using numerical models validated with the results of static buckling experiments.

ABSTRACT: It has been long recognized that the buckling behaviour of thin-walled pressure vessels, subjected to axial loading, is characterized by a bifurcation on an asymmetrical mode. It is also known that the carrying capacity of this type of structure greatly depends on geometrical imperfections characterizing the surface. This drastic effect of geometrical faults leads to a conservative design in most cases. In the design of the principal cryotechnic stage of the launcher Ariane 5, a thin-walled vessel was studied under complex loading conditions combining: pressurization, axial loading and a shear force coupled to a bending moment. Thus, the risk of buckling requires a precise estimation of pressure effects on geometrical imperfections. This is performed in two different cases: in the case of a non-stiffened configuration, and with the presence of axial stiffeners.

References listed at the end of the paper:

ABSTRACT: The effects of geometrical imperfections on the critical load of elastic cylindrical shells when subjected to axial compression are studied through analytical modelling. In addition to distributed defects of both axisymmetric or asymmetric forms, emphasis is put on the more severe case of localized defects satisfying the axial symmetry. The Von Kármán - Donnell shell equations were used. The obtained results show that shell strength at buckling varies very much with the defect amplitude. These variations are not monotonic in general. They indicate however a clear reduction of the shell critical load for some defects revealed as the most dangerous ones. The proposed method does not consider the complete coupled situation that may arise from interactions between several localized defects. It facilitates nevertheless straightforward initializing of closer analyses if such couplings are to be taken into account by means of special numerical approaches, because it enables fast a priori selection of the most hazardous isolated defects.

“Buckling of elastic cylindrical shells considering the effect of localized axisymmetric imperfections”, Thin-
ABSTRACT: The effect of localized axisymmetric initial imperfections on the critical load of elastic cylindrical shells subjected to axial compression is studied through analytical modeling. Some classical results regarding sensitivity of shell buckling strength with respect to distributed defects having axisymmetric or asymmetric forms are recalled. Special emphasis is placed after that on the more severe case of localized defects satisfying axial symmetry by displaying an analytical solution to the Von Kármán–Donnell shell equations under specific boundary conditions. The obtained results show that the critical load varies very much with the geometrical parameters of the localized defect. These variations are not monotonic in general. They indicate, however, a clear reduction of the shell critical load for some defects recognized as the most hazardous isolated ones. Reduction of the critical load is found to reach a level which is up to two times lower than that predicted by general distributed defects.

RÉSUMÉ: Les structures cylindriques élastiques sont des constructions courantes dans les domaines de l’ingénierie civile et mécanique. Ces structures à parois minces peuvent occasionner un ébavouissement lorsqu’elles sont soumises à la compression axiale. L’ébavouissement limite à un grand degré leurs performances en termes de résistance. Ce phénomène dépend énormément des imperfections initiales distribuées ou localisées géométriques qui sont présentes sur la structure de la coque. Les imperfections géométriques localisées ont en général été obtenues par l’assemblage de la coque par le soudage de strakes. Dans cet essai, une étude de la fiabilité de la résistance d’ébavouissement en prenant en compte la variation de la coque a été effectuée. Les imperfections géométriques localisées étaient choisies pour être entrantes et avoir une forme triangulaire ou onde. L’interaction entre trois imperfections localisées avait également été considérée. Approach: Un logiciel spécifique était utilisé permettant d’analyser le problème d’ébavouissement de la coque à travers le procédé d’Éuler linéaire. Un ensemble de cinq facteurs y compris les rapports d’aspect de la coque, les caractéristiques de l’imperfection et la distance séparant les imperfections localisées avaient été trouvés pour gérer le problème. Un paramétrage a été effectué pour déterminer leur influence relative sur la déformation de la coque. L’analyse de fiabilité a été menée à l’aide de la méthode de premier ordre. Résultats: L’imperfection ondulée a été trouvée plus sévère que celle triangulaire dans la gamme de faible amplitude des imperfections. Il a été montré par comparaison avec le cas unique que la diminution de la charge critique est obtenue pour trois imperfections interactives. La distance inter-imperfections a été trouvée de grande importance sur l’indice de fiabilité. Conclusion/Recommandations: Dans la gamme de paramètres examinés, la fiabilité a été trouvée d’augmenter avec la distance séparant les imperfections géométriques localisées. Cela peut aider à effectuer un design optimal des strakes assemblés.

ABSTRACT: Buckling of cylindrical shells under axial compression is an important problem. The buckling load is affected by the initial geometric imperfections. Several studies have been performed to investigate the effect of initial geometric imperfections on the buckling load of cylindrical shells. The imperfections of entering triangular form were assumed to be positioned symmetrically at the middle shell length. The buckling load was assessed in terms of shell aspect ratios, imperfection amplitude and wavelength, and the distance separating the imperfections. The obtained results have shown that amplitude and wavelength have major effects, particularly for short and thin shells. Two interacting imperfections were found to be more severe than a single imperfection.
imperfection, but the distance separating them has small influence.

ABSTRACT: A thin-walled pressurised cylindrical shell is sensitive to buckling phenomena when it experiences locally a compressive stress. It is often considered that its behaviour under bending is rather similar to pure compression, but very few are the experimental investigations that precise the real behaviour of a thin pressurised cylinder submitted to a bending load. A large amount of experimental results is presented here, obtained on thin shells (550<\(R/t<1450\)) of moderate length (\(L/R\approx 2\)). The evolution of the cylinders' behaviour that has been recorded when internal pressure increases is outlined. It is shown that one must distinguish between local buckling and global collapse of the structure. A comparison of our experimental data to design recommendations given by two standards (NASA SP8007 and Eurocode 3) is finally achieved, putting in advance safety margins provided by these codes.

ABSTRACT: Experimental and numerical methods are used to study the stability problem of cylindrical shells with cut-outs. The paper presents parametric research of the shape (square, rectangular, circular), the dimensions (axial and circumferential sizes, diameter) of the hole. The effect of the location and the number of the holes are also studied. The analysis indicates that the critical load is sensitive to the opening angle or circumferential size of the hole. The function (critical load-opening angle) is linear for large openings and independent of the geometrical imperfections of the shell. However for small openings, it is necessary to take into account the coupling between the initial geometrical imperfections and the openings. The linear approach does not fit because of the importance of the evolution of the displacements near the openings. These results will be used for the development of European rules.

ABSTRACT: Aggressive environments can provoke corrosion of thin cylindrical shells widely used in different engineering applications. Localised decrease of shell thickness usually causes buckling load reduction. Recently in 1994, Koiter et al. investigated the influence of modal thickness variation on a buckling load of an axially compressed shell. The thickness variation is assumed to be axisymmetrical and sufficiently small. In this paper Koiter et al. show that thickness imperfection can provoke a loss of buckling load which is, for small imperfection amplitude, a linear function.

ABSTRACT: Stability of imperfect elastic cylindrical shells which are subjected to uniform axial compression is analyzed by using the finite element method. Multiple interacting localized axisymmetric initial geometric imperfections, having either triangular or wavelet shapes, were considered. The effect of a single localized geometric imperfection was analyzed in order to assess the most adverse configuration in terms of shell aspect ratios. Then two or three geometric imperfections of a given shape and which were uniformly distributed along the shell length were introduced to quantify their global effect on the shell buckling strength. It was shown that with two or three interacting geometric imperfections further reduction of the buckling load is obtained. In the ranges of parameters that were investigated, the imperfection wavelength was found to be the major factor influencing shell stability; it is followed by the imperfection amplitude, then by the interval distance separating the localized imperfections. In a wide range of parameters this last factor was recognized to have almost no effect on buckling stresses.

ABSTRACT: Reliability assessment of buckling limit state for imperfect stiffened panels made from elastic homogenous and isotropic material and subjected to uniform axial compression was performed in this work. The stiffened panel was assumed to suffer a single localized geometric imperfection having the form of a rectangular depression patch that is situated either on a web or a segment of the panel. A parametric study was performed with regards to the buckling strength variations for both perfect and imperfect panels as affected by the defect depth and position. Imperfect panels were generated by placing a depression square of fixed size and variable depth at various locations of the web and the plate. The obtained results have shown that buckling strength of stiffened panels is largely affected by the system geometric parameters and the defect characteristics. For an imperfect stiffened panel with a defect present either on a web or a segment, a drastic reduction of the buckling stress was obtained. The relative influence of defect position and depth was found to depend on whether the defect is located on a web or a segment of the stiffened panel. For a given configuration of the panel, focus was done on the effect of uncertainties affecting the plate geometric dimensions, the defect characteristics and the applied loading. These parameters were assumed to be random variables. Their means and standard deviations were assumed to be known, while no prior information is available about their densities of probabilities. First Order Reliability Method was applied to a response surface representation of the buckling limit state which was derived through quadratic polynomial regression of finite element results that were collected according to a full factorial design of experiment table built on the key intervening factors. The influence of the distributions of probabilities chosen to model the problem uncertainties for the perfect and imperfect stiffened panels was analyzed. It was found that these modify significantly reliability results.

ABSTRACT: Sixteen torispherical heads were tested under internal pressure. These heads, which were 500 mm in diameter, had diameter/thickness ratios ranging from 330 to 1000. They were all prepared by spinning mild steel plates. Deflections along the axis and in the knuckle area were recorded. The most practical result is the buckling pressure and this can be exceeded without fracturing the head. The tests show that the buckling pressure is relatively unaffected by geometric imperfections. These experimental results are used to assess the validity of the different plastic bifurcation analysis methods. Five different methods were employed using the CASTEM general-purpose computer program. The method based on the incremental theory of plasticity proved to be incapable of correctly predicting head buckling. If this method is modified by replacing the elastic shear modulus by the secant modulus, the results obtained show good agreement with experimental results.

ABSTRACT: The Liquid Metal Fast Breeder Reactor poses special problems in the design and construction of its important components. Its low pressures permit utilization of less expensive, thin cross-sections. But the high temperatures result in serious thermal stress and buckling problems. This paper describes the buckling design rules for the French Fast Reactor design for Class I and II components. The paper contains a simplified analysis method, offers experimental validation, and a comparison with the ASME Section III code.

PARTIAL INTRODUCTION: In Liquid Metal Fast Breeder Reactors (LMFBR) potential shear buckling failures of the primary vessel, induced through seismic excitations, have to be considered. The problem is particularly severe in pool type reactors due to their large size, radius of approximately 10 m, coupled with small wall thicknesses of 50 mm and less. In addition, the primary vessel material, typically 316 stainless steel, has a low yield strength at the normal operating temperatures of around 400 degrees C to 500 degrees C. These characteristics tend to make the structure relatively flexible and subject to potential elasto-plastic shear buckling failure…

ABSTRACT: A modal method of analysis is used to determine the response of an infinitely long stiffened cylindrical shell of revolution to a transient lateral pressure produced by an underwater explosion and propagating in an acoustic fluid. The shell is initially immersed, hence prestressed by the external hydrostatic pressure. A theory of dynamic buckling is then developed for cylindrical shells subjected to transverse pressure pulses of different durations.

ABSTRACT: The plastic bifurcation buckling pressures of 60 internally-pressurised, perfect, complete toroidal shells of elliptical cross-section are given in the present paper, assuming elastic, perfectly plastic, material behaviour. The shell buckling programs employed in the computations were BOSOR 5 and INCA. Denoting the major-to-minor axis ratio by $k$, the numerical results show that the plastic buckling pressures are considerably lower than their elastic counterparts in the range $1.25 \leq k \leq 1.5$ and are approximately equal to them for $k=2.5$. A limited study of the effects of non-axisymmetric initial geometric imperfections on the buckling pressures of the shells was also carried out using the INCA code. For the four cases studied the post-buckling behaviour was stable. This means that designers can use the buckling pressures given herein for perfect shells as a basis for their initial designs.

ABSTRACT: Imperfection sensitivity of thin shells of constant thickness was widely studied during the last 50 years (J.G. Teng, Appl. Mech. Rev. 1996:49(4)). Recently, Koiter et al. (Int. J. Solids Struct. 1994:31(6):797–805) investigated the influence of axisymmetric modal thickness variation on the buckling load of an axially compressed shell. In this paper, the influence of harmonic thickness variation in the circumferential direction on thin cylindrical shell buckling under external pressure is analysed by means of FE bifurcation analysis. Two different FE codes were used, one with quasi-axisymmetrical multimodal Fourier analysis (A. Combescure, Etude de la stabilité des coques minces sous chargements complexes dans INCA. Rapport DMT/94-460, in French, 1994; Modélisation des coques axissymétriques avec imperfection quelconque: L’élément COMI (in French). Rapport DMT/97-189, 1997; Schauder B. Flambage des Coques Cylindriques en Fléxion. Thèse de doctorat, INSA de Lyon, in French, 1997), and the second one with 3D shell elements. A new quasi-
axisymmetric element (COMI) is presented. It uses Fourier series expansion in the circumferential direction coupled with a full numerical integration around the circumference, which allows any variation of thickness or of initial imperfections.

ABSTRACT: This paper concerns the influence of thickness imperfections on the nonlinear buckling of cylinders under uniform external pressure. The material is assumed to behave elastically. A parametric study is performed using the COMI finite element, which allows to perform nonlinear analyses of shells of revolution with any kind of nonaxisymmetric initial imperfection. Let us assume that the perfect shell buckles with a Fourier mode $m$ and that the initial thickness imperfection is on Fourier mode $1$, $m$ or $2m$. As shown in a previous study on linear buckling of cylinders with thickness imperfections, $1$ and $2m$ are the most harmful thickness imperfections. We show that the nonlinear pre-buckling does not affect the buckling pressures very much. We then study the coupling with geometrical imperfections. We show that the geometry and thickness imperfections have a multiplicative effect on the decrease in buckling load in the nonlinear range. Finally, we show that if one uses only the measured outer radius of a shell to input initial imperfections, very different nonlinear buckling pressures can be obtained under the assumptions that the imperfection is purely geometric, purely thickness, or a combination of both.

ABSTRACT: The buckling behavior of thin-walled pressurized cylinders under bending load is investigated through an intensive experimental campaign on thin shells ($550 < R/t < 1450$) of moderate length ($L/R$ about equal to 2.0). The experimental buckling behavior of pressurized shells under bending is somewhat similar to the behavior under axial compression: for low pressurization cases, the load-carrying capacity is strongly sensitive to geometrical imperfections, whereas above a sufficiently high level of pressure, the buckling occurs for a stress value close to the theoretical prediction. A major difference between bending and pure compression lies in the post-critical behavior; the reaching of the critical load under bending is accompanied by wrinkles or buckles confined to a small area around the (maximally) compressed fiber. It allows, in the case of sufficiently pressurized cases, stress redistribution around the buckling zone. Therefore the collapse moment is much higher than the bifurcation moment, in contrast to the case of pure axial compression. In a second section, non-linear finite element analyses are carried out to simulate the conducted tests. The numerical model correctly follows the experimental results.

ABSTRACT: The objective of this work is to answer the following question: Is a multilayer shell model always
appropriate for the prediction of the buckling of a thin structure? In order to do that, we chose to analyze the buckling of a three-layer cylindrical tube in uniform axial compression. We compared three approaches for the calculation of the theoretical buckling load: a fully analytical formula, a Fourier series buckling model of a multilayer axisymmetric shell and a calculation based on a mechanical mesh of the axisymmetric medium of the middle layer. This analysis shows that two buckling modes are in competition: a global beam mode and a local skin buckling mode (wrinkling) which develops when the stiffness of the middle layer is quite small. The critical loads can be estimated analytically for both types of modes, leading to a critical length under which the cylinder fails by skin buckling; otherwise, it fails in beam mode. Then the problem was solved by finite elements using two models: first, a multilayer axisymmetric shell model, then a model with two types of elements in each section (an 8-node axisymmetric element for the middle layer, and axisymmetric shell elements for the two skins). We showed that both models can predict the beam mode, but only the latter was capable of predicting the skin buckling mode. Similar results are proposed for the prediction of the buckling of a three-layer cone under internal pressure. We also compared the formulations for geometrically nonlinear problems with nonlinear materials and showed that in such problems the nonlinearities cause even more pronounced differences. This clearly raises the question of the choice of the type of finite element for the prediction of buckling in a multilayer structure in which some layers have only a small relative stiffness. The analytical solution and the analysis of the nonlinear response in the case of the cone confirm that the poor prediction of the skin buckling mode is due to a failure to account for the flexibility perpendicular to the mean surface.

ABSTRACT: A series of fabric-reinforced concrete shells are tested for buckling under uniform normal pressure in an air chamber. The test results are compared with previous experimental results for steel-reinforced concrete shells, and are used to provide a tentative design procedure for fabric-reinforced spherical shells. The design procedure is illustrated with an example, comparing results with the results obtained by design methods for steel-reinforced shells described in earlier studies. Experiments to maximize buckling stiffness per unit material cost in the shell cross section are summarized. Practical limitations on shapes of fabric-reinforced shells are described as well as their buckling sensitivity to variables in construction procedure.

“Nondestructive Load Predictions of Concrete Shell Buckling”, ASCE J. Struct. Engrg. 115, 1191 (1989 );
ABSTRACT: Nondestructive test methods are evaluated for predicting the buckling capacity and buckling location of fabric-reinforced concrete shells. The load-deformation methods consist of measuring vertical deflections of 10-20 points on the shell surface under increasing vacuum pressures, curve fitting of the deflection-pressure response at each point, calculating a characteristic pressure on each curve, and using the lowest such calculated pressure as a predictor of shell buckling capacity. The curve fits are updated at each pressure increment and the test is continued to a pressure equal to a safe fraction of predicted buckling load,
based on prior testing experience. Predicted and actual buckling pressures are compared for six experimental shells. The chosen method was selected from a comparison of four extrapolation methods, based on its least standard deviation between predicted and actual buckling pressures for the six shells. Vacuum tests can also indicate approximate buckling locations, for installing reinforcing arches before placing shells in service, and provide an inexpensive means for proof loading shells to any specified overload factor.

ABSTRACT: A degenerated 9-node-shell element and interpolation formulation for stress resultant vectors were utilized in this work. Selected experiments previously performed by the second author on the elastic buckling of clamped thin-walled shallow spherical shells under external pressure are compared with the present finite element analytical results. The measured geometric initial imperfection distributions are incorporated in the finite element analytical procedure. Good agreement between the numerical simulations and the experimental measurements of not only maximum loads but also displacement distributions were obtained.

ABSTRACT: In contrast with the pressure buckling of a complete cylinder, even a perfect cylindrical shell panel displays a complex form of nonlinear snap buckling behaviour. The prebuckling nonlinearity has been understood to be induced by the total equivalent imperfections involving the potential-load-induced imperfection and the actual geometric imperfection. Based on this concept, an alternative estimation procedure of the elastic and elastoplastic buckling load-carrying capacities is proposed and the resulting simple equations and formulae for design are represented.

ABSTRACT: An elastic nonlinear Ritz analysis is used to investigate the behavior of axially loaded imperfect cylindrical shells. It is shown how the initially positive contributions arising from the shells membrane energy are eroded with increasing levels of both deformations and imperfections. This loss of membrane energy is shown to be responsible for the notoriously imperfection sensitive buckling of the shell. Extensive parameter studies demonstrate the existence of a well-defined lower bound to buckling loads and the dominance of characteristic incremental deformation modes as this lower bound is approached. For the first time the physically based hypotheses of the reduced stiffness method are theoretically demonstrated. Furthermore, it is shown how a slightly modified form of the reduced stiffness method provides very close predictions of the lower bounds to buckling loads.

Seishi Yamada (Dept. of Architecture and Civil Engineering, Toyohashi University of Technology, Japan),

ABSTRACT: A rational design evaluation procedure is investigated for the elastic overall buckling load carrying capacity of single layer cylindrical lattice shell roof structures. The nature of the imperfection sensitivity of these structures is for the first time reviewed in this paper. This allows the development of the reduced stiffness buckling analytical concept for the lattice shells based upon the introduction of a simple lower bound estimation equation through the use of the so-called continuum shell analogy theory. The linear and nonlinear buckling loads found from conventional finite element analyses are compared with the present estimations. Finally, the elastic-plastic load carrying capacity estimation method through the use of the present elastic lower bound criteria is also proposed.

ABSTRACT: In this paper, dynamic buckling of a martensitic transformation dominated super-elastic TiNi thin cylindrical shell under single loading was studied and analyzed. The results showed that the buckling mode was mainly the non-axisymmetric diamond model, and recovered when unloading, and related with martensitic transformation and the behavior of the transformation hinge, and was significantly different from the traditional elastic-plastic cylindrical shell. The article also discussed that the influence of the length-to-diameter rate and boundary conditions on buckling mode, specific energy, critical instability threshold, and so on. The study showed, as length and boundary conditions changed, TiNi thin cylindrical shells showed a variety of buckling modal development. Under the same boundary condition, Se was reduced as length-diameter ratio increased, had the similar law with the quasi-static compression experiments. But the specific energy of a TiNi thin cylindrical shell was greater than that in the quasi-static compression experiments.

ABSTRACT: The containment vessel of a nuclear power plant, the LMFBR reactor vessel, and a tall cylindrical tower are thin cylindrical shell structures with large diameter. Therefore, development of an evaluation technology for dynamic buckling for these structures due to wind or seismic loading is becoming very important. Some research works are found recently, but the analysis generally needs unpractical huge CPU time. The development and the utility of a practical dynamic buckling analysis code using FEM, in which lumped masses and initial imperfection etc. can be taken into account, are reported here.

ABSTRACT: The paper considers the buckling of complete spherical shells. The main purpose could be, as a basis for real design, to find the lower critical load. Three scientists developed the idea that the buckled shape of the shell is the isometrically transformed shape of the original shell surface. Applying this idea using rotationally symmetric buckled shape the lower critical load can be calculated fairly easily for spherical shells. In reality the buckled shape has rather discrete rotation symmetry. Considering this kind of buckled shape is the main task of our research. Some preliminary results related to this buckling form will be presented here.

ABSTRACT: Metal silos used to store granular solids often take the form of a cylindrical shell with an aspect ratio in the range 2 < H/D < 6. It has long been recognized that the most serious load case for silos is the condition of eccentric discharge of its stored solid, and more failures have occurred under this condition than any other. Two of the chief reasons for this high failure rate are the difficulty in characterizing the pressure distribution caused by eccentric solids flow, and the difficulty in understanding the pattern of stresses that develops in a shell wall under such unsymmetrical pressure regimes. The nonsymmetric behavior of a shell structure under such a loading condition is not at all well described in the voluminous shell structures literature, and only a few studies have explored the mechanics leading to high local stresses which in turn lead to buckling failure under eccentric discharge. In this study, the pressures caused by eccentric discharge are characterized using the new rules of the European Standard EN 1991-4 [5] that defines the Actions in Silos and Tanks. Using this new improved description of unsymmetrical pressures, it is now possible to perform relatively realistic calculations relating to this common but complicated shell buckling condition. The calculations described here are part of a wider study believed to be the first of its kind and are undertaken using geometrically and materially nonlinear analyses in accordance with the European Standard EN 1993-1-6 [6] on Strength and Stability of Shells. The paper explores the structural behavior leading to buckling during eccentric discharge, including the critical effects of changes of geometry and imperfection sensitivity.

ABSTRACT: This paper aims to develop practical design equations and charts estimating the buckling strength of the cylindrical shell and tank subjected to axially compressive loads. Both geometrically perfect and imperfect shells and tanks are studied. Numerical analysis is used to evaluate buckling strength. The modeling method, appropriate element type and necessary number of elements to use in numerical analysis are recommended. According to the results of the parametric study of the perfect shell, the buckling strength decreases significantly as the diameter-to-thickness ratio increases, while it decreases slightly as the height-to-diameter ratio increases. These results are different from those in the case of columns. The buckling strength of the perfect tank placed on an extremely soft foundation and a stiff foundation increases by up to 1.6% and 5.6%,
respectively, compared with that of the perfect shell. The buckling strength of the shell and tank decreases significantly as the amplitude of initial geometric imperfection increases. Convenient and sufficiently accurate design equations and charts used for estimating buckling strength are provided.

ABSTRACT: The free vibration problem of a thin composite cross-ply laminated non-circular cylindrical shell subjected to an axial compression is studied. The equations of motion are derived, in the framework of the Donnell-type theory, in terms of the shell middle surface displacement components. The differential equations of motion have variable coefficients and they are solved by employing Galerkin's method. As an application, the problem of the free vibrations and buckling of cross-ply laminated oval cylinders is studied. Numerical results for antisymmetric and unsymmetric cross-ply laminated shells of graphite-epoxy are presented and discussed.

ABSTRACT: The buckling and free vibration problem of a thin composite antisymmetric angle-ply laminated circular cylindrical shell is studied. The Donnell-type equations of motion, in terms of the shell middle surface displacement components, are used and solved approximately by means of Galerkin's method. Numerical results are presented and the expectation that the bending-stretching coupling phenomenon rapidly dies out as the number of layers increases is confirmed.

ABSTRACT: For a generally anisotropic laminated thin elastic non-circular cylindrical shell, subjected to a combined loading, the equations of motion of a second approximation Flugge-type theory are derived and expressed in terms of the shell middle-surface displacement components. As an application, for the free vibration problem of a cross-ply laminated non-circular cylindrical shell subjected to S2 simply supported edge boundary conditions, these equations are solved by employing the method of Galerkin. For a family of regular antisymmetric cross-ply laminated oval shells, numerical results are obtained and discussed. Comparisons are also made between some of the obtained results and corresponding results obtained from the solution of the quasi-shallow shell Donnell-type equations of motion.

ABSTRACT: The free vibration problem of thin elastic cross-ply laminated circular cylindrical panels is considered. For this problem, a theoretical unification as well as a numerical comparison of the thin shell theories most commonly used (in engineering applications) is presented. In more detail, the problem is formulated in such a way that by using some tracers, which have the form of Kronecker's deltas, the stress-
strain relations, constitutive equations and equations of motion obtained produce, as special cases, the corresponding relations and equations of Donnell's, Love's, Sanders' and Flugge's theories. By using a closed form solution, obtained for simply supported panels, a comparison of corresponding numerical results obtained on the basis of all of the aforementioned shell theories is attempted.

ABSTRACT: The present paper is concerned with the development and certain applications of a refined shear deformable theory suitable for the dynamic analysis of laminated anisotropic plates as well as cylindrical shells of either circular or non-circular configuration. The theory accounts for parabolic variation of transverse shear strains and it is capable of satisfying zero shear traction boundary conditions at the external shell or plate surfaces, and makes no use of transverse shear correction factors. It can be considered as a transverse shear deformable analogue of the classical laminate Donnell-type and Love-type shell theories while, through certain new definitions of force and moment resultants, the higher order moment and transverse shear force resultants occurring acquire some physical substance. Under certain conditions, some dynamical problems studied earlier by the present author are considered as applications of the refined theory developed. As a further application, the present theory is employed for the study of the free vibration problem of antisymmetric angle-ply laminated closed circular cylindrical shells. This problem is solved by two different mathematical techniques; namely, the helical modal pattern approach and an approach based on Galerkin's method. Numerical results based on both solutions obtained are presented and compared and the efficiency of both approaches, with regard to the prediction of the natural frequencies of vibration, is discussed.

ABSTRACT: A general two-dimensional theory, suitable for the static and/or the dynamic analysis of transverse shear deformable laminated plates, is presented. This displacement-based theory is capable of satisfying continuity of both displacements and transverse shear stresses at the plate material interfaces. The derivation of its governing differential equations is based on the application of Hamilton's principle in conjunction with the method of Lagrange multipliers. Moreover, this new theory is capable of accounting for unlimited multiple choices of continuous displacement distributions, through the plate thickness, while, starting with the smallest possible number of independent displacement components (five, for a shear deformation theory), it is capable of further operating with as many degrees of freedom as desired. With such a double-infinite freedom, it is concluded that for the analysis of the particular laminated plate considered one may start with the solution of the governing equations of the 5-degrees-of-freedom theory derived for relatively simple choices of through-the-thickness displacement distributions. Then, either increasing the number of the degrees of freedom or reforming, suitably, the aforementioned displacement distributions, one may iteratively improve the efficiency of the theory until a sufficient degree of accuracy is achieved for the results obtained.

ABSTRACT: This paper deals with the buckling problem of antisymmetric angle-ply laminated circular cylindrical panels subjected to a uniform axial compression. Since a flat plate configuration occurs as a particular case of the cylindrical panel geometry (zero shallow angle parameter), the corresponding flat plate problem is studied as a particular case of the problem considered. The theoretical analysis is based on a nonlinear theory developed in a previous paper (Soldatos, 1992), which accounts for parabolically distributed transverse shear strains through the shell thickness. The linearized differential equations, governing the buckling behavior of a simply supported panel, are solved on the basis of Galerkin’s method. Comparisons of corresponding numerical results, based on both the refined shell theory employed and a classical Love-type shell theory, show the influence of transverse shear deformation on the buckling loads of such laminated composite panels.

ABSTRACT: This paper deals with a refined formulation of a general, geometrically nonlinear, shear deformable, static plate theory which allows a multiple choice of trial displacement and, consequently, stress distributions through the plate thickness. This is achieved with the incorporation, into a basic trial displacement approximation, of a general function of the transverse coordinate. An appropriate choice of the derivative of that function is, essentially, adequate for an a posteriori control of the transverse shear strain and stress distributions. However, a particular choice of that general function is not provided, leaving, therefore, the theory in its most general form. The development of the theory is based on the concept of small strains and moderate rotations. Its force and moment equilibrium equations are derived variationally, on the basis of the principle of the total potential energy. Under certain conditions, the present nonlinear theory becomes analogous to several linear and nonlinear plate theories available in the literature, in the sense that it can easily adopt and make use of their main characteristics.

ABSTRACT: A successive approximation method proposed and applied in connection with static and dynamic analyses of homogeneous isotropic, orthotropic and cross-ply laminated hollow cylinders and cylindrical panels is outlined and its applicability is extended in connection with corresponding thermoelastic analyses. Nevertheless, the method is further applied in connection with the buckling problem of simply supported hollow cylinders and cylindrical panels subjected to certain external mechanical loadings. To deal with finite cylinders subjected to more complicated loading that simply supported edge conditions, an approach is outlined which is suitable for corresponding analyses of hollow cylinders having fixed edge boundaries.

ABSTRACT: It is well known that composite thin-walled structures are considerably more sensitive in transverse deformation effects than corresponding structures made from isotropic materials. However, buckling studies of composite cylinders and cylindrical shells are mainly based on two-dimensional shell theories. It is only very recently that three-dimensional buckling analyses of composite cylinders subjected to certain mechanical loading have appeared in the literature [1–4].

ABSTRACT: This paper extends the applicability of the Ritz-type method presented in a previous publication [1] towards an advanced study of the influence of the edge boundary conditions on the vibration characteristics of complete, cross-ply laminated cylindrical shells. The analysis is based on a combination of the Ritz method with appropriate, complete bases of orthonormal polynomials and its subsequent application on the energy functional of the love-type version of a unified shear-deformable shell theory. As a result, two different kinds of shear deformable Love-type shell theories are employed, including versions that either fulfil or violate the continuity of the interlaminar stresses through the shell thickness. Apart from the study of the physical problem itself, several features related to the theoretical model as well as to the analytical procedure are further addressed and investigated. As far as the modelling is concerned, particular emphasis is given to the version of the parabolic shear-deformable shell theory that considers continuity of interlaminar stresses. Moreover, the relation of this version of the theory as well as its performance with respect to the corresponding older version that violates this continuity requirement [8] is further investigated. It is concluded that the accurate modelling of the interlaminar stress distribution may become a serious issue for further investigation, as it already is for the stress analysis of laminated composite structural elements.

ABSTRACT: This paper extends the applicability of a new stress analysis method (Soldatos KP, Watson PA. Acta Mech 1997;123:163–186) towards the accurate prediction of stresses within cross-ply laminated doubly curved shell segments having a rectangular plan-form. The method is based on the successful incorporation of three-dimensional elasticity information for stress distributions into a two-dimensional five-degrees-of-freedom shallow shell theory. This successful matching is achieved by means of a set of two shape functions, which are incorporated within the two-dimensional shell model whereas their form depends on the particular problem considered. In the present case, two different sets of shape functions are developed and tested, one of which is more accurate than the other is, the later being however simpler than the former.

ABSTRACT: This paper develops complex potential formalisms for the solution of the bending problem of inhomogeneous anisotropic plates, on the basis of the most commonly used refined plate theories. Being an initial step in that direction, it works out such formalisms only in connection with the bending problem of shear deformable homogeneous plates as well as plates having a special type of inhomogeneity along their thickness direction. The adopted type of inhomogeneity is however still general enough to include certain classes of plates made of functionally graded material as well as the classes of cross- and angle-ply symmetric laminates as particular cases. The basic formalism, similar to that developed by Stroh in plane strain elasticity, is detailed in relation with the equilibrium equations of a generalized plate theory that accounts for the effects of transverse shear deformation and includes conventional, refined theories as particular cases. Some interesting specializations, related to the most important of those conventional plate theories, are then presented and discussed separately. Hence, the outlined formalisms provide, for the first time in analytical form, the general solution of the partial differential equations associated with the most commonly used refined, elastic plate theories.

ABSTRACT: The initial postbuckling behavior and imperfection sensitivity of truss-type structures in which the joints do not transmit moments is determined by means of the Lyapunov-Schmidt-Koiter approach. Such structures possess local buckling modes involving the buckling of individual members, and global modes involving axial deformations of all members but no member buckling. Of particular interest is the case in which through optimization (or otherwise) a number of local and global modes are coincident. The worst shape of imperfection for this case is determined from the bifurcated equilibrium branch on which the load drops most rapidly. It is shown that this critical bifurcated branch initially involves the buckling of one member only. The general theory is illustrated by a number of examples involving two- and three-dimensional lattice columns. The leading order asymptotic results for these examples are compared to exact results obtained by tracking the appropriate equilibrium branch numerically.
References listed at the end of the paper:

ABSTRACT: Beginning with the work of Koiter in 1945, valuable insights into the postbuckling behavior of structures have been gained by Lyapunov-Schmidt decomposition of the displacements followed by an asymptotic expansion about the bifurcation point. Here this methodology is generalized to include nonlinear prebuckling behavior, as well as multiple, not necessarily coincident buckling modes. The expansion of the reduced equilibrium equations is performed about a reference point (which need not coincide with any of the bifurcation points), and applies no matter whether the modes are coincident, closely spaced, or well separated. From a variety of possible decompositions of the admissible space of displacements, two are incorporated into a finite element program. Theoretical considerations, and numerical examples in which asymptotic results are compared to ‘exact’ results, indicate that one of the decompositions has some important advantages over the other. Examples include a shallow arch, and a beam on elastic foundation problem exhibiting symmetry-breaking modal interaction.

ABSTRACT: Buckling and imperfection sensitivity are the primary considerations in analysis and design of thin shell structures. The objective here is to develop accurate and efficient capabilities to predict the postbuckling behavior of shells, including imperfection sensitivity. The approach used is based on the Lyapunov–Schmidt–Koiter (LSK) decomposition and asymptotic expansion in conjunction with the finite element method. This LSK formulation for shells is derived and implemented in a finite element code. The method is applied to cylindrical and spherical shells. Cases of linear and nonlinear prebuckling behavior, coincident as well as non-coincident buckling modes, and modal interactions are studied. The results from the asymptotic analysis are compared to exact solutions obtained by numerically tracking the bifurcated equilibrium branches. The accuracy of the LSK asymptotic technique, its range of validity, and its limitations are illustrated.

ABSTRACT: The problem of a tube under pure bending is first solved as a generalised plane strain problem. This then provides the prebifurcation solution, which is uniform along the length of the tube. The onset of wrinkling is then predicted by introducing buckling modes involving a sinusoidal variation of the displacements along the length of the tube. Both the prebuckling analysis and the bifurcation check require only a two-dimensional finite element discretisation of the cross-section with special elements. The formulation does not rely on any of the approximations of a shell theory, or small strains. The same elements can be used for pure bending and local buckling a prismatic beam of arbitrary cross-section. Here the flow theory of plasticity with isotropic hardening is used for the prebuckling solution, but the bifurcation check is based on the incremental moduli of a finite strain deformation theory of plasticity. For tubes under pure bending, the results for limit point collapse (due to ovalisation) and bifurcation buckling (wrinkling) are compared to existing analysis and test results, to see whether removing the approximations of a shell theory and small strains (used in the existing analyses) leads to a better prediction of the experimental results. The small strain analysis results depend on whether the true or nominal stress–strain curve is used. By comparing small and finite strain analysis results it is found that the small strain approximation is good if one uses (a) the nominal stress–strain curve in compression to predict bifurcation buckling (wrinkling), and (b) the true stress–strain curve to calculate the limit point collapse curvature. In regard to the shell theory approximations, it is found that the three-dimensional continuum theory predicts slightly shorter critical wrinkling wavelengths, especially for lower diameter-to-wall-thickness (D/t) ratios. However this difference is not sufficient to account for the significantly lower wavelengths observed in the tests.

ABSTRACT: Wrinkle formation at electromagnetic tube compression was simulated using finite element (FE) method. Three-dimensional (3D) calculations were performed using a staggered coupling scheme between the electromagnetic and structural sides of the problem. Introducing the tube’s contour imperfections into the FE model makes the simulation of the wrinkle formation possible. The results show good correspondence with the experiments.

ABSTRACT: Buckling load sensitivity calculations in the shell-of-revolution program FASOR are discussed. This development is based on Koiter's initial postbuckling theory, which has been generalized to include the effect of stiffness changes, as well as geometric imperfections. The implementation in FASOR is valid for anisotropic, as well as orthotropic, shells. Examples are presented for cylindrical panels under axial compression, complete cylindrical shells in torsion, and antisymmetric angle-ply cylindrical panels under edge
Shear.

ABSTRACT: Based on small-deflection buckling equation, a weighted solution for critical load is presented. Usually, it is very difficult to solve the equation for general problems, especially those with complicated boundary conditions. Axisymmetric problem was studied as an example. Influencing factors were found from the equation and averaged as the buckling load by introducing weights. To determine those weights, some special known results were applied. This method solves general complicated problems by using the solutions of special simple problems, simplifies the solving procedure and expands the scope of solvable problem. Compared with numerical solution, it also has fine precision.

ABSTRACT: Usually, fuselage structures are stiffened by longitudinal and circumferential structural elements in a way that rectangular fields evolve. In the case of modern manufacturing technologies for aircraft structures, new topologies can be produced and possibly replace a conventional fuselage design. This paper deals with the buckling analysis of metallic non-rectangular stiffened structures with triangular skin panels. In order to assess the benefits, the buckling behaviour of triangular and rectangular stiffened structures due to various load combinations is compared.

DOI: 10.1108/IJSI-08-2012-0018
ABSTRACT: Purpose – In former work, test results of cracks in aluminium panels under cyclic shear buckling showed that cracks in the tensile stress field of a buckle propagate. The main influencing factor for the crack growth rate is the maximum principle stress. A simplified approach for crack propagation analyses based on this finding showed limitations for application on larger cracks because it disregarded the increasing out-of-plane deformation for larger cracks as well as stress redistributions. The purpose of this paper is to improve the results of the simplified approach with the help of finite element method (FEM).

Design/methodology/approach – An approach for crack propagation based on FEM is presented taking into account the mutual interaction of cracks and buckling. The finite element (FE) model, which is described in detail, respects the boundary conditions of the test-set-up. Different initial crack positions, loads and panel thicknesses are analyzed. Results of the stress intensity factors KI calculated by the ABAQUS FE model provide a function which is used to run a crack propagation analysis based on Forman law.

Findings – The results of the FE-based crack propagation solution are in good agreement with test results and improve the prediction of the simplified approach. It is not restricted in terms of panel thickness, crack position or applied shear load.

Research limitations/implications – Limitations of the FE-based crack propagation solution compared to the experimental results are discussed. These are, the sensitivity of crack propagation analyses to initial crack length and deviations of the experimental settings from the ideal FE model.

Originality/value – The interaction of cracks and buckling in aluminium shells is mainly disregarded both in research and industrial work, but can be of interest considering, accidental damages in fuselage side shells. Cracks propagate under shear load as it was shown in former work. The FE modeling of the tests presented in this paper proves the mutual interactions of crack propagation and buckling deformation.

ABSTRACT: Reliable and accurate method of the experimental buckling prediction of thin-walled cylindrical shell under an eccentric load is presented. The experimental arrangement and specimens are discussed in detail, including the measurement of the geometric imperfections of the specimen's surface using a coordinate measuring machine. Different FE models, in terms of complexity, are used to simulate the experiment arrangement in an attempt to get a good agreement with the experimental buckling loads and study the effect of measured initial geometric imperfections, load eccentricity, load eccentricity position along the shell's circumferential direction and different experimental arrangement that influence the boundary conditions. It has been demonstrated that FE models with simplified rigid support conditions overestimate the prediction of the experimental buckling load even though these models included the effects of the measured initial geometric imperfections and load eccentricity. By contrast, FE models with realistically modeled support conditions achieved the best result. The average deviation "_1.59% from the experimental buckling loads was achieved using the FE model simulating the mounting devices as elastic bodies and with surface-to-surface contact interaction behavior on the support. The presented work also demonstrated the strong influence of the eccentric load position along the imperfect shell's circumferential direction on the buckling of the thin-walled shell.

ABSTRACT: The conventional degenerated shell element which involves numerical integration in three dimensions becomes inefficient when applied to multilayered shells. For the computational efficiency, layered element based on the explicit integration through thickness assumes importance. The explicit integration becomes possible due to the assumption concerning the variation of inverse Jacobian through the thickness. Depending on the level of approximation, whether linearly varying or constant Jacobian inverse along the thickness, three models are discussed. Examples of stress analysis and classical buckling are considered for the comparative studies relating to the computational efficiency and numerical accuracy. The model, which assumes linear variation of Jacobian inverse through thickness with further approximations is seen to be the best from numerical accuracy and computational efficiency points of view.

ABSTRACT: This paper presents experimental studies on buckling of cylindrical shell models under axial and transverse shear loads. Tests are carried out using an experimental facility specially designed, fabricated and installed, with provision for in-situ measurement of the initial geometric imperfections. The shell models are made by rolling and seam welding process and hence are expected to have imperfections more or less of a kind similar to that of real shell structures. The present work thus differs from most of the earlier investigations. The measured maximum imperfections are of the order of plus or minus 3 x thickness. The buckling loads obtained experimentally are compared with the numerical buckling values obtained through finite element method (FEM). In the case of axial buckling, the imperfect geometry is obtained in four ways and in the case of transverse shear buckling, the FE modelling of imperfect geometry is done in two ways. The initial geometric imperfections affect the load carrying capacity. The load reduction is considerable in the case of axial compression and is marginal in the case of transverse shear buckling. Comparisons between experimental buckling loads under axial compression, reveal that the extent of imperfection, rather than its maximum value, in a specimen influences the failure load. Buckling tests under transverse shear are conducted with and without axial constraints. While differences in experimental loads are seen to exist between the two conditions, the
numerical values are almost equal. The buckling modes are different, and the experimentally observed and numerically predicted values are in complete disagreement.

ABSTRACT: Thin cylindrical shells in large civil engineering steel shell structures such as steel silos and tanks are subject to both axial compression and internal pressure. Buckling under axial compression often governs their design. These shells are commonly constructed by joining a large number of rolled panels using many short vertical welds and continuous circumferential welds. This fabrication method leads to unique geometric imperfections which have been argued to be severely detrimental to the shell axial buckling strength. In addition, welding-induced residual stresses in these shells may also have a significant effect on this buckling strength. A review of the existing literature reveals that few previous studies have examined the buckling behavior of these shells with a rigorous treatment of the geometric imperfections and residual stresses in these shells. This thesis presents both theoretical and experimental studies aimed at correcting this important deficiency in existing knowledge. The first part of the thesis, consisting of Chapters 3-5, presents the results of theoretical studies into the characteristics of geometric imperfections measured in three large steel silos at Port Kembla, Australia, and their effect on buckling strength. In order to accurately represent these imperfections measured at non-uniformly spaced sampling points, a new iterative Fourier decomposition method was proposed. The traditional Fourier decomposition method cannot produce accurate Fourier representations, and the reasons for this difficulty are clarified in the thesis. This new iterative method was then employed in deducing accurate Fourier series representing the measured imperfections. It is explained in the thesis that these real imperfections, due to their non-zero values at the boundaries, can only be accurately represented using half-wave cosine series in the meridional direction, an important phenomenon overlooked by all previous researchers. The characteristics of the imperfections are next examined by studying the spectra of the deduced Fourier series, including both 1D and 2D Fourier series. It is shown that the dominant components of the imperfections in each shell are in the lower Fourier terms, with some of these components being closely associated with the weld pattern. Finite element analyses of the three silo shells (referred to as Shells A, B, and C) showed that these shells have buckling strengths which are much lower than those of shells with many known forms of imperfections. A systematic parametric study revealed that the buckling strength of Shell A is dominated by significant axisymmetric imperfections, while those of Shells B and C are governed by highly complex imperfections.
non-symmetric imperfections. Based on the specification of Eurocode 3, an automated computer procedure was developed to numerically 'measure' the local dimples and out-of-roundness of these shells. This was undertaken to determine the quality classes of the three shells so that their buckling strengths as predicted by Eurocode 3 could be found. A comparison between the predictions of the code and finite element results from nonlinear analyses reveals that the existing rule in Eurocode 3 is too optimistic about shells of Class A but too pessimistic about shells of Classes B and C. While detailed measurements of imperfections are available for the three large silos, the residual stresses in these shells due to welding are unknown. As residual stresses may have a significant effect on the buckling strength, an experimental study aimed at an indirect evaluation of this effect is presented in Chapters 6-8. In this experimental study, an innovative two-stage model fabrication technique was proposed and implemented with a sophisticated experimental set up for the fabrication of small models simulating large cylindrical shells with many welds. Three model shells were fabricated and tested under axial compression, each of which had a different weld pattern. The initial geometric imperfections in these model shells were precisely measured and decomposed into Fourier series. The imperfections were also found to be dominated by lower Fourier terms and closely associated with the weld patterns. The buckling loads of the model shells are very low compared to the value of a corresponding perfect shell, demonstrating the serious deleterious effect of the imperfections in these shells. Finite element buckling loads obtained from non-linear analyses with the measured imperfections accurately modeled are also presented. These buckling loads are close but slightly lower than the experimental buckling loads, indicating that the effect of residual stresses and other factors in these shells is small but beneficial, and may be safely ignored. Finally, a parametric study is presented in Chapter 9, in which the buckling behavior and strength of the three real silo shells under the combined action of axial compression and internal pressure were explored. Nonlinear finite element analyses revealed that the strengths of Shell A are considerably lower than those of Shells B and C, as the dominant imperfection components are significantly axisymmetric in Shell A, but are highly non-symmetric in Shells B and C. Comparisons between the finite element results and the predictions of Eurocode 3 indicate that the code overestimates the failure strengths of Shell A considerably. Modifications to the existing design rule are thus presented to achieve safe predictions.

Vishwanath Hegadekatte and Yahai Shi, “Buckling of beverage cans under axial loading”, SIMULIA India Regional Users Meeting, 2011

ABSTRACT: Wrinkling is one of the major defects in sheet metal forming processes. It may become a serious obstacle to implementing forming process and assembling the parts, and may also play a significant role in the wear of the tool. Wrinkling is a local buckling phenomenon that results from compressive stresses (compressive instability) e.g., in the hoop direction for axisymmetric systems such as beverage cans. In the present work, we have studied the buckling of ideal (no imposed imperfections like dents) beverage cans under axial loading both by laboratory testing and finite element analysis. Our laboratory test showed that 2 out of 11 cans fail by sidewall buckling. We have developed finite element models to study the effect of a couple of manufacturing parameters on the buckling of beverage cans. Further we have studied the buckling of dented beverage cans under axial compression through both laboratory testing and finite element analysis using Abaqus and LS-Dyna. Our results show that Abaqus did not predict sidewall buckling during axial compression of beverage cans while LS-Dyna predicted buckling in a few cases.

Pattaramon Jongpradist, Rattharong Rojbunsongsri, Thoatsanope Kannerdtong and Somchai Wongwises (Dept. of Mechanical Engineering, King Mongkut’s University of Technology Thonburi, Bangkok, Thailand), “Parametric study and optimization of a food can corrugation design using a response surface method”, Journal
of Mechanical Science and Technology, Vol. 27, No. 7, pp 2043-2052, July 2013

ABSTRACT: This paper presents the parametric design and functional optimization of a thin-walled food container with a corrugated surface. The configuration of the can corrugation should be designed to minimize the use of raw material subject to the constraints of the targeted structural performance. In the present study, the failure behaviors and the buckling strengths of a commercial food can under paneling pressure and axial loading are investigated with a series of experiments and finite element analyses. Full factorial design is implemented to study the effects of the geometric parameters of the corrugation (e.g., depth, radius, spacing and number of beadings) on its strength. Parameter optimization using a rotatable central composite design is employed to identify an optimal corrugation design by approximating the response surfaces of the can strength in terms of the significant design variables. The obtained surfaces are derived through the analysis of variance, and the suitability of the response is justified. A light-weight can body is then achieved by reduction of the can body thickness according to the required strength characteristics. Finite element analysis of the optimal model is also performed to confirm the predicted results. By using the proposed procedure, the can-body weight can be reduced by up to 12% compared with the original design.

Caitríona de Paor, Department of Civil and Environmental Engineering, University College Cork (UCC),
ABSTRACT: Thin-walled structures, also known as shells, combine light weight with high strength and are used in a diverse range of fields including aerospace engineering, civil engineering and chemical engineering. Common applications of these shells include oil and gas storage tanks, powder or liquid storage tanks in pharmaceutical plants as well as airplane frames and ship bodies. Although these thin-walled shells have a wide variety of uses, this research is motivated by storage tank collapse in the process industry. Thin-walled cylindrical tanks common in the food and biotechnology sectors are prone to buckling (or inward collapse) due to accidentally induced internal vacuum. During the sterilisation process, steam can condense, causing a reduction in volume. This results in an equivalent increase in external pressure, triggering collapse, or buckling of the tank. Such a collapse, if it occurs, tends to be catastrophic resulting in the complete destruction of the vessel (see Fig.1). Notwithstanding that the basis of this type of failure is understood and can generally be averted, it is still a regular occurrence, often due to the inadvertent closure of line control valves during a sterilisation cycle.

ABSTRACT: The buckling capacity of thin cylindrical shells subject to uniform external pressure is investigated in this paper. Thin cylindrical shells are known to be highly sensitive to geometric and material imperfections such as wall thickness variation, non-circularity and random geometric imperfections. The effect of imperfection on the buckling load is studied using finite element (FE) models and laboratory experiments. Imperfection measurements are taken on small scale steel cans and these measurements are modelled and analysed using a geometrically non-linear static finite element analysis. The cans are then tested in the laboratory and the results compared with those predicted by the FE models and theory.

varying thickness subjected to uniform external pressure”. Thin-Walled Structures, 44(8), pp. 904–909.

ABSTRACT: Analysis of indenting, buckling and piercing of aluminum beverage cans using both physical testing and computer simulation was performed in order to develop a better understanding of the sidewall structural strength of the cans. This understanding can be used to help design better cans and/or improve manufacturing processes. Simulation of the sidewall indentation was done with an impacting sphere. Parameters investigated included the sphere size and velocity, and the impact height along the sidewall. Buckling simulation of the dented can was then performed. Results from the deformed can buckling model compared well with physical testing based on buckled geometry, buckling load, and external work to buckle. Severe damage to a can that might occur during the manufacturing process was investigated by studying piercing of the can sidewall. Impacts of 5 and 10 m/s were performed with both blunt (flat) and sharp (45° tip) steel rods. It was found that separated elements with tied nodal constraints more accurately represent the failure behavior of the can subjected to a piercing load than merged element nodes. It was also found that the more crushing a can
undergoes before piercing occurs, the more energy the can material absorbs. However, there is an upper limit to the crushing based on the speed and shape of the impactor.

“Model validation for the collapse of spherical shells” (publisher and date not given in the pdf file. The most recent citation is 2003.)

ABSTRACT: There is a growing need to quantify the level of credibility that can be associated with model predictions. Model verification and validation (V&V) is a methodology for the development of models that can be used to make engineering predictions with quantified confidence. Model V&V procedures are needed by government and industry to reduce the time, cost and risk associated with component and full-scale testing of products, materials, and weapons. Consequently, the development of guidelines and procedures for conducting a V&V program are currently being defined by a broad spectrum of researchers. This paper describes an ongoing effort to validate a model that predicts the collapse load of a spherical shell structure. Inherent variations in geometric shape and material parameters are included in the uncertainty model. Results from a recently completed probabilistic validation test to measure the variation in collapse load are compared to the predicted collapse load variation.

ABSTRACT: The collapse of shell-shaped membranes due to buckling is investigated experimentally using droplets of latex suspension left to dry. The evaporation of water, limited by diffusion in air, first leads to the formation, on the surface, of a spheroidal envelope of gel. During the later evolution, spontaneous buckling of this envelope occurs. The later evolution leads to a large-amplitude invagination and for certain concentrations to a transition to a toroidal shape. This specific evolution of a spheroidal envelope, linked with its inhomogeneous mechanical properties, is similar to that observed during the gastrulation of sea-urchin embryos.

[13] This process was observed in the drying of a hydro-soluble polymer solution, Dextran, deposited on super-hydrophobic substrates. In that case, the resulting rigid glassy shell being transparent, the growth of a basal bubble inside the drop is observed directly.

ABSTRACT: We herein present the results of a study of the direct fabrication of buckled patterns in flexible organic light-emitting devices (FOLEDs) that had a conducting polymer anode on a polyethersulfone substrate. These patterns were produced spontaneously by the thermal deposition of an aluminum cathode on an electroluminescent (EL) composite layer. The polymer used for the anode was modified poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) and the EL layer was composed of a solution-processable small molecular composite including phosphorescent Iridium complex mixed with a poly(vinylcarbazole) host. It is shown that FOLEDs produced with buckled patterns can exhibit a luminance as high as ca. 14,900 cd/m² with a peak efficiency of 50.5 cd/A. The patterned structure formed by the buckling of the EL layer allows FOLEDs to be produced with a high peak external quantum efficiency of 15% with an increase in light extraction by a factor of ca. 3.1. These results show that spontaneous buckling yields patterned structures that offer considerable promise for the production of high performance, reproducible and reliable FOLEDs.
E Bagherizadeh, Y Kiani, M.R and M Sadighi. (Department of Mechanical Engineering, Amirkabir University, Hafez street Tehran), “Elastic buckling of FGM cylindrical shell surrounded by an elastic foundation”, 2nd International Conference on Composites: Characterization, Fabrication and Application, 1983 (should the date be 2013?).

ABSTRACT: This research inspects the elastic buckling of FGM cylindrical shell, resting on two-parameters elastic foundation, subjected to external pressure load. Material properties of functionally graded cylindrical shell are graded in the thickness direction according to a power law direction. Theoretical formulations are derived based on the classical shell theory. The effects of shell geometry, volume fraction exponent, and foundation parameters on critical buckling load of FGM cylindrical shells are investigated. It is inferred from the results that the elastic foundation postpones the critical buckling load and swifts mode shapes of elastic buckling.

ABSTRACT: In this article, non-linear stability analysis of monomorph functionally graded piezoelectric material beams is investigated based on the Ritz formulation of the finite elements method. Each thermo–electro–mechanical property of the beam is assumed to be graded across the thickness based on a power law form. Geometrically non-linear behaviour of the structures is included based on the von-Karman simplifications of the complete Green strain tensor. Timoshenko beam theory and trigonometric distribution of electrical potential assumptions are held to obtain the governing equations, describing the equilibrium state of the beam. Non-linear equilibrium equations are solved based on both Newton–Raphson and Picard iterative techniques. It is shown that response of a monomorph functionally graded piezoelectric material beam cannot be considered as a bifurcation-point behaviour. While in some types of boundary conditions, there are critical temperatures through the load–deflection path of the beam.

ABSTRACT: Based on the Donnell theory of shells combined with the von-Karman type of geometrical nonlinearity, three coupled equilibrium equations for a through-the-thickness functionally graded cylindrical shell embedded in a two parameter Pasternak elastic foundation are obtained. Equivalent properties of the shell are obtained based on the Voigt rule of mixture in terms of a power law volume fraction for the constituents. Properties of the constituents are considered to be temperature dependent. The temperature profile through the shell thickness is obtained by means of the central finite difference method. Linear prebuckling analysis is performed to obtain the prebuckling forces of the cylindrical shell. Stability equations are derived based on the well-known adjacent equilibrium criterion. Three coupled partial differential stability equations are solved with the aid of a hybrid Fourier-GDQ method. After validating the numerical results, some parametric studies are conducted to investigate the influence of various parameters, especially foundation interaction. It is shown that

ABSTRACT: In the present work, genetic algorithm (GA) and artificial neural networks (NN) are used to...
optimize the stacking sequence of a laminated cylindrical shell with natural frequency and buckling load as the objective functions. Vibration analysis is based on fully three dimensional elasticity equations and the stability solution is presented using equations governed by the Donnell type of approximation. Artificial neural network models are developed and tested to predict the natural frequency and buckling load of the structure. A genetic algorithm then uses the trained neural network prediction models to obtain the maximum fundamental frequency and critical buckling load, simultaneously. Optimization is performed for the shell geometry with different sets of thickness to radius and length to radius ratios. The results obtained, using the NN-GA combination are compared with those using the GA directly. A satisfactory verification is observed meanwhile a considerable reduction is achieved in computational time.

ABSTRACT: This paper is concerned with the elastic buckling of stiffened cylindrical shells by rings and
stringers made of functionally graded materials subjected to axial compression loading. The shell properties are assumed to vary continuously through the thickness direction. Fundamental relations, the equilibrium and stability equations are derived using the Sander’s assumption. Resulting equations are employed to obtain the closed-form solution for the critical buckling loads. The results show that the inhomogeneity parameter and geometry of shell significantly affect the critical buckling loads. The analytical results are compared and validated using the finite element method.

ABSTRACT: The static stability analysis of stiffened functionally graded cylindrical shells by isotropic rings and stringers subjected to axial compression is presented in this paper. The Young's modulus of the shell is taken to be function of the thickness coordinate. The fundamental relations, the equilibrium and stability equations are derived using the Sander's assumption. Resulting equations are employed to obtain the closed-form solution for the critical axial loads. The effects of material properties, geometric size and different material coefficient on the critical axial loads are examined. The analytical results are compared and validated using the finite element model.

ABSTRACT: The nonlinear strain-displacement relations in general cylindrical coordinates are simplified by Sander's assumptions for the cylindrical shells and substituted into the total potential energy function for thermoelastic loading. The Euler equations are then applied to the functional of energy, and the general thermoelastic equations of nonlinear shell theory are obtained and compared with the Donnel equations. An improvement is observed in the resulting equations as no length limitations are imposed on a thin cylindrical shell. The stability equations are then derived through the second variation of potential energy, and the same improvements are extended to the resulting thermoelastic stability equations. Based on the improved equilibrium and stability equations, the magnitude of thennoelastic buckling of thin cylindrical shells under different thermal loadings is obtained. The results are extended to short and long thin cylindrical shells.

ABSTRACT: In this article the buckling of specially orthotropic laminated composite cylindrical shells is investigated. The nonlinear equilibrium equations based on the Sander's assumption of simplified nonlinear strain-displacement relations and the linearized stability equations for a circular cylindrical thin shell are considered. The equations include the rotations and transverse shear force. The resulting equations are improved compared to the Donnell stability equations. The mechanical and thermal buckling loads of a thin composite circular cylindrical shell based on Donnell and improved stability equations are obtained.

**ABSTRACT:** The nonlinear strain-displacement relations for thin orthotropic plates are considered and substituted into the potential energy function of thermoelastic loadings. The Euler equations are then applied to the functional of energy, and the general thermoelastic equations of thin orthotropic plates are obtained. The stability equations are then derived through the second variation of the potential energy function. The thermal loadings include the uniform temperature rise, axial temperature difference, and the gradient temperature through the thickness. The thermoelastic buckling of a thin plate under these thermal loadings is investigated. The results are extended to isotropic and orthotropic thin plates with and without imperfections.

**ABSTRACT:** Buckling, free and forced vibration analyses of orthotropic plates are studied numerically using Isogeometric analysis. The present formulation is based on the classical plate theory (CPT) while the NURBS basis function is employed for both the parametrization of the geometry and the approximation of plate deflection. An efficient and easy-to-implement technique is used for imposing the essential boundary conditions. Numerical examples for free and forced vibration and buckling of orthotropic plates with different boundary conditions and configurations are considered. The numerical results are compared with other existing solutions to show the efficiency and accuracy of the proposed approach for such problems.

**ABSTRACT:** Thermoelastic stability of thin perfect spherical shells based on deep and shallow shell theories is presented. To derive the equilibrium and stability equations according to deep shell theory, Sanders's nonlinear kinematic relations are substituted into the total potential energy function of the shell and the results are extremized by the Euler equations in the calculus of variation. The same equations are also derived based on quasi-shallow shell theory. An improvement is obtained for equilibrium and stability equations related to the deep shell theory in comparison with the same equations related to shallow shell theory. Approximate one-term solutions that satisfy the boundary conditions are assumed for the displacement components. The Galerkin-Bubnov method is used to minimize the errors due to this approximation. The eigenvalue solution of the stability equations is obtained using computer programs. For several thermal loads it is found that the deep shell theory results are slightly more stable as compared to the shallow shell theory results under the same thermal loads. The results are compared with the Algor finite element program and other known data in the literature.

ABSTRACT: This study presents the buckling analysis of radially loaded solid circular plate made of functionally graded material. The edge of the plate is either simply supported or clamped and the plate is assumed to be geometrically perfect. The equilibrium and stability equations, derived through variational formulation, are used to determine the prebuckling forces and critical buckling loads. The equations are based on Love–Kirchhoff hypothesis and the Sander's non-linear strain-displacement relation. The results are verified with the known results in the literature.

ABSTRACT: Equilibrium and stability equations of a rectangular plate made of functionally graded material under thermal loads are derived, based on the classical plate theory. When it is assumed that the material properties vary as a power form of the thickness coordinate variable, z, and when the variational method is used, the system of fundamental differential equations is established. The derived equilibrium and stability equations for functionally graded plates are identical with the equation for homogenous plates. Buckling analysis of functionally graded plates under four types of thermal loads is carried out, resulting in closed-form solutions. The buckling loads are reduced to the critical buckling temperature relations for functionally graded plates with linear composition constituent materials and homogeneous plates. The results are validated with the reduction of the buckling relations for functionally graded plates to those of isotropic homogeneous plates given in the literature.

ABSTRACT: Equilibrium and stability equations of a rectangular plate made of functionally graded material (FGM) under thermal loads are derived, based on the higher order shear deformation plate theory. Assuming that the material properties vary as a power form of the thickness coordinate deformation variable z and using the variational method, the system of fundamental partial differential equations is established. The derived equilibrium and stability equations for functionally graded plates (FGPs) are identical to the equations for laminated composite plates. A buckling analysis of a functionally graded plate under four types of thermal loads is carried out and results in closed-form solutions. The critical buckling temperature relations are reduced to the respective relations for functionally graded plates with a linear composition of constituent materials and homogeneous plates. The results are compared with the critical buckling temperatures obtained for functionally graded plates based on classical plate theory given in the literature. The study concludes that higher order shear deformation theory accurately predicts the behavior of functionally graded plates, whereas the classical plate theory overestimates buckling temperatures.

ABSTRACT: In this article, the thermal buckling loads of cylindrical shells of functionally graded material are considered. Derivation of equations are based on the first-order shell theory and the Sanders kinematic equations. The derived equilibrium and stability equations for the functionally graded cylindrical shell are identical with the equations for homogeneous shells expressed in the form of forces and moments per unit length. Assuming that the material properties vary linearly through the thickness direction, the system of fundamental partial differential equations in terms of the displacement components is established. Buckling analysis of functionally graded cylindrical shells under two types of thermal loads with simply supported boundary conditions are carried out. Results are obtained in the analytical form. The results are validated with the known data in the literature.

ABSTRACT: A thermal buckling analysis of an imperfect functionally graded cylindrical shell is considered using the Wan-Donnell model for initial geometrical imperfections. Derivation of the equations is based on the first-order classical shell theory using the Sanders nonlinear kinematic relations. Results for the buckling loads are obtained in the closed form. The effects of shell geometry and volume fraction exponent of functionally graded material on the buckling load are investigated. The results are validated with known data in the literature.

ABSTRACT: In this paper, thermal instability of shallow spherical shells made of functionally graded material (FGM) is considered. The governing equations for a thin spherical shell based on the Donnell-Mushtari-Vlasov theory are obtained. The equations are derived using the Sanders simplified kinematic relations and variational method. It is assumed that the mechanical properties vary linearly through the shell thickness. The constituent material of the functionally graded shell is assumed to be a mixture of ceramic and metal. Analytical solutions are obtained for three types of thermal loading including Uniform Temperature Rise (UTR), Linear Radial Temperature (LRT), and Nonlinear Radial Temperature (NRT). The results are validated with the known data in the literature.

ABSTRACT: A thermal buckling analysis is presented for functionally graded cylindrical shells that are integrated with surface-bonded piezoelectric actuators and are subjected to the combined action of thermal load and constant applied actuator voltage. The material properties are assumed to vary as a power form of the thickness coordinate. Derivation of the equations is based on the higher-order shear deformation shell theory
using the Sanders nonlinear kinematic relations. Results for the buckling temperatures are obtained in the closed form solution. The effects of the applied actuator voltage, shell geometry, and volume fraction exponent of functionally graded material on the buckling temperature are investigated. The results for simpler states are validated with known data in the literature.

ABSTRACT: Elastic buckling analysis of imperfect FGM cylindrical shells under axial compression in thermal environments is carried out, using two different models for geometrical imperfections. The material properties of the functionally graded shell are assumed to vary continuously through the thickness of the shell according to a power law distribution of the volume fraction of the constituent materials, also temperature dependency of the material properties is considered. Derivation of equations is based on classical shell theory using the Sanders nonlinear kinematic relations. The stability and compatibility equations for the imperfect FGM cylindrical shell are obtained, and the buckling analysis of shell is carried out using Galerkin’s method. The novelty of the present work is to obtain closed form solutions for critical buckling loads of the imperfect FGM cylindrical shells, which may be easily used in engineering design applications. The effects of shell geometry, volume fraction exponent, magnitude of initial imperfections, and environment temperature on the buckling load are investigated. The results reveal that initial geometrical imperfections and temperature dependency of the material properties play major roles in dictating the bifurcation point of the functionally graded cylindrical shells under the action of axial compressive loads. Also results show that for a particular value of environment temperature, critical buckling load is almost independent of volume fraction exponent.

ABSTRACT: The thermomechanical instability of truncated conical shells made of functionally graded material under different uniform temperature rises is studied in this paper. It is assumed that the shell is a mixture of metal and ceramic, where its properties change as functions of the shell thickness. The mechanical properties of metal and ceramic are assumed to be temperature dependent. The governing equations are based on the first-order theory of shells and the Sanders non-linear kinematics equations. The results are obtained under different thermal conditions for three types of mechanical loading, namely hydrostatic pressure, axial compressive loading, and their combination. The results are validated with the known data in the literature.

ABSTRACT: The thermomechanical buckling of simply supported thin shallow spherical shells made of functionally graded material is presented in this paper. A metal-ceramic functionally graded shell with a power law distribution for volume fraction is considered, where its properties vary gradually through the shell thickness direction from pure metal on the inner surface to pure ceramic on the outer surface. The mechanical properties of the metal and ceramic are assumed to be temperature dependent. The governing equations are derived using the first-order shell theory of Love and Kirchhoff, the Donnell-Mushtari-Vlasov kinematics
equations, and the calculus of variations. The analytical results are obtained for various types of loadings. The detailed results are compared and validated with the known data in the literature.

ABSTRACT: In this study, the mechanical buckling of functionally graded material cylindrical shell that is embedded in an outer elastic medium and subjected to combined axial and radial compressive loads is investigated. The material properties are assumed to vary smoothly through the shell thickness according to a power law distribution of the volume fraction of constituent materials. Theoretical formulations are presented based on a higher-order shear deformation shell theory (HSDT) considering the transverse shear strains. Using the nonlinear strain–displacement relations of FGMs cylindrical shells, the governing equations are derived. The elastic foundation is modelled by two parameters Pasternak model, which is obtained by adding a shear layer to the Winkler model. The boundary condition is considered to be simply-supported. The novelty of the
present work is to achieve the closed-form solutions for the critical mechanical buckling loads of the FGM cylindrical shells surrounded by elastic medium. The effects of shell geometry, the volume fraction exponent, and the foundation parameters on the critical buckling load are investigated. The numerical results reveal that the elastic foundation has significant effect on the critical buckling load.

ABSTRACT: Thermal buckling analysis of deep imperfect functionally graded (FGM) spherical shell is considered in this paper. A mixture of ceramic and metal is considered for the FGM shell and the material properties, such as the modulus of elasticity and coefficient of thermal expansion, vary by a power law function through the thickness. Employing the Sanders non-linear kinematic relations, total potential energy function is derived and the equilibrium and stability equations are obtained for the imperfect shell. Approximate solutions satisfying the simply supported boundary condition are assumed and using the Galerkin method the error due to the approximation is minimized. The geometrically imperfect shell is considered and three types of thermal loadings, such as the uniform temperature rise (UTR), linear temperature rise through the thickness (LTR), and non-linear temperature rise through the thickness (NLTR) are considered and their associated buckling temperatures are obtained. The effects of different temperature functions and the magnitude of initial geometric imperfection are examined on the thermal buckling loads of the shell.

M.R. Eslami and J. Torabi, “Thermal buckling of functionally graded truncated conical shells”, 20th Annual Conference of Mechanical Engineering, (publisher and date not given)

ABSTRACT: In this paper, linear thermal buckling of a thin functionally graded material (FGM) truncated conical shell subjected to the uniform temperature rise loading is presented. Material properties of the FGM shell are assumed to vary continuously through the thickness direction. Equilibrium and stability equations are obtained based on the variational approach considering the first order shell theory and Sander's nonlinear kinematics equations. Galerkin method is adopted to obtain the critical buckling temperature difference of the conical shell. The results are compared with the known data in the literature. Upon the numerical results, effects of various parameters such as semi-vertex angel and FG parameter of material distribution are investigated on thermal instability of the conical shell.

DEFINITIONS: One of the failure phenomena in thin circular shells is instability due to buckling. When the conical shells with simply supported boundary conditions are subjected to thermal loads, due to the temperature changes, compressive stresses may be produced and lead to the buckling of the shell. Recent achievements in material engineering are the development of smart materials, such as piezoelectric structures. In this entry, thermal buckling analysis of isotropic conical shells embedded with piezoelectric layers and subjected to uniform temperature rise is investigated. The governing equations are obtained based on the variational approach and the Donnell and Sanders shell theories. Immovable simply supported boundary conditions are assumed at both ends of the cone. Considering membrane solutions of linear equilibrium equations and the effect of piezoelectric layers, the prebuckling force resultants are obtained. Finally, the Galerkin method is applied to stability equ..

• Wind Issues... –Shell Buckling –Tank Overturning –Roof Damage
• Flooding Issues... –Floating Off of Foundation –Shell Buckling

Summary:
• Design for the expected conditions (primarily wind)
• Maintain your tanks
• A well maintained tank will fair better than a ragged tank.
• Add liquid to prevent flotation, overturning, wind buckling, & shell buckling from external pressure (rising water)
• A full tank will fair better than an empty tank.
Some very nice photographs of very large buckled tanks.

ABSTRACT: The buckling of thin shells is in general very sensitive to imperfections. A consistent numerical analysis for the determination of the buckling load has to consider the “correct” imperfections. Instead of assuming load or deformation imperfections, a new approach is presented which applies to the minimum of perturbation energy with respect to all possible disturbance patterns as criteria for the stability degree of the shell. Thus, by starting from the perfect shell the engineer may compute the least energy necessary to reach the critical state of equilibrium and may introduce this approach for determining safety against buckling. A nonlinear eigenvalue problem is solved to find the adjacent buckling mode of smallest energy. The concept has been developed so far only for elastically buckling shells of arbitrary shape. As examples to demonstrate the method, cylindrical shells under axial loads are investigated.

ABSTRACT: We revisit the classical problem of the buckling of a long thin axially compressed cylindrical shell. By examining the energy landscape of the perfect cylinder we deduce an estimate of the sensitivity of the shell to imperfections. Key to obtaining this is the existence of a mountain pass point for the system. We prove the existence on bounded domains of such solutions for all most all loads and then numerically compute example mountain pass solutions. Numerically the mountain pass solution with lowest energy has the form of a single dimple. We interpret these results and validate the lower bound against some experimental results available in the literature.

ABSTRACT: A perturbation strategy is outlined, which enables systematic calculation of secondary solution paths in the nonlinear solution manifold of thin-walled imperfection-sensitive structures. The strategy consists of three steps. First, the perturbation pattern is determined, second its critical amplitude is calculated to reach a secondary path and third the iteration to the secondary path itself is performed. The steps are formulated by means of constraints in the solution space. Examples are given for application to arches, plate strips and shells.

ABSTRACT: Among all mechanical joining processes, welding has been employed for its advantage in design flexibility, cost saving, reduced overall weight and enhanced structural performance. However, for structures made of relatively thin components, welding can introduce significant buckling distortion which causes loss of dimensional control, structural integrity and increased fabrication costs. Different parameters can affect buckling behavior of welded thin structures such as, heat input, welding sequence, dimension of structure. In this work, a 3-D thermo elastic-viscoplastic finite element analysis technique is applied to evaluate the effect of shell dimensions on buckling behavior and entropy generation of welded thin shells. Also, in the present work, the approximated longitudinal transient stresses which produced in each time step, is applied to the 3D-eigenvalue analysis to ratify predicted buckling time and corresponding eigenmode. Besides, the possibility of buckling prediction by entropy generation at each time is investigated and it is found that one can predict time of buckling with drawing entropy generation versus out of plane deformation. The results of finite element analysis show that the length, span and thickness of welded thin shells affect the number of local buckling, mode shape of global buckling and post-buckling behavior of welded thin shells.

Abstract: Ten cylindrical pressure vessels with torispherical ends, all of the same constant nominal thickness, were tested under internal pressure to observe the buckling behaviour of the toroidal knuckle. All specimens were of constant internal cylinder diameter to thickness ratio of 531.5. The sphere radius was equal to the cylinder diameter and only the torus radius was varied. Buckling was detected by rotating probes at the sphere/torus junction and at the mid-point of the torus. The buckling pressure increased with increasing torus radius and the two specimens with the largest torus radii did not buckle. For all specimens, the change of meridional shape with increase in pressure was measured. For one specimen, strain gauges were used to study the variation of circumferential strain on the inside and outside surface at the sphere/torus junction due to variation in thickness round the circumference. A simple theoretical expression for the buckling pressure, similar to the Rankine formula for a strut, is suggested.

ABSTRACT: Hamilton Principle was used to derive the general governing equations of nonlinear dynamic stability for laminated cylindrical shells in which factors of nonlinear large deflection, transverse shear and longitudinal inertia force were included. Equations were solved by variational method. Analysis reveals that under the action of dynamic load, laminated cylindrical shells will fall into a state of parametric resonance and enter into the dynamic unstable region that causes dynamic instability of shells. Laminated shells of three typical composites were computed: i.e. T300/5 208 graphite epoxy, E-glass epoxy, and ARALL shells. Results show that all factors will induce important influence for dynamic stability of laminated shells. So, in research of dynamic stability for laminated shells, to consider these factors is important.

“Theoretical studies on dynamic stability of composite laminated cylindrical shells subjected to periodic loading”, Proceedings of the School of Engineering of Tokai University, 26, 50, 2001, Tokai University  
ABSTRACT: This paper deals with the problem of dynamic stability of angle-ply and cross-ply laminated cylindrical shells subjected to periodic axial compressive loading, external pressure and hydrostatic pressure. Several cases of the dynamic stability problem for composite laminated cylindrical shells are solved explicitly. The solutions for the prebuckling motion and the perturbated motion are obtained by the use of Galerkin's method. Calculations are carried out for composite laminated cylindrical shells and the instability regions are determined by utilizing Mathieu's equation. The inevitability of dynamically unstable behavior is proved analytically and the effects of various factors, such as static buckling, load ratio, number of layers, stacking sequence, vibrated amplitude, fundamental frequency, lamination angle, dimension of cylinder and dynamic unstable mode, are clarified.  

ABSTRACT: The parametric instability characteristics of doubly curved panels subjected to various in-plane static and periodic compressive edge loadings, including partial and concentrated edge loadings are studied using finite element analysis. The first order shear deformation theory is used to model the doubly curved panels, considering the effects of transverse shear deformation and rotary inertia. The theory used is the extension of dynamic, shear deformable theory according to the Sander’s first approximation for doubly curved shells, which can be reduced to Love's and Donnell's theories by means of tracers. The effects of static load factor, aspect ratio, radius-to-thickness ratio, shallowness ratio, boundary conditions and the load parameters on the principal instability regions of doubly curved panels are studied in detail using Bolotin's method. Quantitative results are presented to show the effects of shell geometry and load parameters on the stability boundaries. Results for plates and cylindrical shells are also presented as special cases and are compared with those available in the literature.  

ABSTRACT: The parametric resonance characteristics of laminated composite doubly curved panels subjected to various in-plane static and periodic compressive edge loadings, including partial and concentrated edge loading are studied using finite element analysis. The first order shear deformation theory is used to model the doubly curved panels, considering the effects of transverse shear deformation and rotary inertia. The theory used is the extension of dynamic, shear deformable theory according to the Sander’s first approximation for doubly curved laminated shells, which can be reduced to Love’s and Donnell’s theories by means of tracers. The effects of number of layers, static load factor, side to thickness ratio, shallowness ratio, boundary
conditions, degree of orthotropy, ply orientations and various load parameters on the principal instability regions of doubly curved panels are studied in detail using Bolotin’s method. Quantitative results are presented to show the effects of shell geometry, lamination details and load parameters on the stability boundaries. Results of plates and cylindrical shells are also presented as special cases and are compared with those available in the literature.

ABSTRACT: The present investigation deals with the dynamic stability behavior of laminated composite curved panels with cutouts subjected to in-plane static and periodic compressive loads, analyzed using the finite element method. A generalized shear deformable Sanders’ theory with tracers is used in this study. Numerical results obtained for vibration and buckling of composite panels with cutouts compare well with literature. The principal dynamic instability region of composite perforated panels is obtained using Bolotin’s approach. The study reveals that curved panels with cutouts depict higher stiffness with the addition of curvatures. The laminated hyperbolic paraboloid panel shows the highest stiffness with the onset of instability at higher excitation frequencies. The effect of curvature in laminated composite curved panels is reduced with an increase in size of the cutout. The principal instability regions are influenced by the lamination parameters. Thus, the laminate construction, coupled with cutout geometry, can be used to the advantages of tailoring during design of composite structures for practical applications.

Sahoo (Department of Civil Engineering, NIT, Rourkela-769008, Orissa, India), “Parametric Instability of Laminated Composite Doubly Curved Shell Panels Subjected to Hygrothermal Environment”, (publisher and date not given in the pdf file. The most recent citation is dated 2003.)
ABSTRACT: The dynamic stability behavior of laminated composite shells subjected to hygrothermal loadings are studied in the present investigation. A simple laminated model is developed for the vibration and stability analysis of laminated composite shells subjected to hygrothermal conditions. A computer program based on
FEM in MATLAB environment is developed to perform all necessary computations. An eight-node isoparametric element is employed in the present The analysis with five degrees of freedom per node. Element elastic stiffness matrices, mass matrices, geometric stiffness matrix due to mechanical and hygrothermal loads and load vectors are derived using the principle of minimum potential energy. Quantitative results are presented to show the effects of curvature, ply-orientation, degrees of orthotropy and static load factors of laminate on dynamic stability of composite shells for different temperatures and moisture concentrations.

ABSTRACT: This article deals with the stability analysis of angle-ply laminated composite twisted panels using the finite element method. Here, a eight-noded isoparametric quadratic shell element is used to develop the finite element procedure. To investigate the vibration and stability behavior of twisted panels, the effect of various geometrical parameters like angle of twist, aspect ratio, lamination parameters, shallowness ratio, etc. are studied. The influence of various parameters on the vibration and stability characteristics of twisted panels have been examined. Numerical results are presented to show the effects of pretwist angles, geometry, and lamination details on the stability characteristics of twisted plates.

ABSTRACT: The static stability of the curved panels subjected to varieties of non-uniform loading including partial and concentrated in-plane compressive edge loading is studied using finite element method, considering the effects of transverse shear deformation and rotary inertia. An eight nodded quadratic isoparametric element is employed in the present analysis. The study reveals that the stability behaviour of the flat and curved panels is greatly influenced by the geometry, boundary conditions, the type and position of loads.

ABSTRACT: The present study deals with the dynamic stability of laminated composite pre-twisted cantilever panels. The effects of various parameters on the principal instability regions are studied using Bolotin's approach and finite element method. The first-order shear deformation theory is used to model the twisted curved panels, considering the effects of transverse shear deformation and rotary inertia. The results on the dynamic stability studies of the laminated composite pre-twisted panels suggest that the onset of instability occurs earlier and the width of dynamic instability regions increase with introduction of twist in the panel. The instability occurs later for square than rectangular twisted panels. The onset of instability occurs later for pre-twisted cylindrical panels than the flat panels due to addition of curvature. However, the spherical pre-twisted panels show small increase of nondimensional excitation frequency.

ABSTRACT: The buckling and vibration analysis of cross-ply laminated cantilever twisted plates are investigated. The analysis is carried out using the finite element method with first order shear deformation theory. An eight-nodded isoparametric quadratic element is employed in the present analysis with five degrees of freedom per node. The element elastic stiffness matrix, mass matrix and load vector are derived using the principle of Stationery Potential Energy. Plane stress analysis is carried out using the finite element method to determine the stresses and these are used to formulate the geometric stiffness matrix. The overall stiffness and mass matrices are obtained by assembling the corresponding element matrices using skyline technique. The eigenvalues are determined using subspace iteration scheme. Extensive results are presented to show the effects of various parameters such as aspect ratio, number of layers, angle of twist, ply orientation, etc on the buckling and vibration behavior of cross-ply laminated twisted cantilever plates. It was noticed that both the non-dimensional buckling and frequency parameter decreased with the increase in the angle of twist of the plate. The non-dimensional frequency parameters as well as buckling loads also increase with increase in the number of layers of the plate. There is significant decrease in the buckling load of the plate with increase of aspect ratio unlike the frequencies of vibration. These can be used to advantage in tailoring of laminated cross-ply twisted cantilever plates.
ABSTRACT: The present paper deals with the study of the vibration, buckling and parametric instability characteristics of general laminated cross-ply pre-twisted cantilever flat and curved panels. The effects of angles of pre-twist, aspect ratio, static load factor, and the lamination parameters of the cross-ply twisted curved panels on the principal instability regions are studied using Bolotin's approach. An eight-noded isoparametric quadratic shell element with five degrees of freedom per node is used to develop the finite element procedure. The first order shear deformation theory is used to model the twisted cross-ply curved panels considering the effects of transverse shear deformation and rotary inertia. The linear part of the strain is used to derive the elastic stiffness matrix and the non-linear part of the strain is used to derive the geometric stiffness matrix. The global matrices are obtained by assembling the corresponding element matrices using skyline technique. Subspace iteration method is used throughout to solve the eigenvalue problem. Reduced integration technique is adopted in order to avoid possible shear locking. Based on the parametric studies, it is found that the instability behavior of twisted cross-ply cantilever panels is greatly influenced by the geometry, material, angle of twist and lamination parameters. So, this can be used to advantage in tailoring during design of cross-ply twisted cantilever panels.

ABSTRACT: This paper reviews most of the research done in the field of tensile buckling characteristics pertaining to aerospace structural elements with special attention to local buckling and parametric excitation due to periodic loading on plate and shell elements. The concepts of buckling in aerospace structures appear as the result of the application of a global compressive applied load or shear load. A less usual situation is the case, in which a global tensile stress creates buckling instability and the formation of complex spatial buckling pattern. In contrast to the case of a pure compression or shear load, here the applied macroscopic load has no compressive component and is thus globally stabilizing. The instability stems from a local compressive stress induced by the presence of a defect, such as a crack or a hole, due to partial or non-uniform applied load at the far end. This is referred to as tensile buckling. This paper discusses all aspects of tensile buckling, theoretical and experimental. Its far reaching applications causing local instability in aerospace structural components are discussed. The important effects on dynamic stability behaviour under locally induced periodic compression have been identified and influences of various parameters are discussed. Experimental results on simple and combination resonance characteristics on plate structures due to tensile buckling effects are elaborated. References listed at the end of the paper:

Susumu Toda (National Aerospace Laboratory, Tokyo, Japan), “Buckling of cylinders with cutouts under axial compression” (Experimental results are presented for circular cylindrical shells with both reinforced and unreinforced holes under axial compression), Experimental Mechanics, Vol. 23, No. 4, 1982, pp. 414-417, doi: 10.1007/BF02330057

ABSTRACT: An experimental study was carried out to clarify the effects of circular holes on the buckling of circular cylinders under axial compression. The effect of reinforcements was also examined by placing thin annular plates around the cutouts. Tests were performed on polyester shells with radius-to-thickness ratio of 400 and 100 and with two diametrically opposed circular holes. If a hole is small enough, there are no appreciable effects on the buckling strength of the cylinder. However larger cutouts result in a significant reduction of the buckling load. When doublers are placed around the holes, the buckling load approaches the value for the complete cylinder with no cutouts as the stiffening volume increases.

ABSTRACT: The tensile buckling and vibration behaviour of curved panels of square planform subjected to combinations of tension-tension, tension-compression and compression-compression edge loadings have been studied using the finite element method. The first order shear deformation theory is used to model the doubly curved panels, considering the effects of transverse shear deformation and rotary inertia. The theory used is extended from the dynamic, shear deformable theory based on the Sander’s first approximation for doubly curved shells, which can be reduced to Love’s and Donnell’s theories by means of tracers. The in-plane non-uniform stress field has been analysed under plane-stress conditions with reasonable accuracy. The effects of biaxial concentrated and patch loading on the edges are also considered in the analysis.

ABSTRACT: This paper deals with the study of vibration and dynamic instability characteristics of laminated composite doubly curved panels subjected to non-uniform follower load, using finite element approach. First order shear deformation theory is used to model the doubly curved panels, considering the effects of shear deformation and rotary inertia. The formulation is based on the extension of dynamic, shear deformable theory according to Sanders’ first approximation for doubly curved laminated shells, which can be reduced to Love’s and Donnell’s theories by means of tracers. The modal transformation technique is applied to reduce the number of equilibrium equations for subsequent analysis. Structural damping is introduced into the system in terms of viscous damping. Instability behaviour of curved panels have been examined considering the various parameters such as width of edge load, load direction control, damping, influence of fiber orientation and lay up sequence etc. The results show that under follower loading the panel may lose its stability due to either flutter or divergence, depending on the system parameters.
Buckling and dynamic instability analysis of stiffened shell panels are investigated in this paper. The eight-noded isoparametric degenerated shell element and a compatible three-noded curved beam element are used to model the shell panels and the stiffeners, respectively. As the usual formulation of degenerated beam element is found to overestimate the torsional rigidity, an attempt has been made to reformulate it in an efficient manner. Moreover, the new formulation for the beam element requires five degrees of freedom per node as that of shell element. The method of Hill's infinite determinant is applied to analyze the dynamic instability regions. Numerical results are presented through convergence and comparison with the published results from the literature. The effects of various parameters like shell geometry, stiffening scheme, static and dynamic load factors, stiffener size and position, and boundary conditions are considered in buckling and dynamic instability analysis of stiffened panels subjected to uniform in-plane harmonic loads along the boundaries.

ABSTRACT: The static and dynamic instability characteristics of stiffened shell panels subjected to uniform in-plane harmonic edge loading are investigated in this paper. ABSTRACT: The dynamic instability characteristics of stiffened shell panels subjected to partial in-plane harmonic edge loading are investigated in this paper. The eight-noded isoparametric degenerated shell element and a compatible three-noded curved beam element are used to model the shell panels and the stiffeners, respectively. As the usual formulation of degenerated beam element is found to overestimate the torsional rigidity, an attempt has been made to reformulate it in an efficient manner. Moreover, the new formulation for the beam element requires five degrees of freedom per node as that of shell element. The method of Hill's infinite determinant is applied to analyze the dynamic instability regions. Numerical results are presented through convergence and comparison with the published results from the literature. The effects of parameters like loading type and shell geometry are considered in the dynamic instability analysis of stiffened panels subjected to non-uniform in-plane harmonic loads along the boundaries. The tension buckling aspect of the stiffened panels are also considered and the dynamic stability behavior due to tensile in-plane edge loading is studied for the concentrated load.

ABSTRACT: Delaminations may reduce the buckling load of the laminated structure greatly. In this paper, various examples were analyzed by using the model in part I. First, by comparing with the results of the classical theory and first-order shear-deformation theory, the model was validated and the usable range of each theory was pointed out. Three different buckling modes of delaminated shell were considered. The influence of different ratios of radius to thickness, boundary condition and length, depth and position of the delamination on
the buckling load was analyzed. Finally, the buckling analysis of delaminated orthotropic shell and the influences of ply orientation of the material on the buckling load of a delaminated shell were given.

1789

ABSTRACT: An analytical methodology is presented for predicting the buckling initiation of delaminated composite plates. Both global and local sublaminate buckling deformation modes are predicted for rectangular plates of any thickness. The global behavior of the delamination zone is accounted for by summing the individual stiffness contributions of each sublaminate constituting the delamination zone. This allows for the delamination zone to be treated as a single plate when performing global buckling predictions. Local buckling predictions are obtained by modeling a sublaminate adjacent to the surface as a separate elliptical plate. These analytical predictions compare closely with the results of detailed finite element models investigating several cases of delaminated plates. The methodology presented is found to be accurate for the cases considered and versatile as it can accommodate plates of any aspect ratio and having arbitrarily sized and located delaminations.

ABSTRACT: This paper contributes newly developed closed-form buckling solutions for generic one-edge-free problems common to partially disbanded composite structures. These solutions are shown to be accurate by comparison with experimentally measured buckling loads which are also reported in this paper. The buckling of partially disbanded regions in adhesive joints is a safety concern due to the potential for ensuing buckling-driven disbond growth. In order to design structures to be tolerant to these flaws, closed-form expressions that predict buckling load have been developed based on a one-edge-free buckling model. Comparison of the closed-form predictions with the finite element results verifies the accuracy of the solutions. Validation of these analyses was achieved by comparison with the experimentally determined buckling loads. These were measured to fall within a range of predicted values, as defined by the choice of boundary condition opposite the disbonded flange-free-edge: either clamped or simply-supported. Assumption of either boundary condition provides upper-and lower-bound predictions of buckling in partially disbanded joint flange configurations.

PARTIAL ABSTRACT: This paper investigates how geometrical imperfections, which in most cases are present for impacted laminates, affect the postbuckling behaviour of delaminated composite plates under compression. Delaminations are one of the most frequently appearing material damage due to impact. The influence of different shapes of the geometrical imperfections on the response has been studied. The program system, DEBUGS, which is developed and specialized to simulate delamination buckling and growth, is used for the analyses. DEBUGS is based on the finite element program ADINA. It is found that the geometrical
imperfections influence the buckling behaviour, and thus also possibly the initiation of delamination growth. A more accurate model of delamination buckling of impact-damaged laminated composites should thus include a feature where the initial shape of the composite may be varied, e.g. in a model where the material degradation in the impact damaged zone is modeled.

ABSTRACT: The influence of impact damage on the structural performance of composite laminates was investigated by a joint effort and included nondestructive evaluation (NDE), mechanical testing and analysis. The impacted NASA Industry Standard Compression After Impact test specimen was chosen. Damage characterization incorporated ultrasonic and radiographic methods. Computerized and manual ultrasonic testing from both sides of the test panels provided accurate information on the damaged area. The findings were confirmed by a destructive X-ray microfocus technique combined with an opaque penetrant for damage enhancement. From the NDE data, a simplified damage model was constructed and analyzed for strength and stability. Failure loads and modes were predicted and compared to compression after impact test results. Preliminary tests showed very good agreement.

doi: 10.1243/095440603322407254
ABSTRACT: Delamination buckling analysis of laminates is of considerable interest to the mechanical and materials engineering sectors, as well as having wider applications in geology and civil engineering. With advances in computing power, the ability to model ever increasingly complex problems at more detailed levels becomes more of a reality. However, many of the common finite element packages, with the exception of all but the most specialized, do not perform particularly well where complex non-linear problems are dealt with. In many cases, these packages can fail to determine the full range of solutions or accurately predict the properties and geometry of the final state. This is particularly the case where large deformations and buckling of laminates are considered. Because of this, many researchers prefer to use what they perceive to be more reliable techniques, such as the symbolic computation of the underlying differential equations, rather than finite element approaches. The use of finite element packages is further frustrated by the steep learning curve and implicit restrictions imposed by using third-party software. In this paper, a finite element approach and an energy formulation method are considered and used to model the delamination buckling in a geometrically constrained system. These methods are compared with experimental results and their relative merits are discussed. In particular, the accuracy and the ability to represent the geometry of the buckled system are discussed. Both the finite element approach and the energy formulation are described in detail and the numerical results are compared.

ABSTRACT: Shell structures have been widely used in engineering applications such as pipelines, aerospace and marine structures, and cooling towers. Occurring suddenly and generally inadvertently due to its nature, buckling is one of the main failure considerations in the design of these structures. Presence of defects, such as cracks, corrosion pits, blow-out holes, in shell structures may severely compromise their buckling behavior and jeopardize the structural integrity.

In this study, a numerical investigation on the buckling behavior of a cracked cylindrical shell reinforced with an elastic liner and subjected to combined axial compression was carried out. The effect of supporting liner on the buckling behavior of the cracked shell at different crack sizes and orientations were investigated. In the next step, the buckling behavior of a cracked cylindrical shell with an elastic liner subjected to the internal pressure and axial compression was studied. Different buckling modes of the cracked shell, including global, transition and locales modes are identified for different loading conditions.

The results showed that longitudinal crack has a more detrimental effect on the buckling strength of the cylindrical shell in cylinders with no elastomeric liner or with elastomeric liners with low relative stiffness. In addition, cylinders with elastomeric liners of high relative stiffness circumferential crack have a more detrimental effect on the buckling strength of the cylindrical shell.

The finite element analysis also showed that increasing the thickness of the supporting layer or increasing its stiffness, can significantly increase the critical crack size at each angle. The shells reinforced with elastic liners subjected to the internal pressure and axial compression shown that the internal pressure does not affect the overall buckling behavior of perfect cylindrical shells. For circumferential crack, the internal pressure increases the buckling load of the cylindrical shell. In contrast, for longitudinal crack, the internal pressure decreases the buckling load of the cylindrical shell. We found that the critical buckling load of the cracked cylinder with various thicknesses of the elastomeric liner can be expressed at each crack angle by a single parameter, namely stretching stiffness ratio of liner and shell layers.

ABSTRACT: Linear eigenvalue analysis of cracked cylindrical shells under combined internal pressure and axial compression is carried out to study the effect of crack type, size and orientation on the buckling behavior of cylindrical thin shells. Two types of crack are considered; through crack and thumbnail crack. Our calculations indicate that depending on the crack type, length, orientation and the internal pressure, local buckling may precede the global buckling of the cylindrical shell. The internal pressure, in general, increases the buckling load associated with the global buckling mode of the cylindrical shells. In contrast, the effect of internal pressure on buckling loads associated with the local buckling modes of the cylindrical shell depends mainly on the crack orientation. For cylindrical shells with relatively long axial crack, buckling loads associated with local buckling modes of the cylindrical shell reduce drastically on increasing the shell internal pressure. In contrast, the internal pressure has the stabilizing effect against the local buckling for circumferentially cracked cylindrical shells. A critical crack length for each crack orientation and loading condition is defined as the shortest crack causing the local buckling to precede the global buckling of the cylindrical shell. Some insight into the effect of internal pressure on this critical crack length is provided.

ABSTRACT: Potential sensitivity of the buckling behavior of cracked composite cylindrical shells to service life cracking is explored by carrying out linear buckling analysis. Computational models of cracked composite cylindrical shells are developed by exploiting a special meshing scheme in which the element size is reduced incrementally from the element size employed in the uncracked region by approaching the crack tip. The effect of crack size and orientation, as well as the composite ply angle on the buckling behavior of cylindrical shells under axial compression is investigated. The results provide some insight into designing a composite laminate, which enhances the load capacity of cylindrical shells and minimizes their potential sensitivity to the presence of defects.

ABSTRACT: The response of low-dimensional solid objects combines geometry and physics in unusual ways, exemplified in structures of great utility such as a thin-walled tube that is ubiquitous in nature and technology. Here we provide a consequence of this confluence of geometry and physics in tubular structures: our analysis shows that the persistence of a localized pinch in an elastic pipe whose effect decays as an oscillatory exponential with a persistence length that diverges as the thickness of the tube vanishes, which we confirm using simulations and simple experiments. The result is more a consequence of geometry than material properties, and is thus equally applicable to carbon nanotubes as it is to oil pipelines.

ABSTRACT: The dried raisin, the crushed soda can, and the collapsed bicycle inner tube exemplify the nonlinear mechanical response of naturally curved elastic surfaces with different intrinsic curvatures to a variety of different external loads. To understand the formation and evolution of these features in a minimal setting, we consider a simple assay: the response of curved surfaces to point indentation. We find that for surfaces with zero or positive Gauss curvature, a common feature of the response is the appearance of faceted structures that are organized in intricate localized patterns, with hysteretic transitions between multiple metastable states. In contrast, for surfaces with negative Gauss curvature the surface deforms nonlocally along characteristic lines that extend through the entire system. These different responses may be understood quantitatively by using numerical simulations and classified qualitatively by using simple geometric ideas. Our ideas have implications for the behavior of small-scale structures.

ABSTRACT: Emergence of new technological applications, in addition to the constantly growing interest in biological materials has accentuated the importance of studying the mechanics of highly deformed shells. The key challenge is the intricate interplay of physics and geometry, which leads to a mechanical response much different from the response of solid objects. The quest to understand the underlying phenomena has spawned theoretical and experimental studies, which have helped in understanding the underlying mechanisms of deformation and response of shells. Here, we use numerical simulations to study the response of shells when they are deformed deeply into the nonlinear regime. We use computational models to study the mechanics of highly deformed elastic shells in several classical problems: indentation of elastic spherical caps by a flat rigid plate and a rigid sharp indenter and pure bending of circular and oval cylinders. These assays are used to highlight some of the key aspects of the mechanics of highly deformed elastic shells, while an overview of the current state-of-the-art and suggestions for future research on this subject are also provided.

ABSTRACT: We study the formation of localized structures formed by the point loading of an internally pressurized elastic shell. While unpressurized shells (such as a ping-pong ball) buckle into polygonal structures, we show that pressurized shells are subject to a wrinkling instability. We study wrinkling in depth, presenting scaling laws for the critical indentation at which wrinkling occurs and the number of wrinkles formed in terms of the internal pressurization and material properties of the shell. These results are validated by numerical simulations. We show that the evolution of the wrinkle length with increasing indentation can be understood for highly pressurized shells from membrane theory. These results suggest that the position and number of wrinkles may be used in combination to give simple methods for the estimation of the mechanical properties of highly pressurized shells.

ABSTRACT: Thin-walled structural components, such as plates and shells, are used in several aerospace, naval, nuclear power plant, pressure vessels, mechanical and civil structures. Due to their high slenderness, the safety assessment of such structural components requires to carefully assess the buckling collapse which can strongly
limit their bearing capacity. For very thin plate, buckling collapse can occur under shear, compression or even under tension. In the latter case, fracture or plastic failure can also take place instead of elastic instability. In the present paper, the effects of a central straight crack on the buckling collapse of rectangular elastic thin-plates—characterized by different boundary conditions, crack length and orientation—under compression, tension or shear loading are analysed. Accurate FE numerical parametric analyses have been performed to get the critical load multipliers in such loading cases. Moreover the effect of crack faces contact is examined and discussed. Some useful conclusions related to the sensitivity to cracks of the buckling loads for thin plates, especially in the case of shear stresses, are drawn. Cracked plates under tension are finally considered in order to determine the most probable collapse mechanism among fracture, plastic flow or buckling and some failure-type maps are determined.

ABSTRACT: Linear eigenvalue buckling analysis was carried out for singly and doubly cracked cylindrical thin shells under axial compression using the finite element method. First, the effect of crack size and orientation on the buckling behavior of an axially loaded shell with a single crack was studied. Then, the buckling behavior of a cylinder with two parallel longitudinal cracks was investigated. Two different buckling shapes with cross-sectional deformation profiles that resemble letters M (symmetric) and N (anti-symmetric) were identified as the first buckling modes of the cylinder. The exchange between these local buckling modes due to variation of crack size and spacing was illustrated. The transition between these two buckling shapes can be used to estimate the ‘maximum interaction distance’ of the cylinder cracks—the separation distance beyond which the two cracks do not interact in affecting the buckling load of the cylindrical shell. The influence of shell thickness and crack length on the maximum interaction distance was quantified for cylinders with two co-centered (i.e., parallel offset) or collinear longitudinal cracks. Additional simulations were carried out for cylinders with multiple symmetrically spaced longitudinal cracks to show how the behavior of single and double cracks can give the buckling load and mode shape of cylinders with multiple cracks.

ABSTRACT: More recently, we have been studying the emergence and evolution of point and linear-like loci of localization on thin shells indented well into the nonlinear regime. For large enough indentation, sharp points of localized curvature form, which we refer to as 's-cones' (for shell-cones), in contrast with their developable cousins in plates, 'd-cones'. Through experiments and FEM, we have found that the shape of the indenter has a significant effect on the mechanical response and that there is a qualitative difference between sharp and blunt indenters. Given the importance of geometry and the scale-invariance of this problem, our results should find uses at the microscale, e.g. for AFM, where it is crucial to understand how the curvature of the tip, relative to the object being indented, affects the mechanical response.

ABSTRACT: Elastic liners are used for in situ repair and retrofitting of pipes as a cost effective alternative to the replacement of damaged parts and sections. In this paper, we studied the role of an elastic liner on the buckling behavior of a cracked cylindrical shell using finite element method. A special meshing scheme that could mimic the stress singularity at the crack tip was employed to model the cracked shells. Linear eigenvalue analysis was carried out to study the effect of crack geometry (length and orientation) as well as the material properties and thickness of the elastic liner on the buckling load and buckling shape of the cylindrical shell. We considered a combination of axial compression and internal pressure which is a typical loading for pipelines and pressurized liquid-retaining structures. Our results show that cracked shell's strength and mode of buckling for different crack length and orientations can be largely influenced by thickness and relative stiffness of the liner layer. In particular we report a gradual transition from local to global instability due to these size and orientation effects. Finally, the role of internal pressure on structural stability and local buckling of cracked shells, which strongly depends on the crack orientation and liner thickness, is discussed.

ABSTRACT: An approach to obtain analytical closed-form expressions for the macroscopic ‘buckling strength’ of various two-dimensional cellular structures is presented. The method is based on classical beam-column end-moment behaviour expressed in a matrix form. It is applied to sample honeycombs with square, triangular and hexagonal unit cells to determine their buckling strength under a general macroscopic in-plane stress state. The
results were verified using finite-element Eigenvalue analysis.

ABSTRACT: We tested the mechanical properties of single microtubules by lateral indentation with the tip of an atomic force microscope. Indentations up to about 3.6 nm, i.e., 15% of the microtubule diameter, resulted in an approximately linear elastic response, and indentations were reversible without hysteresis. At an indentation force of around 0.3 nN we observed an instability corresponding to an approximately 1-nm indentation step in the taxol-stabilized microtubules, which could be due to partial or complete rupture of a relatively small number of lateral or axial tubulin-tubulin bonds. These indentations were reversible with hysteresis when the tip was retracted and no trace of damage was observed in subsequent high-resolution images. Higher forces caused substantial damage to the microtubules, which either led to depolymerization or, occasionally, to slowly reannealing holes in the microtubule wall. We modeled the experimental results using finite-element methods and find that the simple assumption of a homogeneous isotropic material, albeit structured with the characteristic protofilament corrugations, is sufficient to explain the linear elastic response of microtubules.

from continuum mechanics have a similarity with the two-dimensional Stokes flows, and we use a nonlinear stream function for the exact treatment of the incompressibility constraint. A free energy approach allows the extension both to arbitrary hyperelastic strain energies and to additional interactions, such as surface energies. We find that, at constant volumetric growth, the threshold for a wavy instability is completely governed by the amount of growth. Nevertheless, the determination of the wavelength at threshold, which scales with the initial thickness of the gel layer, requires the coupling with a surface effect. Our findings, which are valid in proximity of the threshold, are compared to experimental results. The proposed treatment can be extended to weakly nonlinearities within the aim of the theory of bifurcations.

ABSTRACT: Static deflection as well as free and forced nonlinear vibration of thin square plates made of hyperelastic materials are investigated. Two types of materials, namely rubber and soft biological tissues, are considered. The involved physical nonlinearities are described through the Neo-Hookean, Mooney-Rivlin, and Ogden hyperelastic laws; geometrical nonlinearities are modeled by the Novozhilov nonlinear shell theory. Dynamic local models are first built in the vicinity of a static configuration of interest that has been previously calculated. This gives rise to the approximation of the plate’s behavior in the form of a system of ordinary differential equations with quadratic and cubic nonlinear terms in displacement. Numerical results are compared and validated in the static case via a commercial finite element software package: they are found to be accurate for deflections reaching 100 times the thickness of the plate. The frequency shift between low- and large-amplitude vibrations weakens with an increased initial deflection.

ABSTRACT: Static and dynamic responses of a circular cylindrical shell made of hyperelastic arterial material are investigated. The material is modeled as a combination of Neo-Hookean and Fung hyperelastic materials. Two pressure loads are implemented: distributed radial force and deformation-dependent pressure. The static responses of the shell under these two different loads differ essentially at moderate strains, while the behavior is similar for small loads. The main difference is in the axial displacements that are much larger under distributed radial forces. Free and forced vibrations around pre-loaded configurations are analyzed. In both cases the nonlinearity of the single-mode (driven mode) response of the pre-loaded shell is quite weak but a resonant regime with co-existing driven and companion modes is found with more complicated nonlinear dynamics. ABSTRACT: The shape of plants and other living organisms is a crucial element of their biological functioning. Morphogenesis is the result of complex growth processes involving biological, chemical and physical factors at different temporal and spatial scales. This study aims at describing stresses and strains induced by the production and reorganization of the material. The mechanical properties of soft tissues are modeled within the framework of continuum mechanics in finite elasticity. The kinematical description is based on the multiplicative decomposition of the deformation gradient tensor into an elastic and a growth term. Using this formalism, the authors have studied the growth of thin hyperelastic samples. Under appropriate assumptions, the dimensionality of the problem can be reduced, and the behavior of the plate is described by a two-dimensional surface. The results of this theory demonstrate that the corresponding equilibrium equations are of the Föppl–von Kármán type where growth acts as a source of mean and Gaussian curvatures. Finally, the cockling of paper and the rippling of a grass blade are considered as two examples of growth-induced pattern formation.

ABSTRACT: Generation of shapes in biological tissues is a complex multiscale phenomenon. Biochemical details of cell proliferation, death and mobility can be incorporated within a continuum mechanical framework by specifying locally the amplitude and direction of growth. For tissues exhibiting an elastic behavior, equilibrium shapes of growing bodies can be evaluated through the minimization of an appropriate energy. This model is applied to thin shells and plates, a geometry relevant to nuts and pollen grains but also leaves, petals and algae.
Localized growth of layered tissues

ABSTRACT: Due to their structural heterogeneity, stratified media usually lose their initial symmetry when they grow. Mismatching expansions between distinct layers create elastic stresses that lead to the emergence of wavy patterns. In the context of morphogenesis, this process of constrained growth has been used to explain patterns in biological soft-layered tissues such as the fingerprints of the skin. Discovery of morphogens has however revealed that growth is not always a homogeneous process and can be highly localized. Spatially concentrated growth processes are thought to be responsible for the formation of various structures, from placodes in the chicken embryo to nevus and skin tumours. On a different ground, the processing of complex textured surfaces requires to understand the connection between the local variation of mass and the resulting surface profile. In this paper, we investigate a model of a locally growing thin sheet bound to a soft infinite substrate. We show that, in two dimensions, bending effects select the shape of the growing sheet, therefore preventing the fabrication of an arbitrary surface. In three dimensions, the high energetic cost of stretching sets a stronger constraint on the attainable patterns and provides a simple relation between the profile of the surface and the local properties of the growth process.
ABSTRACT: Using swelling hydrogels, we study the evolution of a thin circular artificial tumor whose growth is confined at the periphery. When the volume of the outer proliferative ring increases, the tumor loses its initial symmetry and bifurcates towards an oscillatory shape. Depending on the geometrical and elastic parameters, we observe either a smooth large-wavelength undulation of the swelling layer or the formation of sharp creases at the free boundary. Our experimental results as well as previous observations from other studies are in very good agreement with a nonlinear poroelastic model.

ABSTRACT: Morphologies of soft materials in growth, swelling or drying have been extensively studied recently. Shape modifications occur as the size varies transforming ordinary spheres, cylinders and thin plates into more or less complex objects. Here we consider the genesis of biofilm patterns when a simple disc containing initially bacteria with moderate adhesion to a rigid substrate grows according to very simple rules. The initial circular geometry is lost during the growth expansion, contour undulations and buckling appear, ultimately a rather regular periodic focussing of folds repartition emerges. We theoretically predict these morphological instabilities as bifurcations of solutions in elasticity, characterized by typical driving parameters established here. The substrate plays a critical role limiting the geometry of the possible modes of instabilities and anisotropic growth, adhesion and toughness compete to eventually give rise to wrinkling, buckling or both. Additionally, due to the substrate, we show that the ordinary buckling modes, vertical deviation of thin films, are not observed in practice and a competitive pattern with self-focussing of folds can be found analytically. These patterns are reminiscent of the blisters of delamination in material sciences and explain recent observations of bacteria biofilms. The model presented here is purely analytical, is based on a neo-Hookean elastic energy, and can be extended without difficulties and applied to polymer materials.

ABSTRACT: The stability of the wrinkling mode experienced by a compressed half-space of neo-Hookean material is investigated using analytical and numerical methods to study the post-bifurcation behavior of periodic solutions. It is shown that wrinkling is highly unstable due to the nonlinear interaction among the multiple modes associated with the critical compressive state. Concomitantly, wrinkling is sensitive to exceedingly small initial imperfections that significantly reduce the compressive strain at which the instability occurs. The study provides insight into the connection between wrinkling and an alternative surface mode, the finite amplitude crease, or sulcus. The shape of the critical combination of wrinkling modes has the form of an incipient crease, and a tiny initial imperfection can trigger a wrinkling instability that collapses into a crease.

ABSTRACT: A soft dielectric membrane is prone to snap-through instability. We present theory and experiment to show that the instability can be harnessed to achieve giant voltage-triggered deformation. We mount a membrane on a chamber of a suitable volume, pressurize the membrane into a state near the verge of the instability, and apply a voltage to trigger the snap without causing electrical breakdown. For an acrylic membrane we demonstrate voltage-triggered expansion of area by 1692%, far beyond the largest value reported in the literature. The large expansion can even be retained after the voltage is switched off.

ABSTRACT: The creasing instability of elastomer films under compression is studied by a combination of experiment and numerical simulation. Experimentally, we attach a stress-free film on a much thicker and stiffer pre-stretched substrate. When the substrate is partially released, the film is uniaxially compressed, leading to formation of an array of creases beyond a critical strain. The profile of the folded surface is extracted using confocal fluorescence microscopy, yielding the depths, spacings, and shapes of creases. Numerically, the onset and development of creases are simulated by introducing appropriately sized defects into a finite-element mesh and allowing the surface of the film to self-contact. The measurements and simulations are found to be in excellent agreement.

ABSTRACT: In the emerging field of soft machines, large deformation of soft materials is harnessed to provide functions such as regulating flow in microfluidics, shaping light in adaptive optics, harvesting energy from ocean waves, and stretching electronics to interface with living tissues. Soft materials, however, do not provide
all of the requisite functions; rather, soft machines are mostly hybrids of soft and hard materials. In addition to requiring stretchable electronics, soft machines often use soft materials that can deform in response to stimuli other than mechanical forces. Dielectric elastomers deform under a voltage. Hydrogels swell in response to changes in humidity, pH, temperature, and salt concentration. How does mechanics meet geometry, chemistry, and electrostatics to generate large deformation? How do molecular processes affect the functions of transducers? How efficiently can materials convert energy from one form to another? These questions are stimulating intriguing and useful advances in mechanics. This review highlights the mechanics that enables the creation of soft machines.

ABSTRACT: Soft, elastic materials are capable of large and reversible deformation, readily leading to various modes of instability that are often undesirable, but sometimes useful. For example, when a soft elastic material is compressed, its initially flat surface will suddenly form creases. While creases are commonly observed, and have been exploited to control chemical patterning, enzymatic activity, and adhesion of surfaces, the conditions for the formation and disappearance of creases have so far been poorly controlled. Here we show that a soft elastic bilayer can snap between the flat and creased states repeatedly, with hysteresis. The strains at which the creases form and disappear are highly reproducible, and are tunable over a large range, through variations in the level of pre-compression applied to the substrate and the relative thickness of the film. The introduction of bistable flat and creased states and hysteretic switching is an important step to enable applications of this type of instability.

ABSTRACT: Theory and experiment are presented to show that an interface between two soft materials under compression can form creases, a type of bifurcation distinct from wrinkles. While creases bifurcate from a state of flat interface by a deformation localized in space and large in amplitude, wrinkles bifurcate from a state of flat interface by a deformation nonlocal in space and infinitesimal in amplitude. The interfacial creases set in at a lower critical compression than interfacial wrinkles, but higher than surface creases. The condition for the onset of interfacial creases is scale-free, and is calculated in terms of elastic moduli, pre-strains and applied strains.

“Buckling of elastomeric beams enables actuation of soft machines”, Advanced Materials, 2015, DOI: 10.1002/adma.201503188

ABSTRACT: This article demonstrates the utility of a special type of non-linear behavior—the reversible, cooperative torsion, and collapse of a set of elastomeric beams (fabricated as one connected piece) under pressure. Understanding the motions exhibited in these systems started with observations and analyses by Boyce and co-workers of cooperative transformations in the shapes of patterns of through-holes cut into elastomeric slabs, on applying external pressure to these structures in the plane of the slab. Our work extends these studies, and greatly increases the ability of this kind of system, by using negative pressure (e.g., vacuum) applied to an elastomeric structure containing a number of elastic beams and interconnected, deformable cavities sealed within a thin elastomeric membrane. When negative pressure is applied, cooperative interactions among the components of the structure cause its elements (beams) to bend and buckle in ways that produce a range of useful motions. Buckling of materials is ordinarily considered an undesired mode of mechanical and structural failure, as it often causes permanent damage to structural components (e.g., metal frames, concrete pillars). The buckling of elastomeric materials, however, is reversible, and can provide useful new functions when designed properly. One such useful function is a rotary motion that provides a torque.

ABSTRACT: When a stiff film on a soft substrate is compressed, the surface of the film forms wrinkles, with tunable wavelengths and amplitudes that enable a variety of applications. As the compressive strain increases, the film undergoes post-wrinkling bifurcations, leading to period doubling and eventually to formation of localized folds or ridges. Here we study the post-wrinkling bifurcations in films on pre-stretched substrates. Through a combination of experiments and simulations, we demonstrate that pre-stretched substrates not only show substantial shifts in the critical strain for the onset of post-wrinkling bifurcations, but also exhibit qualitatively different post-wrinkled states. In particular, we report on the stabilization of wrinkles in films on pre-tensioned substrates and the emergence of ‘chaotic’ morphologies in films on pre-compressed substrates.
Subject to compression, elastic materials may undergo bifurcation of various kinds. A homogeneous material forms creases, whereas a bilayer consisting of a stiff film and a compliant substrate forms wrinkles. Here, we show several new types of bifurcation behavior for bilayers consisting of films and substrates of comparable elastic moduli. Depending on the ratios of moduli and thicknesses of the two materials, the critical strain for the onset of creases can be either smaller or larger than that for the onset of wrinkles. When the critical strain for the onset of creases is lower than that of wrinkles, creases can be subcritical or supercritical. When the critical strain for the onset of wrinkles is lower than that of creases, wrinkles can further channel to creases at a strain much lower than the critical strain for the onset of creases in a homogeneous material. Experiments, conducted with bilayer polydimethylsiloxane (PDMS) structures subject to compressive loading, show that the different types of bifurcation behavior agree with the theoretical
predictions.

ABSTRACT: Fingerprints (epidermal ridges) have been used as a means of identifications for more than 2000 years. They have also been extensively studied scientifically by anthropologists and biologists. However, despite all the empirical and experimental knowledge, no widely accepted explanation for the development of epidermal ridges on fingers, palms and soles has yet emerged. In this article we argue that fingerprint patterns are created as the result of a buckling instability in the basal cell layer of the fetal epidermis. Analysis of the well-known von Karman equations informs us that the buckling direction is perpendicular to the direction of greatest stress in the basal layer. We propose that this stress is induced by resistance of furrows and creases to the differential growth of the basal layer and regression of the volar pads during the time of ridge formation. These ideas have been tested by computer experiments. The results are in close harmony with observations. Specifically, they are consistent with the well-known observation that the pattern type is related to the geometry of the fingertip surface when fingerprint patterns are formed.

ABSTRACT: Cortical folding, characterized by convex gyri and concave sulci, has an intrinsic relationship to the brain's functional organization. Understanding the mechanism of the brain's convoluted patterns can provide useful clues into normal and pathological brain function. In this paper, the cortical folding phenomenon is interpreted both analytically and computationally, and, in some cases, the findings are validated with experimental observations. The living human brain is modeled as a soft structure with a growing outer cortex and inner core to investigate its developmental mechanism. Analytical interpretations of differential growth of the brain model provide preliminary insight into critical growth ratios for instability and crease formation of the developing brain. Since the analytical approach cannot predict the evolution of cortical complex convolution after instability, non-linear finite element models are employed to study the crease formation and secondary morphological folds of the developing brain. Results demonstrate that the growth ratio of the cortex to core of the brain, the initial thickness, and material properties of both cortex and core have great impacts on the morphological patterns of the developing brain. Lastly, we discuss why cortical folding is highly correlated and consistent by presenting an intriguing gyri-sulci formation comparison.

ABSTRACT: Mechanical instabilities in soft materials, specifically wrinkling, have led to the formation of unique surface patterns for a wide range of applications that are related to surface topography and its dynamic tuning. In this progress report, two distinct approaches for wrinkle formation, including mechanical stretching/releasing of oxide/PDMS bilayers and swelling of hydrogel films confined on a rigid substrate with a depth-wise modulus gradient, are discussed. The wrinkling mechanisms and transitions between different wrinkle patterns are studied. Strategies to control the wrinkle pattern order and characteristic wavelength are suggested, and some efforts in harnessing topographic tunability in elastomeric PDMS bilayer wrinkled films for various applications, including tunable adhesion, wetting, microfluidics, and micro-lens arrays, are highlighted. The report concludes with perspectives on the future directions in manipulation of pattern formation for complex structures, and potential new technological applications.

ABSTRACT: Physically self-assembled microstructures can be realized by utilizing the stress relief process in buckling that usually leads to the formation of random wrinkles. This physical self-assembly occurs when the wrinkle formation is guided by a periodic pattern on an elastomeric mold that is simply placed on the surface of a bilayer of metal on polymer, which is then heated above its glass-transition temperature.

ABSTRACT: Constrained swelling or shrinkage of such soft materials as elastomers, polymeric hydrogels, and biological tissues can create various surface patterns through surface wrinkling and subsequent morphological evolution. Here we study, both theoretically and numerically, the swelling-driven surface wrinkling and pattern evolution of cylindrical elastomers with core–shell structure. The results demonstrate that the system may buckle into different morphologies under different geometric and material parameters. When the swelling of the shell or the shrinkage of the core reaches a threshold, the cylindrical surface will first buckle into a periodically buckling pattern. With further swelling/shrinkage, wrinkle-to-fold transition may occur, rendering a period-doubling surface topography. The energetic mechanisms underlying this process of wrinkling pattern evolution are analyzed. This study not only benefits the understanding of the morphogenesis in soft materials and tissues (e.g., tumors), but also opens a new avenue for the fabrication of multi-periodic or aperiodic patterns on curved surfaces through self-organization.

Vishnesh Ranjan Kar, Nonlinear Thermoelastic Static Vibration and Buckling Behaviour of Functionally Graded Shell Panel. PhD thesis, Biju Patnaik Central Library, National Institute of Technology, Rourkela, Odisha, 2015 (Supervisor: Dr. Subrata Kumar Panda)

ABSTRACT: Functionally graded material (FGM) has created the interest of many researchers due to its tailor-made material properties. FGMs are the advanced form of composites that exhibit an inhomogeneous character especially designed for the high-temperature applications such as aircraft engines, rocket heat shields, thermal barrier coatings, heat exchanger tubes, etc. This material has been developed by taking the gradual variation of metal and ceramic constituents in a very efficient manner to suit the needs of the engineering structure. The effective material properties of the FGM follow the rule-based grading of two counterparts as discussed above, metals and ceramics. Shell structures made of FGMs are subjected to different kind of loading during their service life, and the structural responses (deformations, buckling/post-buckling, and linear/nonlinear natural frequencies) are affected considerably due to that. In this regard, a general nonlinear mathematical model has been developed for the FGM doubly curved shell panel using Green-Lagrange geometrical nonlinear kinematics in the framework of the higher-order shear deformation theory. The effective material properties of FGM shell panels are evaluated using Voigt’s micromechanical model via the power-law distribution. The material properties each constituent are assumed to be temperature-dependent. In addition, to achieve the true flexure of the structure, all the nonlinear higher-order terms are included in the mathematical model. The system governing equation of the FGM structure is obtained using the variational principle, and the direct iterative method is employed to compute the desired nonlinear responses in conjunction with suitable isoparametric finite element steps. The convergence behaviour of the proposed numerical model has been checked and validated further by comparing the responses with those available published literature. The linear and the nonlinear flexural, free vibration and the buckling responses of the FGM single/doubly curved shell panels are examined under thermo-mechanical loading. Finally, the effects of different geometrical and material parameters, support conditions, loading types on the deflection, frequency and critical buckling load parameter of the FGM single/doubly curved shell panels are examined and discussed in detail. This is also believed that the present study would be beneficial to the analysis and the design of FGM structure and/or structural component for real-life problems.

ABSTRACT: This work focuses on the static analysis of functionally graded (FGM) and laminated doubly-curved shells and panels resting on nonlinear and linear elastic foundations using the Generalized Differential Quadrature (GDQ) method. The First-order Shear Deformation Theory (FSDT) for the aforementioned moderately thick structural elements is considered. The solutions are given in terms of generalized displacement components of points lying on the middle surface of the shell. Several types of shell structures such as doubly-curved shells (elliptic and hyperbolic hyperboloids), singly-curved (spherical, cylindrical and conical shells), and degenerate panels (rectangular plates) are considered in this paper. The main contribution of this paper is the application of the differential geometry within GDQ method to solve doubly-curved FGM shells resting on nonlinear elastic foundations. The linear Winkler-Pasternak elastic foundation has been considered as a special case of the nonlinear elastic foundation proposed herein. The discretization of the differential system by means of the GDQ technique leads to a standard nonlinear problem, and the Newton-Raphson scheme is used to obtain the solution. Two different four-parameter power-law distributions are considered for the ceramic volume fraction of each lamina. In order to show the accuracy of this methodology, numerical comparisons between the present formulation and finite element solutions are presented. Very good agreement is observed. Finally, new results are presented to show effects of various parameters of the nonlinear elastic foundation on the behavior of
functionally graded and laminated doubly curved shells and panels.

ABSTRACT: The dynamic response of functionally graded skew shell is investigated using a C₀ finite element formulation. Reddy's higher order theory has been employed to perform the analysis and the volume fractions of the ceramic and metallic components are assumed to follow simple linear distribution law. The present study attempts to focus mainly on the influence of skew angle on frequency parameter and displacement of shell panel with various geometries. Comprehensive numerical results are demonstrated for cylindrical, spherical and hypar shells for different boundary conditions and skew angles. The findings obtained for functionally graded skew shell panels are new and can be used as benchmark for researchers in this field.

Engineering and the Center for Nanoscale Science and Engineering, University of Georgia, Athens, Georgia 30602, USA), “Nanoscale surface creasing induced by post-polymerization modification”, NANO, Vol. xxx, No. xx, pp 000-000, 2015 or 2016 (in press), DOI: 10.1021/acs.nano.5b04144

ABSTRACT: Creasing in soft polymeric films is a result of substantial compressive stresses that trigger instability beyond a critical strain and have been directly related to failure mechanisms in different materials. However, it has been shown that programming these instabilities into soft materials can lead to new applications, such as particle sorting, deformable capillaries, and stimuli-responsive interfaces. In this work, we present a method for fabricating reproducible nanoscale surface instabilities using reactive microcontacting printing (μCP) on activated ester polymer brush layers of poly(pentafluorophenyl acrylate). The sizes and structures of the nanoscale creases can be modulated by varying the grafting density of the brush substrate and pressure applied during μCP. Stress is generated in the film under confinement due to the molecular weight increase of the side chains during post-polymerization modification, which results in substantial in-plane growth in the film and leads to the observed nanoscale creases.

ABSTRACT: Although buckling instabilities in elastic solids have been known for a long time, high interest in this phenomenon is relatively recent. The current and prospective applications in flexible electronics, materials with tunable surface properties (adhesion and wettability), responsive photonic and phononic structures, and reinforced nanocomposites led to a surge in the interest in buckling instabilities. In fact, some of the applications, such as flexible electronics and metrology, have advanced at a tremendous pace only within the past few years. In this review, we discuss some of the most recent progress in the fundamental understanding of buckling instabilities in periodic multi-component polymer materials and porous polymer structures. We also discuss how the buckling can be localized to predetermined regions and hence form periodic instability patterns. Finally, we present several recent examples where buckling instabilities have been employed as a patterning tool to realize complex surface arrays of various materials.

ABSTRACT: Non-Euclidean plates are plates (“stacks” of identical surfaces) whose two-dimensional intrinsic geometry is not Euclidean, i.e., cannot be realized in a flat configuration. They can be generated via different mechanisms, such as plastic deformation, natural growth or differential swelling. In recent years there has been a concurrent theoretical and experimental progress in describing and fabricating non-Euclidean plates (NEP). In particular, an effective plate theory was derived and experimental methods for a controlled fabrication of responsive NEP were developed. In this paper we review theoretical and experimental works that focus on shape selection in NEP and provide an overview of this new field. We made an effort to focus on the governing principles, rather than on details and to relate the main observations to known mechanical behavior of ordinary plates. We also point out to open questions in the field and to its applicative potential.

ABSTRACT: The mechanical deformation characteristics of living cells are known to influence strongly their chemical and biological functions and the onset, progression and consequences of a number of human diseases. The mechanics of the human red blood cell (erythrocyte) subjected to large deformation by optical tweezers forms the subject of this paper. Video photography of the cell deformed in a phosphate buffered saline solution at room temperature during the imposition of controlled stretching forces, in the tens to several hundreds picoNewton range, is used to assess experimentally the deformation characteristics. The mechanical responses of the cell during loading and upon release of the optical force are then analysed to extract the elastic properties
of the cell membrane by recourse to several different constitutive formulations of the elastic and viscoelastic behavior within the framework of a fully three-dimensional finite element analysis. A parametric study of various geometric, loading and structural factors is also undertaken in order to develop quantitative models for the mechanics of deformation by means of optical tweezers. The outcome of the experimental and computational analyses is then compared with the information available on the mechanical response of the red blood cell from other independent experimental techniques. Potential applications of the optical tweezers method described in this paper to the study of mechanical deformation of living cells under different stress states and in response to the progression of some diseases are also highlighted.

ABSTRACT: This paper conducts three-dimensional, nonlinear finite element analysis to investigate the results of using different solution methods and the influence of initial imperfections and material plasticity on failure modes and maximum load of various Z-shaped column lengths; it also compares the column buckling responses between various lengths, each with different initial imperfections. Further analyses include investigating the element suitability and computational costs. Results showed that both displacement control method and Riks method are fully capable of receiving promising results from this analysis. In terms of the effects of initial imperfection and material plasticity on the maximum load that column could carry, the imperfection is the major contributing factor when the column is long whereas the plasticity is the major contributing factor when the column is short.

ABSTRACT: In this paper it has been shown that the buckling strength of Columns may be evaluated by a function of ultimate stress, which is obtained by using Limit Analysis Method to analyse the function of bending moment resulted from the axial compressive forces and transverse load acting on the columns. Because of the effects of column's initial deflection and the nonlinear relationship between stress and strain on the bending moment are accounted for in this paper by some proper mathematical-physical parameters, therefore the ultimate stress function established on the basis of strength point of view can illustrate the buckling problem of columns more simply and completely than classical theory of stability. In this paper the ultimate stress function is expressed in nondimensional form, so it may be used as principle of model experiment to evaluate the stability of various structures, such as beams, plates, cylindrical and spherical shells and etc. The good agreement between the experimental data of spherical shells and the nondimensional ultimate stress demonstrates that the difficulty in evaluating stability of spherical shells, which exists in classical theory of stability for a long time, may be solved.

ABSTRACT: The stability of spherical shells including nozzles and reinforced rounds has been investigated theoretically for the loading external force and overturning moment. Limit loads have been established for several geometries emphasizing the overturning moment.

ABSTRACT: In this paper an elastic stability analysis has been developed for spherical shell segments with fixed or horizontally removable edges. The shells are subjected to external hydrostatic pressure or the combination load, namely, hydropressure and frictional resistance. And when these forces act nonconservatively on the surfaces of the shells. It is shown, the dynamic (flutter type) instabilities as well as static (divergence type) instabilities often take place. The authors consider that these analytical results give some contributions to the study of elastic shell stability.

ABSTRACT: The dynamic buckling behavior of a complete spherical shell made of a bilinear or work-hardening material and under a uniform external impulsive loading is investigated. A quasi-bifurcation theory and a minimum principle are employed to determine, respectively, the onset of the dynamic buckling process and the post-bifurcation nonlinear behavior. Numerical results are obtained for a number of elastic and elastic-plastic cases. The results indicate there is a softening effect in the plastic deviated stress-strain relationship which makes the spherical shell less stable. Furthermore, the higher order terms in stress and strain measures and the coupling of symmetric and asymmetric modes of motion cannot be neglected in the post-bifurcation analysis.

ABSTRACT: In this paper, a theory for large deflection of symmetrically laminated composite cylindrically orthotropic shallow spherical shells including transverse shear is proposed. The nonlinear stability of the symmetrically laminated cylindrically orthotropic shallow spherical shell with a rigidly clamped edge under the action of a uniform pressure is studied by the modified iteration method. The analytic solution for critical loads of the shell is obtained, and it can be applied directly to engineering.

ABSTRACT: Thin shells are prone to fail by buckling. In most of the practical situations, shell structures have membrane stresses as well as bending stresses and the response of these shells becomes nonlinear. Linearization of the nonlinear equilibrium equations gives rise to an algebraic eigenvalue problem, solving which, buckling load is obtained. Eigenvalue buckling analysis is computationally much cheaper than nonlinear analysis involving tracing the load-deflection path and finding the corresponding collapse load. But buckling loads obtained by eigenvalue buckling analysis are always overestimated, and for systems with large prebuckling rotations this approach may give highly unconservative results. For better prediction of the actual buckling load of a structure, a new methodology involving the proper combination of eigenvalue buckling analysis and geometric nonlinear analysis is used here. This method is computationally cheaper than nonlinear buckling analysis but more reliable than linear buckling analysis. The methodology is used to calculate the buckling load of shells of revolution. The conical frustum shell element with two nodal circles is used in the present study. Also discussed is how to include the effect of initial geometric imperfection in buckling analysis.

ABSTRACT: The nonlinear stability of composite conical shell under external pressure was studied. The Donnell type governing equations were developed for general anisotropic composite conical shells. The partial differential equations with variable coefficients were changed into differential equations with constant coefficients by means of selecting appropriate displacement function and changing coordinate system which can be solved easily. The stress functions were strictly deduced from compatible equations by the displacement function selected. The stability of orthotropic composite conical shell under external pressure was calculated by means of Galerkin method and the formulas were obtained for the post buckling equilibrium displacement figure curves.

ABSTRACT: Conical steel shells are fairly widely used as elevated water tanks. However, the current code of practice in North America for the design of such reservoir structures provides an obsolete method for
ascertaining their adequacy to resist hydrostatic loadings. Moreover, there are no provisions available for handling liquid-filled conical tanks subjected to seismic forces. The lack of appropriate design methods could not have been demonstrated more vividly when in December of 1990, an elevated conical water tower failed by buckling when being filled for the first time. The steel vessel, located in Fredericton, New Brunswick, is claimed to have "exploded" by eyewitnesses. The work of this thesis, then, was motivated by this failure. It involves non-linear stability analysis of liquid-filled conical steel vessels possessing geometric imperfections and residual stresses, and which can be subjected to hydrostatic and seismic loading. To achieve this, a finite element formulation is developed based on a consistent shell element which is free from spurious shear modes known to exist in the isoparametric shell elements. The consistent shell element employed also exhibits excellent performance in the analysis of plates and shells in the small displacement range. This element is extended to include both geometric and material non-linearities as well as non-linear dynamic analysis. The non-linear finite element model developed is general and can be applied to any thin or thick shell problem. Numerical testing of the non-linear model through static and dynamic analysis of different plate and shell problems indicates the continued excellent performance of the consistent shell element in the non-linear range. Hydrostatically loaded conical steel vessels are modelled using the consistent shell element. Static stability analyses of conical shells with different geometric imperfection patterns are undertaken and the results indicate that the presence of axisymmetric imperfections leads to the lowest limit load for the structure. The sensitivity of the hydrostatically loaded conical vessels to geometric imperfections and residual stresses is investigated by considering three cases: (i) analysis of perfect vessels, (ii) same as case (i) but with axisymmetric geometric imperfections of the order of the thickness of the shell, (iii) same as case (ii) but with the addition of residual stresses due to welding. The results from these analyses indicate that the liquid-filled conical shells are significantly sensitive to geometric imperfections, and that yielding precedes elastic buckling for tanks having practical dimensions. The non-linear dynamic (stability) analysis of elevated liquid-filled conical vessels subjected to both horizontal and vertical accelerations, but free from rocking motion, is then considered. The boundary integral method is used to formulate the fluid added-mass matrix resulting from the impulsive component of the hydrodynamic pressure. This is added to the mass matrix of the shell structure to perform free vibration as well as nonlinear time history analyses for elevated liquid-filled conical tanks treated as either perfect or axisymmetrically imperfect. Tanks with different dimensions and imperfection levels are subjected to an appropriately scaled real input ground motion. Some of these elevated structures exhibit inelastic behaviour and generally develop a localized buckle near the bottom of the vessel which leads to the overall instability of the structure. In general, time history analyses indicate that liquid-filled conical tanks, often possessing apparently adequate safety factors under hydrostatic loading, may not be safe under seismic loading. Therefore, a proper modelling procedure along with time dependent analysis must be followed in order to design such tanks safely. The finite element model developed in this thesis is a means provided for such a purpose.
imperfection patterns are undertaken, and the results indicate that the presence of axisymmetric imperfections leads to the lowest limit load for the structure. The sensitivity of the hydrostatically loaded conical vessels to geometric imperfections and residual stresses is investigated by considering inelastic analyses of three cases: (1) perfect vessels; (2) same as case 1, but with axisymmetric geometric imperfections of the order of the thickness of the shell; and (3) same as case 2, but with the addition of residual stresses due to welding. Results of these analyses indicate that liquid-filled conical shells are quite sensitive to geometric imperfections and that yielding precedes elastic buckling for tanks having practical dimensions.

ABSTRACT: Conical steel shells are widely used as water containments for elevated tanks. However, the current codes for design of water structures do not specify any procedure for handling the seismic design of such structures. In this paper, a numerical model is developed for studying the stability of liquid-filled conical tanks subjected to seismic loading. The model involves a previously formulated consistent shell element with geometric and material non-linearities included. A boundary element formulation is derived to obtain the hydrodynamic pressure resulting from both the horizontal and the vertical components of seismic motion acting on a conical tank which is prevented from rocking. The boundary element formulation leads to a fluid added-mass matrix which is incorporated with the shell element formulation to perform non-linear dynamic stability analysis of such tanks subjected to both horizontal and vertical components of ground motion. Although, the formulation was developed for conical vessels, it is general and can be easily modified to study the stability of any liquid-filled shell of revolution subjected to seismic loading. The accuracy of fluid added-mass formulation was verified by performing the free vibration analysis of liquid-filled cylindrical tanks and comparing the results to those available in the literature.

ABSTRACT: The buckling of laminated composite shells subjected to transverse load is investigated. The geometrical non-linear analysis is carried out using the finite element method based on a higher-order shear deformation theory. An eight noded degenerated isoparametric shell element with nine degrees of freedom at each node is considered. The geometric non-linear behaviour and the collapse pressures with the associated mode shapes are presented for simply supported symmetrically and anti-symmetrically laminated spherical shell panels subjected to uniform normal pressure.

“Buckling Load Characteristic of Conical Shells under Various End Conditions”, 17th Annual Conference of
Mechanical Engineering Network of Thailand, 15-17 October 2003, Prachinburi, Thailand

ABSTRACT: This paper is aimed to investigate the buckling load characteristic of conical shells subjected to axial loading. It was focused on the effect of end conditions, which are believed to promote the buckling resistance of structures. The study was carried out by means of experiment and structural model (FEA). The experimental result was, then, compared with the FEA and good agreement was achieved. The result suggested the strength of conical shells may be enhanced by constraining at the end. Particularly, the top constrained cones provide considerable high strength improvement (3%-10%).

ABSTRACT: The axisymmetric nonlinear stability of a shallow conical shell with a spherical cap was studied using the point collocation method with the cubic B-spline function as a trial function. Formulas were set up to consider arbitrary variable shell thickness and different boundary and loading conditions. A FORTRAN program was written to determine the critical loads and trace the stable parts of the equilibrium paths of the shell by method of gradually applied load. The upper and lower critical loads obtained in this technical note for some specific cases with constant shell thickness are of very good accuracy and agree very well with known solutions and finite-element method results. The method was then expanded successfully to arbitrary variable shell thickness and different boundary and loading conditions.

ABSTRACT: Thermal buckling and free vibration analyses of multi-layered composite conical shells based on a layerwise displacement theory are performed. The Donnell’s displacement-strain relationships of conical shell structure are applied. The natural frequencies are compared with the ones existing in the previous literature for laminated conical shells with several cone semi-vertex angles. Moreover, the thermal buckling behaviors of the laminated conical shell are investigated to consider the effect of the semi-vertex angle, subtended angle, and radius to thickness ratio on the structural stability.

ABSTRACT: The vaulted roofs of oil storage tank are usually designed as shallow spherical shells subjected to external pressure, and have been widely observed that these shallow spherical shells undergo varying degrees of corrosion in service periods. It is important to assessment the stability of these local thinned shallow spherical roofs due to corrosion for preventing them from occurring unexpected buckling failure. In this paper, the uniform eroded part of a shallow spherical oil tank vaulted roof is simplified as a shallow spherical shell with elastic supports. Based on the simplification, a general approach to compute critical pressure of eroded shallow spherical shell is proposed. The modified iteration method that considers the large deformation of shell is used to solve the problem of nonlinear stability of the shallow spherical shells, and then a second-order approximate analytical solution is obtained. The critical pressure calculated by this method is consistent with the classical numerical results and nonlinear finite element method, and the computing errors are less than 10%. It shows that the presented method is feasible.

imperfections in the column specimens and the test rig. At the shortest column height, the onset of local
behaviour of such members is investigated to provide a basis for future assessment of de

ABSTRACT: We discuss the stability of icosadeltahedral shells subjected to a uniform external load in the form of an isotropic pressure. We demonstrate that there exists a universal critical buckling pressure scaling form that defines a locus of buckling instabilities. The parameter that uniquely determines this scaling form is shown to be the Föppl–von Karman number of nonpressurized shells. Numerical results are interpreted in terms of scaling forms for buckling instabilities of spheres and cylinders under isotropic mechanical pressure, and are applied to the case of viruses under osmotic pressure.

References listed at the end of the paper:

8. We contrast outward buckling in the LMN case, thus without any external forcing, with inward buckling that we analyze here, in the presence of external isotropic pressure acting on the shell. We refer to the latter also simply as buckling, where the meaning is clear and there is no possibility of confusion.

ABSTRACT: This paper concerns polymeric composite columns manufactured by the pultrusion process. The behaviour of such members is investigated to provide a basis for future assessment of design methods. The minor-axis buckling characteristics of twelve wide-flange columns are presented. The main parameters varied are height (6·3 m, 4·8 m and 3·3 m) and nominal cross-sectional dimensions (152 × 152 × 9·53 mm, 203 × 203 × 9·53 mm and 203 × 203 × 12·7 mm). Deformation and failure characteristics are presented. It is found that theoretical Euler critical buckling loads generally correlate well with maximum test loads and critical loads derived from Southwell plots. A detailed discussion is presented to show that differences are due to imperfections in the column specimens and the test rig. At the shortest column height, the onset of local
compression flange buckling is found to lower resistance by way of modal-coupling with the global bending deformation.

ABSTRACT: In practice, large diameter, thin wall shells of revolution are never fabricated with constant diameters and thicknesses over the entire length of the assembly. These initial geometric imperfections have significant effect on the load carrying capacity of cylindrical shells. The cylindrical shell in the study is flue gas desulphurization (FGD) “vessel” which is a large hybrid tank-vessel-stack assembly in a major Canadian refinery. The function of the FGD vessel is to contain and support a proprietary process that utilizes an ammonium sulphate scrubbing system to produce environmentally friendly air emissions. FGD vessel stack has internal diameter of 6.1m, height of 45.34m and wall thickness of 9.525mm. Initial imperfections in FGD vessel is in the form of wall thickness variations. FGD wall thickness at 144 points along the circumference and elevation are measured. Monte Carlo method is employed to generate the measured data again. Test of significance is carried out to see the accuracy of the data generated. This Monte Carlo algorithm can be used to create data for any type of shell without spending time in actual measurements. Next, load carrying capacity of shell is determined considering imperfections to be axisymmetric and then asymmetric. Fourier decomposition is used to interpret imperfections as structural features can be easily related to the different components of imperfections. Further, double Fourier series is used to represent asymmetric initial geometric imperfections. The ultimate objective of these representations is to achieve a quantitative assessment of the critical buckling load considering the small axisymmetric and asymmetric deviations from the nominal cylindrical shell wall thickness. Analysis of cylindrical shells when used as pressure vessels and are under external pressure is also carried out. Comparison of reliability techniques that employ Fourier series representations of random axisymmetric and asymmetric imperfections in axially compressed cylindrical shells and shells under external pressure with evaluations prescribed by ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 and 2 is also carried out.

A. Stavref, D. Stefanov, D. Shillinger and E. Rank (Dept. of Civil Engineering and Surveying, Technical University of Munich, Germany), “Comparison of eigenmode based and random field based imperfection modeling for the stochastic buckling analysis of I-section beam-columns”, WSPC, Vol. 5, No. 4, 2013 (accepted draft; full publisher name is not given in the pdf file.)

ABSTRACT: The uncertainty of geometric imperfections in a series of nominally equal I-beams leads to a variability of corresponding buckling loads. Its analysis requires a stochastic imperfection model, which can be derived either by the simple variation of the critical Eigenmode with a scalar random variable, or with the help of the more advanced theory of random fields. The present paper first provides a concise review of the two different modeling approaches, covering theoretical background, assumptions and calibration, and illustrates their integration into commercial finite element software to conduct stochastic buckling analyses with the Monte Carlo method. The stochastic buckling behavior of an example beam is then simulated with both stochastic models, calibrated from corresponding imperfection measurements. The simulation results show that for different load cases, the response statistics of the buckling load obtained with the Eigenmode based and the random field based models agree very well. A comparison of our simulation results with corresponding
Eurocode 3 limit loads indicates that the design standard is very conservative for compression dominated load cases.

ABSTRACT: Presented are results from geometric non-linear finite element analyses to examine the lateral torsional buckling (LTB) resistance of a Pultruded fibre reinforced polymer (FRP) I-beam when initial geometric imperfections associated with the LTB mode shape are introduced. A data reduction method is proposed to define the limiting buckling load and the method is used to present strength results for a range of beam slendernesses and geometric imperfections. Prior to reporting on these non-linear analyses, Eigenvalue FE analyses are used to establish the influence on resistance of changing load height or displacement boundary conditions. By comparing predictions for the beam with either FRP or steel elastic constants it is found that the former has a relatively larger effect on buckling strength with changes in load height and end warping fixity. The developed finite element modelling methodology will enable parametric studies to be performed for the development of closed form formulae that will be reliable for the design of FRP beams against LTB failure.

ABSTRACT: An experimental and analytical research on shear buckling of a comparably large polymer composite I-section is presented. It is known that shear buckling load of a large span composite beam is difficult to determine experimentally. In order to sensitively detect shear buckling of the tested I-section, twenty strain rosettes and eight displacement sensors were applied and attached on the web and flange surfaces. The tested specimen was a pultruded composite beam made of vinylester resin, E-glass, carbon fibers and micro-fillers. Various coupon tests were performed before the shear buckling test to obtain fundamental material properties of the I-section. An asymmetric four-point bending loading scheme was utilized for the shear test. The loading scheme resulted in a high shear and almost zero moment condition at the center of the web panel. The shear buckling load was successfully determined after analyzing the obtained test data from strain rosettes and displacement sensors. An analytical approach was also performed to verify the experimental results and to support the discussed experimental program.

ABSTRACT: Electrostatic properties and stability of charged virus-like nano-shells are examined in ionic solutions with monovalent and multivalent ions. A theoretical model based on a thin charged spherical shell and multivalent ions within the "dressed multivalent ion" approximation, yielding their distribution across the shell and the corresponding electrostatic (osmotic) pressure acting on the shell, is compared with extensive implicit Monte-Carlo simulations. It is found to be accurate for positive or low negative surface charge densities of the shell and for sufficiently high (low) monovalent (multivalent) salt concentrations. Phase diagrams involving electrostatic pressure exhibit positive and negative values, corresponding to an outward and an inward facing force on the shell, respectively. This provides an explanation for the high sensitivity of viral shell stability and self-assembly of viral capsid shells on the ionic environment.

ABSTRACT: The inorganic analogs of carbon fullerenes and nanotubes, like MoS2 and BN, are reviewed. It is
argued that nanoparticles of 2D layered compounds are inherently unstable in the planar configuration and prefer to form closed cage structures. The progress in the synthesis of these nanomaterials, and, in particular, the large-scale synthesis of BN, WS2 and V2O5 nanotubes, are described. Some of the electronic, optical and mechanical properties of these nanostructures are reviewed. The red-shift of the energy gap with shrinking nanotube diameter is discussed as well as the suggestion that zigzag nanotubes exhibit a direct gap rather than an indirect gap, as is prevalent in many of the bulk 2D materials. Some potential applications of these nanomaterials are presented as well, most importantly the superior tribological properties of WS2 and MoS2 nested fullerene-like structures (onions).

ABSTRACT: Recent findings of linear carbon-atom chains (C-chains) inside carbon nanotubes have stimulated considerable interest. In this work, molecular dynamics (MD) simulation and an elastic string–elastic shell model is adopted to study radial pressure-induced buckling of single-walled carbon nanotubes (SWCNT) filled with a C-chain. The continuum model predicts that the C-chain increases critical buckling pressure considerably (about 40%–160%) for SWCNTs of diameters ranging from 0.68 to 0.72 nm, in reasonable quantitative agreement with the prediction of MD simulation. In particular, the MD simulation confirms that the originally circular cross section of filled SWNTs becomes elliptical after buckling, as predicted by the continuum model.

ABSTRACT: The deformation of thin spherical shells by applying an external pressure or by reducing the volume is studied by computer simulations and scaling arguments. The shape of the deformed shells depends on the deformation rate, the reduced volume V/V0 and the Foppl-von Karman number gamma. For slow deformations the shell attains its ground state, a shell with a single indentation, whereas for large deformation rates the shell appears crumpled with many indentations. The rim of the single indentation undergoes a shape transition from smooth to polygonal for gamma approximately 7000(deltaV/V0)^(-3/4). For the smooth rim the elastic energy scales like gamma^(1/4) whereas for the polygonal indentation we find a much smaller exponent, even smaller than the exponent 1/6 that is predicted for stretching ridges. The relaxation of a shell with multiple indentations towards the ground state follows an Ostwald ripening type of pathway and depends on the compression rate and on the Foppl-von Karman number. The number of indentations decreases as a power law with time t following ….(formula with lots of symbols and powers).

ABSTRACT: We studied the elastic properties and mechanical stability of viral capsids under external force-loading with computer simulations. Our approach allows the implementation of specific geometries corresponding to specific phages, such as φ29 and cowpea chlorotic mottle virus. We demonstrate how, in a combined numerical and experimental approach, the elastic parameters can be determined with high precision. The experimentally observed bimodality of elastic spring constants is shown to be of geometrical origin, namely the presence of pentavalent units in the viral shell. We define a criterion for capsid breakage that explains well the experimentally observed rupture. From our numerics we find a crossover from $\gamma^{2/3}$ to $\gamma^{1/2}$ for the dependence of the rupture force on the Föppl-von Kármán number, $\gamma$. For filled capsids, high internal pressures lead to a stronger destabilization for viruses with buckled ground states versus viruses with unbuckled ground states. Finally, we show how our numerically calculated energy maps can be used to extract information about the strength of protein–protein interactions from rupture experiments.

ABSTRACT: A series of hollow biodegradable polymeric microcapsules were prepared, of which their susceptibility to ultrasound was used for triggered release. High speed imaging of the ultrasound experiments showed a strong correlation between the acoustic pressure needed to activate these microcapsules and their shell
thickness to diameter ratio. Based on this information a selective triggering of capsules with two different shell thickness to diameter ratios was successfully performed. The capsules were mixed in a single system and were activated independently from each other by a differentiation in acoustic pressure levels. This application is of great interest in the field of drug delivery, since this system allows for localized multiple drug releases in a selective fashion.

ABSTRACT: The localization of deformation is a simple consequence of the fact that bending a thin sheet is energetically cheaper than stretching it. Thus, on examining a crumpled piece of paper, we find that it is made of nearly-planar or cylindrically curved regions folded along line-like stretched ridges or point-like conical singularities. Since the real crumpled paper problem is fairly difficult to deal with, we investigate two simple model experiments where one or two singularities are isolated and studied. When a cylindrical panel is axially compressed, a crease terminated by two conical type singularities appears. The length of this crease is selected by the width of the panel when the length and the thickness of the panel are kept constant. We study also a single conical singularity. This is achieved by pushing a thin sheet into a hollow cylinder similar to pushing coffee-filter paper in a funnel. We measured the singularity energy of the plate, or the work required to form a scar in the sheet. A simple model is proposed to understand the energetics of the crease formation.

ABSTRACT: Forced crumpling of stiff self-avoiding sheets is studied by discrete element simulations. Simulations display stress condensation and scaling of ridge energy in agreement with theoretical expectations for elastic and frictionless sheets, and extends such behavior to elasto-plastic sheets. Crumpling of ideally elastic and frictionless sheets is compared to that of elasto-plastic sheets and sheets with friction.

ABSTRACT: When a thin elastic sheet crumple’s, the elastic energy condenses into a network of folding lines and point vertices. These folds and vertices have elastic energy densities much greater than the surrounding areas, and most of the work required to crumple the sheet is consumed in breaking the folding lines or “ridges.” To understand crumpling it is then necessary to understand the strength of the ridges. In this work, we consider
the buckling of a single ridge under the action of inward forcing applied at its ends. We demonstrate a simple scaling relation for the response of the ridge to the force prior to buckling. We also show that the buckling instability depends only on the ratio of strain along the ridge to the curvature across it. Numerically, we find for a wide range of boundary conditions that ridges buckle when our forcing increases their elastic energy by 20% over their resting state value. We also observe a correlation between neighbor interactions and the location of initial buckling. Analytic arguments and numerical simulations are employed to prove these results. Implications for the strength of ridges as structural elements are discussed.

ABSTRACT: The wrinkling of thin elastic sheets occurs over a range of length scales, from the fine scale patterns in substrates on which cells crawl to the coarse wrinkles seen in clothes. Motivated by the wrinkling of a stretched elastic sheet, we deduce a general theory of wrinkling, valid far from the onset of the instability, using elementary geometry and the physics of bending and stretching. Our main result is a set of simple scaling laws; the wavelength of the wrinkles \( \lambda \) approximately \( K^{-1/4} \), where \( K \) is the stiffness due to an "elastic substrate" effect with a multitude of origins, and the amplitude of the wrinkle \( A \) approximately \( \lambda \). These could form the basis of a highly sensitive quantitative wrinkling assay for the mechanical characterization of thin solid membranes.

ABSTRACT: Subject to a compressive membrane force, a film bonded to a compliant substrate often forms a pattern of wrinkles. This paper studies such wrinkles in a layered structure used in several recent experiments. The structure comprises a stiff film bonded to a compliant substrate, which in turn is bonded to a rigid support. Two types of analyses are performed. First, for sinusoidal wrinkles, by minimizing energy, we obtain the wavelength and the amplitude of the wrinkles for substrates of various moduli and thicknesses. Second, we develop a method to simultaneously evolve the two-dimensional pattern in the film and the three-dimensional elastic field in the substrate. The simulations show that the wrinkles can evolve into stripes, labyrinths, or herringbones, depending on the anisotropy of the membrane forces. Statistical averages of the amplitude and wavelength of wrinkles of various patterns correlate well with the analytical solution of the sinusoidal wrinkles.

ABSTRACT: The radial stretching of a hollow thin membrane without compressive strength is considered within the framework of the small strain tension field theory. For each type of the uniform boundary conditions, the loading plane is partitioned into the domains of biaxial tension, tension field and buckling. The extent of these domains critically depends on the value of the Poisson’s coefficient and on the aspect ratio of the membrane. The stress and displacement fields are determined at an arbitrary stage of loading, when the outer biaxially stressed (taut) annulus surrounds the inner (tension field) portion of the membrane, characterized by continuously distributed infinitesimal wrinkles. The growth of the tension field as the loading increases is analyzed. It is shown that, depending on the Poisson’s coefficient and the aspect ratio of the membrane, the tension field may or may not spread throughout the whole membrane. For the fixed outer boundary, and the applied tension or a negative displacement at the inner boundary, and for a particular combination of the material and geometric parameters, the tension field instantly spreads to a specific depth within the membrane, dependent on the Poisson’s ratio and the outer radius of the membrane, remaining constant during further increase of the loading.

ABSTRACT: The wrinkled geometry of thin films is known to vary appreciably as the applied stresses exceed their buckling threshold. Here we derive and analyze a minimal, nonperturbative set of equations that captures the continuous evolution of radial wrinkles in the simplest axisymmetric geometry from threshold to the far-from-threshold limit, where the compressive stress collapses. This description of the growth of wrinkles is different from the traditional post-buckling approach and is expected to be valid for highly bendable sheets. Numerical analysis of our model predicts two surprising results. First, the number of wrinkles scales anomalously with the thickness of the sheet and the exerted load, in apparent contradiction with previous predictions. Second, there exists an invariant quantity that characterizes the mutual variation of the amplitude and number of wrinkles from threshold to the far-from-threshold regime.

Karamanos SA, Tassoulas JL (Dept. of Civil Engineering, University of Texas at Austin). Tubular members I:

ABSTRACT: This paper presents a finite-element technique for the analysis of tubular member stability under combined external pressure and structural loads. A tube element is developed for the purposes of this research. While polynomial (quadratic) interpolation is used in the longitudinal direction, Fourier series expansions of the displacement components are adopted at the nodal cross sections. The formulation accounts for large inelastic deformation and recognizes initial imperfections and residual stresses. To trace unstable equilibrium paths, arc-length procedures are implemented. A simple, yet effective estimate of the contribution of external pressure to the tube element stiffness matrix, particularly significant in the analysis of slender tubes, is included. Preliminary results regarding the behavior of tubular members subjected to pressure and bending are reported and discussed. The effects of initial imperfections and residual stresses on the response to pressure along with bending are summarized. Finally, the influence of residual stresses on thrust-moment interaction in tubular beam-columns is examined briefly.

ABSTRACT: The present paper examines instabilities of long thin elastic tubes. Both initially straight and initially bent tubes are analyzed under in-plane bending. Tube response, a combination of ovalization instability and bifurcation instability (buckling), is investigated using a nonlinear finite element (FE) technique, which employs polynomial functions in the longitudinal tube direction and trigonometric functions to describe cross-sectional deformation. It is demonstrated that the interaction between the two instability modes depends on the value and the sign of the initial tube curvature. The ovalization of initially bent tubes is examined in detail and, in particular, the case of opening moments. Furthermore, the paper emphasizes on bifurcation instability. It is shown that buckling may occur prior to or beyond the ovalization limit point, depending on the value of the initial curvature. Using the nonlinear FE formulation, the location of bifurcation on the primary path is detected, post-buckling equilibrium paths are traced, and the corresponding wavelengths of the buckled configurations are calculated. Moreover, results over a wide range of initial curvature values are presented, extending the findings of previous works. Finally, several analytical approaches, introduced in previous research works, are also employed to estimate the moments causing ovalization and bifurcation instability. These approaches are based on nonlinear flexible shell theory or simplified ring analysis. The efficiency and accuracy of those analytical methods with respect to the nonlinear FE formulation are examined.

ABSTRACT: This paper presents an investigation on the buckling behaviour of single-walled carbon nanotubes (NTs) under bending and unveils several aspects concerning the dependence of critical bending curvature on the NT length. The buckling results are obtained by means of non-linear shell finite element analyses using ABAQUS code. It is shown that eigenvalue analyses do not give a correct prediction of the critical curvature of NTs under bending. Conversely, incremental-iterative non-linear analyses provide a better approximation to the
molecular dynamics results due to the progressive ovalization of the NT cross-section under bending. For short NTs, the limit curvature drops with the increasing length mostly due to the decreasing influence of end effects. For moderate to long tubes, the limit curvature remains practically constant and independent on the tube length. An approximate formula based on the Brazier expression is proposed to predict the limit curvature.

ABSTRACT: The work investigates the response of elbows under in-plane bending and pressure, through nonlinear finite element tools, supported by experimental results from real-scale tests. The finite element analysis is mainly based on a nonlinear three-node "tube element", capable of describing elbow deformation in a rigorous manner, considering geometric and material nonlinearities. Furthermore, a nonlinear shell element from a general-purpose finite element program is employed in some special cases. Numerical results are compared with experimental data from steel elbow specimens. The comparison allows the investigation of important issues regarding deformation and ultimate capacity of elbows, with emphasis on relatively thin-walled elbows. The results demonstrate the effects of pressure and the influence of straight pipe segments. Finally, using the numerical tools, failure of elbows under bending moments is examined (cross-sectional flattening or local buckling), and reference to experimental observations is made.

ABSTRACT: The paper examines the nonlinear elastic-plastic response of internally pressurized 90 deg pipe elbows under in-plane and out-of-plane bending. Nonlinear shell elements from a general-purpose finite element program are employed to model the inelastic response of steel elbows and the adjacent straight parts. The numerical results are successfully compared with real-scale experimental measurements. The paper also presents a parametric study, aimed at investigating the effects of diameter-to-thickness ratio and moderate pressure levels on the ultimate bending capacity of 90 deg elbows, focusing on the failure mode (local buckling or cross-sectional flattening) and the maximum bending moment. Special attention is given to the response of 90 deg elbows under out-of-plane bending moments.

ABSTRACT: Mechanical damage in steel pipelines in the form of local buckles due to excessive bending deformation may severely threaten their structural integrity. The present paper describes experimental and numerical research conducted to assess the structural condition of buckled pipes, subjected to both bending and internal pressure. Fatigue failure under repeated loading is mainly investigated, whereas pipe burst due to internal pressure is also examined. Three full-scale buckled pipe specimens are tested under pressure and bending loads to determine their structural capacity. In addition, using nonlinear finite element tools, an extensive parametric study is conducted to determine the critical locations at the buckled area at which maximum strain variation occurs, as well as to investigate the influence of several geometrical and mechanical parameters. Using the maximum strain range from the finite element computations and a simple S-N approach, reasonable predictions are obtained for the number of cycles to failure observed in the tests. The results of the present study demonstrate that, under repeated loading, fatigue failure occurs in the buckled area at the location of maximum strain range. It is also found that the burst pressure may not be affected by the presence of buckles.

SUMMARY: The research examines instabilities of long pressurized thin elastic tubes. The material is isotropic or transversely-isotropic, and it is modeled through a hypo-elastic constitutive equation. Both initially straight and initially bent tubes are analyzed under in-plane bending and pressure. Tube response, a combination of
ovalization instability and bifurcation instability (buckling), is investigated using a nonlinear finite element technique, which employs polynomial functions in the longitudinal tube direction and trigonometric functions to describe cross-sectional deformation. It is demonstrated that the interaction between the two instability modes depends on the value and the sign of the initial tube curvature. The work emphasizes on bifurcation instability. It is shown that buckling may occur prior to or beyond the ovalization limit point, depending on the value of the initial curvature. Using the nonlinear finite element formulation, the location of bifurcation on the primary path is detected, post-buckling equilibrium paths are traced, and the corresponding wavelengths of the buckled configurations are calculated for a range of initial curvature values and in terms of pressure. Results over a wide range of initial curvature values are presented. The effects of anisotropy on the buckling moment, the buckling mode and the post-buckling response are also examined. Finally, an analytical approach is also employed to estimate the bending moment causing bifurcation instability. The approach is based on the DMV shell equations considering pre-buckling solutions from simplified ring analysis. The efficiency and accuracy of the analytical method with respect to the nonlinear finite element formulation are examined.

ABSTRACT: The buckling of isotropic rings under external pressure has attracted the interest of researchers since late 1950s. The formula for critical fluid buckling pressure of thin rings is very well known. This formula was directly extended to account for homogeneous orthotropic rings as well. The buckling of orthotropic cylindrical shells was also a subject of interest since the 1960s. However, the formulations developed, to date, require numerical solutions to obtain the critical pressure. In this work, a generalized closed form analytical formula for the buckling of thin orthotropic multi-angle laminated rings/long cylinders is developed. Standard energy based formulation is used to express the kinematics and equilibrium equations. Classical lamination theory is implemented to introduce the constitutive equations of thin shells. These equations are statically condensed, in terms of the ring's boundary conditions, to produce effective axial, coupling and flexural rigidities for the cases of rings and long cylinders. The critical buckling pressure may be calculated by hand using the derived equation in terms of these effective elastic rigidities. Comparisons are made with some existing results. Parametric studies are conducted to compare the present results with those of the buckling equations implemented by design standards. Various fiber orientations and stacking sequences are considered.

ABSTRACT: An overview of buckling and postbuckling behavior of pipes and tubes is presented, with particular emphasis on nonlinear finite element modeling. Classical bifurcation solutions for isotropic elastic cylinders under external pressure and bending are presented first. Subsequently, the stability of metal tubes and pipes under bending and external pressure is examined, and comparison with available experimental data is conducted. Finally, the behavior of composite cylinders under external pressure is presented, and the important
issue of delamination is thoroughly discussed.

ABSTRACT: The present paper focuses on the structural stability of long uniformly pressurized thin elastic tubular shells subjected to in-plane bending. Using a special-purpose non-linear finite element technique, bifurcation on the pre-buckling ovalization equilibrium path is detected, and the post-buckling path is traced. Furthermore, the influence of pressure (internal and/or external) as well as the effects of radius-to-thickness ratio, initial curvature and initial ovality on the bifurcation moment, curvature and the corresponding wavelength, are examined. The local character of buckling in the circumferential direction is also demonstrated, especially for thin-walled tubes. This observation motivates the development of a simplified analytical formulation for tube bifurcation, which considers the presence of pressure, initial curvature and ovality, and results in closed-form expressions of very good accuracy, for tubes with relatively small initial curvature. Finally, aspects of tube bifurcation are illustrated using a simple mechanical model, which considers the ovalized pre-buckling state and the effects of pressure.

ABSTRACT: The present paper investigates buckling of cylindrical shells of transversely-isotropic elastic material subjected to bending, considering the nonlinear prebuckling ovalized configuration. A large-strain hypoelastic model is developed to simulate the anisotropic material behavior. The model is incorporated in a finite-element formulation that uses a special-purpose “tube element”. For comparison purposes, a hyperelastic model is also employed. Using an eigenvalue analysis, bifurcation on the prebuckling ovalization path to a uniform wrinkling state is detected. Subsequently, the postbuckling equilibrium path is traced through a continuation arc-length algorithm. The effects of anisotropy on the bifurcation moment, the corresponding curvature and the critical wavelength are examined, for a wide range of radius-to-thickness ratio values. The calculated values of bifurcation moment and curvature are also compared with analytical predictions, based on a heuristic argument. Finally, numerical results for the imperfection sensitivity of bent cylinders are obtained, which show good comparison with previously reported asymptotic expressions.

ABSTRACT: The present paper investigates structural response and buckling of long unstiffened thin-walled cylindrical steel shells, subjected to bending moments, with particular emphasis on stability design. The cylinder response is characterized by cross-sectional ovalization, followed by buckling (bifurcation instability), which occurs on the compression side of the cylinder wall. Using a nonlinear finite element technique, the bifurcation moment is calculated, the post-buckling response is determined, and the imperfection sensitivity with respect to the governing buckling mode is examined. The results show that the buckling moment capacity is affected by cross-sectional ovalization. It is also shown that buckling of bent elastic long cylinders can be described quite accurately through a simple analytical model that considers the ovalized prebuckling configuration and results in very useful closed-form expressions. Using this analytical solution, the incorporation of the ovalization effects in the design of thin-walled cylinders under bending is thoroughly examined and discussed, considering the framework of the provisions of the new European Standard EN1993-1-6.

ABSTRACT: The present paper investigates the structural stability of thin-walled steel cylinders surrounded by an elastic medium, subjected to uniform external pressure. A two-dimensional model is developed, assuming no variation of load and deformation along the cylinder axis. The cylinder and the surrounding medium are simulated with nonlinear finite elements that account for both geometric and material nonlinearities. Cylinders of elastic material within a rigid boundary are considered first, and the numerical results are compared successfully with available closed-form analytical predictions. Subsequently, the external pressure response of confined thin-walled steel cylinders is examined, in terms of the initial out-of-roundness of the cylinder, the initial gap between the cylinder and the medium, and the stiffness of the surrounding medium. Numerical results are presented in the form of pressure-deformation equilibrium paths, and show a rapid drop of pressure after reaching the maximum pressure level, as well as a significant imperfection sensitivity. A plastic-hinge mechanism is developed that results in a closed-form expression and illustrates the post-buckling response of the cylinder in an approximate manner. The distributions of plastic deformation, as well as the variation of cylinder-medium contact pressure around the cylinder cross-section are also depicted and discussed. Furthermore, the effects of uniform vertical preloading on the maximum pressure sustained by the cylinder are examined. Finally, the numerical results show good comparison with a simplified closed-form expression, proposed elsewhere, which could be used for design purposes.

ABSTRACT: Thin-walled steel cylinders surrounded by an elastic medium, when subjected to uniform external pressure may buckle. In the present paper, using a two-dimensional model with nonlinear finite elements, which accounts for both geometric and material nonlinearities, the structural response of those cylinders is investigated, toward developing relevant design guidelines. Special emphasis is given on the response of the confined cylinders in terms of initial imperfections; those are considered in the form of initial out-of-roundness of the cylinder and as an initial gap between the cylinder and the medium. Furthermore, the effects of the deformability of the surrounding medium are examined. The results indicate significant imperfection sensitivity and a strong dependency on the medium stiffness. The numerical results are employed to develop a simple and efficient design methodology, which is compatible with the recent general provisions of European design recommendations for shell buckling and could be used for design purposes.

References listed at the end of the paper:

ABSTRACT: Motivated by practical engineering applications, the present study investigates the structural behavior and stability of thin-walled steel cylindrical shells with lateral confinement under two main types of loading, namely external pressure and longitudinal bending, both resulting in structural failure. The present work emphasizes on structural stability in terms of buckling, post-buckling and imperfection sensitivity. The investigation is computational using advanced finite element tools through the employment of a general-purpose finite element program. The cylindrical shells under consideration and the corresponding confinements are simulated with nonlinear finite elements that account for both geometric and material nonlinearities. An extensive literature review on the examined mechanical issues is conducted for the evaluation and assessment of available analytical solutions and experimental data. A numerical simulation methodology is developed and verified in order to model the shell and the interaction with the confinement. Shells of elastic material are considered first, offering the possibility of comparing the numerical results with available closed-form or simplified analytical predictions. Subsequently, the buckling response of steel shells is examined and the results are compared with available experimental data. For the case of external pressure loading, the numerical results are presented in the form of pressure-deformation equilibrium paths, and show an unstable post-buckling response beyond the point of ultimate pressure capacity, indicating significant imperfection sensitivity on the
value of the maximum pressure. The effects of the diameter-to-thickness ratio \((D/t)\), the yield stress, the interface friction, and the medium deformability on the structural response are examined. It is demonstrated that even for rigid confinement medium, the maximum (buckling) pressure is well below the pressure that causes plastification of the entire cylinder (referred to as yield pressure). Finally, based on the numerical results, a simplified and efficient methodology is developed which is compatible with the recent general provisions of European design recommendations for shell buckling, and could be used for design purposes. For the case of longitudinal bending loading of confined cylinders, the analysis refers to the case of the so-called lined pipes, focusing on the behavior of the thin-walled inner pipe (liner) which interacts with the outer pipe. Using a numerical simulation, the stresses and deformations in the compression zone are monitored, with emphasis on possible detachment of the liner from the confining medium, and on the formation of wrinkles. Furthermore, the development of liner ovalization, bending moment, local hoop curvature, axial stress, and hoop stress with increasing level of bending are investigated. The effects of liner thickness, friction, liner prestressing, and stiffness of the confining medium on the buckling curvature and wavelength are investigated. The sensitivity of response on the presence of initial wrinkling imperfections is investigated. Finally, the effect of external pressure on the mechanical response is discussed. The present study aims at establishing the theoretical basis for understanding and solving a significant number of structural instabilities related to confined cylindrical shells, which are encountered often in numerous practical engineering applications.

ABSTRACT: Motivated by practical engineering applications, the present paper examines the mechanical response of thin-walled cylinders surrounded by a rigid or deformable medium, subjected to uniform external pressure. Emphasis is given to structural stability in terms of buckling, postbuckling, and imperfection sensitivity. The present investigation is computational and employs a two-dimensional model, where the cylinder and the surrounding medium are simulated with nonlinear finite elements. The behavior of cylinders made of elastic material is examined first, and a successful comparison of the numerical results is conducted with available closed-form analytical solutions for rigidly confined cylinders. Subsequently, the response of confined thin-walled steel cylinders is examined. The numerical results show an unstable postbuckling response beyond the point of maximum pressure and indicate severe imperfection sensitivity on the value of the maximum pressure. A good comparison with limited available test data is also shown. Furthermore, the effects of the deformability of the surrounding medium are examined. In particular, soil embedment conditions are examined, with direct reference to the case of buried thin-walled steel pipelines. Finally, based on the numerical results, a comparison is attempted between the present buckling problem and the problem of “shrink buckling.” The differences between those two problems of confined cylinder buckling are pinpointed, emphasizing the issue of imperfection sensitivity.

Summary of the work described in the 5 papers just listed:
The research examines the mechanical behavior of lined pipes and investigates extensively the wrinkling of such pipes under bending loading with or without the presence of external pressure. Lined pipe, also referred to as “mechanically clad pipe”, is a new and promising technological solution in energy pipeline applications where the structural integrity of oil and gas steel pipelines requires erosion damage protection from oil or gas pollutants. Lined pipe is a double-wall pipe, consisting of a load-bearing high-strength, low-alloy carbon steel outer pipe, lined with a thin-walled sleeve made from a corrosion-resistant material referred to as “liner” pipe. Lined pipes are produced through an appropriate manufacturing procedure, consisting of heating the outer pipe, inserting the liner and pressurizing it until both pipes come in contact, and finally cooling the outer pipe. Considering the liner pipe as a thin-walled cylindrical shell prone to buckling, the lateral confinement due to the deformable outer pipe constitutes a paramount parameter for its mechanical behavior. In the present investigation, the problem is solved numerically, using nonlinear finite elements capable at simulating the lined pipe and the interaction between the liner and the outer pipe. Nonlinear geometry with large strains is taken into account, and the material of both pipes is elastic-plastic. The lined pipe is considered either stress-free (snug-fit pipe, SFP) or with an initial stress (tight-fit pipe, TFP). The thermo-hydraulic manufacturing process of the lined pipe is simulated to determine the liner hoop prestressing. First, an ovalization bending analysis of the lined pipe is conducted, where a slice of the pipe between two adjacent cross-sections is considered excluding the possibility of buckling. In this analysis, the stress and deformation of the liner in the compression zone is monitored, with emphasis on possible detachment of the liner from the outer pipe. Using a simple buckling hypothesis, it is possible to estimate the curvature at which liner wrinkling would occur. Subsequently, a three-dimensional analysis is conducted to examine buckling of the liner in the form of a uniform wrinkling pattern.
The curvature at which buckling occurs and the corresponding buckling wavelength are determined for different thicknesses of the liner and outer pipe. Furthermore, the transition from a uniform wrinkling configuration to a secondary bifurcation with more localized deformations is investigated, and reference to experimental observations is made. Next, the effects of initial imperfections on the structural behavior of lined pipes are investigated. Subsequently, the effect of the prestressing on the critical wavelength and the buckling curvature is examined. A comparison with available experimental results is conducted in terms of wrinkle height development and the corresponding buckling wavelength. Finally, the structural behavior of lined steel pipes under bending in the presence of external pressure is examined. The results of the present research can be used for safer design of lined pipes in pipeline applications.

“So on the seismic behavior and design of liquid storage tanks”, COMPDYN2011, III ECCOMAS Thematic Conference on Computational Methods in Structural Dynamics and Earthquake Engineering, M. Papadrakakis, M. Fragiadakis and V. Plevris (Editors), Corfu, Greece, 25-28 May, 2011

ABSTRACT: The paper examines some special issues on the structural behaviour of upright cylindrical liquid storage tanks, which are widely used in industrial facilities and for water storage. Two main design standards are considered: EN 1998-4, a relatively new standard, and Appendix E of API 650, which has been through substantial amendments and revisions in its new version (11th edition, 2007). There are significant differences between the two specifications, which are due to the fact that there exist several controversial issues on this subject, open to further research. These issues are (a) the number of modes necessary to estimate accurately the convective seismic force due to the hydrodynamic behaviour of the liquid containment; (b) the appropriate combination of the impulsive and the convective component of seismic force; (c) the uplifting behaviour of unanchored tanks, with emphasis on the base plate behaviour and the increase of meridional compression; (d) the choice of an appropriate reduction (behaviour) factor for calculating both the impulsive and the convective force; (e) the calculation of hydrodynamic hoop stresses due to liquid hydrodynamic motion; (f) the design of tanks against buckling at the top due to liquid sloshing; (g) the importance of nonlinear wave sloshing effects. The present paper is aimed at addressing the above issues based mainly on numerical simulations. To simulate the tank shell and its structural behaviour, general-purpose finite element software ABAQUS is employed, whereas to examine hydrodynamic effects, an in-house numerical technique is developed. Existing data from previous investigations are also considered. The results are aimed at better understanding of liquid storage tank seismic behaviour, bridging the gap between the two major design standards (EN 1998-4 and API 650-Appendix E), towards safer seismic design of industrial facilities.

ABSTRACT: The purpose of this study is to investigate the large strain and stress analysis for pipe elbows subjected to in-plane bending moments. A finite element model for the bend was constructed and loaded taking geometric and material nonlinearities into account using (ABAQUS) nonlinear finite element code. The initiation of yielding for the opening and closing cases appears at the inside surface of the elbow crown. However, further loading causes a significant difference in strain distribution and deformed shapes. The limit moment for the opening cases is higher than that for closing due to the geometric stiffening effects.

ABSTRACT: The purpose of this work is to study the load-carrying capacity of pipe bends, with different pipe bend factor (h) values, under out-of-plane moment loading; and to investigate the effect of internal pressure on the limit moments in this loading mode. The finite element method is used to model and analyze a standalone, long-radius pipe bend with a 16-in. nominal diameter, and a 24-in. bend radius. A parametric study is performed in which the bend factor takes ten different values between 0.0632 and 0.4417. Internal pressure is incremented by 100 psi for each model, until the limit pressure of the model is reached. The limit moments were found to increase when the internal pressure is incremented. However, beyond a certain value of pressure, the effect of pressure is reversed due to the additional stresses it engenders. Expectedly, increasing the bend factor leads to
an increase in the value of the limit loads. The results are compared to those, available in the literature, of a similar analysis that treats the in-plane loading mode. Pipe bends are found to have the lowest load-carrying capacity when loaded in their own plane, in the closing direction. They can sustain slightly higher loads when loaded in the out-of-plane direction, and considerably higher loads under in-plane bending in the opening direction.

ABSTRACT: This article covers the general behaviour of a straight uniform pipe, with built-in open ends, subject to internal pressure and in plane bending or curvature. It is intended as a summary of the basic equations driving the unintuitive phenomena of bending and instability of pipes under internal pressure. The analysis covers in addition the investigation of opposite pressure stabilisation effects that can be observed in some orthotropic material pipes like composite pressure hoses.

ABSTRACT: The experimental part of a study which deals with the response and stability of thin-walled tubes under cyclic bending histories is presented (see [7] for theory). Aluminum and steel tubes are cyclically bent in pure bending into the plastic range. It is found that under curvature-symmetric loading histories the tube progressively ovalizes to a critical value at which it buckles. This critical value of ovalization is approximately equal to the value obtained just prior to buckling under monotonic bending. The influence of the material and geometric parameters of the tubes on the phenomenon is studied. It is shown that for the materials studied, the phenomenon can drastically reduce the life expectancy of tubes in the range of D /t of 15 to 80.

Daniel Peter Miller, “Buckling failure boundary for cylindrical tubes in pure bending”, Master’s thesis, Mechanical Engineering, Brigham Young University, April 2012
ABSTRACT: Bending of thin-walled tubing to a prescribed bend radius is typically performed by bending it
around a mandrel of the desired bend radius, corrected for spring back. By eliminating the mandrel, costly setup time would be reduced, permitting multiple change of radius during a production run, and even intermixing different products on the same line. The principal challenge is to avoid buckling, as the mandrel and shoe are generally shaped to enclose the tube while bending. Without the shaped mandrel, buckling will likely occur sooner, that is, at larger bend radii. A test apparatus has been built for arborless bending. It has been used to determine the limits of bend radius, wall thickness, material properties, etc. on buckling. Key to the process is a set of moveable clamps, which grip the tube and rotate to produce the bend. A complex control system moves the clamps radially to maintain pure bending, without superimposing tension or compression. A series of tests were performed to document the safe region of operation to avoid buckling. Charts have been created to assist the operator, as well as the design engineer, in determining the minimum bend radius. Similar tests will be required for each additional tube size, thickness, material, etc.

“Behavior of Thin-walled circular hollow section tubes subjected to bending”, Thin Walled Struct 73:281–289, December 2013, DOI: 10.1016/j.tws.2013.08.014

ABSTRACT: Thin-walled steel circular hollow sections (CHS) are widely used in wind turbine towers. The tower tubes are mainly subjected to bending. There have been a few experimental studies on the bending behavior of thin-walled CHS steel tubes. This paper describes a series of bending tests to examine the influence of section slenderness on the inelastic and elastic bending properties of thin-walled CHS. In addition, the influence of stiffeners welded in the steel tube is considered. Sixteen bending tests were performed up to failure on different sizes of CHS with diameter-to-thickness ratio (D/t) varying from 75 to 300. The experimental results showed that the specimens with small diameter-to-thickness ratios failed by extensive plastic deformation on the central part of the tube. With the increase of diameter-to-thickness ratio, the local buckling phenomena became more pronounced. The stiffeners in the steel tubes increased the load carrying capacity and improved the ductility of the specimens. The experimental results were compared with current design guidelines on thin-walled steel members in AISC-LRFD, AS4100 and European Specification. It was found that the test results agreed well with the results based on AS4100 design code.

ABSTRACT: This article is concerned with the numerical modelling and analysis of the mechanical behaviour of composite pipes used for offshore oil and gas applications. Specifically, the bending of the reinforced thermoplastic pipes during the reeling process of reel-lay installation is modelled using non-linear finite-element procedures. In particular, the possible buckling of the reeled composite pipes has been investigated. Composite pipes reinforced with one angle-ply and two angle-ply layers are considered and the effects of different diameter-to-thickness ratios and different angle-ply combinations on the mechanical behaviour of these pipes have been studied.

“Buckling analysis of high-temperature pressurized pipelines with soil-structure interaction”, Journal of the
ABSTRACT: High-temperature pressurized pipelines design requires special attention, as restrained thermal stresses are high. Due consideration should be given to thermal expansion, as stresses in bends of expansion loops are significant. Also, the modeling of the soil-pipe interaction using soil characteristics, especially friction and lateral resistance, is important when analyzing high-temperature pipelines. This paper describes a numerical procedure for the analysis of global and local buckling behavior of high temperature pressurized buried pipelines. Results of finite element calculations are presented and discussed.

ABSTRACT: Deformation of a spherical shell adhering onto a rigid substrate due to van der Waals attractive interaction is investigated by means of numerical minimization of the sum of the elastic and adhesion energies. The conformation of the deformed shell is governed by two dimensionless parameters Cs/epsilon and Cb/epsilon, where Cs and Cb are respectively the stretching and the bending constants, and epsilon is the depth of the van der Waals potential. As a function of Cb/epsilon, we find both continuous and discontinuous buckling transitions for small and large Cs/epsilon, respectively, which is analogous to van der Waals fluids or gels. Some scaling arguments are employed to explain the adhesion induced buckling transition.

ABSTRACT: Deformation of a spherical shell adhering onto a rigid substrate due to van der Waals attractive interaction is investigated by means of numerical minimization (conjugate gradient method) of the sum of the elastic and adhesion energies. The conformation of the deformed shell is governed by two dimensionless parameters, i.e., Cs/epsilon and Cb/epsilon where Cs and Cb are respectively the stretching and the bending constants, and epsilon is the depth of the van der Waals potential between the shell and substrate. Four different regimes of deformation are characterized as these parameters are systematically varied: (i) small deformation regime, (ii) disk formation regime, (iii) isotropic buckling regime, and (iv) anisotropic buckling regime. By measuring the various quantities of the deformed shells, we find that both discontinuous and continuous buckling transitions occur for large and small Cs/epsilon, respectively. This behavior of the buckling transition is analogous to van der Waals liquids or gels, and we have numerically determined the associated critical point. Scaling arguments are employed to explain the adhesion induced buckling transition, i.e., from the disk formation regime to the isotropic buckling regime. We show that the buckling transition takes place when the indentation length exceeds the effective shell thickness which is determined from the elastic constants. This prediction is in good agreement with our numerical results. Moreover, the ratio between the indentation length and its thickness at the transition point provides a constant number (2–3) independent of the shell size. This universal number is observed in various experimental systems ranging from nanoscale to macroscale. In particular, our results agree well with the recent compression experiment using microcapsules.

“Dynamics of Snapping Beams and Jumping Poppers”, A. Pandey, D.E. Moulton, D. Vella, and D.P. Holmes,
ABSTRACT: We consider the dynamic snapping instability of elastic beams and shells. We show that the stretchability of the arch plays a critical role in determining not only the post-buckling mode of deformation, but also the timescale of snapping, and the frequency of the arch's vibrations about its final equilibrium state. We show that the growth rate of the snap-through instability, and its subsequent ringing frequency, can both be interpreted physically as the result of a sound wave in the material propagating over a distance comparable to the radius of curvature of the arch. Finally, we extend our analysis of the ringing frequency of indented arches to understand the 'pop' heard when everted shell structures snap-through to their stable state. Remarkably, we find that not only are the scaling laws for the ringing frequencies in these two scenarios identical, but also the respective prefactors are numerically close; this allows us to develop a master curve for the frequency of ringing in snapping beams and shells.

D.P. Holmes, iMechanica - Journal Club, February 2012
Welcome to February 2012's Journal club, which will include a discussion on elastic instabilities for form and function. Not long ago, the loss of structural stability through buckling generally referred to failure and disaster. It was a phenomenon to be designed around, and rarely did it provide functionality*. The increasing focus on soft materials, from rubbers and gels to biological tissues, encouraged scientists to revisit the role of elastic instabilities in the world around us and inspired their utilization in advanced materials. Now the field of elastic instabilities, or extreme mechanics, brings together the disciplines of physics, mechanics, mathematics, biology, and materials science to extend our understanding of structural instabilities for both form and function. In this journal club, we're going to look at research on the wrinkling, crumpling, and snapping of soft or slender structures.

ABSTRACT: Soft materials, e.g. biological tissues and gels, undergo morphological changes, motion, and instabilities when subjected to external stimuli. Tissues can exhibit residual internal stresses induced by growth, and generate elastic deformations to move in response to light or touch, curl articular cartilage, aid in seed dispersal, and actuate hygromorphs, such as pine cones. Understanding the dynamics of such osmotically driven movements, in the influence of geometry and boundary conditions, is crucial to the controlled deformation of soft materials. We examine how thin elastic plates undergo rapid bending and buckling instabilities after exposure to a solvent that swells the network. A circular disc bends and buckles with multiple curvatures, and a large-amplitude traveling wave rotates azimuthally around the disc.

ABSTRACT: A polymer film draping over a point of contact will wrinkle due to the strain imposed by the underlying substrate. The wrinkle wavelength is dictated by a balance of material properties and geometry; most directly the thickness of the draping film. At a critical strain, the stress in the film will localize, causing hundreds of wrinkles to collapse into several discrete folds. In this paper, we examine the deformation of an axisymmetric sheet and quantify the force required to generate a fold. The onset of folding, in terms of a critical force or displacement, scales as the thickness to the four-ninth power, which we predict from the energy balance of the system. The folds increase the tension in the remainder of the film causing the radial stress to increase, thereby decreasing the wavelength of the remaining wrinkles.

ABSTRACT: The topographic control of pattern features is of great interest for a range of applications including the generation of ultrahydrophobic surfaces, microfluidic devices, and the control and tuning of adhesion. In these areas, surface patterning is achieved by a variety of techniques including: photolithography, imprint lithography, and surfaces wrinkling. In this paper, we present a scalable patterning method based on surface plate buckling, or crumpling, to generate a variety of topographies that can dynamically change shape and aspect ratio in response to stimuli.

ABSTRACT: The responsive mechanism of the Venus flytrap has captured the interest of scientists for centuries. Although a complete understanding of the mechanism controlling the Venus flytrap movement has yet to be determined, a recent publication highlights the importance of geometry and material properties for this fast, stimuli-responsive movement. Specifically, the movement is attributed to a snap-through elastic instability whose sensitivity is dictated by the length scale, geometry, and materials properties of the features. Here, we use lessons from the Venus flytrap to design surfaces that dynamically modify their topography. We present a simple, biomimetic responsive surface based on an array of microlens shells that snap from one curvature to another when a critical stress develops in the shell structure.

S-L Fok, University of Manchester Manchester School of Engineering UK,

ABSTRACT: Elastic buckling of a spherical shell, embedded in an elastic material and loaded by a far-field hydrostatic pressure is analysed using the energy method together with a Rayleigh—Ritz trial function. For
simplicity, only axisymmetric deformations are considered and inextensional buckling is assumed. The strains within the structure that are pre-critical are assumed to be small for the linear theory to be applicable. An expression is derived relating the pressure load to the buckling mode number, from which the upper-bound critical load can be determined. It is found that the presence of the surrounding elastic medium increases the critical load of the shell and the corresponding buckling mode number. However, the results also show that the strain of the shell at the point of instability may not be small for typical values of material and geometric constants.

ABSTRACT: This paper considers dynamic buckling of a harmonically base-excited vertical cylindrical shell carrying a top mass. Based on Donnell’s nonlinear shell theory, a semi-analytical model is derived which exactly satisfies the (in-plane) boundary conditions. This model is numerically validated through a comparison with quasi-static and modal analysis results obtained using finite element modelling. The steady-state nonlinear dynamics of the base-excited cylindrical shell with top mass are examined using both numerical continuation of periodic solutions and standard numerical time integration. In these dynamic analyses the cylindrical shell is preloaded by the weight of the top mass. This preloading results in a single unbuckled stable static equilibrium state. A critical value for the amplitude of the harmonic base-excitation is determined. Above this critical value, the shell exhibits an instationary beating type of response with time intervals showing severe out-of-plane deformations (it buckles dynamically). Similar as for the static buckling case, the critical value highly depends on the initial imperfections present in the shell.

doi:10.1016/j.jsv.2010.02.007
ABSTRACT: Considering both an experimental and a numerical approach, the dynamic stability of a harmonically base-excited thin orthotropic cylindrical shell carrying a top mass is examined. To be able to compare the experimentally obtained results with numerical results, a semi-analytical coupled shaker-structure model is derived. Using the semi-analytical model, it is shown that the dynamic stability analysis of the base-excited cylindrical shell with top mass should be concentrated near a low frequency resonance, corresponding to a mode, in which axial vibrations of the (cylindrical shell with) top mass dominate. In this frequency region, the shell may exhibit an aperiodic beating type of response, if some critical value of the amplitude of the harmonic base-excitation is exceeded. This beating response is characterized by severe out-of-plane deformations. The experimental results qualitatively confirm the numerical observations.

ABSTRACT: In this thesis a theoretical investigation of the nonlinear vibrations of imperfect thin-walled cylindrical shells is presented, which is aimed at two objectives. The first one is to investigate the influence of initial geometric imperfections on the nonlinear vibration behaviour of shells, while the second one is to investigate the effect of different boundary conditions. Donnell shallow shell equations are used with the appropriate damping, inertial and initial geometric imperfection terms included. Galerkin's procedure and the method of averaging are employed in order to reduce the problem to the solution of nonlinear algebraic and nonlinear ordinary differential equations, respectively. Numerical solutions indicate that the initial geometric imperfections have strong influence on the nonlinear vibrations of shells if certain coupling conditions are satisfied. The imperfections may not only significantly change the natural frequencies and the degree of non-linearity, but also may change the vibration behaviour. Results show that the effect of boundary conditions on the nonlinear vibrations of shells may be significant especially for shorter shells .

doi:10.1006/jsvi.1996.0827
ABSTRACT: In this paper, the non-linear vibration and dynamic instability of thin shallow spherical and conical shells subjected to periodic transverse and in-plane loads are investigated. The Marguerre type dynamic equations used for the analysis of shallow shells, when treated by the Galerkin method, will result in a system of total differential equations in the time functions, known as Duffing and Mathieu equations, from which the
various kinds of non-linear vibration and dynamic instability are determined by using numerical methods. Numerical results are presented for axisymmetric vibrations and dynamic instabilities of shallow spherical and conical shells with (a) clamped and (b) supported edge conditions. As numerical examples, non-linear vibration frequencies and instability regions for shells are determined. The effects of static load as well as static snap-through buckling on the instability are also investigated.

ABSTRACT: A system of governing equations for non-linear vibrations of heated sandwich shallow shells is derived using Hamilton's principle in combination with Reissner-Hellinger's variational principle. The system contains four unknown functions which characterize the deflection, the Airy stress function and the shearing displacements. For a rectangular simply supported shallow shell due to a temperature difference between the upper and lower faces and prevented from inplane motions on the contour, the governing time equation is derived by means of a Galerkin procedure applied to the field equation of the vertical motion. Numerical results are shown in the graphs.

ABSTRACT: An analytical study of buckling of rectangular sandwich plates, stressed uniaxially by uniform shortening beyond the elastic limits of component materials, is presented. The analysis is based on the inelastic behavior according to both the $J_2$-incremental and $J_2$-deformation theories of plasticity. Taking the loaded edges as simply supported, the governing equations are solved for (a) plates simply supported on all four sides, and (b) plates simply supported on three sides and free on the fourth side. The theory gives rise to two sets of boundary conditions, each representing “simple support”. It is shown that these alternative choices lead to significantly different predictions of the buckling load in the case of sandwich plates simply supported on three sides and free on the fourth, unloaded side. The presented analysis can be specialized to elastic buckling of sandwich plates, and also to elastic or plastic buckling of homogeneous (one-material) plates with or without the transverse shear effects.

ABSTRACT: This paper reports on the development of finite element formulations and computer programs for modelling free and constrained inflation of thin polymeric sheets in the context of thermoforming of plastic articles. In recognition of the generally time-dependent viscoelastic behaviour of polymers, and the large strains encountered in thermoforming applications, the material is modelled as non-linear viscoelastic. For this purpose the constitutive relation proposed by Christensen is adopted, assuming the relaxation function to be exponential. Most of the published work on non-linear viscoelastic membranes deals with simple axisymmetric geometries, while the finite element formulations presented in this work are for both axisymmetric and non-axisymmetric membrane inflations, including contact against constraining surfaces. Both frictionless and slipless idealizations
of contact conditions are studied. The finite element solutions of free and constrained inflations of circular membranes serve as illustrative examples for the axisymmetric case, while those for elliptical membranes demonstrate the non-axisymmetric cases. Comparison of the finite element results with the analytical solutions obtained (Appendix 1) for some simple free and constrained inflation problems shows good agreement.

ABSTRACT: This paper investigated the nonlinear stability problem of dished shallow shells under circular line loads. We derived the dimensionless governing differential equations of dished shallow shell under circular line loads according to the nonlinear theory of plates and shells and solved the governing differential equations by combing the free-parameter perturbation method (FPPM) with spline function method (SFM) to analyze the nonlinear instability modes of dished shallow shell under circular line loads. By analyzing the nonlinear instability modes and combining with concrete computational examples, we obtained the variation rules of the maximum deflection area of initial instability with different geometric parameters and loading action positions and discussed the relationship between the initial instability area and the maximum deflection area of initial instability. The results obtained from this paper provide some theoretical basis for engineering design and instability prediction and control of shallow-shell structures.

ABSTRACT: A simple and computationally efficient numerical approach is employed in this study for free vibrations of complicated shaped layered shells of revolution. Each layer of the shell is assumed to be constructed from an orthotropic material. The effects of shear deformation and rotary inertia have been included in the formulation, where stiffness and consistent mass matrices are evaluated using reduced integration technique. The approach yields accurate results for shells, if the mid-surfaces are represented by a series of mutually tangential circular arcs. Numerical examples include the natural frequencies and corresponding mode shapes of three-layered freely supported circular cylindrical shells, clamped shallow spherical shells and a cylindrical shell closed by a torispherical head.

ABSTRACT: This paper deals with the free flexural vibration of laminated quadrilateral plates and shallow shells using the Rayleigh–Ritz method. Equations are derived using the first order shear deformation theory of plates and shells. Nonlinearity is present only in the in-plane strain components. The transverse shear strains, curvature and inertial terms are linear. The geometry is mapped using the natural coordinates. Admissible displacement fields are constructed by taking the product of two simple polynomials in each of the two parametric coordinates. By controlling the coefficients of these polynomials, the geometric boundary conditions are satisfied. Numerical results are presented for the four-layer angle-ply plates and cylindrical shallow shells supported on trapezoidal boundary. The influences of the large amplitude and also of the geometry on the natural frequency are examined.

ABSTRACT: An analysis is presented for the vibration and stability of a circular cylindrical shell subjected to a torque. The displacements of a circular shell are written in a series of beam eigenfunctions satisfying the boundary conditions. The kinetic and strain energies of the shell are evaluated analytically, and the frequency equation of the shell is derived by the Ritz method. The method is applied to circular cylindrical shells under two types of boundary conditions at the edges; the natural frequencies and the divergence torques are calculated numerically, and the effects of the thickness ratio, length ratio and edge conditions on the vibration and stability are studied.

Gen Yamada, Toshihiro Irie and Mitsuo Tsushima (Department of Mechanical Engineering, Faculty of Engineering, Hokkaido University, Sapporo, 060 Japan), “Vibration and stability of orthotropic circular cylindrical shells subjected to axial load”, J. Acoust. Soc. Am. 75, 842 (1984); http://dx.doi.org/10.1121/1.390594
ABSTRACT: An analysis is presented for the vibration and stability of an orthotropic circular cylindrical shell subjected to an axial static load by use of the transfer matrix approach. The applicability of the thin-shell theory is assumed, and the governing equations of free vibration of the shell are written in a matrix differential equation by using the transfer matrix of the shell. Once the matrix has been determined by a solution to the equation, the natural frequencies and the critical loads are calculated numerically in terms of the elements of the matrix for a given set of boundary conditions at the edges. This method is applied to orthotropic circular cylindrical shells simply supported at the edges, and the effects of the length ratio, orthotropy, and axial load on the vibration and stability are studied.

ABSTRACT: This paper examines non-linear free vibration characteristics of first and second vibration modes of laminated shallow shells with rigidly clamped edges. Non-linear equations of motion for the shells based on the first order shear deformation and classical shell theories are derived by means of Hamilton's principle. We apply Galerkin's procedure to the equations of motion in which eigenvectors for first and second modes of linear vibration obtained by the Ritz method are employed as trial functions. Then simultaneous non-linear ordinary differential equations are derived in terms of amplitudes of the first and second vibration modes. Backbone curves for the first and second vibration modes are solved numerically by the Gauss–Legendre integration method and the shooting method respectively. The effects of lamination sequences and transverse shear deformation on the behavior are discussed. It is also shown that the motion of the first vibration mode affects the response for the second vibration mode.

ABSTRACT: This paper presents the response of symmetric crossply laminated shallow shells with an internal resonance omega2 approximately equal to omega3, where omega2 and omega3 are the linear natural frequencies of the asymmetric vibration modes (2,1) and (1,2), respectively. Galerkin's procedure is applied to the nonlinear governing equations for the shells based on the von Kármán-type geometric nonlinear theory and the first-order shear deformation theory, and the shooting method is used to obtain the steady-state response when a driving frequency Omega is near omega2. In order to take into account the influence of quadratic nonlinearities, the displacement functions of the shells are approximated by the eigenfunctions for the linear vibration mode (1,1) in addition to the ones for the modes (2,1) and (1,2). This approximation overcomes the shortcomings in Galerkin's procedure. In the numerical examples, the effect of the (1,1) mode on the primary resonance of the (2,1) mode is examined in detail, which allows us to conclude that the consideration of the (1,1) mode is indispensable for analyzing nonlinear vibrations of asymmetric vibration modes of shells.

T.L.C. Chen and C.W. Bert (Mechanical Engineering, The University of Oklahoma, Norman, Oklahoma),

ABSTRACT: A linear stability analysis is presented for a thin-walled, circular cylindrical shell of orthotropic material conveying a swirling flow. Shell motion is modeled by using the dynamic orthotropic version of the Sanders shell theory and fluid forces are described by inviscid, incompressible flow theory. The critical flow velocities are determined for piping made of composite and isotropic materials conveying swirling water. Fluid rotation strongly degrades the stability of the shell/fluid system, i.e. increasing the fluid rotating speed severely decreases the critical flow velocity.

ABSTRACT: Consideration is given to problems of nonlinear stability of inertial collapse of spherical and cylindrical shells filled with a viscous incompressible fluid homogeneous in density. Using Lyapunov’s direct method, we determine: 1) the necessary and sufficient condition for stability of spherically symmetrical inertial collapse of a thick spherical shell with respect to finite disturbances of symmetry of the same type and 2) absolute stability of cylindrically symmetrical inertial collapse of a cylindrical shell relative to finite disturbances of the same symmetry.

ABSTRACT: This paper deals with the dynamics of a cluster of parallel flexible cylinders in a cylindrical channel in the presence of an axially flowing fluid. The equations of motion are derived, taking into account inviscid and viscous hydrodynamic coupling of small arbitrary motions of the cylinders. Solutions of the equations of motion yield the eigenfrequencies and modal shapes of the system. For sufficiently high flow velocities the system loses stability by divergence and flutter, similarly to a solitary cylinder in unbounded flow; however, the critical flow velocities are much lower, as proximity to other cylinders and to the channel wall severely destabilize the system.

ABSTRACT: This paper presents an analytical model for the dynamics and stability of coaxial cylindrical shells conveying incompressible or compressible fluid in the inner shell and in the annulus between the two shells. Shell motions are described by Flügge's thin-shell equations and the fluid forces are determined by means of linearized potential flow theory and formulated with the aid of generalized force Fourier transform techniques. Calculations have been conducted with two flexible shells or with one replaced by an identical rigid
cylinder, with inner or annular flow, or both, mainly with incompressible flows but also with compressible ones; with steel or rubber shells conveying either water or air. It is found that, for the systems studied, annular flow destabilizes the system at lower flow velocities than flow in the inner shell and that the stability threshold is lower when both shells are flexible. The critical flow velocities are in the range of interest for industrial systems. The effect of compressibility is found to be small.

ABSTRACT: In this paper the dynamics and stability characteristics of coaxial cylindrical shells containing incompressible, viscous fluid flow are examined in contrast to previous studies where the fluid has been considered to be inviscid. Specifically, upstream pressurization of the flow (to overcome frictional pressure drop) and skin friction on the shell surfaces are taken into account, generating time-mean normal and tangential loading on the shells. Shell motions are described by Flügge’s thin shell equations, suitably modified to incorporate the time-mean stress resultants arising from viscous effects. The fluctuating fluid forces, coupled to shell vibration, are determined entirely by means of linearized potential flow theory and formulated with the aid of generalized-force Fourier-transform techniques. It is found that the effect of viscosity in the annular flow generally tends to destabilize the system, vis-à-vis inviscid flow, whereas viscous effects in the inner flow stabilize the system. These effects can be quantitatively very important, so that, generally, neglect of viscous effects cannot be justified.

ABSTRACT: This paper considers analytically the dynamics of a flexible cylinder in a narrow coaxial cylindrical duct, subjected to annular flow. In the present analysis, in contrast to existing theory, the viscous forces are not derived by an adaptation of Taylor’s unconfined-flow relationships, but by a systematic, albeit approximate, solution of the Navier-Stokes equations, which accounts for the unsteady viscous effects much more fully than heretofore; it is found that, for very narrow annuli, the contribution of these unsteady viscous forces to the overall unsteady forces on the cylinder can be much larger than that of the steady skin friction and pressure-drop effects alone. The present analysis also differs from existing theory in that the in-viscid forces are not derived via the slender-body approximation, and hence the analysis is also applicable to bodies of relatively small length-to-radius ratio. The dynamics and stability of typical systems with fixed ends is investigated, concentrating mainly on viscous effects and comparing the results with those of previous work. It is found that, as the annular gap becomes narrower, the system loses stability by divergence at smaller flow velocities, provided the gap size is such that inviscid fluid effects are dominant. For very narrow annuli, however, where viscous forces predominate, this trend is reversed, and further narrowing of the annular gap has a stabilizing effect on the system; furthermore, in some cases the system loses stability by flutter rather than divergence.

“Low-dimensional model for nonlinear vibration of circular cylindrical shells”, (publisher and date not given in
the pdf file. Most recent reference is dated 1998.)

ABSTRACT: The response-frequency relationship in the vicinity of a resonant frequency, the occurrence of travelling wave response and the presence of internal resonances are investigated for simply supported, circular cylindrical shells. Donnell's nonlinear shallow-shell theory is used. The boundary conditions on radial displacement and the continuity of circumferential displacement are exactly satisfied. The problem is reduced to a system of ordinary differential equations by means of the Galerkin method. The mode shape is expanded by using four degrees of freedom. The effect of internal dense fluid is studied. The solution is obtained by the Method of Normal Forms. Comparison of a three and a four degree-of-freedom model is performed. A water-filled shell presenting the phenomenon of 1:1:1:2 internal resonances is investigated; specific Normal Forms are developed for this study.

ABSTRACT: The non-linear vibration of simply supported, circular cylindrical shells is analysed. Geometric non-linearities due to finite-amplitude shell motion are considered by using Donnell's non-linear shallow-shell theory; the effect of viscous structural damping is taken into account. A discretization method based on a series expansion of an unlimited number of linear modes, including axisymmetric and asymmetric modes, following
the Galerkin procedure, is developed. Both driven and companion modes are included, allowing for travelling-wave response of the shell. Axisymmetric modes are included because they are essential in simulating the inward mean deflection of the oscillation with respect to the equilibrium position. The fundamental role of the axisymmetric modes is confirmed and the role of higher order asymmetric modes is clarified in order to obtain the correct character of the circular cylindrical shell non-linearity. The effect of the geometric shell characteristics, i.e., radius, length and thickness, on the non-linear behaviour is analysed: very short or thick shells display a hardening non-linearity; conversely, a softening type non-linearity is found in a wide range of shell geometries.

ABSTRACT: The study presented is an investigation of the non-linear dynamics and stability of simply supported, circular cylindrical shells containing inviscid incompressible fluid flow. Non-linearities due to large-amplitude shell motion are considered by using the non-linear Donnell's shallow shell theory, with account taken of the effect of viscous structural damping. Linear potential flow theory is applied to describe the fluid–structure interaction. The system is discretized by Galerkin's method, and is investigated by using a model involving seven degrees of freedom, allowing for travelling wave response of the shell and shell axisymmetric contraction. Two different boundary conditions are applied to the fluid flow beyond the shell, corresponding to: (i) infinite baffles (rigid extensions of the shell), and (ii) connection with a flexible wall of infinite extent in the longitudinal direction, permitting solution by separation of variables; they give two different kinds of dynamical behaviour of the system, as a consequence of the fact that axisymmetric contraction, responsible for the softening non-linear dynamical behaviour of shells, is not allowed if the fluid flow beyond the shell is constrained by rigid baffles. Results show that the system loses stability by divergence.

Part I of this study, are studied by using a code based on the collocation method. The validation of the present
results is checked by comparing the obtained solutions with those of the literature and, if possible, with
an analytical solution. The nonlinear sction of the study is organized as follows:

**ABSTRACT:**

The non-linear vibration of a cylindrical shell containing a flowing fluid is investigated. Both modal and point
excitations have been considered. The model is suitable to study simply supported shells with and without axial
constraints. Donnell's non-linear shallow-shell theory is used. The boundary conditions on radial displacement and
the continuity of circumferential displacement are exactly satisfied. The radial deflection of the shell is expanded by
using a basis of seven linear modes. The effect of internal quiescent, incompressible and inviscid fluid is investigated.
The equations of motion, obtained in Part I of this study, are studied by using a code based on the collocation method. The validation of the present
model is obtained by comparison with other authoritative results. The effect of the number of axisymmetric modes used in the expansion on the response of the shell is investigated, clarifying questions open for a long time. The results show the occurrence of travelling wave response in the proximity of the resonance frequency, the fundamental role of the first and third axisymmetric modes in the expansion of the radial deflection with one longitudinal half-wave, and limit cycle responses. Modes with two longitudinal half-waves are also investigated.

ABSTRACT: The response of simply supported circular cylindrical shells to harmonic excitation in the spectral neighbourhood of one of the lowest natural frequencies is investigated by using improved mode expansions with respect to those assumed in Parts I and II of the present study. Two cases are studied: (1) shells in vacuo;
and (2) shells filled with stagnant water. The improved expansions allow checking the accuracy of the solutions previously obtained and giving definitive results within the limits of Donnell's non-linear shallow-shell theory. The improved mode expansions include: (1) harmonics of the circumferential mode number n under consideration, and (2) only the principal n, but with harmonics of the longitudinal mode included. The effect of additional longitudinal modes is absolutely insignificant in both the driven and companion mode responses. The effect of modes with 2n circumferential waves is very limited on the trend of non-linearity, but is significant in the response with companion mode participation in the case of lightly damped shells (empty shells). In particular, the travelling wave response appears for much lower vibration amplitudes and presents a frequency range without stable responses, corresponding to a beating phenomenon. A liquid (water) contained in the shell generates a much stronger softening behaviour of the system. Experiments with a water-filled circular cylindrical shell made of steel are in very good agreement with the present theory.

ABSTRACT: (none given)
ABSTRACT: The non-linear dynamics and stability of simply supported, circular cylindrical shells containing inviscid, incompressible fluid flow is analyzed. Geometric non-linearities of the shell are considered by using the Donnell's non-linear shallow shell theory. A viscous damping mechanism is considered in order to take into account structural and fluid dissipation. Linear potential flow theory is applied to describe the fluid–structure interaction. The system is discretized by Galerkin's method and is investigated by using two models: (i) a simpler model obtained by using a base of seven modes for the shell deflection, and (ii) a relatively high-dimensional dynamic model with 18 modes. Both models allow travelling-wave response of the shell and shell axisymmetric contraction. Boundary conditions on radial displacement and the continuity of circumferential displacement are exactly satisfied. Stability, bifurcation and periodic responses are analyzed by means of the computer code AUTO for the continuation of the solution of ordinary differential equations. Non-stationary motions are analyzed with direct integration techniques. An accurate analysis of the shell response is performed by means of phase space representation, Fourier spectra, Poincaré sections and their bifurcation diagrams. A complex dynamical behaviour has been found. The shell bifurcates statically (divergence) in absence of external dynamic loads by using the flow velocity as bifurcation parameter. Under harmonic load a shell conveying flow can give rise to periodic, quasi-periodic and chaotic responses, depending on flow velocity, amplitude and frequency of harmonic excitation.

ABSTRACT: In the present study, the dynamic stability of simply supported, circular cylindrical shells subjected to dynamic axial loads is analysed. Geometric nonlinearities due to finite-amplitude shell motion are considered by using the Donnell’s nonlinear shallow-shell theory. The effect of structural damping is taken into account. A discretization method based on a series expansion involving a relatively large number of linear modes, including axisymmetric and asymmetric modes, and on the Galerkin procedure is developed. Axisymmetric modes are included; indeed, they are essential in simulating the inward deflection of the mean oscillation with respect to the equilibrium position and in describing the axisymmetric deflection due to axial loads. A finite length, simply supported shell is considered; the boundary conditions are satisfied, including the contribution of external axial loads acting at the shell edges. The effect of a contained liquid is investigated. The linear dynamic stability and nonlinear response are analysed by using continuation techniques and direct simulations.

ABSTRACT: The vibration response of a thin circular cylindrical panel to harmonic excitation in the neighborhood of the first three natural frequencies has been measured for different force levels. The experimental boundary conditions approximate (i) on the curved edges: zero radial, axial and circumferential displacements; all rotations were allowed; (ii) on the straight edges: zero radial and axial displacements; all rotations and circumferential displacements were allowed. The different levels of excitation permitted reconstruction of the relatively strong, softening type non-linearity of the panel.

ABSTRACT: Large-amplitude (geometrically non-linear) vibrations of circular cylindrical shells subjected to radial harmonic excitation in the spectral neighbourhood of the lowest resonances are investigated. The Lagrange equations of motion are obtained by an energy approach, retaining damping through Rayleigh's dissipation function. Four different non-linear thin shell theories, namely Donnell's, Sanders–Koiter, Flügge–Lur’e-Byrne and Novozhilov's theories, which neglect rotary inertia and shear deformation, are used to calculate the elastic strain energy. The formulation is also valid for orthotropic and symmetric cross-ply laminated composite shells. The large-amplitude response of perfect and imperfect, simply supported circular cylindrical shells to harmonic excitation in the spectral neighbourhood of the lowest natural frequency is computed for all these shell theories. Numerical responses obtained by using these four non-linear shell theories are also compared to results obtained by using the Donnell's non-linear shallow-shell equation of motion. A validation of calculations by comparison with experimental results is also performed. Both empty and fluid-filled shells are investigated by using a potential fluid model. The effects of radial pressure and axial load are also studied. Boundary conditions for simply supported shells are exactly satisfied. Different expansions involving from 14 to 48 generalized co-ordinates, associated with natural modes of simply supported shells, are used. The non-linear equations of motion are studied by using a code based on an arclength continuation method allowing bifurcation analysis.

ABSTRACT: The present paper focuses on the theory and experiments for geometrically nonlinear vibrations of shell type structures made of traditional and advanced materials. Closed shells, curved panels and rectangular plates made of isotropic, sandwich and laminated composite materials are studied. Several original aspects of nonlinear vibrations of shells and panels including the effects of geometric imperfections, geometry and boundary conditions have been addressed and consistent reduced-order models essential to capture shell dynamics are obtained. The numerical analysis is based on multi-dimensional Lagrangian approach and pseudo arc-length continuation technique is used for bifurcation analysis. Moreover, the experimental analysis, an example of the set-up is shown in Figure 1, is carried out following a stepped-sine testing procedure and by increasing and decreasing the excitation frequency in very small steps at specific force amplitudes controlled in a closed-loop. Comparisons between experimental results and numerical simulations are performed and show good agreement for shells and panels oscillating at large-amplitude vibrations.

ABSTRACT: This study presents experimental results on the non-linear dynamics and stability characteristics of a thin-walled clamped-clamped circular cylindrical shell in contact with fluid. It also discusses theoretical results for simply-supported shells conveying inviscid and incompressible fluid. The non-linear Donnell shallow shell theory, with structural damping, is used to describe the large-amplitude shell vibrations. The interaction between the flowing fluid and the shell structure is formulated with linear potential flow theory. The aim of the experimental study was to gather for the first time important data points of the critical flow velocity for instability and maximum flexural displacement, and to analyze the experimental results to validate the theoretical model. The experimental study involved two set-ups: one containing a clamped-clamped silicone rubber shell and flowing air in internal and external flow configurations, and the second an aluminum shell and water as the flowing fluid. The interaction between the shell and the fully developed flow, in both cases, gives instabilities in the form of divergence at sufficiently high flow velocities. The experimental results show a softening type nonlinear behaviour with a large hysteresis in the velocity for the onset and cessation of divergence.

ABSTRACT: Large-amplitude (geometrically nonlinear) vibrations of circular cylindrical panels with rectangular base, simply supported at the four edges and subjected to radial harmonic excitation in the spectral neighbourhood of the lowest resonances are investigated. Two different nonlinear strain–displacement relationships, from the Donnell's and Novozhilov's shell theories, are used to calculate the elastic strain energy. In-plane inertia and geometric imperfections are taken into account. The solution is obtained by Lagrangian approach. The nonlinear equations of motion are studied by using (i) a code based on arclength continuation method that allows bifurcation analysis and (ii) direct time integration. Numerical results are compared to those available in the literature and convergence of the solution is shown. Interaction of modes having integer ratio among their natural frequencies, giving rise to internal resonances, is also discussed.

ABSTRACT: Large amplitude (geometrically non-linear) vibrations of doubly curved shallow shells with rectangular base, simply supported at the four edges and subjected to harmonic excitation normal to the surface in the spectral neighbourhood of the fundamental mode are investigated. Two different non-linear strain–displacement relationships, from the Donnell's and Novozhilov's shell theories, are used to calculate the elastic strain energy. In-plane inertia and geometric imperfections are taken into account. The solution is obtained by Lagrangian approach. The non-linear equations of motion are studied by using (i) a code based on arclength continuation method that allows bifurcation analysis and (ii) direct time integration. Numerical results are compared to those available in the literature and convergence of the solution is shown. Interaction of modes having integer ratio among their natural frequencies, giving rise to internal resonances, is discussed. Shell stability under static and dynamic load is also investigated by using continuation method, bifurcation diagram from direct time integration and calculation of the Lyapunov exponents and Lyapunov dimension. Interesting phenomena such as (i) snap-through instability, (ii) subharmonic response, (iii) period doubling bifurcations and (iv) chaotic behaviour have been observed.

ABSTRACT: Large-amplitude vibrations of circular cylindrical panels (open shells) subjected to harmonic excitation are numerically and experimentally investigated. The Donnell nonlinear strain–displacement relationships are used to describe the geometric nonlinearity; in-plane inertia is taken into account. Specific boundary conditions, with zero transverse displacement at the panel edges and free or elastically restrained in-plane displacements, not previously considered, have been introduced in order to model the experimental boundary conditions. The nonlinear equations of motion are obtained by the Lagrange equations with multi-mode approach, and are studied by using a code based on the pseudo-arclength continuation method. Two thin circular cylindrical panels of different dimensions and made of stainless steel have been experimentally tested in the laboratory for several excitation amplitudes in order to characterize the nonlinearity. The dimensions of the two panels have been chosen in order to have the fundamental mode with one and two circumferential half-
waves, respectively. Numerical results are able to reproduce the experimental results with high accuracy for both panels. The effect of geometric imperfections on the trend of nonlinearity and on natural frequencies is shown; convergence of the solution with the number of generalized coordinates is numerically verified.

ABSTRACT: In this paper, the nonlinear stability of circular cylindrical shells subjected to internal incompressible flow is studied by means of the Donnell nonlinear shallow shell equations and a linear fluid–structure interaction model. Specifically, the effect of varying the thickness-to-radius (h/R) and length-to-radius (L/R) ratios is investigated. In general, the system loses stability by a subcritical pitchfork bifurcation, leading to a stable divergence of increasing amplitude with flow; no oscillatory solutions are found. Increasing the value of the circumferential wavenumber for shells with the same h/R ratio reduces the natural frequency and enhances the subcritical behaviour of the shell. Interesting results are found for different L/R cases in which the solution changes from subcritical to supercritical nonlinear behaviour.

INTRODUCTION: Most of studies on large-amplitude (geometrically nonlinear) vibrations of circular cylindrical shells used Donnell's nonlinear shallow-shell theory to obtain the equations of motion, as shown in Chapter 5. Only a few used the more refined Sanders-Koiter or Flügge-Lur'e-Byrne nonlinear shell theories. The majority of these studies do not include geometric imperfections, and some of them use a single-mode approximation to describe the shell dynamics. This chapter presents a comparison of shell responses to radial harmonic excitation in the spectral neighborhood of the lowest natural frequency computed by using five different nonlinear shell theories: (i) Donnell's shallow-shell, (ii) Donnell's with in-plane inertia, (iii) Sanders-Koiter, (iv) Flügge-Lur'e-Byrne and (v) Novozhilov theories. These five shell theories are practically the only ones applied to geometrically nonlinear problems among the theories that neglect shear deformation. Donnell's shallow-shell theory has already been used in Chapter 5, and the numerical results presented there are used for comparison. Shell theories including shear deformation and rotary inertia are not considered in this chapter. The results presented are based on the study by Amabili (2003).

(Note: Many additional citations are given, but several of them seem to be repetitions of the citations just listed.)
INTRODUCTION: Doubly curved shells are largely used in aeronautics and aerospace and are subjected to dynamic loads that can cause vibration amplitudes of the order of the shell thickness, giving rise to significant nonlinear phenomena. In order to reduce the weight, traditional materials are often substituted with laminated panels. This justifies the study of nonlinear vibrations of isotropic and laminated curved panels. Nonlinear (large amplitude) forced vibrations of doubly curved shallow-shells are initially studied by using Donnell's theory retaining in-plane inertia and the Lagrange equations. The effect of the geometry and curvature are investigated for isotropic shells. Then, nonlinear free vibrations of laminated composite shells are studied by using both the Donnell and the first-order shear deformation theories in order to compare numerical results. It is observed that a shear deformation theory should be adopted for moderately thick laminated shells for which the ratio between the thickness and the largest of the in-plane curvilinear dimensions is equal or larger than 0.04. The stability of a spherical shell under static normal load is discussed. Finally, the example of buckling analysis of the external tank of the NASA space shuttle, taking into account the effect of initial geometric imperfections, is performed following the study of Nemeth et al. (2002).

INTRODUCTION: Circular cylindrical shells are very stiff structural elements with optimal use of the material. Therefore, they are also very light. This is one of the reasons why they are used for rockets (see Figure 13.1). Similarly to other thin-walled structures, the main strength analysis of circular cylindrical shells is a stability analysis; in fact, these structural elements buckle much before the failure stress of the material is reached. In this chapter, the stability and the postcritical behavior of circular cylindrical shells under the action of axial static and periodic loads are investigated. Because of the strongly subcritical nature of the pitchfork bifurcation associated with buckling, even if the static compression load is much smaller than the critical load, shells collapse under small perturbation with a jump from the trivial equilibrium configuration to the stable bifurcated solution. Moreover, circular cylindrical shells subjected to axial loads are highly sensitive to geometric imperfections. Periodic axial loads generate large-amplitude asymmetric vibrations due to period-doubling bifurcation of axisymmetric small-amplitude vibration. Period-doubling bifurcation arises for frequency of axial load close to twice the natural frequency of an asymmetric mode; this is usually referred as parametric instability. In fact, most of the studies are based on Donnell's nonlinear shallow-shell theory, so that axial loads do not appear directly in the equations of motion obtained with this shell theory, where only radial loads are directly inserted. They appear through boundary conditions, giving the so-called parametric excitation in the equation of motion.

ABSTRACT: The geometrically nonlinear forced vibrations of laminated circular cylindrical shells are studied by using the Amabili–Reddy higher-order shear deformation theory. An energy approach based on Lagrange equations, retaining modal damping, is used in order to obtain the equations of motion. An harmonic point
excitation is applied in radial direction and simply supported boundary conditions are assumed. The equations of motion are studied by using the pseudo-arclength continuation method and bifurcation analysis. A one-to-one internal resonance is always present for a complete circular cylindrical shell, giving rise to pitchfork bifurcations of the nonlinear response with appearance of a second branch with travelling wave response and quasi-periodic vibrations. The numerical results obtained by using the Amabili–Reddy shell theory are compared to those obtained by using an higher-order shear deformation theory retaining only nonlinear term of von Kármán type and the Novozhilov classical shell theory.

“ABSTRACT: Human aortas are subjected to large mechanical stresses because of blood flow pressurization and through contact with the surrounding tissue. It is essential that the aorta does not lose stability by buckling with deformation of the cross-section (shell-like buckling) (i) for its proper functioning to ensure blood flow and (ii) to avoid high stresses in the aortic wall. A numerical bifurcation analysis employs a refined reduced-order model to investigate the stability of a straight aorta segment conveying blood flow. The structural model assumes a nonlinear cylindrical orthotropic laminated composite shell composed of three layers representing the tunica intima, media and adventitia. Residual stresses because of pressurization are evaluated and included in the model. The fluid is formulated using a hybrid model that contains the unsteady effects obtained from linear potential flow theory and the steady viscous effects obtained from the time-averaged Navier–Stokes equations. The aortic segment loses stability by divergence with deformation of the cross-section at a critical flow velocity for a given static pressure, exhibiting a strong subcritical behaviour with partial or total collapse of the inner wall. Preliminary results suggest directions for further study in relation to the appearance and growth of dissection in the aorta.

ABSTRACT: The static and dynamic behavior of a compressed circular cylindrical shell having geometric imperfections is analyzed. The analysis is mainly performed by means of the Donnell’s nonlinear shallow-shell theory. However, the refined Sanders shell theory is also used for comparison. A suitable expansion of the radial displacement, able to describe both buckling and dynamic behaviors is developed; the effect of geometric imperfections is accounted for by means of a modal representation. The response of the shell subjected to a sinusoidal axial excitation at its ends, giving rise to a parametric excitation, is considered. The effect of imperfections on the critical value of the dynamic load, that causes the loss of stability of the system, is analyzed. Interesting nonlinear dynamic phenomena are observed: direct resonance with softening behavior and parametric instability with period doubling response.

ABSTRACT: In the present paper the dynamic stability of circular cylindrical shells subjected to static and dynamic axial loads is investigated. Both Donnell’s nonlinear shallow shell and Sanders–Koiter shell theories have been applied to model finite-amplitude static and dynamic deformations. Results are compared in order to evaluate the accuracy of these theories in predicting instability onset and post-critical nonlinear response. The effect of a contained fluid on the stability and the post-critical behaviour is analyzed in detail. Geometric imperfections are considered and their influence on the dynamic instability and post-critical behaviour is investigated. Chaotic dynamics of pre-compressed shells is investigated by means of nonlinear time-series techniques, extracting correlation dimension and Lyapunov exponents.

ABSTRACT: The dynamics of a circular cylindrical shell carrying a rigid disk on the top and clamped at the base is investigated. The Sanders–Koiter theory is considered to develop a nonlinear analytical model for moderately large shell vibration. A reduced order dynamical system is obtained using Lagrange equations: radial and in-plane displacement fields are expanded by using trial functions that respect the geometric boundary conditions. The theoretical model is compared with experiments and with a finite element model developed with commercial software: comparisons are carried out on linear dynamics. The dynamic stability of the system is studied, when a periodic vertical motion of the base is imposed. Both a perturbation approach and a direct numerical technique are used. The perturbation method allows to obtain instability boundaries by means of elementary formulae; the numerical approach allows to perform a complete analysis of the linear and nonlinear response.

ABSTRACT: In the present paper, the dynamic stability of circular cylindrical shells is investigated; the combined effect of compressive static and periodic axial loads is considered. The Sanders–Koiter theory is applied to model the nonlinear dynamics of the system in the case of finite amplitude of vibration; Lagrange equations are used to reduce the nonlinear partial differential equations to a set of ordinary differential equations. The dynamic stability is investigated using direct numerical simulation and a dichotomic algorithm to find the instability boundaries as the excitation frequency is varied; the effect of geometric imperfections is investigated in detail. The accuracy of the approach is checked by means of comparisons with the literature.

ABSTRACT: The present paper is focused on the experimental and theoretical analysis of circular cylindrical shells under base excitation. The shell axis is vertical, it is clamped at the base and connected to a rigid body on the top; the base provides a vertical seismic-like excitation. The goal is to investigate the shell response when a resonant harmonic forcing is applied: the first axisymmetric mode is excited around the resonance at relatively low frequency and low amplitude of excitation. A violent resonant phenomenon is experimentally observed as well as an interesting saturation phenomenon close to the previously mentioned resonance. A theoretical model is developed to reproduce the experimental evidence and provide an explanation of the complex dynamics observed experimentally; the model takes into account geometric shell nonlinearities, electrodynamic shaker equations and the shell shaker interaction.

ABSTRACT: The axisymmetric buckling behavior of clamped shallow spherical shells under uniform pressure is investigated using Marguerre's shallow-shell equations of 1939. The deflected shape of the shell as well as the stress function are described by linear combinations of Bessel functions and modified Bessel functions that satisfy all the relevant boundary and continuity conditions. The buckling characteristics of these caps are examined using a fully nonlinear Galerkin solution procedure, a classical bifurcation analysis, and a reduced-stiffness bifurcation analysis. This allows the elucidation of the imperfection sensitivity and nonlinear behavior of this important class of shell structures. A systematic parametric analysis highlights the interplay between these contrasting approaches, and demonstrates the lower boundedness of the reduced-stiffness analytical procedure for predicting imperfection-sensitive elastic-collapse pressures and its potential importance as a design methodology. A simple closed-form solution is given for this analytical lower bound. This compares favorably with a large collection of available experimental results but demonstrates the variability and possible inadequacies in some of the existing design rules for spherical shell structures.

ABSTRACT: Based on Donnell shallow shell equations, the nonlinear vibrations and dynamic instability of axially loaded circular cylindrical shells under both static and harmonic forces is theoretically analyzed. First the problem is reduced to a finite degree-of-freedom one by using the Galerkin method; then the resulting set of coupled nonlinear ordinary differential equations of motion are solved by the Runge–Kutta method. To study the nonlinear behavior of the shell, several numerical strategies were used to obtain Poincaré maps, Lyapunov exponents, stable and unstable fixed points, bifurcation diagrams, and basins of attraction. Particular attention is paid to two dynamic instability phenomena that may arise under these loading conditions: parametric excitation of flexural modes and escape from the pre-buckling potential well. Calculations are carried out for the principal and secondary instability regions associated with the lowest natural frequency of the shell. Special attention is given to the determination of the instability boundaries in control space and the identification of the bifurcational events connected with these boundaries. The results clarify the importance of modal coupling in the post-buckling solution and the strong role of nonlinearities on the dynamics of cylindrical shells.

ABSTRACT: The non-linear vibrations and instabilities of cylindrical shells under pulsating axial loads are investigated using Donnell’s shallow shell equations. Based on physical and mathematical reasoning, a meaningful low dimensional model is derived and used together with Galerkin method to obtain a set of coupled non-linear equations of motion. Particular attention is paid to the investigation of modal interaction between non-linear vibration modes with equal or nearly equal natural frequencies and to its influence on parametric instability and snap-through buckling. A parametric analysis using continuation techniques identifies the relevant bifurcations connected with the modal interaction and highlights their relevance in design.

ABSTRACT: This paper discusses the non-linear oscillations and dynamic instabilities of thin walled shells subjected to harmonic loads. Due to the presence of strong non-linearities and high sensitivity to small variations in control parameters, thin shells may display a complex dynamic behavior and, despite the recent advances in this field, there is still a lack of satisfactory solutions to this class of problems. There are several complicated issues relating to the dynamics of such structures. In this work some of these topics are addressed, namely shell discretization processes, influence of modal coupling on non-linear vibration modes, modal interaction between different non-linear vibration modes, imperfection sensitivity and fractal basin boundaries. To this end, the theory for quasi-shallow shells is used to study the non-linear vibrations and instabilities of thin cylindrical shells under axial load.

ABSTRACT: This paper discusses the derivation of discrete low-dimensional models for the non-linear vibration analysis of thin shells. In order to understand the peculiarities inherent to this class of structural problems, the non-linear vibrations and dynamic stability of a circular cylindrical shell subjected to dynamic axial loads are analyzed. This choice is based on the fact that cylindrical shells exhibit a highly non-linear behavior under both static and dynamic axial loads. Geometric non-linearities due to finite-amplitude shell motions are considered by using Donnell’s nonlinear shallow shell theory. A perturbation procedure, validated in previous studies, is used to derive a general expression for the non-linear vibration modes and the discretized equations of motion are obtained by the Galerkin method. The responses of several low-dimensional models are compared. These are used to study the influence of the modelling on the convergence of critical loads, bifurcation diagrams, attractors and large amplitude responses of the shell. It is shown that rather low-dimensional and properly selected models can describe with good accuracy the response of the shell up to very large vibration amplitudes.

The transient and steady state stability of cylindrical shells under harmonic axial loads is investigated through the evolution of basins of attraction. Both parametric instability and steady state basins of attraction but must be considered with care when transient stability is of interest. Based on these results, the behavior of the shell under harmonic axial load is investigated through the evolution of basins of attraction. Both parametric instability and escape from a safe pre-buckling well are considered. It is shown that damping has a beneficial influence on the magnitude of the steady-state basins of attraction but must be considered with care when transient stability is of interest.

ABSTRACT: The transient and steady-state instability of an axially loaded cylindrical shell is discussed in the present paper. Donnell's shallow shell theory is used and the shell spatial discretization is obtained by the Galerkin method. First, an alternative vision of the buckling problem through the evolution and erosion of safe basins using energy and geometric considerations is presented, using an autonomous conservative low dimensional but qualitatively consistent model. Then, the response of the corresponding dissipative system is studied in terms of transient and steady-state behavior. Based on these results, the behavior of the shell under harmonic axial load is investigated through the evolution of basins of attraction. Both parametric instability and escape from a safe pre-buckling well are considered. It is shown that damping has a beneficial influence on the magnitude of the steady-state basins of attraction but must be considered with care when transient stability is of interest.
This paper investigates the large deformations of an extended thick cylindrical tube under internal pressure. The methodology presented in this work is particularly suited to structural systems liable to unstable bifurcation.
pressure, with emphasis on the static nonlinear behavior and instabilities of the shell. Thick elastic tubes that undergo large elastic deformations under internal pressure can exhibit novel instabilities. After some deformation, part of the tube becomes highly deformed taking the form of a bulge, while the remainder appears almost unchanged. This local instability phenomenon corresponds to a limit point along the nonlinear equilibrium path. After the onset of these highly nonuniform deformations, the local bulge initially grows with a marked decrease in internal pressure while the rest of the tube unloads. First, a detailed experimental analysis is carried out involving different geometries and initial axial forces and the influence of the axial force and of the internal pressure on the critical pressure is investigated. The shell used in the experiments is composed of an isotropic, homogeneous and hyperelastic rubber, which is modeled as a Mooney–Rivlin incompressible material, described by two elastic constants. These constants are obtained by comparing the experimental and numerical solutions for the shell under axial tension. The governing shell equations are solved numerically using the finite-element method, using the program ABAQUS. The experimental results are, as shown in the paper, in satisfactory agreement with the numerical analysis.

ABSTRACT: Structural systems liable to asymmetric bifurcation usually become unstable at static load levels lower than the linear buckling load of the perfect structure. This is mainly due to the imperfections present in real structures. The imperfection sensitivity of structures under static loading is well studied in literature, but little is know on the sensitivity of these structures under dynamic loads. The aim of the present work is to study the behavior of an archetypal model of a harmonically forced structure, which exhibits, under increasing static load, asymmetric bifurcation. First, the integrity of the system under static load is investigated in terms of the evolution of the safe basin of attraction. Then, the stability boundaries of the harmonically excited structure are obtained, considering different loading processes. The bifurcations connected with these boundaries are identified and their influence on the evolution of safe basins is investigated. Then, a parametric analysis is conducted to investigate the influence of uncertainties in system parameters and random perturbations of the forcing on the dynamic buckling load. Finally, a safe lower bound for the buckling load, obtained by the application of the Melnikov criterion, is proposed which compare well with the scatter of buckling loads obtained numerically.

ABSTRACT: In formulating mathematical models for dynamical systems, obtaining a high degree of qualitative correctness (i.e. predictive capability) may not be the only objective. The model must be useful for its intended application, and models of reduced complexity are attractive in many cases where time-consuming numerical procedures are required. This paper discusses the derivation of discrete low-dimensional models for the nonlinear vibration analysis of thin cylindrical shells. In order to understand the peculiarities inherent to this class of structural problems, the nonlinear vibrations and dynamic stability of a circular cylindrical shell subjected to static and dynamic loads are analyzed. This choice is based on the fact that cylindrical shells exhibit a highly nonlinear behavior under both static and dynamic loads. Geometric nonlinearities due to finite-amplitude shell motions are considered by using Donnell's nonlinear shallow-shell theory. A perturbation procedure, validated in previous studies, is used to derive a general expression for the nonlinear vibration modes and the discretized equations of motion are obtained by the Galerkin method using modal expansions for the displacements that satisfy all the relevant boundary and symmetry conditions. Next, the model is analyzed via the Karhunen–Loève expansion to investigate the relative importance of each mode obtained by the perturbation solution on the nonlinear response and total energy of the system. The responses of several low-dimensional models are compared. It is shown that rather low-dimensional but properly selected models can describe with good accuracy the response of the shell up to very large vibration amplitudes.

ABSTRACT: In this work, Donnell’s nonlinear shallow shell equations are used to study the dynamic buckling and bifurcations of simply supported cylindrical shells subjected to axial or lateral load. A modal expansion with eight degrees of freedom containing the fundamental, companion, axially asymmetric and five axi-symmetric modes is used to describe the lateral displacement of the shell. The Galerkin method is used to obtain the nonlinear equations of motion which are, in turn, solved by the Runge-Kutta method. Several studies on the nonlinear dynamics of cylindrical shells are found in literature but they are restricted to specific geometries. In this paper we intend to study through a detailed parametric analysis the influence of the shell geometry, specifically Batdorf’s parameter, length to radius ratio and radius to thickness ratio on the main nonlinear dynamic characteristics of the shell.

ABSTRACT: In this work, Donnell’s non-linear shallow shell equations are used to study the dynamic instability of perfect simply supported orthotropic cylindrical shells with internal flowing fluid and subjected to either a compressive axial static pre-load plus a harmonic axial load or a harmonic lateral pressure. The fluid is assumed to be non-viscous and incompressible and the flow, isentropic and irrotational. An expansion with eight degrees of freedom, containing the fundamental, companion, gyroscopic, and four axi-symmetric modes is used to describe the lateral displacement of the shell. The Galerkin method is used to obtain the non-linear equations of motion which are solved by the Runge–Kutta method. A detailed parametric analysis clarifies the influence of the orthotropic material properties on the non-linear buckling and vibration characteristics of the shell. Numerical methods are used to identify the effect of the fluid flow and applied loads control parameters on the bifurcations and stability of the shell motions.

an axially pre-loaded, partially fluid-filled cylindrical shell. The Donnell non-linear shallow shell theory is used to study the nonlinear vibrations of the shell. For this, the Galerkin method is used, together with a suitable expansion that takes into account the main nonlinear interactions, to discretize the shell. The resulting nonlinear equations of motion are solved by numerical integration. The fluid is assumed to be non-viscous and incompressible and its inertial effects on the shell surface are obtained by the potential flow theory. A detailed parametric analysis is carried out to demonstrate the influence of the fluid height within the shell on the parametric instability load and on the snap-through buckling load in the main parametric resonance region. Using bifurcations diagrams, the main bifurcation events associated with these stability boundaries are identified. The influence of the different types of bifurcation and fluid height on the safety is also discussed.

ABSTRACT: A theoretical analysis is presented for determining the elastic non-linear vibrations of a prestressed thin-walled cylindrical shell filled with an ideal fluid. For the vibrations of the shell itself, the dynamic version of the Sanders non-linear equations for the case of moderately small rotations is employed. Modal expansions are used for the displacements of the shell middle surface that are required to satisfy the “classical simply supported” boundary conditions and the circumferential periodicity condition. The fluid is taken as non-viscous and incompressible, and the coupling between the deformable shell and this medium is taken into account. The velocity potential is expanded in terms of harmonic functions which satisfy the Laplace equation term by term. The Galerkin method is used to reduce the problem to a system of coupled algebraic non-linear equations for the modal amplitudes. Solutions are presented to show the effects of fluid and shell parameters on the non-linear vibrations of the shell.

model of a parametrically excited cylindrical shell”, Nonlinear Dynamics, Vol. 63, pp. 61-82

ABSTRACT: In this paper the global dynamics and topological integrity of the basins of attraction of a parametrically excited cylindrical shell are investigated through a two-degree-of-freedom reduced order model. This model, as shown in previous authors’ works, is capable of describing qualitatively the complex nonlinear static and dynamic buckling behavior of the shell. The discretized model is obtained by employing Donnell shallow shell theory and the Galerkin method. The shell is subjected to an axial static pre-loading and then to a harmonic axial load. When the static load is between the buckling load and the minimum post-critical load, a three potential well is obtained. Under these circumstances the shell may exhibit pre- and post-buckling solutions confined to each of the potential wells as well as large cross-well motions. The aim of the paper is to analyze in a systematic way the bifurcation sequences arising from each of the three stable static solutions, obtaining in this way the parametric instability and escape boundaries. The global dynamics of the system is analyzed through the evolution of the various basins of attraction in the four-dimensional phase space. The concepts of safe basin and integrity measures quantifying its magnitude are used to obtain the erosion profile of the various solutions. A detailed parametric analysis shows how the basins of the various solutions interfere with each other and how this influences the integrity measures. Special attention is dedicated to the topological integrity of the various solutions confined to the pre-buckling well. This allows one to evaluate the safety and dynamic integrity of the mechanical system. Two characteristic cases, one associated with a sub-critical parametric bifurcation and another with a super-critical parametric bifurcation, are considered in the analysis.

PARTIAL ABSTRACT: Using Donnell non-linear shallow shell equations in terms of the displacements and the potential flow theory, this work presents a qualitatively accurate low dimensional model to study the nonlinear dynamic behavior and stability of a fluid-filled cylindrical shell under lateral pressure and axial loading. First, the reduced order model is derived taking into account the influence of the driven and companion modes. For this a modal solution is obtained by a perturbation technique which satisfies exactly the in-plane equilibrium equations and all boundary, continuity, and symmetry conditions. Finally, the equation of motion in the transversal direction is descritized by the Galerkin method.…. References listed at the end of the paper:

ABSTRACT: A smart laminate model developed using the nonlinear piezoelectric model, i.e., electroelastic and electrostrictive effects, and von Kármán type geometric nonlinearity is proposed. On the basis of the proposed model, the analytical solutions for extensional and bending deformations of symmetrically constructed piezoelectric laminates under large electric fields are calculated. A comparison between the present nonlinear extension deformation of a piezoelectric laminated plate and the induced strain model shows that more realistic results are obtained with the present model. Numerical simulation reveals that the calculated results agree well with the experimental data.

ABSTRACT: In this paper, a detailed analysis is conducted to study the influence of the geometric parameters, boundary conditions as well as initial imperfections on the nonlinear response and imperfection sensitivity of L-frames. An efficient nonlinear finite element formulation for the analysis of planar elastic frames is used together with incremental-iterative strategies. This enables one to obtain the highly nonlinear equilibrium paths exhibited by L-frames under certain loading conditions and identify the bifurcation and limit points along these equilibrium paths. These results provide some insight as to the source and mechanism of asymmetric bifurcation and imperfection sensitivity in frames thus helping engineers to evaluate the importance of geometric nonlinearities in the analysis and design of slender elastic frames.

“Dynamic instability of cylindrical shells subjected to sudden step loads”, Proceedings of the 19th International Congress of Mechanical Engineering, November 5-9, 2007, Brasilia DF, Brazil

ABSTRACT: In this work the nonlinear behavior of a simply supported cylindrical shell under a sudden axial step load of infinite duration is investigated. The shell is modelled through the nonlinear shell theory of Donnell and the discretized equations of motion are obtained by the method of Galerkin based on a low dimensional modal solution derived in previous publications by the authors. The shell is initially considered to be at rest inside a potential well associated with the stable pre-buckling configuration. The effects of small initial geometric imperfections on the shell behavior is presented. The variation of the dynamic buckling load as a function of the geometric imperfection using Budiansky’s stability criterion is evaluated. It is observed that the escape occurs in the neighborhood of the saddle point that defines the frontier of the stable region. The erosion of the safe region of the basin of attraction with the load increment is also investigated. The sudden reduction of the safe region highlights the imperfection sensitivity of the shell under this type of load.

ABSTRACT: In the present study, the large-amplitude vibrations and stability of a perfect circular cylindrical shell subjected to axial harmonic excitation in the neighborhood of the lowest natural frequencies are investigated. Donnell’s shallow shell theory is used and the shell spatial discretization is obtained by the Ritz method. An efficient low-dimensional model presented in previous publications is used to discretize the continuous system. The main purpose of this work is to discuss the use of basins of attraction as a measure of the reliability and safety of the structure. First, the nonlinear behavior of the conservative system is discussed and the basin structure and volume is understood from the topologic structure of the total energy and its evolution as a function of the system parameters. Then, the behavior of the forced oscillations of the harmonically excited shell is analyzed. First the stability boundaries in force control space are obtained and the bifurcation events connected with these boundaries are identified. Based on the bifurcation diagrams, the probability of parametric instability and escape are analyzed through the evolution and erosion of basin boundaries within a prescribed control volume defined by the manifolds. Usually, basin boundaries become fractal. This together with the presence of catastrophic subcritical bifurcations makes the shell very sensitive to initial conditions, uncertainties in system parameters, and initial imperfections. Results show that the analysis of the evolution of safe basins and the derivation of appropriate measures of their robustness is an essential step in the derivation of safe design procedures for multiwell systems.

ABSTRACT: This work investigates the influence of Young’s modulus, shells thickness, and geometrical imperfection uncertainties on the parametric instability loads of simply supported axially excited cylindrical
shells. The Donnell nonlinear shallow shell theory is used for the displacement field of the cylindrical shell and the parameters under investigation are considered as uncertain parameters with a known probability density function in the equilibrium equation. The uncertainties are discretized as Hermite-Chaos polynomials together with the Galerkin stochastic procedure that discretizes the stochastic equation in a set of deterministic equations of motion. Then, a general expression for the transversal displacement is obtained by a perturbation procedure which identifies all nonlinear modes that couple with the linear modes. So, a particular solution is selected which ensures the convergence of the response up to very large deflections. Applying the standard Galerkin method, a discrete system in time domain that considers the uncertainties is obtained and solved by fourth-order Runge-Kutta method. Several numerical strategies are used to study the nonlinear behavior of the shell considering the uncertainties in the parameters. Special attention is given to the influence of the uncertainties on the parametric instability and time response, showing that the Hermite-Chaos polynomial is a good numerical tool.

ABSTRACT: Slender structural systems liable to unstable buckling usually become unstable at load levels lower than the linear buckling load of the perfect structure. In some cases, experimental buckling loads can be just a small fraction of the theoretical critical load. This is mainly due to the imperfections present in real structures. The imperfection sensitivity of structures under static loading is well studied in the literature, but little is known on the sensitivity of these structures under dynamic conditions. In a dynamic environment not only geometric imperfections but also initial conditions (disturbances), physical and geometrical system parameters uncertainties and excitation noise influence the bifurcation scenario and basins of attraction. The aim of this work is to investigate the influence of inherent uncertainties of real systems and load noise on the dynamic integrity and stability of their solutions in a dynamic environment. To illustrate the system sensitivity, an archetypal model of slender systems liable to unstable buckling is used. Special attention is given to the influence of uncertainties and random noise on the basins of attraction of the system and consequently on the integrity measures of the unforced and forced system. The Melnikov criterion, erosion profiles based on different integrity measures and stochastic differential equations and polynomial chaos are discussed as possible tools to obtain reliable lower bounds for design.

ABSTRACT: In this work the influence of geometry, load and material properties on the non-linear vibrations of a simply supported viscoelastic circular cylindrical shell subjected to lateral harmonic load is studied. Donnell’s non-linear shallow shell theory is used to model the shell, assumed to be made of a Kelvin-Voigt material type, and a modal solution with six degrees of freedom is used to describe the lateral displacements. The Galerkin method is applied to derive a set of coupled non-linear ordinary differential equations of motion. Obtained results show that the viscoelastic dissipation parameter has significant influence on the instability loads and resonance curves.

ABSTRACT: Collapse loads for thin walled cylinders loaded in axial compression can be estimated by considering the buckling failure of equivalent space frames. These loads are presented in the form of a design chart where the collapse load for any cylinder can be determined provided the radius to thickness ratio of the cylinder and the size of the shape defects in the cylinder are known. It is demonstrated how these defects can be evaluated by an optical examination of a proof loaded cylinder. There is good agreement between estimated collapse loads for cylinders with known shape defects and measured collapse loads.

ABSTRACT: Experiments on the axial compression buckling of high-quality epoxy cylindrical shells with imposed dimple-type defects are described. Additionally, a technique for the manufacture of high-quality epoxy conical shells which buckle at loads approaching the classical critical load is presented. For both types of shells,
prebuckling deformations have been monitored optically. The sizes of defects determined from the optical examination when applied in the space-frame approach to shell buckling have led to predicted knock-down factors which are remarkably consistent with measured knock-down factors (i.e., the ratio of actual collapse to classical critical load).

ABSTRACT: In this paper an optical technique for the measurement of radial deformation in circular cylindrical shells is discussed. The technique is a modification and improvement on an earlier method, using a conical mirror of simple geometry to view a grating reflected from the inner surface of the shell. The new system allows more precise alignment of the components of the optical system with the shell. Fringes obtained by superposition as in the Ligtenberg moiré method, or deviations of lines from a regular pattern in a
photographic image provide a measure of the slope changes on the surface of the shell. Theoretical relations are presented for three grid orientations, at least two of which have to be used in conjunction to determine the two components of slope. Illustrations for the use and accuracy of the technique are presented for two cases. In the first, deflections due to a tilt of the axis of the test shell are measured; in the second, deformations associated with a radial point load applied at the free end of a cylindrical shell with one end built in are determined.

“Measurement of axisymmetric prebuckling deformations in axially compressed cylindrical shells”,
ABSTRACT: This paper describes tests that were conducted on high-quality circular cylindrical shells loaded in axial compression. During the loading sequence the shells were continuously examined by an optical technique employing reflected grid lines. Because of the high sensitivity of the optical system, axisymmetric-ripple-type prebuckling deformations were detected even though the shells collapsed into the conventional dimple-type buckle pattern. Although this axisymmetric-type deformation is predicted by theoretical considerations only limited evidence of its existence has been previously reported.

ABSTRACT: The influence of large localized geometric imperfections on the stability and axial load carrying capacity of thin isotropic circular cylindrical shells was investigated experimentally. Diamond shaped “Yoshimura facet type” dimples were introduced in otherwise near perfect cylinders, and their behavior under compressive load was monitored using a whole-field grid reflection technique. Buckling tests were conducted to determine the effects of shell geometry and variations in the size and number of defects. An empirical formula was developed for estimating the degradation in buckling strength caused by single or multiple local facet type defects.

S. Krishnakumar and C. G. Foster, “Axial load capacity of cylindrical shells with local geometric defects”
ABSTRACT: The effect of local geometric defects on the buckling load of axially compressed thin circular cylindrical shells is investigated experimentally. Defects, in the form of diamond-shaped local dimples, similar to the buckles of the Yoshimura pattern, were introduced in otherwise near perfect isotropic epoxy shells by locally heating the shell wall. The behavior of the defects under load was monitored optically using a special whole-field grid-reflection technique. The effects of variations in shell geometry and defect size are also
investigated. In general, the results indicate that the effect of local diamond-shaped defects on the stability of the axially loaded cylinder is not as detrimental as that of the global initial imperfections hitherto investigated.

FOREWORD: This Guide for the Buckling and Ultimate Strength Assessment of Offshore Structures is referred to herein as “this Guide”. This Guide provides criteria that can be used in association with specific Rules and Guides issued by ABS for the classification of specific types of Offshore Structures. The specific Rules and Guides that this Guide supplements are the latest editions of the following.

- Rules for Building and Classing Offshore Installations [for steel structure only]
- Rules for Building and Classing Mobile Offshore Drilling Units (MODUs)
- Rules for Building and Classing Single Point Moorings (SPMs)
- Rules for Building and Classing Floating Production Installations (FPIs) [for non ship-type hulls].

In case of conflict between the criteria contained in this Guide and the above-mentioned Rules, the latter will have precedence.

ABSTRACT: The objective of this paper is to perform dynamic nonlinear analysis of shell structures using a vector form intrinsic finite element (VFIFE). The procedures of VFIFE are designed to carry out a vector-mechanics-based theory, vector form analysis in which a fundamental concept called point value description is proposed. It enables VFIFE to deliberately treat the shell problems with large deflections, large overall motions and even fragmentations. The interaction forces amid particles are complemented by the generalized forces evaluated by a triangular element of VFIFE family recently developed using physical modeling procedures. In this paper, the problems with large overall motion, large deflection, nonlinear material property and contact/impact are further tested to justify the performance of the element on highly nonlinear analysis. It is reveals that the VFIFE element has good reliability and accuracy on solving shell problems with multiple nonlinearities.

ABSTRACT: Cylindrical shells, unstiffened or stiffened with rings and/or stringers are commonly used in offshore structures as main loading-carrying members. Comprehensive theoretical work and experimental studies on the buckling behavior of cylindrical shells have been carried out in the past. The increasing offshore application of stiffened cylindrical shells has raised some new challenges that need to be addressed. This paper provides the fundamental principles and technical background of the ABS buckling strength assessment criteria for cylindrical shells applied in offshore structures. The accuracy of ABS buckling criteria for assessing the cylindrical shells is established by benchmarking the results against an extensive database of test results assembled by American Bureau of Shipping. The results are also compared against current recognized offshore standards, such as API Bulletins 2U and DnV CN30.1. It is demonstrated that the ABS criteria provide very effective and sufficiently accurate predictions for the cylindrical shell buckling
calculations.

ABSTRACT: The pressure hulls of submersibles are frequently designed to BS5500 which evolved from RN submarine design. In this, failure by local interframe shell collapse is sought as a basis for design since the strength predictions are based on good experimental data. Overall modes of failure involving frame bending or tripping are avoided because of their greater shape sensitivity. This is achieved by a combination of higher safety factors and/or conservative assumptions.

ABSTRACT: A Level 1 code format is proposed for the buckling design of ring-stiffened cylindrical shells under external pressure. Depth independent partial safety factors to be applied to the resistance (collapse pressures) are proposed for the four relevant collapse modes (Interframe Shell Collapse, Frame Yield, Plate Yield and Frame Tripping), covering design and fabrication factors. A partial safety factor to be applied to the load (external pressure), and varying with the design pressure and the maximum expected overdiving, is proposed to cover operational factors. For deep diving vessels or in cases in which the risk of overdiving is not relevant, it is proposed that the overall safety factors used in design may be smaller than those presently recommended. In order to obtain such partial safety factors, different aspects of strength modeling and Structural Reliability had to be addressed. On the strength modeling side, the work was focused on the frame collapse modes. Seventy two experimental results were compiled, corresponding to machined models failing by elastic General Instability. Finite Element (FE) meshes were validated in view of mesh studies and experimental results and further used in parametric studies. The effect of boundary conditions on the elastic General Instability pressure \( p(n) \) was investigated in view of both experiments and results of the FE models. Statistical properties were obtained for the model uncertainty associated with \( p(n) \). Thirty five experimental results were compiled corresponding to welded models failing by General Instability. FE models were validated in view of the most relevant of these experiments as well as in view of other numerical results found in the literature. A closed form solution for the elastic Frame Tripping pressure, based on energy methods and showing good agreement with FE and other numerical results, was introduced. FE parametric studies showed the effects of
initial tilting angles of up to 4 degrees to be considerably less harmful than an initial o-o of 0.5%R, supporting the use of a modified Tangent Modulus approach for inelastic Tripping. On the Structural Reliability side, different reliability methods were reviewed, implemented and compared and the possibility of obtaining the failure probability in case of overdiving (or as a function of the external pressure in general) was verified, using any of the above methods. Notional safety levels of various types of existing structures were reviewed and target safety levels were proposed for externally pressurized, internally ring-stiffened cylinders in the four modes under consideration. Finally, partial safety factor optimization was carried out to obtain the partial safety factors.

ABSTRACT: Ring frame design is the aspect least well treated in the available design codes for orthogonally stiffened cylinders, particularly where axial load is dominant. Recent advances in this particular area are reviewed, together with the relevant theory and experiments. Detailed Finite Element analyses of a typical TLP column, as well as of its redesigned version, are presented and the results are compared with present prediction methods.

doi:10.1016/0951-8339(95)00020-8
ABSTRACT: This paper addresses the problem of designing ring frames in externally pressurised cylinders to avoid sideways tripping. A closed form solution is proposed for the elastic tripping pressure, including the effect of the rotational constraint provided by the shell to the toe of the web as well as the web deformation effect. Such theory compared reasonably well with numerical results given by ABAQUS as well as BOSOR4 and N9E. The differences become unimportant when a column curve is used for inelastic tripping, calculated with a structural tangent modulus approach. A safety factor for preliminary design is proposed based on parametric studies.

ABSTRACT: The work presented in this paper forms part of a broader task in establishing a guide to serve as technical documentation for buckling and ultimate strength assessment of various types of marine structural components using the best state-of-the-art knowledge for extreme environmental loading. This paper concentrates on buckling and ultimate strength assessment of ring stiffened shells and ring and stringer stiffened shells involving various modes of buckling and under various loading like axial compression, radial pressure and combined loading. Comparisons are made with screened test data, which have realistic imperfections and various radius to thickness ratio values in the range generally used in offshore structures. The statistical data of
model uncertainty factors in terms of bias and coefficient of variation (COV) are calculated and may be used in a further reliability study. Comparisons are also made with the codified rules, API BUL 2U and DNV buckling strength of shells.

ABSTRACT: The paper gives the results of an experimental study on three sets of AMT aluminum alloy cylindrical shells under axial impact. The length of the shell is 100 mm. Three different thicknesses 1.00mm, 1.42mm, and 2.00mm are used, and the shell is fixed on a jig and struck by a moving mass M (54gm.). The influence of different impact velocities on buckling behavior is discussed (see Fig. 2 and photographs 1, 2). It is found that when the impact velocity is less than a certain critical value Vc1, eq. (4), the shell will only exhibit uniform plastic deformation in both the axial and radial directions and does not produce sinusoidal waves. Vc1 is the critical velocity usually discussed in the literature, when this velocity is exceeded, the shell buckles. When the impact velocity exceeds another critical value Vc2, the shell will further change from the axisymmetric mode into a non-uniform type of large deformation. The shell shortens greatly and it begins to lose its load carrying capacity. We believe that this second critical velocity is also quite important in the study of dynamic plastic buckling characteristics. An approximate theoretical formula for estimating Vc2 based on strain rate reversal (violation of eq. 5) is given by eq. (7).

ABSTRACT: A dynamic plastic buckling analysis of three AMT aluminum alloy circular cylindrical shell with different thickness under external pressure and axial impact is presented in this paper. Experiments discover the presence of a critical speed vc2. which is corresponding to the collapse of the shell with large deformation and not the same as usually mentioned the critical speed vc1. In this paper the emphases of study are buckling mode and the relationship between vc2 and parameters of the axial deformation and the thickness of the shell.

ABSTRACT: Generally, thin cylindrical shells are susceptible for geometrical imperfections like non-circularity, non-cylindricity, dents, swellings etc. All these geometrical imperfections decrease the static buckling strength of thin cylindrical shells, but in this paper only effect of a dent on strength of a short (L / D "<1 and R/t = 280) stainless steel cylindrical shell is considered for analysis. The dent is modeled on the FE surface of perfect cylindrical shell for different angles of inclination and sizes at half the height of cylindrical shell. The cylindrical shells with a dent are analyzed using non-linear static buckling analysis. From the results it is found that in case of shorter dents, size and angle of inclination dents do not have much effect on static buckling strength of thin cylindrical shells, where as in the case of long dents, size and angle of inclination of dents have significant effect. But both short and long dents reduce the static buckling strength drastically.

ABSTRACT: One of the common failure modes of thin cylindrical shell subjected external pressure is buckling. The buckling pressure of these shell structures are dominantly affected by the geometrical imperfections present in the cylindrical shell which are very difficult to alleviate during manufacturing process. In this work, only three types of geometrical imperfection patterns are considered namely (a) eigen affine mode imperfection pattern, (b) inward half lobe axisymmetric imperfection pattern extended throughout the height of the cylindrical shell and (c) local geometrical imperfection patterns such as inward dimple with varying wave lengths located at the mid-height of the cylindrical shell. ANSYS FE non-linear buckling analysis including both material and geometrical non-linearities is used to determine the critical buckling pressure. From the analysis it is found that when the maximum amplitude of imperfections is 1t, the eigen affine imperfection pattern gives out the lowest critical buckling pressure when compared to the other imperfection patterns considered. When the amplitude of imperfections is above 1t, the inner half lobe axisymmetric imperfection pattern gives out the lowest critical buckling pressure when compared to the other imperfection patterns considered.

ABSTRACT: Thin plate structures are more widely used in many engineering applications as one of the structural members. Generally, buckling strength of thin shell structures is the ultimate load carrying capacity of these structures. The presence of cracks in a thin shell structure can considerably affect its load carrying capacity. Hence, in this work, static buckling strength of a thin square plate with a centre or edge crack under axial compression has been studied using general purpose Finite Element Analysis software ANSYS. Sensitivity of static buckling load of a plate with a centre or a edge crack for crack length variation and its vertical and horizontal orientations have been investigated. Eigen buckling analysis is used to determine the static buckling strength of perfect and cracked thin plates. First, bifurcation buckling loads of a perfect thin plate with its mode shapes from FE eigen buckling analysis are compared with analytical solution for validating the FE models. From the analysis of the cracked thin plates, it is found that vertical cracks are more dominant than horizontal cracks in reducing buckling strength of the thin plates. Further, it is also found that as the crack length increases, buckling strength decreases.

ABSTRACT: It is well known that thin cylindrical shell structures have wide applications as one of the important structural elements in many engineering fields and its load carrying capacity is decided by its buckling strength which in turn predominantly depends on geometrical imperfections present in it. Geometrical imperfections can be classified as local and distributed geometrical imperfections. But in this work, only local geometrical imperfection namely dent is considered for analysis. The main aim of this study is to determine the more influential dimensional parameter out of two dent dimensional parameters, one is the extent of dent present over a surface area and the other is dent depth, which affect the buckling strength of the cylindrical shells drastically. To account for the parameter “extent of dent present over an area”, the dent is considered as circular dent and its amplitude is considered as dent depth. For this purpose, finite element (FE) models of cylindrical shells with a circular dent at half the height of cylindrical shells having different dent sizes are generated. These FE models are analyzed using ANSYS non-linear buckling analysis. It is concluded that extent of dent present over an area is more influential than dent depth. To verify this conclusion further, FE models of cylindrical shells with two circular dents at half the height of cylindrical shell placed at 180° apart having different dent sizes are generated and analyzed.

ABSTRACT: Generally, thin cylindrical shells are susceptible for geometrical imperfections like non-circularity, non-cylindricity, dents, swellings, etc. All these geometrical imperfections decrease the static buckling strength of thin cylindrical shells, but in this paper only effect of a dent on strength of a short (Lc/Rc, vert, similar1, Rc/t=117, 175, 280) cylindrical shell is considered for analysis. The dent is modeled on the FE surface of perfect cylindrical shell for different angles of inclination and sizes at half the height of cylindrical shell. The cylindrical shells with a dent are analyzed using non-linear static buckling analysis. From the results it is found that in case of shorter dents, size and angle of inclination of dents do not have much effect on static buckling strength of thin cylindrical shells, whereas in the case of long dents, size and angle of inclination of dents have significant effect. But both short and long dents reduce the static buckling strength drastically. It is also found that the reduction in buckling strength of thin cylindrical shell with a dent of same size and orientation increases with increase in shell thickness.

ABSTRACT: Thin shell structures are efficient structures because of their high load-carrying capacity and small weight. Thin plates are one of the common structural elements. Their load-carrying capacity mainly depends on their buckling behavior, which is in turn affected by the imperfections present in them. Dent is one of the common geometrical imperfections in thin shell structures, which may be formed in the plate as an impact of sharp objects, among other reasons. Using ANSYS nonlinear FEA, the present work conducts a numerical study of the effect of various dent parameters on the ultimate strength of a thin plate, with a longitudinal or a transverse dent located centrally on the plate, under uniaxial compressive loading with simply supported boundary conditions.

the effect of single dent. It is found that the effect of two short dents and its nearness effect seem to be negligible compared with analysis and their buckling behaviours are compared with that of cylindrical shell with a short circumferential centre distance between the dents. These cylindrical shells are analysed using non linear FE modelled on the FE surface of perfect cylindrical shell at half the height of the cylindrical shell by varying the dents on the buckling behaviour of thin short stainless steel cylindrical shell is studied in detail. The dents are modelled on the FE surface of perfect cylindrical shell at half the height of the cylindrical shell by varying the centre distance between the dents. These cylindrical shells are analysed using non linear FE static buckling analysis and their buckling behaviours are compared with that of cylindrical shell with a short circumferential dent. It is found that the effect of two short dents and its nearness effect seem to be negligible compared with the effect of single dent in reducing the buckling strength of cylindrical shell.

ABSTRACT: In this paper, individual and combined effects of distributed and local geometrical imperfections on the limit load of an isotropic, thin-walled cylindrical shell under axial compression are investigated. First eigen affine mode shape imperfection pattern (FEAMSIP) is taken as distributed geometrical imperfections and dent as local geometrical imperfections. Limit load of the cylindrical shells are determined using non-linear static finite-element analysis module of general purpose FE software ANSYS. A parametric study on the effect of both imperfection patterns is done by varying the size and orientation of the dent. From the numerical results obtained, it is found that distributed geometrical imperfections namely, FEAMSIP have more influence on buckling strength than local geometrical imperfections namely dent.

ABSTRACT: One of the common failure modes of thin cylindrical shell subjected to external pressure is buckling. The buckling pressure of these shell structures are dominantly affected by the geometrical imperfections present in the cylindrical shell which are very difficult to alleviate during manufacturing process. Dent is one of the common geometrical imperfections present in thin shell structures which may be formed due to mechanical damage caused by accidental loading or impact. In this work, influence of various dent parameters (dent length, dent width, dent depth and angle of orientation of the dent) on the critical buckling pressure of thin cylindrical shells with a centrally located dent is studied using non-linear static finite-element analysis of ANSYS under external pressure with simply supported boundary conditions at the top and bottom edges of the thin cylindrical shell.

ABSTRACT: One of the common failure modes of thin cylindrical shells subjected to external pressure is buckling. The critical buckling pressures of these shell structures are mainly affected by the geometrical imperfections present in the cylindrical shell which are very difficult to alleviate during manufacturing process. Dent is one of the common geometrical imperfections present in thin shell structures which may be formed due to mechanical damage caused by accidental loading or impact. In this work, numerical parametric study is carried out to study the influence of dent parameters of centrally located dent (dent length, dent width, dent depth and angle of orientation of the dent), cylindrical shell parameters (L/R ratio and R/t ratio) and yield stress on the critical buckling pressure of externally pressurized thin dented cylindrical shells with simply supported boundary conditions at both top and bottom edges using non-linear static finite-element analysis of ANSYS.

ABSTRACT: The exact relation between strain and displacement is given for nonlinear deformation of thin shell. The fundamental formula of large deformation when the deflection is on the same class with the thickness of the shell is derived after simplified rationally. The fundamental formula of large deformation when the deflection is on the same class with the length of the shell is derived exactly for cylinder shell deformed cylindrical shaped.

ABSTRACT: An incremental variational formulation and a curved-shell element were proposed in the companion paper. In this part, the material model and solution techniques are discussed in detail. The strain-hardening plastic approach is employed to model the compressive behavior of the concrete. A dual criterion is considered for yielding and crushing in terms of stresses and strains, which is completed with a tension cut-off representation. Both the crack interface effects and dowel action are accounted for by using an average shear
modulus, and a full bond is assumed at the steel-concrete interface. A total Lagrangian approach making use of the second Piola-Kirchhoff stress tensor is employed in this analysis. An incremental and iterative modified Newton-Raphson scheme is used for the solution of nonlinear problem. An energy criterion in terms of both forces and displacements is implemented. The applicability and validity of this analytical model incorporating both geometrical and material nonlinearities is amply demonstrated through several numerical examples. The solution technique proposed in this paper has been shown to be successful in preventing the drifting of the solution in incremental process.

ABSTRACT: The cylindrical shells under global bending with different geometric parameters display different failure behavior. The size of typical buckles under axial compressive stress regimes is rather small and extends over a very small zone, with the axial compressive stress reaching the critical value. The first estimate of the elastic buckling strength in bending is the condition in which the most compressed fiber reaches the buckling stress for uniform axial compression. For short cylinders, local bifurcation buckling occurs at the middle of the most compressed side of the shell, and geometric nonlinearity has a little effect on the buckling strength, while for medium-length and long cylinders, the geometric nonlinearity and the ovalization of the cross-section should be considered. This paper explores the failure behavior in elastic cylinders in pure bending.

ABSTRACT: On the project background of the large-scale thin-walled cylindrical shells of a practical desulphurizing absorption tower, the investigations are conducted into the buckling mode and buckling capacity of the large-scale thin-walled cylindrical shells under wind loading by nonlinear finite element methods. In the buckling path, it firstly presents the buckling mode similar to that of the stocky cylinder under uniform external radial compression. In the post-buckling stage, the snap-through takes place, the buckling mode turns to being similar to the axial compressive buckling mode of the medium-height cylinder that horizontal buckles occur in the upper half of the front area. The buckling capacity of the cylindrical shells of desulphurizing tower is some more than the linear elastic buckling pressure of the cylinder under uniform radial pressure.

ABSTRACT: During the years 1994 – 1999 a European research project under the title “Design and Validation of Imperfection-Tolerant Laminated Shells” (DEVILS) was carried out. In this project 11 European partners were involved. A goal of the project was an analytical and experimental study of the buckling behavior of thin-walled carbon fibre reinforced polymer (CFRP) laminated shells under combined axial and torsion loading. An
additional aim was to compose a guideline for the dimensioning of such shells. This paper deals with the experimental and the analytical work conducted by DLR (Institute of Structural Mechanics, Braunschweig), ETH Zurich (former Institute of Lightweight Structures and Ropeways) and EMPA Dübendorf (Department of Polymers/Composites) in that project. The study was aimed at the determination of buckling loads of circular cylindrical shells of different laminate lay-ups. Nine shells were tested at DLR in Braunschweig for axial compression and at EMPA in Dübendorf under axial load and under combined axial compression and superimposed torsion. To determine the geometrical quality the internal and external surfaces of the specimens were mapped. ETH used photogrammetry and laser scanning prior to loading, while EMPA applied coordinate measurements for the unloaded shells and Moiré projection to monitor the lateral deflection of the cylindrical wall during loading and after buckling. At DLR strain measurements were performed to assess regularity of the load distribution throughout the loading. The investigation showed that buckling loads of cylinders which are imperfection-sensitive under axial loading may not be so sensitive to combined loads. Furthermore, it was found that the stiffness eccentricity of the laminate played a significant role on the magnitude of the axial buckling load, while for combined loads this effect was somewhat reduced. This paper contains the results of those tests and also the comparison with results of analytical investigations and FE modeling. The obtained data can be used as benchmark reference.

ABSTRACT: On the basis of extensive buckling tests and analytical and numerical buckling analyses for composite cylinders it became desirable to provide a recommendation for the most reliable evaluation of stability limits for imperfect CFRP cylinders subjected to axial compression. This paper reports on different approaches including linear, non-linear and dynamic non-linear FE analysis results and discusses the related effects and potential difficulties.

ABSTRACT: This article deals with the linear static and buckling analysis of an asymmetric square sandwich plate with orthotropic stiffness properties in the face layers. Two analytical formulations related to thin and thick face layers, respectively, have been taken from (Zenkert, D. (1995). An Introduction to Sandwich Construction, Chameleon Press Ltd, London, UK (ISBN 0 947817 77 8)), slightly modified to account for unequal faces, orthotropic properties in the face layers, and individual Poisson’s ratios, and applied to square sandwich plates of 1 m lateral dimension and a variety of different face layer thickness. All cases assume simply supported edges. The obtained deflections and buckling loads are compared with the results of a 3D analysis (Meyer-Piening, H.-R. (2004). Application of the Elasticity Solution to Linear Sandwich Beam, Plate and Shell Analyses, J. of Sandwich Structures & Materials, 6(4): 295-312) and of finite element calculations. The objectives of this study are to gain insight into the limits of validity of the published formulas in view of unequal thick face layers and orthotropic properties. The obtained results are meant to serve as a benchmark for further studies.

PARTIAL INTRODUCTION: In systems with a large aspect ratio, a band of solutions with different wavenumbers \( q \) may exist above the instability threshold. …

ABSTRACT: We present a new asymptotic-numerical method for the buckling analysis of imperfect elastic structures. It improves the classical estimate given by the theories of postbuckling or of perturbed bifurcation. By this way, we are able to compute numerically a class of nonlinear problems by inverting only one stiffness matrix.

ABSTRACT: This paper deals with the buckling of thin cylindrical shells with very large Batdorf parameters under external pressure. We first perform a simplified analysis from which we obtain explicit formulae for the critical load. An asymptotic analysis is carried out with a view to determining the effects of the boundary conditions on the critical loads and buckling shapes. The inverse of the Batdorf parameter is the convenient small parameter of the analysis. Among the whole set of boundary conditions, the axial boundary conditions are found to have crucially important at the first order. This analysis also shows the existence of boundary layers in which the remaining boundary conditions are only significant at the second order, at the very most.

ABSTRACT: We revisit the delicate problem of choosing an appropriate constitutive law to model buckling of thin walled structures. The classical flow and deformation theories are compared with a micromechanical model. We establish that a polycrystalline modelling is able to explain why the deformation theory is better than the flow theory to predict plastic buckling. This comparison is achieved for a simple buckling problem, with a view to design characterization tests for the evaluation of the tangent stiffness matrix.

ABSTRACT: Severe thin strip cold rolling conditions usually induce heterogeneity of in-bite plastic deformation always translated to irregular stress field. This stress field may dwell sufficiently compressive in several out-of-bite areas to cause buckling (flatness defects) which generates stress reorganisation in rolled strip and probably affects the bite zone. Hence, out-of-bite buckling, in-bite elastic-(visco)plastic deformation and thermo-mechanical roll-stack/strip interaction may be strongly coupled. However, a completely coupled model providing realistic rolled strip shape specially when flatness defects occur is not easy to establish. This call for two ways of flatness defect modelling in thin strip rolling: with a completely coupled approach but using a simple buckling criterion, or using an uncoupled approach by chaining strip rolling model calculation with shell element models presenting good buckling computing capabilities. Our objective is the improvement of the flat product rolling – specialized FEM software Lam3/Tec3 [1] using Counhaye simple buckling criterion [3] and
Asymptotic Numerical Method (ANM) for shell element model [9,10] respectively with coupled and uncouple approaches detailed in the present paper. These two approaches bring computed stress profiles to very good agreement with experiments and the most important result at this stage is the weak influence of buckling on in-bite stress and strain fields providing a more rigorous justification of the traditional decoupled methods [2,5-8]. ABSTRACT: In many industrial conditions, light thin titanium shells are well used under various severe loading conditions. It is of interest to know the real conditions that govern the instability of a cracked panel subject to buckling loads in order to conserve as maximum as possible the strength of the structure. Several parameters can be varied in order to achieve this objective. The aim of this study is to determine the evolution of these parameters in order to achieve optimal crack propagation conditions while keeping these parameters within “reasonable” limits of physical and economic feasibility. For the purpose of the current study the considered structure can be regarded as thin cylindrical shell of radius r, thickness t with an initial through crack of length a. The titanium cylindrical shell is sealed on one edge and compression is applied on the other. An additional applied pressure can generates a stress and deformation field around the crack tip that has bending stresses and membrane stresses and appears as a bulge around the crack area. This paper give details of a simulation with FEA numerical analysis that determine governing instability conditions of a Titanium shell under particular loading conditions and to put in light the effect of bulging on the stress intensity factor at the crack tips. This bulging factor measures the severity of the stress intensity in the bulged crack compared to a plane shell subjected to equivalent loading conditions.

ABSTRACT: In this paper we present the elastic postbuckling theory, but we introduce two modifications with respect to its classical statement. First, we account for the influence of symmetries. Second, the singularities will be classified according to their robustness, what was introduced by Catastrophe Theory. Various recent progresses are discussed; mathematical foundations of the energy criterion, buckling of structures with a large aspect ratio, contribution of catastrophe theory ...

ABSTRACT: In the framework of the cellular bifurcation theory, we investigate the effect of distributed and/or localized imperfections on the buckling of long cylindrical shells under axial compression. Using a double scale perturbative approach including modes interaction, we establish that the evolution of amplitudes of instability patterns is governed by a non-homogeneous second order system of three non-linear complex equations. The localized imperfections are included by employing jump conditions for their amplitude and permitting discontinuous derivatives. By solving these amplitude equations, we show the influence of distributed and/or localized imperfections on the reduction of the critical load. To assess the validity of the present method, our results are compared to those given by two finite element codes.

ABSTRACT: In this paper the buckling and post-buckling of elastic structures taking into account large rotations are investigated using an asymptotic-numerical method. The critical points are detected by two different ways: first by a bifurcation indicator, second by analysing the poles of a Padé approximant. The first step of the post-buckling branch is computed starting from the bifurcation point and using an extended system. The remaining bifurcating branch is followed by the same algorithm as for the fundamental path. Several
examples are tested to show the effectiveness of the proposed method.

“Buckling of a functionally graded coating with an embedded crack bonded to a homogeneous substrate”,
doi: 10.1007/s10704-006-9031-8

ABSTRACT: In an attempt to simulate buckling of nonuniform coatings, we consider the problem of an embedded crack in a functionally graded coating bonded to a homogeneous substrate subjected to a compressive loading. The coating is graded in the thickness direction and the material gradient is orthogonal to the crack direction which is parallel with the free surface. The loading consists of a uniform compressive strain applied away from the crack region. The graded coating is modeled as a nonhomogeneous medium with an isotropic stress-strain law. Using a nonlinear continuum theory and a suitable perturbation technique, the plane strain problem is reduced to an eigenvalue problem describing the onset of buckling. Using integral transforms, the resulting plane elasticity equations are converted analytically into singular integral equations which are solved numerically to give the critical buckling strain and the corresponding crack opening displacement shapes. The main objective of the paper is to study the influence of material nonhomogeneity on the buckling resistance of the graded layer for various crack positions and coating thicknesses.

Afagh (Department of Mechanical and Aerospace Engineering, Carleton University, Ottawa, Ontario, Canada), “Analysis of active closed cross-section slender beams based on asymptotically correct thin-wall beam theory”, Smart Materials and Structures, Vol. 18, No. 1, January 2007

ABSTRACT: An asymptotically correct theory for multi-cell thin-wall anisotropic slender beams that includes the shell bending strain measures is extended to include embedded active fibre composites (AFCs). A closed-form solution of the asymptotically correct cross-sectional actuation force and moments is obtained. Active thin-wall beam theories found in the literature neglect the shell bending strains, which lead to incorrect predictions for certain cross-sections, while the theory presented is shown to overcome this shortcoming. The theory is implemented and verified against single-cell examples that were solved using the University of Michigan/Variational Beam Sectional Analysis (UM/VABS) software. The stiffness constants and the actuation vector are obtained for two-cell and three-cell active cross-sections. The theory is argued to be reliable for efficient initial design analysis and interdisciplinary parametric or optimization studies of thin-wall closed cross-section slender beams with no initial twist or obliqueness.

ABSTRACT: Based on a non-linear stability model, analytical solutions are derived for simply supported beam-column elements with bi-symmetric I sections under combined bending and axial forces. An unique compact closed-form is used for some representative load cases needed in design. It includes first-order bending distribution, load height level, pre-buckling deflection effects and presence of axial loads. The proposed solutions are validated by recourse to non-linear FEM software where shell elements are used in mesh process. The agreement of the proposed solutions with bifurcations observed on non-linear equilibrium paths is good. It is proved that classical linear stability solutions underestimate the real resistance of such element in lateral buckling stability especially for I section with large flanges. Numerical study of incidence of axial forces on lateral buckling resistance of redundant beams is carried out. When axial displacements of a beam are prevented
important tension axial forces are generated in the beam. This results in important reduction of displacements and for some sections, the beam behaviour becomes non-linear without any bifurcation.

ABSTRACT: New results are presented for the finite element analysis of wrinkling in curved elastic membranes under-going large deformation. Concise continuum level governing equations are derived in which singularities are eliminated. A simple and efficient algorithm with robust convergence properties is established to find the real strain and stress of the wrinkled membrane for Hookean materials. The continuum theory is implemented into a finite element code. Explicit formulas for the internal forces and the tangent stiffness matrix are derived. Numerical examples are presented that demonstrate the effectiveness of the new theory for predicting wrinkling in membranes undergoing large deformation.

ABSTRACT: Thin-film membrane structures are under consideration for use in many future gossamer spacecraft systems. Examples include sunshields for large-aperture telescopes, solar sails, and membrane optics. The development of capabilities for testing and analyzing pretensioned, thin-film membrane structures is an important and challenging aspect of gossamer spacecraft technology development. Results are presented from experimental and computational studies performed to characterize the wrinkling behavior of thin-film membranes under mechanical loading. The test article is a 500-mm-square Kapton membrane subjected to symmetric corner loads. Data are presented for loads ranging from 0.49 to 4.91 N. The experimental results show that as the load increases the number of wrinkles increases, while the wrinkle amplitude decreases. The computational model uses a finite element implementation of Stein–Hedgepeth membrane wrinkling theory to predict the behavior of the membrane. Comparisons were made with experimental results for the wrinkle angle and wrinkled region. There was reasonably good agreement between the measured wrinkle angle and the predicted directions of the major principle stresses. The shape of the wrinkled region predicted by the finite element model matches that observed in the experiments; however, the size of the predicted region is smaller that that determined in the experiments.

ABSTRACT: A buckling solution and a non-linear post buckling solution were employed for the wrinkling analysis of a tensioned Kapton square membrane. The buckling solution with significantly reduced bending stiffness creates localized buckling modes accounting for the wrinkle formation in the membrane. The non-linear post buckling solution with an updated Lagrangian scheme describes the detailed wrinkle evolution during the loading process. Simulations show wrinkle amplitudes decrease as the tension load increases. The wrinkle number and distribution remain stable until loads exceed a certain level, then new wrinkles occur usually by splitting from existing wrinkles. The evolution of existing wrinkles and formation of new wrinkles in simulations are consistent with experimental observations.

ABSTRACT: In this paper three fundamental issues regarding modeling and analysis of wrinkled membranes are addressed. First, a new membrane model with viable Young's modulus and Poisson's ratio is proposed, which physically characterizes stress relaxation phenomena in membrane wrinkling, and expresses taut, wrinkled and slack states of a membrane in a systematic manner. Second, a parametric variational principle is developed for the new membrane model. Third, by the variational principle, the original membrane problem is converted to a non-linear complementarity problem in mathematical programming. A parametric finite element discretization and a smoothing Newton method are then used for numerical solution. The proposed membrane model and numerical method are capable of delivering convergent results for membranes with a mixture of wrinkled and slack regions, without iteration of membrane stresses. Three numerical examples are provided.

ABSTRACT: The computational challenge in dealing with membrane systems is closely connected to the lack of bending stiffness that constitutes the main feature of this category of structures. This manifests numerically in badly conditioned or singular systems requiring the use of stabilized solution procedures, in our case of a ‘pseudo-dynamic’ approach. The absence of the flexural stiffness makes the membrane very prone to local instabilities which manifest physically in the formation of little ‘waves’ in ‘compressed’ areas. Current work presents an efficient, sub-iteration free ‘explicit’, penalty material based, wrinkling simulation procedure suitable for the solution of ‘static’ problems. The procedure is stabilized by taking full advantage of the pseudo-dynamic solution strategy, which allows to retain the elemental quadratic convergence properties inside the single solution step. Results are validated by comparison with published results and by setting up ‘numerical experiments’ based on the solution of test cases using dense meshes.

ABSTRACT: This paper reviews conventional wrinkle models for anisotropic membrane and shows the
A new wrinkle model is proposed which assumes virtual shear as well as virtual elongation of the membrane to estimate the real strain in the wrinkled region. This model coincides with the other models if the virtual shear and elongation is determined so that the strain energy is minimized. Another wrinkle/slack model is proposed for the dynamic analysis of thin isotropic membrane undergoing large overall motion with wrinkle and slack. It can take into account the residual compressive stress in the wrinkled and slack regions, i.e. the stiffness in the post-buckling state. It is shown that the proposed model is a generalization of the conventional ones. Finite element formulation of the proposed model is described. Furthermore, the energy momentum conservation framework is constructed for the proposed membrane element, which achieves the unconditionally stable time integration. The total of the proposed method enables us to compute the overall motion of thin isotropic membrane such as the deployment of folded membrane, which has been one of the most difficult problems in aerospace engineering.

ABSTRACT: A simple computer implementation of membrane wrinkle behaviour is presented within the classical elastic plane stress constitutive model. In the present method, a projection technique is utilized for modelling of the wrinkle mechanisms, in which the total strains in wrinkled membranes are decomposed into elastic and zero-strain energy parts, and a projection matrix that extracts the elastic parts from the total strains is derived. The resulting modified elasticity matrix that represents the stress–strain relations in wrinkled membranes is thus obtained as product of the classical elasticity matrix and the projection matrix. The modified elasticity matrix is straightforward to implement within the context of the finite element method. Numerical examples are presented to demonstrate the accuracy and effectiveness of the proposed method.

ABSTRACT: In this paper, a new technique using slowly variable Fourier coefficients and the asymptotic Landau–Ginzburg approach are re-discussed and compared. The aim is to define simple macroscopic models describing the influence of local wrinkling on membrane behaviour. This question is analyzed by considering the simple example of a beam resting on a non-linear Winkler foundation.

This paper presents a detailed experimental study of the formation and evolution of the wrinkle pattern that form in flat elastic and isotropic membranes under the action of in-plane tension. The experiments were carried out on a cruciform specimen stretched along two uncoupled axes using various loading paths. The wrinkled shapes of the membrane were digitized by using a full-field measurement based on the fringe analysis method. Over this experiment, several phenomena were observed: the mechanism of wrinkle division, the influence of the membrane thickness on the wrinkle pattern, and the reproducibility of a kinematic configuration of wrinkles. The main result is that non-unique wrinkle shapes have been observed over repeated experiments for nominally identical boundary conditions. The uncertainty of the experimental wrinkle shape has been explained using comparison with the results of a post-buckling finite element analysis.

ABSTRACT: Membrane modeling in the presence of wrinkling is revisited from a multi-scale point of view. In the engineering literature, wrinkling is generally accounted at a macroscopic level by nonlinear constitutive laws without compressive stiffness, but these models ignore the properties of wrinkles, such as their wavelength, size and spatial distribution. A new multi-scale approach is discussed that belongs to the family of Ginzburg-Landau bifurcation equations. By using the method of Fourier series with variable coefficients, several nonlinear macroscopic models are derived that couple the membrane response with equations governing the evolution of the wrinkles. Contrary to previous approaches, these macroscopic models are completely deduced from the “microscopic” shell model without any phenomenological assumptions. Some analytical and numerical solutions are discussed that prove the relevance of the presented modeling. A new
class of models has been established. It permits to predict the characteristics of the wrinkles and their influence on membrane behavior.

ABSTRACT: This paper presents a detailed Finite Element Analysis study of the formation and evolution of wrinkle pattern that observed in stretched thin membranes. The model problem is set up under the various load conditions. As a precondition for wrinkling, development of compressive stresses in the transverse direction is found to depend on both the length-to-width aspect ratio & thickness of the rectangular membrane. Shape and size of wrinkle also depends on applied tensile strain and shear strain. The analysis has been done in two parts; in first part we see the effect of thickness of membrane and number of element variation on number of wrinkles and eigenvalue frequency. In second part, two-dimensional stress analysis is performed under the plane-stress condition to finding out stretch-induced stress distribution patterns in the elastic membrane. The analysis has been carried out on the rectangular membrane with tensile loading with assuming imperfections in the structure with the ABAQUS a commercially available finite element package. Wrinkling patterns are presented to show how wrinkle formation with increasing shear loads, tensile loads, membrane thickness and number of elements.

ABSTRACT: Mechanics of tympanic membrane (TM) is crucial for investigating the acoustic transmission through the ear. In this study, we studied the wrinkling behavior of tympanic membrane when it is exposed to mismatched air pressure between the ambient and the middle ear. The Rayleigh–Ritz method is adopted to analyze the critical wrinkling pressure and the fundamental eigenmode. An approximate analytical solution is obtained and validated by finite element analysis (FEA). The model will be useful in future investigations on how the wrinkling deformation of the TM alters the acoustic transmission function of the ear.

ABSTRACT: We investigate the buckling behavior of thin cylindrical shape-memory shells at room temperature, using a modified split Hopkinson bar and an Instron hydraulic testing machine. The quasi-static buckling response is directly observed using a digital camera with a close-up lens and two back mirrors. A high-speed Imacon 200 framing camera is used to record the dynamic buckling modes. The shape-memory shells with an austenite-finish temperature less than the room temperature, buckle gradually and gracefully in quasi-static loading, and fully recover upon unloading, showing a superelastic property, whereas when suitably annealed, the shells do not recover spontaneously upon unloading, but they do so once heated, showing a shape-memory effect. The gradual and graceful buckling of the shape-memory shells is associated with the stress-induced martensite formation and seems to have a profound effect on the unstable deformations of thin structures made from shape-memory alloys.

References listed at the end of the paper:

ABSTRACT: To investigate the buckling behavior of thin and relatively thick cylindrical shape-memory shells, uniaxial compression tests are performed at a 295 K initial temperature, using the CEAM/UCSD's modified split Hopkinson bar systems and an Instron hydraulic testing machine. The quasi-static buckling response of the shells is directly observed and recorded using a digital camera with a close-up lens and two back mirrors. To document the dynamic buckling modes, a high-speed Imacon 200 framing camera is used. The shape-memory shells with an austenite-finish temperature of $A(f) = 281$ K, buckle gradually and gracefully in quasi-static loading, and fully recover upon unloading, showing a superelastic property, whereas when suitably annealed, the shells do not recover spontaneously upon unloading, but they do so once heated, showing a shape-memory effect. The thin shells had a common thickness of 0.125 mm a common outer radius of 2.25 mm (i.e., a common radius, $R$, to thickness, $t$, ratio, $R/t$, of 18). A shell with the ratio of length, $L$, to diameter $D$ ($L/D$) of 1.5 buckled under a quasi-static load by forming a nonsymmetric chessboard pattern, while with a $L/D$ of 1.95 the buckling started with the formation of symmetrical rings which then changed into a nonsymmetric chessboard pattern. A similar buckling mode is also observed under a dynamic loading condition for a shell with $L/D$ of 2. However thicker shells, with 0.5 mm thickness and radius 4 mm ($R/t = 8$), buckled under a dynamic loading condition by the formation of a symmetrical ring pattern. For comparison, we have also tested shells of similar geometry but made of steel and aluminum. In the case of the steel shells with constrained end conditions, the buckling, which consists of nonsymmetric (no rings) folds (chessboard patterns), is sudden and catastrophic, and involves no recovery upon unloading. The gradual buckling of the shape-memory shells is associated with the stress-induced martensite formation and seems to have a profound effect on the unstable deformations of thin structures made from shape-memory alloys.

ABSTRACT: We report experiments and simulations of the dynamic and quasistatic compressive response of single and hex-arrayed thick aluminum tubes. The investigation aims to further characterize how tube-based sandwich structures absorb energy. First, we study by compression tests the quasistatic buckling of single tubes of 7075 aluminum, an alloy showing sufficient ductility and plasticity to make it potentially a good choice for energy absorbing devices. The experiments show geometry-dependent buckling modes. The corresponding finite element numerical simulations correlate well and will help estimate the maximum load level, and the buckling and postbuckling responses. Second, we study the dynamic buckling of sandwiched, hex-arrayed 3003 aluminum tubes. The simulations and experimental results correlate well and show a remarkable increase in energy absorbing capacity, which is caused by the postbuckling interaction of neighboring tubes. They also show that, as the tube spacing is decreased, the overall energy absorbed increases significantly. We also simulate how varying tube length and thickness affect the buckling of the array under dynamic loading.

Karman nonlinear displacement–strain relationships are applied to consider large deflections due to thermal loads. The cylindrical arc-length method is used to take account of the snapping phenomenon which is an unstable behavior observed in the shell panels. A nonlinear finite element procedure based on Brinson's model is developed to investigate the behaviors of shape memory alloy (SMA) wire. The results of numerical analysis show that the recovery stresses of SMA wires can enhance the stiffness of structure and the SMAHC shell panel exhibits superior behaviors of thermal post-buckling compared to the conventional composite panel. It is also shown that embedding SMA wires in a composite structure can prevent the unstable post-buckling behavior.

Xinzhen He, Huadong Yong and Youhe Zhou (Key Laboratory of Mechanics on Disaster and Environment, Department of Mechanics and Engineering Science, College of Civil Engineering and Mechanics, Lanzhou University, Lanzhou, Gansu 730000, People's Republic of China), “The characteristics and stability of a dielectric elastomer spherical shell with a thick wall”, Smart Materials and Structures, Vol. 20, No. 5, 2011, doi:10.1088/0964-1726/20/5/055016
ABSTRACT: When a voltage is applied between the internal and external surface of a dielectric elastomer spherical shell, positive charges appear on one surface and negative charges on the other. This gives rise to Coulomb forces between opposite charges, generating a pressure. Thus, the shell reduces in thickness and stretches in area, and a higher electric field is produced. This positive feedback may make the shell continually thin down, eventually causing electrical instability. In this paper we use the neo-Hookean model and the Arruda–Boyce model to analyze the electromechanical instability of the thick-walled shell respectively. The electric field in the shell is inhomogeneous and varies with the radius of the shell. The instability in spherical shells with different thicknesses and boundary conditions is discussed. When the elastomer obeys the Arruda–Boyce model, the stability is related to the parameter $n$. The spherical shell will appear with snap-through instability and pull-in instability for different values of the parameter $n$.

Guanghui Shi, Qingsheng Yang and Qiang Zhang (Beijing Univ. of Technology, China), “Investigation of buckling behavior of carbon nanotube/shape memory polymer composite shell”, Proc. SPIE 8409, Third International Conference on Smart Materials and Nanotechnology in Engineering, 840916 (April 2, 2012); doi:10.1117/12.923313
ABSTRACT: Shape memory polymer (SMP) is a class of smart materials used in intelligent biomedical devices and industrial application as sensors or actuators for their ability to change shape under a predetermined stimulus. Carbon nanotube (CNT)/shape memory polymer (SMP) composites demonstrate good mechanical properties and shape memory effect. In this work, a model of CNT/SMP composite shell with a vaulted cross-section was established. This composite shell structure could further elevate the recovery stress of CNT/SMP composites. The folding properties of CNT/SMP composite shell structure were analyzed by finite element method and the influence of structural parameters on the buckling behavior of the shell was studied using the energy conservation principle. The results indicate that vaulted cross-section shell had unique mechanical properties. The structural parameters, such as the vaulted radius and the total length have a great impact on buckling moment of the shell. This shell structure is expected to achieve effective control of buckling and deploying process, relying on the special shape memory property of SMP and high elastic modulus CNTs. Moreover, it could also largely avoid the vibration problem during the deploying process.

ABSTRACT: Shape-memory alloys can sustain relatively large strains and fully recover without noticeable residual strains. This is referred to as superelasticity. We have been studying quasi-static and dynamic buckling of relatively thin circular cylindrical shells consisting of shape-memory alloys in order to understand the response when used as the core of the sandwich structures. The work consists of experimental characterization of the buckling process, as well as numerical simulation. For comparison, we have also studied both dynamic and quasi-static buckling of aluminum tubes of similar dimensions. This presentation will focus on numerical simulation of dynamic buckling of these tubes and correlation with experimental observations.

References listed at the end of the paper:

ABSTRACT: The analysis of imperfect, stiffened, thin circular cylindrical shells, subjected to suddenly applied pressure, is presented. Moreover, a solution scheme for the complete (including post-limit point behavior) static analysis is described. The concept of dynamic stability is discussed for suddenly loaded structures. In addition, a fairly complete review of the reported works on the subject is presented. Results are presented for a ring-stiffened geometry. These include critical dynamic loads, critical static loads (limit point loads), as well as minimum post-limit point loads.

ABSTRACT: The problem of instability of imperfect, laminated, circular cylindrical shells under the action of
uniform axial compression is investigated. The analysis is based on nonlinear kinematic relations where the
effect of transverse shear deformation is taken into account. The buckling is assumed to be elastic and the
geometry to have initial geometric imperfections. The kinematic relations, governing equations and the related
boundary conditions for the nonlinear analysis are derived and presented. A solution methodology has been
developed and employed in generating results. The imperfection sensitivity is investigated. The results obtained
indicate that geometric imperfections have little effect on the limit point load for moderately thick cylindrical
shells.

Cincinnati, Cincinnati, OH 45221-0070, U.S.A.), “Instability of laminated cylindrical shells with material non-
doi:10.1016/S0020-7462(97)00030-9
ABSTRACT: An analytical methodology is presented to study the post-buckling behavior of laminated
cylindrical shells under axial compression and lateral pressure. Non-linear inplane stress-strain relations for
transverse (E22) and shear (G12) modulus is considered. The user defined material subroutine UMAT in finite
element analysis package, ABAQUS, with an updated Lagrangian formulation, and large displacement and
small strain kinematic relations, is employed in this study. Numerical analyses are conducted to demonstrate the
effect of material non-linearity and stacking sequence on the post-buckling behavior of laminated shells.

Romil Tanov and Ala Tabiei (Center of Excellence in LS-DYNA Analysis University of Cincinnati, Cincinnati,
OH 45221-00700, “Static and Dynamic Buckling of Laminated Composite Shells”, Mechanics of Composite
ABSTRACT: This paper presents the results from numerical investigation of the behavior of cylindrical
laminated shells subjected to suddenly applied loading. A numerical approach is used combining the finite
element method with two different stability criteria namely the Budiansky-Roth and the phase-plane buckling
criteria. In the finite element analysis an explicit time integration scheme is used implemented in the LS-DYNA
commercial code. The response of the composite shells has been investigated at the presence and absence of
static preloading. Results are presented for different values of the shell length, imperfection factors, stacking
sequence, and laminae orientation, and for different static preloading magnitudes. Based on the presented
results important conclusions can be drawn concerning the shell behavior and its sensitivity to different system
parameter variations.

ABSTRACT: The present work concentrates on the development of correct representation of the transverse shear strains and stresses in Mindlin-type displacement-based shell finite elements. The formulation utilizes the robust standard first-order shear deformation shell finite element for implementation of the proposed representation of the transverse shear stresses and strains. In this manner the need for the shear correction factor is eliminated. In addition, modification to any existing shell finite element for the correct representation of transverse shear quantities is minimal. Some modifications to correct Mindlin-type elements are presented in the literature. These modifications correct the distribution of the transverse shear stresses only and use the constant transverse shear strains through the thickness. As compared to the above, the present formulation uses the correct distribution and is consistent for both transverse shear stresses as well as transverse shear strains.

ABSTRACT: The ultimate goal of the present research is to come up with an accurate and efficient analysis
approach for composite and sandwich shells, which is simple enough to be capable of implementing into a FE code without significantly affecting its computational efficiency, and at the same time gives good accuracy in predicting the behavior of layered shells. It has to be capable of accurately modeling both overall behavior, and the local distribution of strains and stresses in all layers and all constituents in the composite laminae. Two different approaches are utilized in the attempt to fulfill the final research objective of the present work. First, a homogenization procedure for the FE analysis of sandwich shells is developed. The procedure works on the material constitutive level. A homogenization of the sandwich shell is performed at each call of the corresponding constitutive subroutine. Thus the sandwich nature of the problem is hidden from the main FE program. As a consequence there is no need to develop a new shell element formulation, but instead the available homogeneous shell elements in the utilized FE code can be used for the analysis of sandwich shells. However, the defined homogenization procedure works with first order shear deformable shell elements, which sets a limit to the accuracy with which the transverse distribution of the unknowns is represented. To overcome this, a higher order shear deformable shell element is formulated and implemented into a general nonlinear explicit FE code. Using the differential equilibrium equations and the interlayer requirements, special treatment is developed for the transverse shear, resulting in a continuous, piecewise quartic distribution of the transverse shear stresses through the shell thickness. A similar approach is applied to the transverse normal stresses, which are represented by a continuous piecewise cubic function. The FE implementation is cast into a 4-noded quadrilateral shell element with 9 degrees of freedom per node. Only C0 continuity of the displacement functions is required in the shell plane, which makes the present formulation applicable to the most popular 4-noded bilinear isoparametric shell elements. Expressions are developed for the critical time step of the explicit time integration for orthotropic homogeneous and layered shells based on the developed third order formulation. Finally, to be able to analyze shells with woven composite layers, two micromechanical models for analysis of woven fabric composites are developed. Both models utilize the representative volume cell approach and divide a representative unit of the woven lamina into sub-cells of homogeneous material. Starting with the average strains in the representative volume cell and based on continuity requirements at the sub-cell interfaces, the strains and stresses in the composite constituents are determined as well as the average stresses in the lamina. Equivalent homogenized material properties are also determined. Their very good accuracy together with the simplicity of formulation makes these models attractive for the nonlinear FE analysis of composite laminates and can be efficiently utilized in explicit and implicit FE codes. The formulations developed within the research provide an efficient analysis approach to layered shells including sandwich shells with composite facings. Furthermore, the developed micromechanical models can be used to determine the stress and strain fields in the composite layer constituents. This would enable important strength and durability phenomena as failure, damage, and property degradation of the constituents to be included into the FE analysis of layered shells.

ABSTRACT: The presence of cracks or similar imperfections can considerably reduce the buckling load of a shell structure. In this paper, buckling analysis of cylindrical shells with a longitudinal crack is presented. Numerical buckling analyses of cylindrical shells were performed using FEM, and verified by experiment. The numerical analyses and experiments were conducted for several crack lengths and radius of curvature, and two different boundary conditions were applied, i.e. simply support and clamp in all sides. The results show the effect of the presence of crack to the critical buckling load of the shells. There are good agreements between experimental and numerical results.

ABSTRACT: The theoretical analysis of finite element method for buckling phenomenon to finite-sized shell structure is first introduced. Then, a real application using a probe for detecting the pressure inside turboprops is analyzed thoroughly with ANSYS10.0, including section profile, dimensions, and local characteristics. Based on the solved results, several rules between critical load and influence factors are obtained, which would be helpful for similar structures design and application. Finally, several useful conclusions about the best profile and ratio between dimensions are obtained.

ABSTRACT: A reduced stiffness method is presented for the estimation of lower bounds to the imperfection sensitive general buckling of axially loaded, orthotropically stiffened, elastic cylinders. It predicts many previously inexplicable empirical observations and provides lower bounds to the scatter of available test buckling loads, thus becoming useful as a design tool.

ABSTRACT: Buckling of pressure loaded cylindrical panels is investigated using a fully nonlinear Ritz solution procedure and a classical bifurcation analysis of an idealized model. The dialectic between these two contrasting approaches is shown to produce greater understanding than if either one of them were to be used alone. Apart from illuminating the specific buckling behavior of the pressure loaded panel and demonstrating the lower boundedness of the reduced stiffness analytical procedure, the paper suggests that a similar interplay between classical and numerical analysis could be useful in elucidating behavior and providing design analysis procedures for many other shell buckling problems.

ABSTRACT: Nonlinear Ritz analysis is used to investigate the elastic buckling behavior of pressure loaded cylinders. Careful analysis of the energy changes during the buckling process allows definition of a reduced stiffness theoretical model. This reduced stiffness model provides a convenient means for estimating lower bounds to the imperfection sensitive elastic buckling behavior.

ABSTRACT: The ‘reduced stiffness method’ for the analysis of shell buckling was developed to overcome a trend towards increasingly sophisticated analysis that has become divorced from its basically simple underlying physics. This paper outlines the developments of the reduced stiffness method from its origins in the late 1960s, through its experimental confirmation, generalisation and elaboration over the past 20 years, to its more recent consolidation using carefully controlled non-linear numerical experiments. It is suggested that the method has now reached a stage where it could profitably be adopted as a basis for an improved shell buckling design methodology.

ABSTRACT: The reduced-stiffness method is used to establish the lower bounds of buckling loads for stringer- or ring-stiffened cylindrical shells. The numerical results obtained by using this method are compared with the experimental data. We also consider the problem of applicability of the reduced-stiffness method in design practice as well as the prospects for its development and generalization.

J.G.A. Croll: The following text is most of a July 8, 2013, email message from J. G. A. Croll to Chris Calladine and Mike Thompson, with copies to Allan McRobie, John Hutchinson, Isaac Elishakoff, Giles Hunt, Alan Champneys, Gert Van Der Heijden, Mark Peletier, David Bushnell:
I have been arguing the case for the remarkably simple and effective reduced stiffness method for more than 40 years. For the first 15 or so years the theory was founded upon simple mechanics reasoning and some remarkably good correlations between its predictions and experimental observation, for wide classes of shell buckling problem. You may also recall that at the IUTAM Symposium we held in London (1982) Professor Yamaki brought over a number of his co-workers who presented to the best of my understanding the first fully non-linear analysis of axial load shell buckling; this reproduced in every detail carefully conducted experimental observation on shells for which the precise form of the initial geometric imperfections had been recorded. After the IUTAM Symposium I contacted Prof. Yamaki to suggest we undertake a joint research programme to see if the predictions from reduced stiffness theory could be reproduced through carefully controlled numerical experiment in which the levels and forms of initial imperfection could be systematically varied in order to accurately identify the lower bounds. Yamaki’s response was to send to London one of the young researchers, Dr Seishi Yamada, who had developed their so successful non-linear shell buckling analysis algorithm. Seishi spent a year working with me in I think 1986 and we had been working together since in what I believe has been an extremely successful collaboration. This has allowed the identification of the imperfection sensitive lower bounds for most of the classical shell buckling problems, and most gratifyingly the relevance of the reduced stiffness theory in predicting these lower bounds. For his remarkable contributions Seishi was awarded a Gold medal by the Japan Architectural Institute.

Were it not for Seishi’s tragic and untimely death a few weeks ago I would probably have not taken the time to respond to the dialogue your very interesting paper has generated. After all, if more than 200 papers by increasingly large numbers of independent workers has not convinced you and others of the relevance of the RSM [Reduced Stiffness Method], it is unlike any short email within the context of this discussion will change too many minds! But I have to say I have found it difficult to understand why so many good friends and colleagues have found it so difficult to accept the beautiful simplicity of the RSM and the remarkable effectiveness of its predictions.

I would of course welcome the chance to enter into any discussion as to the relevance of the RSM with your contributors.

Ciao, Jim

ps here is a selection of articles describing various contributions showing the relevance of the RSM; some of these might be of interest.
1. (with A H Chilver) Approximate Estimation of the Stability of Cooling Towers under Wind Loading, Int. Assoc. Shell Structures Colloquium, Brussels, May, 1971. This was the first use of what I then characterised as a quasi-inextensional theory of shell buckling. This was extended and presented to TWSG in:

2. Towards Simple Estimates of Shell Buckling Loads, presented to Thin Walled Structures Study Group, Cranfield, March, 1972. Later that year I spent a few weeks presenting similar papers at a number of German universities including Darmstadt where colleagues of Prof Kloppel urged me to publish the work in der Stahlbau. I submitted this in late 1972 only to find the paper sat upon until 1975! It eventually appeared:

3. Towards Simple Estimates of Shell Buckling Loads, Der Stahlbau: Part I, Heft 8, August 1975; Part II, Heft 9, September 1975. While the work to this point was able to explain buckling of pressure loaded shells there was clearly something missing for the explanation of axially loaded rotationally symmetric shells – including axially loaded cylinders. It was this problem I asked Ronaldo Batista to address in his PhD research. The result was I believe extremely important and allowed the method to be extended to this thorny old problem. See for example:

5. (with R C Batista) A Design Approach to the Buckling of Cylinders under External Pressure, International Conference on Thin Walled Structures, 3-6 April 1979, University of Strathclyde. It was around this time that I tried to get some research council funding under the umbrella of the Marine technology Programme only to find that the approach was rejected on the grounds that it did not cover the problem of plasticity which was clearly so important for the shell scantlings being used in the offshore context. For this reason a couple of papers were prepared showing how easily the method could be extended to provide lower bounds to the elastic-plastic buckling. See for example:

16. (with S Yamada) 'Non-linear Buckling Response of Pressure Loaded Cylindrical Panels and its
Interpretation for Design', Technology Report of Tohoku University, 153, March 1988, 71-95. This was the first joint work from the collaboration with Seishi Yamada. It was quickly followed by others including:

21. (with Yamada, S) Buckling and Post-buckling Buckling Characteristics of Pressure Loaded Cylinders, J Applied Mechanics, ASME, 60, 1993, 290-299. This was an important work that demonstrated the relevance of the RSM to the buckling of pressure loaded shells.

30. (with Yamada, S) Contributions to Understanding the Buckling of Axially Compressed Cylinders, J of Applied Mechanics, ASME, 66, 1999, 299-309. This was an important work that demonstrated the relevance of the Batista extension to the RSM to handle the additional stabilizing membrane energy terms experienced with axially loaded cylinders.

31. (with Ohga, M et alia) Elastic Buckling Strengths of Cylindrical Sandwich Shells under External Pressure, xxxx

32. (with Ohga, M and Nakamura, D) Buckling Strength of Spherical Sandwich Shells by Reduced Stiffness Method, xxxx, 45, 1999, 1-6.

ABSTRACT: We consider parametrically excited vibrations of shallow cylindrical panels. The governing system of two coupled nonlinear partial differential equations is discretized by using the Bubnov–Galerkin method. The computations are simplified significantly by the application of computer algebra, and as a result low dimensional models of shell vibrations are readily obtained. After applying numerical continuation techniques and ideas from dynamical systems theory, complete bifurcation diagrams are constructed. Our principal aim is to investigate the interaction between different modes of shell vibrations under parametric excitation. Results for system models with four of the lowest modes are reported. We essentially investigate periodic solutions, their stability and bifurcations within the range of excitation frequency that corresponds to the parametric resonances at the lowest mode of vibration.

ABSTRACT: Based on the discrete-structural theory of thin plates and shells, a variant of the equations of buckling stability, containing a parameter of critical loading, is put forward for the thin-walled elements of a layered structure with a weakened interfacial contact. It is assumed that the transverse shear and compression stresses are equal on the interfaces. Elastic slippage is allowed over the interfaces between adjacent layers. The stability equations include the components of geometrically nonlinear moment subcritical buckling conditions for the compressed thin-walled elements. The buckling of two-layer transversely isotropic plates and cylinders under axial compression is investigated numerically and experimentally. It is found that variations in the kinematic and static contact conditions on the interfaces of layered thin-walled structural members greatly affect the magnitude of critical stresses. In solving test problems, a comparative analysis of the results of stability calculations for anisotropic plates and shells is performed with account of both perfect and weakened contacts between adjacent layers. It is found that the model variant suggested adequately reflects the behavior of layered thin-walled structural elements in calculating their buckling stability.

ABSTRACT: This master thesis involves the design of a roof for a basketball arena, which has a capacity of 20,000 spectators and it needs to be designed as a concrete shell structure. The size of the stadium is large enough to demand a long spanned shell structure. This thesis attempts to find an elegant solution to this problem, which combines aesthetic and structural beauty with efficiency during construction. These points are judged to be important aspects of a complete structural design. A literature study is done in an attempt to create a plan for the design of the shell roof. The general theory of shells is studied to understand their forms, structural behaviour and modes of failure. This helps the designer to understand the mechanics of shells which heavily influence the design procedure. Prominent shell designers of yesteryears and some of their projects are the next object of interest. Existing basketball arenas are also examined to find out the loading requirements for the roof in this thesis. The literature study is concluded by gathering details of high strength concrete and finite element software, both of which are relatively new in the shell industry. A design procedure is defined based on the findings of the studies mentioned above. The shell is chosen to be designed as a spherical dome. The initial geometrical details are stipulated after conducting sightline analysis, capacity calculations and hanging model analysis. Varying values of the span and thickness are chosen, leading to multiple design formulation, one of which is chosen based on a linear stability analysis. The selected design is then structurally investigated with inclusion of nonlinear effects and imperfections. The above mentioned process is executed using a combination of different softwares, for modelling, meshing and analyzing. Once the structural behaviour has been verified, the stresses are checked and the design is finalized by defining the structural framework, and proposing the paneling and connection details.

ABSTRACT: A study is presented of internal auto-parametric instabilities in the free non-linear vibrations of a cylindrical shell, focused on two modes (a concertina mode and a chequerboard mode) whose non-linear interaction breaks the in–out symmetry of the linear vibration theory: the two mode interaction leads to preferred vibration patterns with larger deflection inwards than outwards, and at internal resonance, significant energy transfer occurs between the modes. A Rayleigh–Ritz discretization of the von Kármán–Donnell equations leads to the Hamiltonian and transformation into action-angle co-ordinates followed by averaging provides readily a geometric description of the modal interaction. It was established that the interaction should be most pronounced when there are slightly less than $2\sqrt{N}$ square chequerboard panels circumferentially, where $N$ is the ratio of shell radius to thickness.

A.A. Popov (School of Mechanical, Materials and Manufacturing Engineering and Management, University of Nottingham, University Park, Nottingham NG7 2RD, UK), “The application of Hamiltonian dynamics and averaging to nonlinear shell vibration”, Computers & Structures, Vol. 82, Nos. 31-32, December 2004, pp.2659-2670, Special Issue: Nonlinear Dynamics of Continuous Systems, doi:10.1016/j.compstruc.2004.03.078

ABSTRACT: Internal auto-parametric instabilities in the nonlinear vibration of undamped and unloaded cylindrical shells are discussed. The focus is on the coupling between a few simple modes that can combine to break the in–out symmetry and give an energetically favourable pattern of deformation. When the ratio of the natural frequencies is close to a resonance, internal auto-parametric instability triggers energy transfer between
some of the modes. A Rayleigh–Ritz discretization of the von Kármán–Donnell equations leads to the Hamiltonian and transformation into action-angle coordinates followed by averaging provides readily a geometric description of the modal interaction. It is established that the interaction should be most pronounced between concertina and chequerboard modes with no energy transfer between the chequerboard modes. A simple mechanical system that exhibits similar dynamics is the extensible (spring) spherical pendulum.

ABSTRACT: We suggest the theoretical fundamentals of the method of reduced stiffness for the determination of the lower bounds of sensitivity of longitudinally compressed shells whose shapes are close to cylindrical to imperfections of the shape under the conditions elastic buckling. The theoretical and experimental data demonstrating the validity of the method of reduced stiffness are also presented.

ABSTRACT: We present a promising method for the investigation of the load-carrying capacity of imperfect shells based on simple analytic approaches. This method is called the reduced-stiffness method. In many cases, it enables one to obtain analytic relations for the estimation of the lower bounds of buckling loads for actual shells. We present the exact lower bounds of the buckling loads for compressed smooth cylindrical shells. For comparison, we also used the classical approach to the analysis of the critical loads for shells.

ABSTRACT: A reduced stiffness lower bound method for the buckling of laterally pressure loaded sandwich cylindrical shell is proposed. Also, an attempt is made to assess the validity of the proposed reduced stiffness lower bound with FEM numerical examples. In addition, the proposed method is compared with classical and Plantema's approaches of the buckling of the laterally pressure loaded sandwich cylindrical shell. Comparison of the proposed reduced stiffness lower bound with that obtained from non-linear FEM analysis verifies that it indeed provides a safe lower bound to the buckling of laterally pressure loaded sandwich cylindrical shells. The attractive feature of the proposed reduced stiffness method is that it can be readily used in designing laterally pressure loaded sandwich cylindrical shells without being concerned about geometrical imperfections.

ABSTRACT: This paper charts the various ways in which a close working relationship with Michael Thompson, during our early years within the Stability Research Group at UCL, came to have such a profound
influence on the direction of my own research activities. In particular, his fascination with energy and its use in providing a systematic framework for looking at the initial post-buckling of systems was especially contagious, opening up for me new ways of approaching the interpretation of shell buckling. In a sense my own work moved from chaos to stability in shells while Mike's was the reverse.

ABSTRACT: Effects of the lateral pressure on the FEM and reduced stiffness lower bound buckling strength of axially loaded sandwich cylindrical shell are examined. Further, a reduced stiffness lower bound buckling strength for the axially loaded sandwich cylindrical shell under lateral pressure is proposed. The effect of the lateral pressure on the FEM and reduced stiffness lower bounds are corresponding; it causes them to reduce slightly. However, reduced stiffness buckling mode shape remains the same. In addition, the proposed reduced stiffness lower bound buckling strength is shown to provide effective and valid for cores having different shear stiffness. It provides comparatively lower bounds to short axially loaded sandwich cylindrical shells under lateral pressure. Further, it provides a safe lower bound that does not depend on precise geometrical imperfection spectra and lateral pressure and it is simple and easy to employ.

ABSTRACT: A direct procedure for the evaluation of imperfection sensitivity in bifurcation problems is presented. The problems arise in the context of the general theory of elastic stability for discrete structural systems, in which the energy criterion of stability of structures and the total potential energy formulation are employed. In cases of bifurcation buckling the sensitivity of the critical load with respect to an imperfection parameter $e$ is singular at the state given by $e = 0$, so that, a regular perturbation expansion of the solution is not possible. In this work we describe a direct procedure to obtain the relations between the critical loads, the generalized coordinates at the critical state, the eigenvector, and the amplitude of the imperfection, using singular perturbation analysis. The expansions are assumed in terms of arbitrary powers of the imperfection parameter, so that both exponents and coefficients of the expansion are unknown. The solution of the series exponents is obtained by searching the least degenerate solution. The formulation is here applied to asymmetric bifurcations, for which explicit expressions of the coefficients are obtained. The use of the method is illustrated by a simple example, which allows consideration of the main features of the formulation.

ABSTRACT: This paper investigates ways to have a computational implementation of a lower bound approach for the buckling of imperfection-sensitive shells using general purpose finite element codes. This approach was developed by Croll and others, and has been mainly employed by developing special purpose programs or analytical solutions. However, it is felt that this limits the possibilities of the user, and this shortcoming is addressed in the paper. First, the formulation is presented in a way to highlight what computations can be done following a reduced energy approach. Then, a methodology is implemented in conjunction with a general purpose program to compute the lower bound buckling load for cylindrical shells with different geometric configurations under uniform pressure. The accuracy of the procedure and the difficulties in the implementation, depending on the finite element chosen for the discretization are shown. Results demonstrate that the proposed reduced energy model can predict the lower bound load for cylindrical shells under uniform pressure distributions.

ABSTRACT: This paper reports on the implementation of a lower bound approach to the buckling analysis of cylindrical shells for tanks subjected to wind loads. The formulation is based on a reduced energy model of the shell adapted to a special purpose, semi-analytical, finite element program in which it is possible to separately compute the membrane and bending energy contributions. First, the energy components are investigated, in order to identify stabilizing and destabilizing contributions. Second, an eigenvalue analysis is carried out using a reduced value of the stiffness, in which membrane components are eliminated on the basis that they are...
assumed to be eroded as a result of mode coupling catalyzed by imperfections. The methodology is employed for thin-walled, above ground, tanks under wind pressures. It is shown that the resulting critical loads constitute lower bounds to those obtained using a nonlinear analysis of the shell, including imperfections, and also to those obtained from experiments.

ABSTRACT: In the context of aerospace and marine applications there are considerable incentives for designers to adopt thin shells, whose performances are enhanced by appropriately chosen rib stiffeners or using high-performance composite materials. Imperfection-sensitive buckling in these circumstances is controlled by extremely high numbers of independent material and geometric parameters. As a basis for design, traditional reliance upon scatter of test results is suggested to be untenable and the increasing tendency to replace this approach by use of nonlinear finite elements is argued to bring with it all sorts of other quite considerable practical problems. This paper describes how the long established and very simple “reduced stiffness method” (RSM) is able to provide an alternative design strategy. It shows how a very straightforward extension of classical critical load analysis allows the definition of lower bounds to the potential imperfection sensitivity in each mode and consequently the delineation of the mode and load likely to provide the controlling influence on design. Reliability of its predictions is briefly demonstrated through comparisons with extensive test programmes and confirmation through carefully controlled nonlinear numerical studies. Use of the RSM is shown to offer scope for identifying material and geometric parameters that result in improved and even “optimum” buckling loads. Case studies from past and a current programme of research looking at the buckling of composite shells are used to illustrate this design potential.

Hongtao Wang and James G A Croll (Department of Civil, Environmental, and Geomatic Engineering, University College London, London, WC1E 6BT, UK), “Finite Element Validation of s Lower-Bound Design Method for Optimising Buckling Capacities of FRP Shells”, (cocomat.de, publisher and date not given in the pdf file; most recent reference is 2007)

ABSTRACT: The buckling loads of thin FRP laminated shells are sensitive to initial geometric imperfections. A large number of geometric and material variables prohibit the traditional lower-bound experimental design methodology for isotropic shells from being applied to composite shells. As an alternative, a so-called “reduced stiffness method” (RSM) has been applied to the lower-bound buckling analysis of FRP laminated shells. The RSM analysis has shown that the classical critical mode which gives the lowest reduced stiffness critical load is often different from the mode giving the minimum classical critical load. This paper presents a series of finite element numerical experiments to test the validity of the RSM. By examining the effects of initial imperfections in the form of the recognised classical critical modes, it is shown that the RSM provide a reliable lower-bound method for buckling design of FRP shells.

ABSTRACT: A sequential linear programming method with a simple move-limit strategy is used to investigate the following three important buckling optimization problems of composite shells: (1) optimization of fiber orientations for maximizing buckling resistance of composite shells without cutouts; (2) optimization of fiber orientations for maximizing buckling resistance of composite shells with circular cutouts; and (3) optimization of cutout geometry for maximizing buckling resistance of a composite shell. From the results of optimization study, it has been shown that, given a structural geometry, loading condition and material system, the buckling resistance of a cylindrical composite shell is strongly influenced by fiber orientations, end conditions, the presence of cutout and the geometry of cutout.

ABSTRACT: In an earlier report (TAM Report No. 80), the authors considered the buckling and post-buckling behavior of an ideal elastic cylindrical shell loaded by uniform external pressure on its lateral surface, and by an axial compressive force. Assumptions were introduced which reduced the shell to a system with one degree of freedom. The present investigation is a generalization and a refinement of this theory. The shell is treated as a system with 21 degrees of freedom. By the imposition of constraints on the 21 generalized coordinates, various end conditions can be realized; for example, simply supported ends with flexible end plates (no axial constraint), simply supported ends with rigid end plates, and clamped ends. Also, effects of reinforcing rings have been incorporated in a more general way than in TAM Report No. 80. The restrictive assumption that the centroidal axis of a ring coincides with the middle surface of the shell has been eliminated. A pressure-deflection curve for an ideal cylindrical shell that is loaded by external pressure has the general form shown in Figure 1. The falling part of the curve (dotted in the figure) represents unstable equilibrium configurations. Also, the continuation of line OE (dotted) represents unstable unbuckled configurations. Actually, the shell snaps from some configuration A to another configuration B, as indicated by the dashed line in Figure 1. Theoretically, point A coincides with the maximum point E on the curve, but initial imperfections and accidental disturbances prevent the shell from reaching this point. Point E is the buckling pressure of the classical infinitesimal theory (called the "Euler critical pressure", since Euler applied the infinitesimal theory to columns). To some extent, point A is indeterminate, but it is presumably higher than the minimum point C unless the shell has excessive initial dents or lopsidedness. In TAM Report No. 80, a hypothesis of Tsien was used to locate point A. In the present investigation, point A is not considered. Rather, attention is focused on the development of a theory that will determine the entire load-deflection curve. For short thick shells, such as the inter-ring bays of a submarine hull, the Euler critical pressures, determined by TAM Report No. 80, are too high, presumably because the assumption that the shell buckles without incremental hoop strain is inadmissible in this range. The present report corrects this error. Numerical data on the Euler critical pressures of shells with simply supported ends and flexible end plates have been obtained with the aid of the Illiac, an electronic digital computer. The data are tabulated at the end of this report. For short shells without rings, the buckling pressures are appreciably lower than those determined by von Mises' theory. The numerical data for the Euler buckling pressures of shells with uniformly spaced reinforcing rings are sufficiently extensive to permit interpolation to estimate effects of various ring sizes. Some exploratory numerical investigations of post-buckling behavior have
been conducted with the Illiac. It is not feasible, at the present time, to handle nonlinear equilibrium problems for systems with 18 degrees of freedom. Consequently, for the numerical work, some higher harmonics were discarded so that the system was reduced to 7 degrees of freedom. Even then, the numerical problem is formidable. The calculations were confined principally to the determination of the minimum point C on the post-buckling curve (Figure 1). The pressure at point C is the minimum pressure at which a buckled form can exist. It is found that the ordinate of point C, determined by TAM report No. 80, is somewhat too high. The two theories are compared by a table and curves at the end of this report.

ABSTRACT: The thermal snapping and vibration analysis of cylindrical laminated panel subject to thermal load and pressure is performed using layerwise finite elements. To consider large deflections due to thermomechanical loads, von-Kármán nonlinear displacement–strain relationships based on the layerwise theory are applied. Cylindrical arc-length method is used to take into account the snapping phenomena. Thermal snapping and vibration characteristics versus various parameters such as thickness ratio, shallowness, boundary conditions and loading type are investigated. The present results show that thermal snapping changes vibration characteristics as well as static deformations.

ABSTRACT: The finite element method based on the total Lagrangian description of the motion and the Hellinger–Reissner principle with independent strain is applied to investigate the non-linear static and dynamic
responses of spherical laminated shells under external pressure. The non-linear dynamic problem is solved by employing the implicit time integration method. The critical load of thin spherical laminated panels is investigated by examining the static and dynamic responses. The critical dynamic load is determined by the phase-plane and the Budiansky–Roth criteria. The effect of the artificial coefficient of Rayleigh damping on the dynamic response is considered. The dynamic response with damping included converges to the static response. The damping coefficient greatly affects a highly non-linear dynamic response. For a thin spherical panel with the snapping phenomena, the critical dynamic load is lower than the static one.

ABSTRACT: The thermal post-buckling responses of shape memory alloy hybrid composite (SMAHC) shell panels are investigated using a finite element method formulated on the basis of the layerwise theory. The von Kármán nonlinear displacement–strain relationships are applied to consider large deflections due to thermal loads. The cylindrical arc-length method is used to take account of the snapping phenomenon which is an unstable behavior observed in the shell panels. A nonlinear finite element procedure based on Brinson's model is developed to investigate the behaviors of shape memory alloy (SMA) wire. The results of numerical analysis show that the recovery stresses of SMA wires can enhance the stiffness of structure and the SMAHC shell panel exhibits superior behaviors of thermal post-buckling compared to the conventional composite panel. It is also shown that embedding SMA wires in a composite structure can prevent the unstable post-buckling behavior.

ABSTRACT: A finite element procedure for the inelastic dynamic analysis of cylindrical structures subjected to lateral dynamic load and axial thrust is given. The plastic strains developed in the structure are treated as fictitious equivalent loads and the neutral axis at each section is determined by using a subsection concept. Equations of motion are then solved numerically by the direction integration method. The finite element procedure is verified by the exact solution using a continuum analysis. Application of the procedure is made to investigate the effects of axial thrust on the inelastic dynamic response of a tall cylindrical structure. The present method may be applied to the analysis of practical designs of cylindrical structures.

ABSTRACT: The effect of shape memory alloy (SMA) on the buckling behavior of a rectangular composite laminate was investigated by the finite element method. The influence of SMA on buckling of composite
laminates by varying the SMA fiber spacing was studied. The formulation of the location-dependent stiffness matrix due to non-homogeneous material properties and the temperature-dependent recovery stress stiffness matrix were derived. The results show that the Active Strain Energy Tuning method is much better than the Active Property Tuning method in improving the buckling performance of the plate. When the SMA fibers are concentrated in the center area of the plate, the buckling load of the plate will be improved significantly. If the stiffness of the SMA layer is lower than other layers, the influence of the SMA on the buckling load of the plate will become subordinate.

ABSTRACT: The snap-through dynamics of bi-stable buckled IPMC actuators with double clamped boundary conditions was investigated to generate much larger displacement and periodical stable locomotion based on jumping phenomena with relative low input power. Among square, convex, and concave buckled IPMC actuators, the jumping phenomenon of the concave IPMC actuator was remarkably observed in the harmonic responses of high input voltage and low excitation frequency. Present results show that the end-shortening, the driving voltage and the excitation frequency of the double clamped IPMC actuators strongly affect the large deformation, rapid jumps, and low power consumption due to the snap-through phenomena.

“Thermal Post-buckling and Vibration Characteristics of Composite Conical Shell Structures”, (publisher and date not given in the pdf file; latest reference is 2006)
ABSTRACT: The vibration and the thermal post-buckling responses of the composite conical shell structures are investigated. The nonlinear finite element formulations of the composite conical shell are derived based on the layerwise displacement theory. The von Karman nonlinear displacement strain relationships are applied to consider large deflections due to thermal loads. The cylindrical arc-length method is used to account for the snapping phenomenon. The effect of structural parameters, such as the semi-cone angle, thickness ratio, and shallowness angle (curvature), on the structural stability of composite conical shell subjected to thermal load is observed.

“Helical Buckling of Pipes in Extended Reach and Horizontal Wells—Part 1: Preventing Helical Buckling”,
doi:10.1115/1.2905992
ABSTRACT: This paper studies the helical buckling of pipes (drillstring and tubing) in extended reach and horizontal wells, theoretically and experimentally, resulting in new equations to correctly predict and effectively prevent the helical buckling of pipes in such wells. The theoretical study shows that the so-called helical buckling load that appears in the current literature is only the average axial load in the helical buckling development process. The laboratory experiments confirm the theoretical analysis. The new helical buckling load equations are formalized by combining the theoretical analysis and the experimental results, thereby resolving the existing assumption-and-result inconsistency in the current literature. The new equation predicts the true helical buckling load to be about 1.3 times the so-called helical buckling load in the current literature, and about 1.8 times the critical buckling load that predicts the onset of sinusoidal buckling. Consequently, larger bit weights or packer setting loads can be applied to increase the drilling rate or to ensure a proper seal, before the helical buckling of the pipes can occur.

ABSTRACT: This paper studies the frictional drag of helically buckled pipes (drillstring and tubing) in extended reach and horizontal wells to correctly predict the actual bit weight or packer load, in cases where helical buckling of pipes may have occurred. Helical buckling of pipes in such wells may occur, since large axial loads are often required. The differential equation of axial force balance with consideration of the axial friction for helically buckled pipes is resolved, and the solution shows that when the pipes are helically buckled, the frictional drag will become very large. The actual bit weight for drilling or packer load for well completion may therefore become much smaller than estimated under the unbuckled pipe conditions. The analytical solution is also shown to agree with the results from laboratory experiments, which simulate the real wellbore-pipe conditions. An example is provided to show the calculation procedure and the importance of the results.

ABSTRACT: This paper studies sinusoidal and helical buckling of tubulars in inclined wellbores and the “lockup” of tubulars due to buckling. The results show that tubular buckling starts from the tubular bottom in low-inclination wellbores, where the axial compressive load is largest due to tubular weight. In high-inclination wellbores it may start from the top portion of the tubular, where the axial compressive load is largest due to frictional drag. This clarifies the confusion on whether or not the tubular buckles at once on its entire length in inclined wellbores. New sinusoidal and helical buckling load equations are presented to better predict tubular
buckling in inclined wellbores (0–90 deg). The lower the wellbore inclination angle, the smaller the axial compressive load required to initiate tubular buckling. However, a certain nonzero axial compressive load is still needed to buckle the tubulars in vertical wellbores. When tubulars buckle helically, a large wall contact force will be generated, and the “slack-off” weight at the surface will not be fully transmitted to the tubular bottom due to large resultant frictional drag. The “lockup” of tubulars may even occur, where the tubular bottom load cannot be increased by slacking-off weight at the surface.

ABSTRACT: The buckling of liner shells is a major problem in reactor containment design. In this paper, the local liner shell is considered as the liner plate with special initial imperfection form, based on which, Koiter's asymptotic theory of initial post-buckling is used to obtain expressions for the post-buckling equilibrium paths and post-buckling minimum loads for perfect and imperfect liner shells. The post-buckling behaviors of three liner shell models (four point-supported liner shell, clamped liner shell, and five-point-supported liner shell) are investigated. The influence of the initial imperfection stud spacing and liner thickness on the post-buckling minimum loads is also given.

C.D. Babcock (Department of Aeronautical Engineering, California Institute of Technology), “The Propagating Buckle In Marine Pipelines”, Paper No. 82-M001, Annual Meeting Papers, Division of Production, April 4 - 7, 1982, San Antonio, TX, American Petroleum Institute
ABSTRACT AND INTRODUCTION: An investigation has been carried out in order to understand the dynamics of the propagating buckle and to find a basis for designing efficient and effective arresting devices. The velocity of propagation was measured as a function of diameter to thickness ratio and pressure. These were carried out in different pressure media. It was found that the propagation velocity is affected by the pressurizing medium used as well as the pressure. A methodology for experimentally studying the efficiency of arrestors was established. The so called "Slip-On" arrestor was studied using this method. An empirical formula is derived for the efficiency of this arrestor. It was also found that quasi-static design criteria underestimate the arrestor efficiency under dynamic conditions. Any gap between the arrestor and the pipe greatly reduces the efficiency. Introduction: The propagating buckle is one of the new problems that has appeared as a result of the increased interest in offshore natural resources. The problems can occur during offshore pipelaying operations when the pipe is under combination of loads such as external pressure and bending moment. A local buckling initiated by these loads can propagate down the pipeline if the external pressure is above a critical pressure known as the propagation pressure. A number of investigators (ref. 1, L) have studied the problem. Their studies resulted in empirical relations for the propagation pressure. Tests on some buckle arrestors designs (ref. 3) were also carried out.

ABSTRACT: The response and stability of elastoplastic circular pipes under combined bending and external pressure are investigated both analytically as well as experimentally. A virtual work approach is used to formulate the problem, which results in a set of nonlinear algebraic equations which are solved numerically. The maximum moment and curvature for different pressures are determined as a function of the material and geometric parameters of the problem. For the range of parameters where limit load instability dominates, the results compare very well with experimental results for both steel and aluminium pipes.

ABSTRACT: The paper presents a study of the large deflection collapse of circular rings confined in a rigid cavity under external pressure. The ring is assumed to be inextensional and to have an initial localized imperfection which causes a small section of its circumference to be detached from the confining wall. The cavity formed is pressurized and its growth examined. The formulation is general enough to allow for large deflections of the ring as well as material nonlinearities. The pressure versus change in volume response of the confined ring is found to be characterized by a limit load for both elastic and inelastic material behavior. The limit load is shown to be dependent on both the geometry of the initial imperfection as well as the yield and post yield characteristics of the ring material. The response beyond the limit load is unstable until the crown of the ring touches the opposite side after which it becomes stable again.

ABSTRACT: In many practical engineering applications, relatively stiff, long, circular cavities are lined with more compliant liner shells. Pressure applied through the porous walls of the confining medium can cause buckling of the shells. Such buckling is usually local in nature and occurs at a section with the biggest geometric imperfection. The paper presents experimental evidence which demonstrates that, once such a shell has been locally dented, a buckle which propagates within the confines of the cavity can be initiated. Such a buckle has the potential of completely collapsing the liner. The lowest pressure at which this buckle will propagate is established experimentally through a parametric study of the problem. The phenomenon is found to be physically similar to the propagating buckle problem which can develop in offshore pipelines. A difference is that in the case of the confined shell, the instability is shown to have a strong geometric dependence and, as a result, it can be developed in the case of thin elastic as well as elasto-plastic shells.

ABSTRACT: When inflating long circular tubes made from some rubber compounds it is possible for a localization type of instability to occur. The localization takes the form of a bulge which forms somewhere.
along the length of the tube. Further inflation results in axial enlargement of the bulged section. This occurs at a value of pressure which is substantially lower than the pressure at which the bulge was first initiated. The paper presents experimental and analytical results which show how the initiation and steady state propagation of such bulges in latex rubber tubes is affected by the presence of axial tensile load.

ABSTRACT: Cyclic bending of tubes into the plastic range of the material leads to a progressive accumulation of ovalization of the tube cross-section. Persistent cycling leads to local catastrophic buckling of the tube. This paper presents an experimental study of the problem. The main objective of the study was to establish the effect of the cyclic bending history and of the external pressure on the rate of accumulation of ovalization and on the onset of instability. The cyclic loading histories examined include curvature symmetric bending, bending about a mean value of curvature and moment-controlled bending about a mean value of moment. The rate at which ovalization accumulates in curvature-controlled cyclic bending was found not to be significantly affected by a mean curvature in the cycles. Moment-controlled bending about a mean moment leads to ratcheting in curvature as well as in ovalization. External pressure accelerates the accumulation of ovalization and leads to buckling in fewer cycles than in the corresponding pure bending cases. This was found to be true for all bending histories considered. Significant similarities were observed between the response and onset of instability in the monotonic bending case and all cyclic bending cases. For a group of aluminum tubes instability was found to occur when the ovalization of the cross-section reached a critical value. This critical value was found to be relatively independent of the bending history followed.

ABSTRACT: A thin elastic tube, when inflated, first expands to a cylindrical shape. after some deformation, this is interrupted by the development of a bulge somewhere along the length of the tube. For some rubber materials, the bulge initially grows with decreasing pressure, whereas the rest of the tube unloads. after growing to a certain diameter, the bulge starts spreading axially. This can occur at a well defined value of pressure which is much lower than the pressure required to initiate the bulge. the mechanisms through which the bulge is initiated, its initial growth and its eventual propagation along the length of the tube are studied experimentally and analytically. The results vividly illustrate localization and propagation types of instabilities which govern the mechanical behavior of a variety of solids and structures.

ABSTRACT: Local imperfections induced to long tubes subjected to high external pressures can lead to local collapse from which a propagating buckle can be initiated. This can result in catastrophic collapse of large sections of the structure. The lowest pressure at which such a buckle will propagate, known as the propagation pressure of the tube, is typically half an order of magnitude lower than the collapse pressure of the intact tube. In a number of modern deep water applications, long tubular structures are subject to high axial tension in addition to external pressure. The paper describes the results of an experimental study in which the propagation pressure of long metal tubes was measured in the presence of a constant, axial tensile force. Tension was found to significantly reduce the propagation pressure. A parametric study of the problem, augmented by a simple model of the phenomenon, has yielded approximate expressions for the propagation pressure in the presence of axial tension.

ABSTRACT: Local imperfections induced in long tubes subjected to high external pressures can lead to local collapse, from which a propagating buckle can be initiated. This can result in catastrophic collapse of large sections of the structure. The propagation pressure is the lowest pressure at which such a buckle will propagate. For common structural metal tubes with diameter-to-thickness ratios of less than 100, the propagation pressure is typically half an order of magnitude lower than the collapse pressure of the intact tubes. As a result, the design of several tubular structures with external pressure loading requires that the collapse and propagation pressures be accurately known. This paper deals with the experimental and analytical challenges of establishing the propagation pressure. A special purpose three-dimensional analysis, in combination with experimental observations and results, is used to demonstrate a mechanism of initiation of propagating buckles in long tubes, to study the parametric dependence of the propagation pressure and to illustrate the effect of axial tension on the propagation pressure. Propagation pressures predicted with this analysis are used to evaluate the strengths and weaknesses of simpler models developed in the past.

ABSTRACT: In this paper a combination of experimentation and analysis is used to identify and study the mechanisms that govern the failure of unidirectional fiber composites under compression. The experimental part includes experiments in which the compressive strength and the prevalent failure mechanisms of AS4/PEEK composite are established, tests for establishing the constitutive properties of the composite and its constituents, and an evaluation of the extent of misalignment of fibers in manufactured composites. The failure load of the composite was confirmed to be affected by geometric imperfections in the form of fiber waviness, and failure was found to lead to kink bands with distinct orientations and widths. Motivated by the experimental findings, the composite was idealized as a two-dimensional solid with alternating fiber and matrix layers, each having the measured properties of the two constituents. The compressive responses of microsections of finite width with imperfections of various spatial distributions were established numerically. The calculated responses are characterized by an initially stiff, stable regime terminated by a limit load instability which is associated with
the strength of the composite. Following the limit load, the deformation localized into inclined bands with distinct widths. It has been verified that, as the localization process progresses, the fiber bending stresses at the ends of these bands grow to values comparable to those of the fiber strength. The sensitivity of the calculated response to the geometric characteristics of the imperfections was studied parametrically.

ABSTRACT: It is well known that certain larger structures are susceptible to a type of collapse which starts locally but under favorable conditions can spread and has the potential of affecting the whole structure. The lowest load which can sustain this spreading of collapse propagation load is usually significantly lower than the critical buckling load of the geometrically intact structure. As a result, the option of avoiding the potentiality of propagating collapse by using the propagation load as the design criterion can result in significant penalties in cost and weight. An alternative is to base the design on the critical buckling load of the structure while including periodic stiffeners to arrest potential propagating collapse and keep its effect local. This paper illustrates this new design philosophy through an example involving a long pressure-loaded panel with sparsely spaced circumferential stiffeners cast in the role of buckle arrestors. An analysis is presented which models the process of quasi-static buckle penetration through such a stiffener. A general measure of arresting performance is defined, based on the maximum pressure experienced during the penetration process. A general framework for establishing the dependence of the stiffener arresting efficiency on the problem parameters is developed. Furthermore, fundamental concepts regarding limiting values for stiffener length and thickness are introduced, and results are presented which indicate that in this problem short, thick stiffeners provide the most arresting capacity for a given amount of stiffener material.

ABSTRACT: In this paper the reduction in the collapse pressure of long cylinders which have local dents is evaluated through a combination of experiment and analysis. A number of stainless steel tubes, with diameter-to-thickness ratios of approximately 33, 24 and 19, were indented to various degrees with spherical indentors of two diameters. The geometry of each dent was recorded using an imperfection scanning system and the cylinders were subsequently collapsed under external pressure. Denting reduces the local collapse resistance of the cylinder. For larger dents the collapse pressure was found to approach the propagation pressure of the tube. Collapse was found to be relatively insensitive to the detailed geometry of a dent but to be critically dependent on the maximum ovalization of its most deformed cross section (delta0d). The collapse pressures of tubes with dents produced by indentors of different diameters could be well correlated through this measure of the dent geometry. The denting and collapse processes were simulated numerically using appropriately nonlinear elastoplastic shell analyses. Both steps of such simulations were shown to be in good agreement with experimental results for a broad variation of the parameters of the problem. The key role of the geometric parameter delta0d was exploited in order to generate a Universal Collapse Resistance Curve for dented cylinders. It was possible to show that the post-limit load response (P - delta0d) of a cylinder, with a small but axially uniform initial ovality, provides a very good lower bound to the collapse pressures of the dented
cylinders plotted against the dent parameter \( \Delta_0 d \). The significance of this curve is that it can be used to estimate the reduction in the collapse pressure of a cylinder with any dent geometry from only one relatively simple measurement of the geometry of the dented section.

ABSTRACT: The failure of fiber-reinforced composites in compression is sudden, uncontrolled and results in the dynamic formation of narrow zones of inclined kinked fibers and in a drastic reduction in load bearing capacity. Experimental results are presented which demonstrate that such materials do maintain significant post-failure strength and “ductility.” Following the onset of failure, kink bands which were initiated dynamically could be made to propagate (broaden) in the fiber direction. Under displacement controlled loading, the propagation of the bands takes place in a steady-state manner. In the case of the APC-2/AS4 composite analyzed, quasi-static propagation of this failure took place at a stress level which was 40% of the strength of the intact material. The propagation of the band involved progressive addition of narrow zones of fibers from the adjacent intact material by rotation and breaking. This new characteristic stress of such materials has been called propagation stress. Several requirements and guidelines for establishing the true value of this material property, free of influence from experimental conditions and specimen geometry, are outlined.

ABSTRACT: A common method of limiting the extent of damage induced by a propagating buckle to a deep water pipeline is to periodically install along the line thick rings welded between adjacent strings of the pipe (integral buckle arrestor). The rings locally increase the resistance to collapse and, when properly designed, arrest an incoming buckle. The effectiveness of this type of local reinforcement as a buckle arrestor was studied through a series of full-scale experiments and through a numerical model. The model was first proven to be capable of accurately simulating the quasi-static crossing of such arrestors by a buckle and was then used to study the arresting efficiency of this device as a function of the pipe and arrestor geometric and material parameters. This paper briefly summarizes these results which are subsequently used to establish some bounds for the arrestor thickness and length and to develop empirical design formulae for such devices.

ABSTRACT: In many fiber composites, longitudinal compressive failure leads to the formation of kink bands. It has been found that these kink bands, once formed, can be made to propagate (broaden) in a steady-state manner at a constant stress level called the propagation stress (\( \sigma_P \)). This is a characteristic stress of the material which, for the AS4/PEEK composite used in the study reported here, is approximately 40% of its compressive strength. This phenomenon is investigated experimentally using a special confining set-up that
allows direct observation of the propagation process. For the composite studied, the kink bands have a repeatable inclination (beta) of approximately 15 degrees, and the fibers within the bands are rotated to about 30 degrees in the absence of a load. When loaded to sigmaP, however, they are found to rotate further to 40 degrees, that is, substantially greater than the 2beta reported elsewhere. The mechanism of propagation is found to be a bend-break-rotate sequence undergone by short segments of fibers at the edge of the kink band. It is well known that polymeric matrix composites such as the one used in this study exhibit rate-dependent behavior. Experimental results are presented which show that the kink band propagation stress is also rate dependent.

ABSTRACT: A new micromechanical model is presented to simulate the steady-state axial propagation of kink bands investigated experimentally in the accompanying paper (Part I). The fibers are in a hexagonal array and are assumed to be isotropic and linearly elastic, while the matrix is modeled as an elastic-powerlaw viscoplastic solid. Matrix properties for the model are determined from shear tests on the composite and compression tests on neat PEEK. The model is used to predict the propagation stress (sigmaP) of the AS4/PEEK composite and to investigate the sensitivity of sigmaP to band inclination, matrix properties, and loading rate. A simple model recently reported in the literature is calibrated to the current material system and compared with the present experimental data and model predictions. The micromechanical model is found to predict the propagation stress reasonably well and to capture the rate dependence of the composite. The simple model is found to capture the trends of the behavior.

ABSTRACT: The initiation and growth of a kink band in a uniaxial composite is investigated experimentally. Experiments on unidirectional plates of AS4/PEEK were conducted using a custom biaxial testing device. A relatively stable post-failure response which occurs for displacement controlled shearing under a compressive preload is exploited to observe quasi-static kink band growth. The band initiates from a stress concentration on one of the free edges and grows across the specimen with a constant inclination of about 12°. Detailed in situ measurements show that the fiber rotation and band width at a point increase as the band goes past it. After traversing the specimen, the band propagates (broadens) with constant fiber rotation. The observed kink band characteristics were similar to those of kink bands which grew dynamically in the same composite tested under pure compression. A difference is that the ends of the bands formed under combined compression and shear are highly bent but not broken.

ABSTRACT: Motivated by the experimental findings in Part I, the growth of a kink band in a uniaxial
composite is investigated using two- and three-dimensional micromechanical models. The models include both a local and a global imperfection and were preloaded in compression and then sheared under displacement control. An inclined kink band initiates from the local imperfection and grows across the specimen. Similar results were obtained for pure compression loading. The simulated kink bands are quite similar to those observed experimentally; though, when J2 plasticity is used to model the inelastic matrix, their inclination is lower than in experiments. The calculated band inclination is shown to be insensitive to many model parameters including imperfection characteristics, fiber diameter, volume fraction, and matrix yield stress. However, it is quite sensitive to the dilatancy of the matrix as demonstrated by the use of the Drucker–Prager constitutive model for the matrix. It was found that the ability of the matrix to deform in the direction transverse to the fibers plays an important role in allowing larger, more realistic kink band inclinations to be obtained.

ABSTRACT: This paper highlights the differences between onshore and offshore pipeline design. It then summarizes the results of combined external pressure, tension, and bending testing on full scale 6 5/8" and 16" pipe, and uses these results to support suggestions for appropriate design formulas for combined external pressure, tension, and bending loads. Finally, purchasing suggestions for pipe subjected to severe deepwater loadings are presented.

ABSTRACT: Progress has been made in the design of buckle arrestors, or more precisely collapse arrestors, for deepwater pipelines. Empirical relationships have been developed for the design of both integral ring and grouted sleeve arrestors, forming the basis of a simple and straightforward design procedure. The good agreement between the latest design formulas and the crossover pressure data obtained from large scale tests by Shell E&P Technology Company and by Professor Kyriakides at U.T. Austin over the past few years, should result in more efficient and reliable buckle arrestors for deepwater pipelines.

ABSTRACT: A design methodology for integral buckle arrestors for deepwater pipelines was presented in a previous study (Park TD, and Kyriakides S., International Journal of Mechanical Sciences 1997;39:643–69). It was based on experiments and analyses in which buckles engaged the arrestors quasi-statically. In this two-part paper series, the performance of the same arrestors is reevaluated under the more realistic dynamic buckle propagation conditions encountered in the sea. The experimental program described in Part I involves tubes with D/t=27.9 and arrestors with La /D=0.5. The quasi-static arresting efficiency of buckle arrestors is first established experimentally as a function of the arrestor thickness. The same arrestor designs are then tested again in constant pressure environments where buckles propagate at velocities of 400–1100 ft/s. Experiments
are conducted using both water and air as pressurizing media. A typical test specimen involves a relatively long upstream section of tube welded to an arrestor and to a downstream tube. The buckle is initiated in the upstream tube, accelerates to steady-state propagation, engages the arrestor and is either arrested or crosses over. For each arrestor design several such tests are required in order to bracket the dynamic crossover pressure. For all cases considered, the dynamic crossover pressure was found to exceed the corresponding quasi-static value. The reasons for this enhancement in performance are discussed in Part II in the light of results from numerical simulations of this process.

ABSTRACT: In the second part of this study we present models for simulating the quasi-static and dynamic propagation and arrest of buckles in pipelines. The models are developed within the framework of the nonlinear finite element ABAQUS and are used to simulate the quasi-static and dynamic arrest experiments in Part I. They are based on finite deformation kinematics and properly treat the contact that develops in the collapsed tube behind the propagating buckle. In the quasi-static model, the tube and arrestor materials are modeled as J2 flow theory solids with isotropic hardening. In the dynamic model, the rate dependence of SS-304 is assumed to exhibit an overstress power-law dependence. The pressurizing medium is assumed to be vacuum. The dynamic model is shown to reproduce accurately the conditions of steady-state buckle propagation as well as the dynamic engagement of a buckle with an arrestor. For buckle velocities of interest, the buckle profile was found to have sharpened considerably compared to the quasi-static one. The numerical results showed the same dynamic enhancement of arrestor performance observed in the experiments. When the much sharper dynamic buckle profile engages an arrestor, it initially induces to it and to the downstream tube significant reverse ovality. This tends to obstruct and delay the flattening of the arrestor and tube which is the cause of the crossing of arrestors with quasi-static efficiencies of less than 0.7. The net result is that a higher pressure is required to cross the arrestors when the buckle is running. As in the experiments, the biggest dynamic enhancement was found to occur for arrestors of efficiencies in the range of 0.35–0.6. Based on the results of this study it is concluded that quasi-static design procedures for integral buckle arrestors proposed previously are conservative.

ABSTRACT: A combined experimental and analytical study of the dynamic propagation of buckles initiated in long pipes under external pressure is presented. The experiments involve measurement of the steady-state velocity of buckles initiated in stainless steel tubes with D/t=27.9. Results from tubes pressurized by air or water are presented for pressure levels ranging from the propagation pressure to the collapse pressure of the tube. The buckle velocity in air was found to be significantly higher than in water at the same pressure. The flip–flop mode of buckle propagation was found to take place for pressure levels 13% below the collapse pressure and higher. A finite element model, capable of simulating the dynamic initiation and propagation of such buckles has been developed. The model accounts for the inertia of the pipe, the nonlinearity introduced by contact between the collapsing walls of the pipe while the material is modeled as a finitely deforming elastic–viscoplastic solid. The buckling and collapse are assumed to take place in vacuum. The model is shown to
reproduce well the dynamic initiation and propagation of buckles in air and the predicted velocities are in good agreement with those measured in this medium. The buckle was found to sharpen significantly with pressure. This sharpening, coupled with higher pressure, causes an increase in the amplitude of reverse ovality in a zone just ahead of the propagating buckle front. At higher pressures, the reverse ovality is shown to be high enough to initiate collapse at a new site. The new collapse is at 90° to the original one. This sequence of events is repeated, resulting in the flip–flop mode of buckle propagation.

ABSTRACT: Pipe-in-pipe systems are extensively used in offshore pipeline applications in which thermal insulation of the pipeline is necessary. Typically, the space between the two pipes is either empty or contains insulation material which provide minimal mechanical support to the system. In deepwater applications, the carrier pipe must be designed to resist collapse due to the ambient external pressure while the design of the inner pipe is usually governed by the pressure of the hydrocarbons it carries. The integrity of the two-pipe system in the event of accidental collapse of the carrier pipe is an issue of concern. In Part I of this two-part report, the results of an extensive experimental study of the problem are presented. The experiments were carried out on two-inch diameter carrier tubes with D/t values of 24.1, 21.1 and 16.7 and inner tubes of several diameters and wall thicknesses. In most cases local collapse of the outer tube led to simultaneous collapse of the inner one. Subsequently, the collapse propagated simultaneously collapsing both pipes. The propagation pressure of the two-pipe system (PP2) has been quantified parametrically. An interesting second mode of collapse propagation was also discovered in which the carrier pipe collapses leaving the inner one intact. Propagation of collapse affecting both pipes is still possible but usually at a higher pressure level. The pressure at which this switch takes place has been found to closely correspond to the propagation pressure of a carrier pipe with a solid rod insert (PPS) of the same diameter as the inner pipe. The parametric dependence of PPS has also been established experimentally. Part I finishes with a discussion of how these new critical pressures of pipe-in-pipe systems should influence the design of such pipelines.

ABSTRACT: In Part II we examine and evaluate the performance of three levels of models for estimating the two new propagation pressures of pipe-in-pipe systems introduced in Part I (PP2 and PPS). The first type of model involves uniform collapse of the system through a kinematically admissible mechanism resulting from the formation of plastic hinges. Closed-form expressions for PP2 and PPS are derived which provide a valuable qualitative view on how they depend on the main parameters of the problem. The predictions, however, significantly underpredict the measured values. The second type of model also involves uniform collapse but is conducted numerically instead. An energy balance between prebuckling and collapsed configurations obtained from a uniform collapse model yields approximate values of PP2 and PPS. It is demonstrated that such predictions are within acceptable engineering accuracy. The third type of model involves fully three-dimensional numerical simulation of the initiation and steady-state propagation of collapse. It is demonstrated that, provided the geometric and material characteristics of the pipes used are accurately represented in such
models, both PP2 and PPS can be predicted to great accuracy. Such models are, however, numerically intensive. Part II finishes with conclusions and design recommendations drawn from both the experimental and analytical parts of the study.

ABSTRACT: A new buckle arrestor concept for pipe-in-pipe systems is introduced and the results of a systematic study of its performance is presented. The concept involves either one single ring or a number of closely packed narrow rings placed in the annulus between the two pipes. Its effectiveness has been studied through a combination of experiments and analyses. The experiments involved two inch carrier tubes of three different D/t values and internal rings of various dimensions. A number of experiments were first conducted using pipe-in-pipe systems. It was found that the inner tube had only a small effect on the crossover pressure of this arrestor and, as a result, in many of the following experiments inner tubes were not included. The crossover pressure of the ring arrestors was studied by varying their length, wall thickness and yield stress. Other parameters varied were the dimensions and properties of the two tubes and the gap between the arrestor and the carrier tube. The process resulted in an empirical design formula for the arresting efficiency expressed as a function of the key nondimensional variables of the problem. Large-scale finite element models which simulate the buckle crossover process have also been developed. They have been shown capable of reproducing experiments accurately. Such models can be used to prove an arrestor design developed through the empirical process described in the report.

ABSTRACT: Experiments and large scale numerical simulations are used to study the dynamics and the arrest of propagating buckles in pipe-in-pipe systems. In the first set of experiments the velocity of buckles initiated in a constant pressure environment is measured as a function of pressure using first water and then air as pressurizing media. For the outer and inner pipe parameters used, the buckle velocities correlated well with values measured in single pipes. The dynamic propagation experiments in air were then simulated numerically. Calculated buckle velocities followed the same trend as the measured values although they were somewhat higher. In the second set of experiments the effectiveness of internal ring buckle arrestors designed with previously developed quasi-static design procedures is re-evaluated under dynamic buckle propagation. In all cases examined the dynamic arresting efficiency was found to be higher than the quasi-static one. The same behavior was also observed in corresponding numerical simulations. This indicates that design of such devices using quasi-static design criteria should be conservative.

ABSTRACT: It is well known that tubular liners of stiff cavities such as grouted oil-well casing can be collapsed by external pressure. Collapse is initially local but can propagate at a relatively low pressure with catastrophic results. The paper presents a quantitative study of the lowest pressure at which confined collapse can propagate known as confined propagation pressure. Experiments and analysis are used to develop an improved expression relating this critical pressure to the material and geometric parameters of the liner tube. It is shown that these include the yield stress and post-yield characteristics of the material, and the tube D/t. The new empirical relationship developed can provide engineering type estimates of the confined propagation pressure. The quasi-static initiation and propagation of confined collapse was also modeled using three-dimensional finite elements. The model accounts for the finite deformations and addresses the contact nonlinearities which govern the phenomenon. The material is modeled as a finitely deforming elastic–plastic solid. It is demonstrated that the model can predict the confined propagation pressure to a very significant degree of accuracy. It is thus a viable tool for obtaining accurate predictions of this critical pressure.

Francois Claude Bardi, “Plastic buckling and collapse of circular cylinders under axial compression”, Ph.D. dissertation, The University of Texas at Austin, August 2006

ABSTRACT: This study is concerned with the plastic buckling of relatively thick tubes and the ensuing succession of instabilities leading to their failure. The first instability is uniform axisymmetric wrinkling that is treated as a plastic bifurcation. As the wrinkles grow, the axial rigidity of the shell is gradually reduced. This eventually leads to a limit load instability beyond which failure in the form of localized deformation takes place. The problem is studied using experiments and analyses. Stainless steel specimens with D/t of 23-52 were custom-designed to avoid stress concentrations and reproduce long uniform pipe conditions. The specimens were compressed to failure under displacement control. In all cases, a second bifurcation involving non-axisymmetric mode of deformation preceded the limit load. The bifurcation into axisymmetric wrinkling was determined by monitoring the development of wrinkles on the surface of the tubes. This critical state was successfully predicted using an anisotropic deformation theory of plasticity. The anisotropy of the material was established experimentally and modeled using Hill's quadratic anisotropic yield criterion. The problem was first modeled as uniform axisymmetric wrinkling. The model uses Sanders’ shell kinematics assuming small strains and moderately small rotations and includes a modified flow theory of plasticity to accommodate the anisotropy observed in the tubes. Small axisymmetric imperfections based on the critical half-wavelength were integrated into the model. The problem was formulated through the principle of virtual work and solved using Newton’s method. The solution correctly simulates the growth of wrinkles resulting in a limit load instability. The model included second bifurcation calculations from axisymmetric to non-axisymmetric configuration. Second bifurcation instabilities were found to occur before the limit load developed. For this reason, a second model was developed in which non-axisymmetric deformation of the shell was simulated by introducing both axisymmetric and non-axisymmetric imperfections. Non-axisymmetric responses were found to be highly
sensitive to the imperfections. Each experiment was first reproduced accurately by choosing the right combination of imperfections. However, to achieve a satisfactory prediction of the limit state over the whole range of D/t, a thorough parametric study of the imperfection sensitivity was performed. The relative amplitude of the axisymmetric imperfection to the non-axisymmetric imperfection was found to define whether the shell deforms axisymmetrically or not. Furthermore, if one of the imperfections governs the deformation configuration, then the effect of the second onto the response is negligible. Thus, a constant axisymmetric imperfection of 0.05% of the pipe wall thickness and a non-axisymmetric imperfection proportional to (D/t)² / m³ yielded accurate predictions of both mode of deformation and limit load.

The plastic buckling and collapse of long cylinders under combined internal pressure and axial compression was investigated through a combination of experiments and analysis. Stainless-steel cylinders with diameter-to-thickness values of 28.3 and 39.8 were compressed to failure at fixed values of internal pressure up to values 75% of the yield pressure. The first effect of internal pressure is a lowering of the axial stress–strain response. In addition, at some plastic strain level, the cylinder develops uniform axisymmetric wrinkling. Under continued compression, the wrinkles grow stably, gradually reducing the axial rigidity of the structure and eventually lead to a limit load instability. All pressurized cylinders remained axisymmetric until the end of the test past the limit load. The critical stress and wavelength were established using classical plastic bifurcation theory based on the deformation theory of plasticity. The evolution of wrinkling, and the resultant limit state, were established by modeling a periodic domain that is one half of the critical wavelength long. The domain was assigned an initial imperfection corresponding to the axisymmetric buckling mode calculated through the bifurcation check. The inelastic material behavior was modeled through the flow theory of plasticity with isotropic hardening. The variations of the axial response and of the limit strain with pressure observed in the experiments were reproduced well by the model. Inclusion of Hill-type anisotropic yielding in all constitutive models was required for good agreement between predictions and experiments.

ABSTRACT: Relatively thin-walled tubes bent into the plastic range buckle by axial wrinkling. The wrinkles initially grow stably but eventually localize and cause catastrophic failure in the form of sharp local kinking. The onset of axial wrinkling was previously established by bifurcation analyses that use instantaneous deformation theory moduli. The curvatures at bifurcation were predicted accurately, but the wrinkle wavelengths were consistently longer than measured values. The subject is revisited with the aim of resolving this discrepancy. A set of new bending experiments is conducted on aluminum alloy tubes. The results are
shown to be in line with previous ones. However, the tubes used were found to exhibit plastic anisotropy, which was measured and characterized through Hill’s quadratic anisotropic yield function. The anisotropy was incorporated in the flow theory used for prebuckling and postbuckling calculations as well as in the deformation theory used for bifurcation checks. With the anisotropy accounted for, calculated tube responses are found to be in excellent agreement with the measured ones while the predicted bifurcation curvatures and wrinkle wavelengths fall in line with the measurements also. The postbuckling response is established using a finite element model of a tube assigned an initial axisymmetric imperfection with the calculated wavelength. The response develops a limit moment that is followed by a sharp kink that grows while the overall moment drops. The curvature at the limit moment agrees well with the experimental onset of failure. From parametric studies of the various instabilities it is concluded that, for optimum predictions, anisotropy must be incorporated in both bifurcation buckling as well as in postbuckling calculations.

ABSTRACT: Integral buckle arrestors are relatively thick wall rings periodically welded in an offshore pipeline at intervals of several hundred meters in order to safeguard the line in case a propagating buckle initiates. They provide additional circumferential rigidity and thus impede downstream propagation of collapse, limiting the damage to the length of pipe separating the two arrestors. The effectiveness of such devices was studied parametrically through experiments and numerical simulations in Park and Kyriakides [On the design of integral buckle arrestors for offshore pipelines. International Journal of Mechanical Sciences 1997;39(6):643–69]. The experiments involved quasi-static propagation of collapse towards an arrestor, engagement of the arrestor, temporary arrest, and the eventual crossing of collapse to the downstream pipe at a higher pressure. The same processes were simulated with finite element models that included finite deformation plasticity and contact. The experimental crossover pressures enriched with numerically generated values were used to develop an empirical design formula for the arresting efficiency of such devices. A recent experimental extension of this work revealed that for some combinations of arrestor and pipe yield stresses, the design formula was overly conservative. Motivated by this finding, a new broader parametric study of the problem was undertaken, which demonstrated that the difference between the pipe and the arrestor yield stress affects significantly the arrestor performance. The original arrestor design formula was then modified to include the new experimental and numerical results producing an expression with a much wider applicability.

ABSTRACT: Circular tubes compressed into the plastic range first buckle into axisymmetric wrinkling modes. Initially the wrinkle amplitude grows with increasing load. The wrinkles gradually induce a reduction in axial rigidity eventually leading to a limit load instability followed by collapse. The two instabilities can be separated by strain levels of a few percent. This work investigates whether a tube that develops small amplitude wrinkles can be subsequently collapsed by persistent cycling. The problem is first investigated experimentally using SAF
2507 super-duplex steel tubes with D/t of 28.5. The tubes are first compressed to strain levels high enough for mild wrinkles to form; they are then cycled axially under stress control about a compressive mean stress. This type of cycling usually results in material ratcheting or accumulation of compressive strain; here it is accompanied by accumulation of structural damage due to the growth of the amplitude of the initial wrinkles. The tube average strain initially grows nearly linearly with the number of cycles, but as a critical value of wrinkle amplitude is approached, wrinkling localizes, the rate of ratcheting grows exponentially and the tube collapses. The rate of ratcheting and the number of cycles to failure depend on the initial compressive pre-strain and on the amplitude of the stress cycles. However, collapse was found to occur when the accumulated average strain reaches the value at which the tube localizes under monotonic compression. A custom shell model of the tube with initial axisymmetric imperfections, coupled to a cyclic plasticity model, are presented and used to simulate the series of experiments performed successfully. A sensitivity study of the formulation to the imperfections and to key constitutive model parameters is then performed.

ABSTRACT: Circular tubes compressed into the plastic range first buckle into axisymmetric wrinkling. Initially, the wrinkle amplitude grows with increasing load, but induces a gradual reduction in axial rigidity that eventually leads to a limit load instability and collapse. For lower D/t tubes, the two instabilities can be separated by strain levels of a few percent. Persistent stress-controlled cycling can cause accumulation of deformation by ratcheting. Here, the interaction of ratcheting and wrinkling is investigated. In particular, it is asked if compressive ratcheting can first initiate wrinkling and then grow it to amplitudes associated with collapse. Experiments on SAF2507 super-duplex steel tubes with D/t of 28.5 have shown that a geometrically intact tube cycled under stress control initially deforms uniformly due to material ratcheting. However, in the neighborhood of the critical wrinkling strain under monotonic loading, small amplitude axisymmetric wrinkles develop. This happens despite the fact that the maximum stress of the cycle can be smaller than the critical stress under monotonic loading. In other words, wrinkling appears to be strain rather than stress driven, as is conventionally understood. Once the wrinkles are formed, their amplitude grows with continued cycling, and as a critical value of amplitude is approached, wrinkling localizes, the rate of ratcheting grows exponentially, and the tube collapses. Interestingly, collapse was also found to occur when the accumulated average strain reaches the value at which the tube localizes under monotonic compression. A custom shell model with small initial axisymmetric imperfections, coupled to a cyclic plasticity model, is used to simulate these cyclic phenomena successfully.

ABSTRACT: The response of long, thin-walled, cross-ply composite tubes subjected to pure bending was studied analytically. The formulation includes three parts: pre-buckling response, material failure and bifurcation buckling. The pre-buckling response is analyzed using nonlinear kinematics to accommodate the ovalization of the cross-section. The formulation is based on the principle of virtual work and is used to generate a numerical solution procedure. The Tsai-Wu failure criterion is used to detect material failure in the pre-buckling response. The maximum stress criterion was also considered for comparison. Finally, the buckling analysis considers the possibility of bifurcation into modes containing periodic displacements along the axis of
the tube. The tubes are assumed to be geometrically perfect and free of residual stress. Three materials-AS3501 graphite-epoxy, Kevlar 49-epoxy, and E-glass-epoxy-and three diameter-to-thickness ratios-50, 100 and 400—are considered. The moment-curvature response of the tubes is non-linear due to the ovalization of the cross-section (Brazier effect) which induces a limit moment instability. Either material failure or bifurcation buckling always occurs prior to the limit moment in the cases considered. Little difference was observed between the failure loads predicted by the Tsai-Wu and the maximum stress criteria. Tubes with plies of circumferentially oriented fibers in the outermost and innermost positions in the wall proved superior in strength compared with the other cases considered.

ABSTRACT: The buckling mode localization of a multiply supported column subjected to fully reversed, displacement-controlled cyclic loading is studied numerically. The results show that localization can take place and lead to limit loads similar to those reported in other structural members in the literature. Analysis of the results reveals the mechanisms by which localization takes place.

OVERVIEW: Long cylindrical tubes and pipes under axial compression will usually bend, behaving as beam columns. Shell-type localized buckling occurs mainly when the structure is restrained from lateral movement. This, for example, is the case for a pipeline buried in a trench (Figure 11.1) or resting on a deformable foundation. Compression can be caused by the passage of hot hydrocarbons carried from the well to a central gathering point by buried flowlines in offshore operations [11.1]. Foundation motion caused by fault movement, landslides, ground subsidence, permafrost melting, or soil liquefaction can also result in severe compression of the lines [11.2 11.6]. Both loading scenarios can impose compressive strains high enough to result in shell-type buckling. In most onshore and offshore pipeline operations, diameter-to-thickness ratios (D/t) and steel grades are such that buckling occurs in the plastic range. In this chapter, the main features of plastic buckling under axial compression are first illustrated experimentally. The formulation for predicting the onset of plastic wrinkling is then developed, followed by a study of how wrinkles grow, localize and lead to collapse.

ABSTRACT: Bending in the presence of external pressure is experienced by pipelines during their installation and also subsequently during their operation. In installation methods such as S-lay (Figure 2.15), J-lay (Figure 2.19), and reeling (Figure 2.4), the pipe is bent under relatively high external pressure in the sagbend [9.1, 9.2]. The pipeline is also bent under external pressure as it conforms to surface undulations on the seafloor. Bending at the sea floor can also be experienced due to snaking resulting from pipe expansion caused by the passage of hot hydrocarbons (in some cases purposely induced, in others accidentally). It is also a condition that can develop in case of upheaval buckling of a section of a buried pipe. Bending ovalizes the pipe cross section, which of course reduces its resistance to external pressure. This interaction through ovalization is aggravated by inelastic material effects, which usually come into play in lower D/t pipes used for offshore applications. This chapter deals with the mechanics of inelastic bending in the presence of external pressure and the associated
limit states. The development of this interaction starts with the behavior under pure bending and pure external pressure. The reader would benefit from exposure to Chapters 4 and 8 before embarking on the following material.

ABSTRACT: Offshore as well as onshore pipelines in operation are under internal pressure. The scenarios for developing axial compression outlined in Chapter 11 also apply to a pressurized pipeline. The general features of plastic buckling under axial compression and internal pressure are similar to those of pure axial loading, presented in Figure 11.2. The cylinder first wrinkles at an increasing load. The wrinkle amplitude grows, leading eventually to a limit load instability. A pipeline will fail by localized collapse at this strain, and as a result this constitutes a limit state. The biaxial state of stress lowers the axial stress levels of the various critical events described in Figure 11.2 but, as will be demonstrated, has a smaller effect on the corresponding strains. In addition, the pressure has a stabilizing effect on the axisymmetric mode, making a switch to non-axisymmetric modes more difficult. These features of the problem are first illustrated experimentally. The formulation for predicting the onset of plastic wrinkling is then developed, followed by a study of how wrinkles grow, localize and lead to collapse.

ABSTRACT: Offshore pipelines are commonly installed empty in order to reduce the installation tension due to the weight of the suspended section (see Chapter 2). In addition, during operation they are periodically depressurized for maintenance. Thus, external pressure is an important load parameter in design; indeed, it is often the prime parameter. This chapter deals with the mechanics of buckling and collapse of long pipes under external pressure. Thinner pipes used in shallower waters buckle elastically, but collapse due to postbuckling inelastic action. The classical elastic buckling pressure is derived in Section 4.1, followed by the derivation of Timoshenko's design formula for the onset of collapse of an initially ovalized pipe. Thicker pipes used in deeper waters buckle and collapse in the plastic range. In Section 4.2, plastic buckling equations are derived. Their relative simplicity makes them useful tools in design. Practical factors that affect collapse include initial imperfections such as ovality and wall thickness variations. Other factors include residual stresses, yield anisotropy, etc. The influence of such factors is best treated numerically. Section 4.3 presents the external pressure part of the formulation and solution procedure of the custom computer code BEPTICO [4.1], capable of including these aspects of the problem. Section 4.4 presents a parametric study of buckling and collapse of elastic-plastic pipe under external pressure. Section 4.5 outlines how actual pipe imperfections can be measured. Examples of typical shape and wall thickness imperfections in seamless pipes are presented and used in collapse calculations.

ABSTRACT: This paper describes an experimental and an analytical and numerical investigation into the buckling behaviour of cylindrical composite tubes under external hydrostatic pressure. The investigations
concentrated on fibre reinforced plastic tube specimens made from a mixture of three carbon and two E-glass fibre layers. The lay-up was $0^\circ/90^\circ/0^\circ/90^\circ/0^\circ$; the carbon fibres were laid lengthwise ($0^\circ$) and the E-glass fibres circumferentially ($90^\circ$). The theoretical investigations were carried out using a simple solution for isotropic materials, namely a well-known formula by “von Mises” and also by finite element analyses using ANSYS. The experimental investigations showed that the composite specimens behaved similarly to isotropic materials tested by various other researchers. The specimens failed by the common modes associated with this study, namely due to elastic buckling, inelastic buckling and axisymmetric yield failure. Furthermore it was discovered that the specimens failed at changes of the composite lay-up due to the manufacturing process of these specimens. These changes seem to be the weak points of the specimens. For the theoretical investigations two different types of material properties were used to analyse the composite. These were calculated properties derived from the properties of the single layers given by the manufacturer and experimentally obtained properties. Two different approaches were chosen for the investigation of the theoretical buckling pressure, a program called “MisesNP”, based on a well-known formula by von Mises for single layer isotropic materials, and two finite element analyses using the famous computer package called “ANSYS”. This latter analyses simulated the composite with a single layer orthotropic element (Shell93) and also with a multi layer element (Shell99). It was found out that the results obtained with ANSYS predicted questionable buckling pressures that could not be reproduced logically. Nevertheless this report provides Design Charts for all approaches and material types. These Design Charts allow the possibility of obtaining a ‘plastic knockdown factor’. The theoretical buckling pressures obtained using MisesNP or ANSYS can then be divided by the plastic knockdown factor, to give predicted buckling pressures. This method can be used for the design of full-scale vessels.

PARTIAL ABSTRACT: The paper reports on the buckling of twelve thin-walled geometrically imperfect tubes, which were tested to destruction under uniform external hydrostatic pressure. The paper also reports on other similar tests to destruction, carried out on a large number of geometrically imperfect tubes. Theoretical studies were also carried out with well-known analytical solutions, together with a numerical solution using a finite element computer package, namely ANSYS. Whereas the theoretical analyses agreed with each other, they did not agree with the experimental data for the shorter tubes; this was because the shorter tubes collapsed by inelastic instability due to initial geometrical imperfections of the tubes. Exact analysis of slightly geometrically imperfect tubes, with random distribution has so far defied reliable theoretical solutions. However, the paper
presents a design chart, which can cater for these geometrical imperfections. The design chart may also be suitable for large vessels such as submarines, off-shore drilling rigs, silos, etc. Circular cylinders under external pressure, often appear in the form of submarine pressure hulls, torpedoes, off-shore drilling rigs, silos, tunnels, immersed tubes, rockets, medical equipment, food cans, etc. Such vessels are good for resisting internal or external pressure, however under uniform external pressure they can collapse at a fraction of the pressure that will cause failure under internal pressure. Failure of these vessels under uniform external pressure is called non-symmetric bifurcation buckling or shell instability [1,2,3]. To improve the resistance of these vessels to the effects of uniform external pressure, the vessels are usually stiffened by ring stiffeners spaced at near equal distances apart. If, however, the ring stiffeners are not strong enough, the entire flank of the vessel can collapse bodily by a mode called general instability. Another mode of failure is known as axisymmetric deformation, where the cylinder implodes axisymmetrically, so that its cross-section keeps its circular form while collapsing. In this study, we will be concerned with elastic and inelastic shell instability; as such vessels can collapse at pressures of a fraction of that which cause the vessels to fail under internal…

Brown and Stefan Arndt, “A theoretical and experimental investigation of externally ring stiffened cylindrical pressure vessels subjected to external pressure”, Proceedings of the International Conference on Computing in Civil and Building Engineering, W. Tizani (Editor), ICCBE2010, 2010 (not sure of date; it is not too legible in the pdf file.)

ABSTRACT: The best shape for withstanding external pressure is a sphere. However, this is not a very efficient shape for payload, and so submarine structures are often based on cylinders. Long cylinders perform worse than short cylinders under external pressure, and so ring-stiffeners are often introduced to reduce the effective length, and increase the resistance to buckling. Under hydrostatic pressure, cylinders fail by lobar buckling. This is where lobes are formed around the circumference, and the number of lobes formed is a characteristic of the vessel. This paper describes an investigation into the buckling of UPVC ring-stiffened pressure vessels subjected to external pressure. Buckling experiments were carried out on five laboratory sized vessels. Two were approximately 50% longer than the other three, but all of them were otherwise identical. Accurate geometric data was obtained from a co-ordinate measuring machine, and this was used to produce finite element models of the vessel. Two finite element packages were used to model the vessel. One was an in-house program CONBUCR which utilises axisymmetric truncated conical elements, with the facility to add nodal stiffness. The second was the commercial code Ansys, where shell elements were used to model the cylinder and beam elements to model the external rings. Reasonable agreement was obtained between the theoretical and experimental results, given the scatter inherent in the determination of experimental buckling pressures. The axisymmetric program was shown to be much quicker to use than Ansys, with little compromise in accuracy. Inhomogeneous material possibly due to the inclusion of impurities can greatly reduce the buckling resistance of a vessel. In addition, cylinders are never perfectly round, and so the practical test results were expected to show buckling resistances less than the theoretical models.

pressure hulls to withstand buckling under external hydrostatic pressure”, Proceedings of the International Conference on Computing in Civil and Building Engineering, W. Tizani (Editor), ICCBE2010, 2010 (not sure of date; it is not too legible in the pdf file.)

ABSTRACT: The paper presents an investigation into various methods of calculating the theoretical collapse loads for a pressure vessel, under uniform external hydrostatic pressure; based on different design codes. The design codes used for the investigation were BS 5500, for vessels under external pressure and also, the design charts of Ross of the University of Portsmouth. It is the opinion of the present authors that the current design methodology, namely BS 5500 was difficult to use and gave inaccurate collapse pressures for some large-scale pressure vessels. Moreover, BS 5500 appeared to be too pessimistic for one mode of failure and too optimistic for another mode of failure. For the present study, a full-scale ‘theoretical’ pressure vessel was used and the aforementioned methodologies applied in its design to see if there were any similarities that each method may have had. From the results obtained, it became apparent that some methodologies were more accurate than others, depending on the mode of collapse. Moreover, it also became apparent that some of the methods themselves were outdated, user-unfriendly and in some cases, may have even been dangerous.

ABSTRACT: This paper reports on theoretical and experimental investigations into the buckling characteristics of a series of six ring-stiffened circular cylinders that experienced general instability when subjected to external hydrostatic pressure. Each study used between 3-5 designs with the same internal and external diameters, but with different numbers and sizes of ring-stiffeners. Four used designs that were machined to a high degree of precision from steel, while the other two were machined from aluminium alloy. The theoretical investigations focused on obtaining critical buckling pressure values, namely $P_{cr}$, for each design from the well-known Kendrick’s Part I and Part III theories, together with an ANSYS finite element prediction. The thinness ratio $\lambda$, which was originally derived by the senior author, was calculated together with a dimensionless quantity called the plastic knockdown factor (PKD), for each model. The plastic knockdown factor was calculated by dividing the theoretical critical buckling pressures $P_{cr}$, by the experimental buckling pressures $P_{exp}$. The thinness ratio was used because vessels such as these, which have small but significant random out-of-circularity, defy “exact” theoretical analysis and it is because of this that the design charts were produced. Three design charts
were constructed by plotting the reciprocal of the thinness ratio \((1/\lambda)\) against the plastic knockdown factor \((P_{cr}/P_{exp})\), using results from Kendrick Part I, Kendrick Part III, and ANSYS. Comparison of the results obtained using Kendrick’s theories and experimentally obtained results was good.

SUMMARY: A number of reinforced concrete (RC) towers constructed in the 1940s to 1970s are still used. In China and India, the construction of towers in power plants has increased and the scale of the tower has also enlarged. Investigations of the collapse accidents in the past and examination of the countermeasures are developing areas of study, and the evaluation of the safety of the existing facilities has become an important topic of research. With respect to the thin RC shells of these towers, much of the research has analysed the buckling-vibration problem and the effect of initial imperfections on structural properties. Several design guidelines have been proposed. To begin with, useful knowledge of the fundamental phenomenon and analysis method was obtained by studying the initial imperfections of a distribution idealized axisymmetrically and asymmetrically. Recommendations for the tolerance limit of the magnitude of the initial imperfections were proposed. According to the results of many leading research studies, the fluctuation in the in-plane stress in the meridian direction caused by the initial imperfections was inversely proportional to the shell thickness due to dead weight and wind load within the elastic stress analysis, and that it largely affects in-plane stress in meridian direction and bending stress in circumferential direction for the circumferential curvature error. In addition, partial initial imperfections with small amplitudes play a major role in meridian and circumferential stresses. In this paper, three-dimensional geometric errors in a collapsed RC cooling tower shell (Ardeer Nylon Works, 1973) were reproduced and analyzed numerically in detail. Further, the effect of the geometric imperfection of the reproduced shape on the elastic stress distribution due to dead weight was examined, and the
The effect on the wind resistance performance was examined using elasto-plastic FE analysis. The results of this study are as follows:

1. The reproduced geometric imperfection widely exists on the shell full face, and it becomes a waveform that recurs in the circumferential and meridian directions.
2. The hoop stress under the action of the dead load can be changed from tension to compression as a result of the imperfection.
3. Due to wind load, the bending cracks develop in the windward direction of the imperfect shell; this leads to the failure of the tower due to the tension that arises because of the bending in the meridian direction.
4. In the model with the imperfection, it is concluded that the turbulence in the remarkable section forces extends further than that in the case of a perfect shell. Moreover, the maximum reduction in the load bearing capacity is predicted to be approximately 18%. The effect of the difference between the wind directions is considered to be a remarkable result (The shape measurement value used in the analysis includes the effect of existing cracks, repetition of wind/thermal stresses and creep).
5. The effect of the comparatively small temperature loading on the lowering of the rigidity and the ultimate strength may be remarkable, and this fact is contrary to the usual behaviour of an RC member. In the case of a thin-shell cooling tower, the temperature crack may become a significant factor in the lowering of the ultimate strength. Therefore, this relationship needs to be examined prudently in the future.
6. In the design and safety assessment of existing towers, an elasto-plastic analysis seems to be necessary.

ABSTRACT: The collapse of steel tubes under external pressure is described using finite element models. The models are validated comparing their predictions against the results of collapse tests performed in our laboratory.

1 INTRODUCTION
The external collapse pressure of very thin steel tubes is governed by classical elastic buckling formulas; however, for thicker tubes more involved elasto-plastic considerations have to be taken into account. There are many factors that have some degree of influence on the external pressure that produce the collapse of a steel tube, among them:

1. The relation (outside diameter/thickness) (D/t ratio).
2. The yield stress of the tube steel (s_y).
3. The work-hardening of the tube steel.
4. The shape of the tube sections (outside diameter shape and thickness distribution).
5. The residual stresses locked in the tube steel.
6. The localized imperfections introduced either...

ABSTRACT: The production of steel OCTG products with guaranteed external collapse pressure (high collapse casing) requires the implementation of an accurate process control. To develop that process control it is necessary to investigate how different parameters affect the external collapse pressure of pipes. Two dimensional finite element models provide an useful tool for performing the “first approach” parametric studies; however a bidimensional representation of the tube geometry (as used in many analytical and semi-empirical formulas) is not enough for determining the external collapse pressure of casings. We use three dimensional models to further investigate the effects of the casing geometry on its external collapse pressure. To acquire the data that describes the geometry of casing samples, we have developed an imperfections measurement system following previous developments by Yeh and Kyriakides. We also present finite element models of OCTG connections which are used as a tool for the evaluation of connections collapse pressure.

ABSTRACT: The production of steel pipes with guaranteed external collapse pressure (e.g. high collapse casings for oil wells) requires the implementation of an accurate process control. To develop that process
control it is necessary to investigate how different parameters affect the external collapse pressure of the pipes. Experimental/numerical techniques implemented to investigate the collapse behavior of steel pipes are presented. The discussion of the experimental techniques includes the description of the facilities for performing external pressure collapse tests and the description of an imperfections measuring system. The numerical techniques include 2D and 3D finite element models. The effects on the value of the pipes’ external collapse pressure of their shape, residual stresses and material properties are discussed.

ABSTRACT: The infinitesimal strain version of the MITC4 shell element (Dvorkin and Bathe [6]) was previously successfully used for the analysis of deep-water applications of steel marine pipelines. The collapse and post collapse responses were modeled and compared with experimental results (Toscano et al. [12]). Even though in those verifications the matching between numerical and experimental results was excellent, it was also noticed that in the post–collapse regime very high strains are developed in the steel shell. In Ref. [12] a version of the MITC4 that uses a posteriori updates of the shell thickness was used to incorporate into the model the finite strain behavior. The results indicated that even though the consideration of finite strains improves the solution, the room for improvement - when the overall equilibrium paths are considered - is so small that it hardly justifies the use of a more expensive numerical model. However, if local strains are sought, the finite strain model produces much better approximations to the actual situation. Hence, the motivation for shell element formulations apt for finite strain elasto-plastic analyses is still open. In previous publications we presented a new shell element formulation, the MITC4-3D that we developed for finite strain analysis (Toscano and Dvorkin [13, 14]) using the MITC4 strains interpolation (Dvorkin and Bathe [6]) and 3D constitutive relations. In this paper we are going to discuss the basic features of the MITC4-3D element and present further verification / validation.

INTRODUCTION: The design of High-Pressure/High-Temperature (HP/HT) pipelines on an uneven seabed has become an important issue in the recent years. The need to gain further insight into how expansion, seabed friction and free spans influence on the pipeline behavior through selected load cases is the background for this chapter. The behavior of such pipelines is largely characterized by the tendency to undergo global buckling, either vertically if trenched or covered, or laterally if the pipeline is left fully exposed on the seabed. The main concern in the design of slender pipelines operating under HP/HT conditions is to control global buckling at some critical axial force. The large horizontal and/or vertical displacements induced by global buckling may result in high stresses and strains in the pipe wall that exceed code limits. The simulation of the designed pipeline in a realistic three-dimensional environment obtained by measurements of the seabed topography, allows the engineers to exploit any opportunities that the pipeline behavior may offer to develop both safe and cost-effective solutions. For example, the designer can first analyze the pipeline behavior on the original seabed. If some of the load cases result in unacceptably high stress or strain, seabed modification can be simulated in the finite element model and the analysis re-run to confirm that the modifications have lead to the desired decrease in stress or strain. The finite element model may be a tool for analyzing the in-situ behavior of a pipeline. By the pipeline in-situ behavior it is here meant the...

ABSTRACT: The production of oil and gas from offshore oil fields is, nowadays, more and more important. As a result of the increasing demand of oil, and being the shallow water reserves not enough, the industry is pushed forward to develop and exploit more difficult fields in deeper waters. In this Thesis, a methodology for using the finite element method as a robust engineering tool for analyzing the effect of the manufacturing tolerance on the collapse and post collapse behavior of steel pipes was discussed and illustrated with practical examples. Even though, using a small strain formulation, the matching between numerical and experimental results was excellent, the model results showed high strains in some areas of the collapsed pipes. Therefore, we developed a new shell element, MITC4-3D, incorporating elasto-plastic finite strains, based in the MITC4 formulation. It was implemented for the analyses of elasto-plastic shell structures and the results indicate that it is a very effective element.

ABSTRACT: A comparison between pipe bends with assumed cross sections, namely elliptic and semi oval to include ovality along with wall thinning, was performed to determine the plastic collapse load under in-plane closing bending moment using finite element limit analysis based on an elastic-perfectly plastic material considering geometric nonlinearity. Twice-elastic-slope method was used to obtain collapse load from the moment-rotation curve drawn for each pipe bend model considered. The effect of ovality on collapse load is significant and higher for elliptic cross sections for almost all cases while the thinning effect is negligible for both the cross sections. The study concludes that the use of elliptic cross section is suitable for analyzing pipe bend with ovality. Therefore, a closed-form solution is proposed to determine collapse load of pipe bend based on the finite element results of elliptic cross sections.

ABSTRACT: Thin-walled shell structures like circular cylindrical shells are prone to buckling. Imperfections which are defined as deviations from perfect shape and perfect loading distributions can reduce the buckling load drastically compared to that of the perfect shell. Design criteria monographs like NASA-SP 8007 recommend that the buckling load of the perfect shell shall be reduced by using a knock-down factor. The existing knock-down factors are very conservative. Furthermore, the structural behaviour of composite material is not considered. A new experimental approach to determine the lower bound of the buckling load of thin-walled cylindrical composite shells is presented. Based on test results the numerical analysis is validated.

ABSTRACT: A fast semi-analytical model for the post-buckling analysis of stiffened cylindrical panels is presented. The panel is comprised of a skin (shell) and stiffeners in both longitudinal (stringers) and circumferential direction (frames). Local buckling modes are considered where the skin may buckle within a bay and may induce rotation of the stiffeners. Stringers and frames are considered as structural elements and are thus not ‘smeared’ onto the skin. Large out-of-plane deflections and thus non-linear strain–displacement relations of skin and stiffeners are taken into account. The displacements of skin and stiffeners are approximated by trigonometric functions (Fourier series). First, a linear buckling eigenvalue analysis is carried out and some combination of buckling eigenmodes is chosen as imperfection. Then the load history is started and the Fourier coefficients are determined by minimizing the stiffened panel's energy at each load level. A curve-tracing algorithm, the Riks method, is used to solve the equations. The present model can be used to assess the post-buckling behavior of stiffened panels, for example, aircraft fuselage sections.
Development and experimental verification of FE-model for stringer-stiffened fibre composite panels under combined thermal and mechanical loading conditions” (Proceedings European Conference on…, 1998, no publisher given)

ABSTRACT: In this paper a buckling design rule for stringer stiffened curved CFRP panels subjected to combined mechanical and thermal loading is derived by parametric studies with the finite element system ANSYS. At first a finite element model to simulate the buckling behaviour of such panels is established and validated with test results from a former study. Then loading and boundary conditions are adapted to those of the Thermex B testing site at DLR in Braunschweig, and results of linear bifurcation analyses with constant material properties under combined mechanical and thermal load are presented. Additional nonlinear computations with temperature-dependent material properties confirm the results of the linear computations. The results of all computations are summarized as the design rule looked for, and then verified by tests.

ABSTRACT: Thin-walled stiffened panels tend to buckle under compressive and/or shear loads with resulting redistribution of stresses in the structure. Provided that the stiffeners are capable of sustaining the additional load, such conditions are acceptable in many structures. Since a complete postbuckling analysis for each state of loading is prohibitive, simple approximations are in use. With the appearance of orthotropic panels it is deemed desirable to extend such approximations to panels with orthotropic properties. A short review of available recommendations is given and a one term approach is used to demonstrate the effect of orthotropy. Further, recent panel test results from ETH Zurich are reviewed accordingly, and two different FE-based postbuckling analyses (postbuckling at Zurich and initial postbuckling at Braunschweig) are performed to provide confirmation that the quality of a crude and simplifying formula is acceptable.

ABSTRACT: The objective of the present paper is to present a simple analytical solution for computing bifurcation buckling loads of thin and moderately thick orthotropic cylindrical shells and panels subjected to axial compression and normal pressure. That solution does not necessarily make use of the simplifying assumptions of shallow shell theory, and takes the flexibility with respect to transverse shear loads into account, which is supposed to be relatively high with laminated composite structures. The analysis is based on the governing nonlinear equations and boundary conditions of deep and shallow shell theory. They are linearised to yield the differential equations for bifurcation buckling. The linearised set admits a single-term analytical solution when the cylinder ends or panel edges are simply supported. It reduces the task to a small size (3*3) algebraic eigenvalue problem that can be solved by standard methods. A computer program BOSCAP
Buckling of Orthotropic Shear-flexible Cylinders And Panels is developed based on the above mentioned formulation which is very quick and easy to use during design trials or in automated optimization. A series of numerical examples is presented to demonstrate effects of transverse shear flexibility and curvature. Good agreement with some test results is shown.

ABSTRACT: A new exact closed-form procedure for free vibration analysis of moderately thick spherical shell panel is presented based on the first-order shear deformation theory. The strain–displacement relations of Donnell and Sanders theories are used to illustrate the procedure. The shell has two opposite edges simply supported (i.e., Lévy-type). Based on the present solution, the governing equations of the vibrated spherical shell panel were exactly solved by introducing the new auxiliary and potential functions as well as using the separation method of variables. The accuracy and superiority of the formulations are validated by comparing the results with those available in the literature and the 3D finite element analysis. The effects of various stretching–bending couplings on the frequency parameters are discussed. Finally, the validity and the range of applicability of the Sanders and Donnell shell theories are investigated.

Christian Huehne, Rolf Zimmermann, Raimund Rolfes, and Bodo Geier, DLR Braunschweig, Institute of Structural Mechanics, Germany, “Sensitivities to geometrical and loading imperfections on buckling of composite cylindrical shells”, (no publisher or date given, but the most recent reference listed at the end of the paper is 2002.)

ABSTRACT: Thin-walled shell structures prone to buckling are sensitive to imperfections. The influence of loading and geometrical imperfections on buckling loads of unstiffened composite cylindrical shells is investigated based on tests and computations. It is shown that their effect depends on laminate set-up. The results show that unification of imperfection sensitivity is allowed; systems sensitive to geometrical imperfections are also sensitive to loading imperfections. The results can be used to define lower limits for knock-down factors of composite shells.

ABSTRACT: Exploitation of structural reserves in thin-walled composite aerospace structures requires accurate and experimentally validated stability analysis of real structures under realistic loading conditions. For stringer-stiffened panels experimental validation of postbuckling analyses and behavior under dynamic loading is presented. For unstiffened cylindrical shells a robust design method relying on b-factors is suggested.

ABSTRACT: European aircraft industry demands for reduced development and operating costs, by 20% and 50% in the short and long term, respectively. Structural weight reduction by exploitation of structural reserves in composite aerospace structures contributes to this aim, however, it requires accurate and experimentally validated stability analysis of real structures under realistic loading conditions. This paper presents different advances from the area of computational stability analysis of composite aerospace structures which contribute to that field. For stringer stiffened panels main results of the finished EU project POSICOSS and the running follow-up EU project COCOMAT are given. Both projects deal with exploitation of reserves in primary fibre composite fuselage structures through an accurate and reliable simulation of postbuckling and collapse. Next, experimental validation of postbuckling analyses, development of two different fast tools for the postbuckling simulation and findings on the structural behaviour under dynamic loading is presented. Finally, for unstiffened cylindrical shells problems of a robust design method are.

ABSTRACT: The European Commission was funding within its 5th Framework Programme the project POSICOSS, which coped with the demand to design fibre composite fuselage structures for postbuckling under ultimate load. The main objective of the work was the development of improved, fast and reliable procedures for postbuckling analysis and design of fibre composite stiffened panels of future fuselage structures. Another substantial objective was the creation of comprehensive experimental data bases for the purpose of validation. This paper deals with the buckling and postbuckling experiments on axially compressed, stiffened CFRP (carbon fiber reinforced plastics) curved panels, performed by DLR within the POSICOSS project for validation purposes, and it compares experimental results with computations.

ABSTRACT: The European Commission was funding within its fifth Framework Programme the project POSICOSS, which coped with the demand to design fibre composite fuselage structures for postbuckling under ultimate load. The main objective of the work was the development of improved, fast and reliable procedures for postbuckling analysis and design of fibre composite stiffened panels of future fuselage structures. They were essential, because so far postbuckling calculations were extremely time consuming and as such not applicable for design. Another substantial objective was the creation of comprehensive experimental data bases for the purpose of validation. The paper presents an introduction to the POSICOSS project; it derives the main objective of the project from the main general objectives for the design of the next generation of aircraft structures, and it summarizes the work done. The results achieved are only touched, because details of them can be found by consulting the references given.

“Buckling and Postbuckling Analysis of a CFRP Stiffened Panel for a Better Material Exploitation”, (no publisher or date given in the pdf file, 2005?; latest reference is dated 2004)
ABSTRACT: This paper will present main results of post-buckling analyses led during the activity of the GARTEUR action group. A CFRP curved stringer stiffened panel under axial compression has been studied. The panel, tested by DLR, has been impacted inducing skin-stringer separation. Partners have carried out several analyses with various in-house and main commercial FE software to identify their abilities and deficiencies. The simulation tools and analysis methods will be compared together with available experimental results.

ABSTRACT: Aerospace industry demands for significantly reduced development and operating costs. Reduction of structural weight at safe design is one avenue to achieve this objective. The running ESA (European Space Agency) study Probabilistic Aspects of Buckling Knock Down Factor acts on this route. It concentrates on thin-walled circular cylindrical CFRP shells subjected to axial compression. It is well known that such structures exhibit not only a high load carrying capacity but also are prone to buckling which is highly imperfection sensitive. Imperfections are defined as deviations from perfect parameters like shape, thickness, material properties and loading distributions, they can reduce the buckling load drastically compared to a perfect shell. In order to account for these imperfections the theoretical buckling load of a perfect cylinder must be multiplied, and therefore reduced, by a knock-down factor (the ratio of buckling loads of imperfect and perfect cylindrical shell). Thus the closer the knock-down factor reflects the effect of imperfections the better is the prediction of the real buckling load. In the still used NASA SP-8007 design guideline from 1968 a lower bound curve for the knock-down factor is proposed. The factor depends on the slenderness (the ratio of radius
and wall thickness) and decreases with increasing slenderness. This factor is rather conservative and the structural behaviour of composite material is not considered adequately. Advanced thin-walled cylindrical shell structures under compression are therefore penalized if the knock-down factor based on this early NASA report must be applied. The current ESA study started in May 2006 and will run for 18 months. Its main objective is to achieve a better buckling knock-down factor for unstiffened CFRP cylindrical shells and to validate the linear and non-linear buckling simulations by test results. The main results will comprise an experimental data base (material properties, measured thicknesses, full scale shape imperfections, load-shortening curves, strains, and deformations) obtained by testing of 10 nominally identical axially compressed CFRP cylindrical shells, sensitivity analyses using Monte-Carlo simulation, validation with tests and a design guideline for that type of structure with a less conservative knock-down factor than taken from NASA SP-8007. All tasks of the ESA study are performed at the Institute of Composite Structures and Adaptive Systems of DLR Braunschweig, which has a rich body of experience in design, manufacturing, testing and analysis of shells prone to buckling. The paper outlines the objectives and expected results of the running ESA study and presents the results achieved so far.

ABSTRACT: The aircraft and space industry strives for significantly reduced development and operating costs. Reduction of structural weight at safe design is one possibility to reach this objective which is aimed by the following two running research projects: the EC project "COCOMAT" and the ESA study "Probabilistic Aspects of Buckling Knock Down Factors". These projects develop improved concepts and tools for a fast and reliable simulation of the buckling and the postbuckling behavior of thin-walled structures up to collapse, respectively, which allow the exploitation of considerable reserves in primary fibre composite structures in aerospace applications. For the validation of the concepts and tools, a sound database of experiments is needed which is also performed within these projects. This paper focuses on the experimental activities within these projects performed at the buckling test facility of the Institute of Composite Structures and Adaptive Systems (DLR). It presents an overview about the DLR buckling, postbuckling and collapse tests which are already finished and gives an outlook to the results which are expected until the end of the running projects. This paper explains the working of the buckling test facility, the advanced measurement systems, which are running in parallel to the tests, and gives exemplarily two test results. The structures considered are unstiffened cylinders (ESA study) as well as panels, which are understood as sections of cylinders, stiffened by stringers (COCOMAT project). The unstiffened cylinders are more related to space applications (e.g. Ariane busters or parts of the international space station ISS) and the stiffened panels focus more on aircraft structures (e.g. fuselage). The load case considered for all investigations presented in this paper is axial compression under static loading although the test facility is also ready to apply torsion and internal pressure, as well as dynamic axial impact.
ABSTRACT: The European aircraft industry demands reduced development and operating costs, by 20% and 50% in the short and long term, respectively. Contributions to this aim are provided by the completed project POSICOSS (5th FP) and the running follow-up project COCOMAT (6th FP), both supported by the European Commission. As an important contribution to cost reduction a decrease in structural weight can be reached by exploiting considerable reserves in primary fibre composite fuselage structures through an accurate and reliable simulation of post-buckling up to collapse. The POSICOSS team developed fast procedures for the post-buckling analysis of stiffened fibre composite panels, created comprehensive experimental data bases and derived suitable design guidelines. COCOMAT builds up on the POSICOSS results and considers in addition the simulation of collapse by taking degradation into account. The results comprise an extended experimental data base, degradation models, and improved certification and design tools as well as extended design guidelines. One major task of POSICOSS and COCOMAT is the development of improved analysis tools that are validated by experiments performed within the framework of the projects. Because the new tools must comprise a wide range of various aspects a considerable number of different structures had to be tested. These structures were designed under different objectives (e.g. large post-buckling region). For the design process, the consortiums applied state-of-the-art simulation tools and brought in their own design experience. This paper deals with the design process as performed within both projects and with the applied analysis procedures. It is focused on the DLR experience in the design and analysis of stringer-stiffened CFRP panels gained within the scope of these two projects.

ABSTRACT: In the field of aerospace engineering but also in the fields of civil and mechanical engineering the industry demands for significantly reduced costs for development and operating. Reduction of structural weight at safe design is one avenue to achieve this objective. In many cases it results in thin-walled structures, which are prone to buckling if subjected to compression or shear. The presented paper is based on a recent European Space Agency (ESA) study, conducted at DLR Braunschweig, on Probabilistic Aspects of Buckling Knock-Down Factors and contributes to this goal by striving for an improved buckling knock-down factor (the ratio of buckling loads of imperfect and perfect structures) for unstiffened CFRP cylindrical shells. Buckling tests and buckling simulations were performed to investigate the imperfection sensitivity and to validate the applied simulation methodologies. Test results as well as deterministic and probabilistic buckling simulation results are presented and compared. Finally, improved knock-down factors are deduced and discussed.
INTRODUCTION: Currently, imperfection sensitive shell structures prone to buckling are designed according the NASA SP 8007 guideline using the conservative lower bound curve. This guideline dates from 1968, and the structural behaviour of composite material is not appropriately considered, in particular since the imperfection sensitivity and the buckling load of shells made of such materials depend on the lay-up design. This is not considered in the NASA SP 8007, which allows designing only so called "black metal" structures. There is a high need for a new precise and fast design approach for imperfection sensitive composite structures which allows significant reduction of structural weight and design cost. For that purpose a combined methodology from the Single Perturbation Load Approach (SPLA) and a specific stochastic approach is proposed which guarantees an effective and robust design. The SPLA is based on the observation, that a large enough disturbing load leads to the worst imperfection; it deals with the traditional (geometric and loading) imperfections [1]. The stochastic approach considers the non-traditional ones, e.g. variations of wall thickness and stiffness. Thus the combined approach copes with both types of imperfections. A recent investigation demonstrated, that applying this methodology to an axially loaded unstiffened cylinder is leading directly to the design buckling load 45% higher compared with the respective NASA SP 8007 design [2]. This chapter presents in its first part the state-of-the-art in buckling of imperfection sensitive composite shells. The second part describes current investigations as to the SPLA, the stochastic approach and their combination. In a third part an outlook is given on further studies on this topic, which will be performed within the framework of the running 3-year project DESICOS (New Robust DESIgn Guideline for Imperfection Sensitive COmposite Launcher Structures) funded by the European Commission; for most relevant architectures of cylindrical and conical launcher structures (monolithic, sandwich - without and with holes) the new methodology will be further developed, validated by tests and summarized in a handbook for the design of imperfection sensitive composite structures. The potential will be demonstrated within different industrially driven use cases.

PARTIAL INTRODUCTION: Numerous applications of numerical optimization to various structural design problems have been addressed in the literature. A comprehensive survey on this issue was given in [1], presenting a historical review and demonstrating the future needs to assimilate this technology into the practicing design environment. Different approaches were applied successfully by several investigators for treating stress, displacement, buckling and frequency optimization problems. In general, design optimization seeks the best values of a set of n design variables represented by the vector, $X_{nx1}$, to achieve, within certain m constraints, $G_{mx1}(X)$, its goal of optimality defined by a set of k objective functions, $F_{kx1}(X)$, for specified environmental conditions. Mathematically, design optimization may be cast in the following standard form:

Find the design variables $X_{nx1}$ that minimize . . .

INTRODUCTION: The primary goal of the research in constrained elastica is to understand the behavior of a thin elastic strip under end thrust when it is subject to lateral constraints. It finds applications in a variety of practical problems, such as in compliant foil journal bearing, corrugated fiberboard, deep drilling, structural core sandwich panel, sheet forming, non-woven fabrics manufacturing, and stent deployment procedure. By assuming small deformation, Feodosyev (1977) included the problem of a buckled beam constrained by a pair
of parallel walls as an exercise for a university strength and material course. Vaillette and Adams (1983) derived a critical axial compressive force an infinitely long constrained elastica can support. Adams and Benson (1986) studied the post-buckling behavior of an elastic plate in a rigid channel. Chateau and Nguyen (1991) considered the effect of dry friction on the buckling of a constrained elastica. Adan et al. (1994) showed that when a column with initial imperfection positioned at a distance from a plane wall is subject to compression, contact zones may develop leading to buckling mode transition. Domokos et al. (1997), Holms et al. (1999), and Chai (1998, 2002) investigated the planar buckling patterns of an elastica constrained inside a pair of parallel plane walls. It was observed that both point contact and line contact with the constraint walls are possible. Kuru et al. (2000) studied the buckling behavior of drilling pipes in directional wells. Roman and Pocheau (1999, 2002) used an elastica model to investigate the post-buckling response of bilaterally constrained thin plates subject to a prescribed height reduction. Chen and Li (2007) and Lu and Chen (2008) studied the deformation of a planar elastica inside a circular channel with clearance. Denoel and Detournay (2011) proposed an Eulerian formulation of the constrained elastica problem. The emphasis of these studies was placed on the static deformations of the constrained elastica. Very often, multiple equilibria under a specified set of loading conditions are possible. Since only stable equilibrium configurations can exist in practice, there is a need to determine the stability of each of these equilibria in order to predict the behavior of the constrained elastica as the external load varies. For an unconstrained elastica, vibration method is commonly used to determine its stability; see Perkins (1990), Patricio et al. (1998), Santillan, et al. (2006), and Chen and Lin (2008). This conventional method, however, becomes useless in the case of constrained elastica. The difficulty of the conventional vibration method arises from the existence of unilateral constraints. A unilateral constraint is capable of exerting compressive force onto the structure, but not tension. Mathematically, this type of constraints can be represented by a set of inequality equations. This poses challenges in determining the critical states of the loaded structure. In order to overcome this difficulty, the conventional stability analysis needs modification. In this chapter, we introduce a vibration method which is capable of determining the stability of a constrained elastica once the equilibrium configuration is known. The key of solving the vibration problem in constrained elastica is to take into account the sliding between the elastica and the space-fixed unilateral constraint during vibration. In this chapter, we consider the vibration of an elastica constrained by a space-fixed point constraint. This particular constrained elastica problem is used to demonstrate the vibration method which is suitable to analyze the stability of a structure under unilateral constraint. In Section 2, we describe the studied problem in detail. In Section 3, we describe the static load-deflection relation. In Section 4, we introduce the theoretical formulation of the vibration method. In Section 5 an imperfect system when the point constraint is not at the mid-span is analyzed. In Section 6, several conclusions are summarized.

INTRODUCTION: This chapter presents advanced analysis methods for space steel frames which consider both geometric and material nonlinearities. The geometric nonlinearities come from second-order P−Δ and P−δ effects as well as geometric imperfections, while the material nonlinearities are due to gradual yielding associated with residual stresses and flexure. The P−Δ effect results from the axial force acting through the relative displacement of the ends of the member, so it is referred to as a member chord rotation effect. The P−Δ effect is accounted in the second-order analysis by updating the configuration of the structure during the analysis process. The P−δ effect is caused by the axial force acting through the lateral displacement of the member relative to its chord, so it is referred to as a member curvature effect. The P−δ effect can be captured by using stability functions. Since the stability functions are derived from the closed-form solution of a beam-
column subjected to end forces, they can accurately capture the P−δ effect by using only one element per member. Another way to capture the P−δ effect without using stability functions is to divide the member into many elements, and consequently, the P−δ effect is transformed to the P−Δ effect. Geometric imperfections result from unavoidable errors during the fabrication or erection. There are three methods to model the geometric imperfections: (1) the explicit imperfection modeling, (2) the equivalent notional load, and (3) the further reduced tangent modulus. The explicit imperfection modeling for braced and unbraced members is illustrated in... For braced members, out-of-straightness is used instead of out-of-plumbness. This is due to the fact that the P−Δ effect due to the out-of-plumbness is vanished by braces. The limitation of this method is that it requires the determination of the direction of geometric imperfections which is often difficult in a large structural system. In the equivalent notional load method, the geometric imperfections are replaced by equivalent notional lateral loads in proportion to the gravity loads acting on the story as described in ... The drawback of this method is that the gravity loads must be known in advance to determine the notional loads before analysis. Another way to account for the geometric imperfections is to further reduce the tangent modulus. The advantage of this method over the explicit imperfection modeling and equivalent notional load methods is its convenience and simplicity because it eliminates the inconvenience of explicit imperfection modeling and equivalent notional load methods.
formulae/charts given in design specifications are developed for uniform members. Thus, there is a need for a practical tool to analyze buckling behavior of nonuniform members. This study investigates elastic buckling behavior of three-segment symmetric stepped compression members with pinned ends (Fig. 1) using three different approaches: (i) analytical, (ii) numerical and (iii) experimental approaches. As already mentioned, such a member can easily be used to strengthen/rehabilitate an existing steel braced frame or can directly be used in a new construction. Surely, the use of stepped elements is not only limited to the structural engineering applications; they can be used in many other engineering applications, such as in mechanical and aeronautical engineering. In analytical studies, first the governing equations of the studied stability problem are derived. Then, exact solution to the problem is obtained. Since exact solution requires finding the smallest root of a rather complex characteristic equation which highly depends on initial guess, the governing equation is also solved using a recently developed analytical technique by He (1999), which is called Variational Iteration Method (VIM). Many researchers (e.g., Abulwafa et al., 2007; Batiha et al., 2007; Coskun & Atay, 2007, 2008; Ganji & Sadighi, 2007; Miansari et al., 2008; Ozturk, 2009 and Sweilan & Khader, 2007) have shown that complex engineering problems can easily and successfully be solved using VIM. Recently, VIM has also been applied to stability analysis of compression and flexural members. Coskun and Atay (2009), Atay and Coskun (2009), Okay et al. (2010) and Pinarbasi (2011) have shown that it is much easier to solve the resulting characteristic equation derived using VIM. In this paper, by comparing the approximate VIM results with the exact results, the effectiveness of using VIM in determining buckling loads of multi-segment compression members is investigated. The problem is also handled, for some special cases, using widely known structural analysis program SAP2000 (CSI, 2008). After determining the buckling load of a uniform member with a hollow rectangular cross section, the stiffness of the member is increased along its length partially in different length ratios and the effect of such stiffening on buckling load of the member is investigated. By comparing numerical results with analytical results, the effectiveness of using such an analysis program in stability analysis of multi-segment elements is also investigated. Finally, buckling loads of uniform and three-segment stepped steel compression members with hollow rectangular cross section are determined experimentally. In the experiments, the “stiffened” columns are prepared by welding additional steel plates over two sides of the member in such a way that the addition of the plates predominantly increases the smaller flexural rigidity of the cross section, which governs the buckling behavior of the member. By changing the length of the stiffening plates, i.e., by changing the stiffened length ratio, the degree of overall stiffening is investigated in the experimental study. The experimental study also shows in what extent the ideal conditions assumed in analytical and numerical studies can be realized in a laboratory research.

Saullo G. P. Castro, Rolf Zimmermann, Mariano A. Arbelo and Richard Degenhardt, “The single perturbation load approach compared with linear buckling mode-shaped, geometric dimple and measured imperfections for the buckling of cylindrical shells”, to be published in Thin-Walled Structures (2015 or 2016?)

ABSTRACT: The important role of geometric imperfections on the decrease of the buckling load for thin-walled cylinders had been recognized by the first authors investigating the theoretical approaches on this topic. Until nowadays there is no closed solution to take imperfections into account already during the early design phases, forcing the analysts to use empirically based lower-bound methods such as the NASA SP-8007 guideline to calculate the required knock-down factors (KDFs). Since 1970s a considerable number of experimental and numerical observations have been found to support new stochastic and deterministic methods for calculating more realistic KDFs. Among the deterministic approaches the single perturbation load approach (SPLA) originally developed by Hühne will be further investigated. Its capability for predicting KDF is compared with three other methods to create an initial geometric imperfection: linear buckling mode-shaped, geometric dimple and real measurements. The implementation of each method is explained in details and their
limitations are compared. The study is part of the European Union (EU) project DESICOS, whose aim is to combine stochastic and deterministic approaches for developing less conservative design guidelines for imperfection sensitive structures.

Professor Dr.-Ing Richard Degenhardt [German Aerospace Center, Institute of Composite Structures and Adaptive Systems, Structural Mechanics, Braunschweig (DLR)], Words about Professor Degenhardt’s research group concerned with STABILITY (see the website: http://www.dlr.de/fa/en/desktopdefault.aspx/tabid-1462/2063_read-3525/)

**Stability of thin-walled composite structures:**

Light weight structures in the aerospace, mechanical engineering or civil engineering are on the one hand under compression or shear loading susceptible for buckling but on the other hand they have large reserve capacities in the postbuckling region. In order to save weight in these fields the use of materials made of Carbon-Fibre-Reinforced-Plastics (CFRP) is increasing. However, the design and computation of composite structures is more challenging than using classic materials. Stability, non-linear computations and degradation have therefore here an essential relevance. The structural behaviour of stability and deformations is simulated by nonlinear numerical simulations and experiments. Figure 1 illustrates the comparison of an experiment and simulation of a buckled, stringer-stiffened (on the reverse side) CFRP panel. The institute has in the field of stability of thin-walled composite structures competence in the following 4 main topics: Postbuckling behaviour, Imperfection tolerance, Buckling due to dynamic loading, Thermo-mechanical buckling. The objective is to develop fast and reliable software tools in order to simulate the buckling and postbuckling behaviour up to collapse. These software tools can then be incorporated into a design process as well as to deduce simple design rules. To fulfil these tasks numerical and experimental work is essential. The experimental examination is employed to provide a better understanding of the physical behaviour of the structure and to validate the developed software tools.

**Our competence:**
- Postbuckling
- Imperfection tolerance
- Dynamic buckling
- Thermal buckling

**Running projects:**
- COCOMAT (Co-ordinator, Improved Material Exploitation of Safe Design of Composite Structures by Accurate Simulation of Collapse, EC 6th FP)
- ALCAS (Advanced low cost Airframe Structures, EC 6th FP)
- MUSCA (Nonlinear static MULTiSCAle analysis of large aero-structures, EC 6th FP)
- Design of optimal CFRP panels for fuselage structures (DLR - China)
- Advanced Aerospace Structures (Fortschrittliche Flugzeugstrukturen, DLR - EADS)
- Composite Fuselage Demonstrator (DLR-Airbus)
- Probabilistic aspects of buckling knock down factors, Tests and analysis (ESA)
- Buckling Handbook (ESA, ECSS-E-30-24)

**Some finished projects:**
- IBUCK - a fast semi-analytical design tool for stiffened panels (DLR - Airbus Deutschland)
- POSICOSS (Coordinator, Improved Post-buckling Simulation for Design of Fibre Composite Stiffened Fuselage Structures, EC 5th FP)
- Robust Design (DLR - Airbus Germany)
- GARTEUR SM AG 25 (WP-leader, Postbuckling and Collapse Analysis, established recommendations for buckling, postbuckling and collapse analysis of CFRP shells)
- Globales Tragverhalten (Virtual testing of stringer and frame stiffened shells, Airbus Germany)
Multiobjective optimisation of fibre composite structures endangered by buckling (DLR - China)
Identification of the Stiffnesses of Stringer Stiffened Laminated Materials (DLR - China)
Schwarzer Rumpf (Black fuselage, DLR - Airbus Deutschland)
Buckling under dynamic loading (German - Israeli foundation)
FESTIP (Refinement of Buckling Prediction Techniques for Large Thin Shells Under Mechanical and Thermal Load Conditions, ESA)
Fracture Mechanics of Composites (Damage tolerance of CFRP panels and cylinders prone to buckling, ESA)
EDAVCOS (Efficient Design and Verification of Composite Structures, EC 5th FP)
DEVILS (Design and Validation of Imperfection-Tolerant Laminated Shell Structures, EC 4th FP)
GARTEUR SM AG05 (Chairman, Buckling and Postbuckling Behaviour of Composite Panels)
Composite Bulkhead (Stability investigation of an Airbus CFRP bulkhead, A340-500 and A340-600)

ABSTRACT: Currently, imperfection sensitive shell structures prone to buckling are designed according to the NASA SP-8007 guideline, from 1968, using its conservative lower-bound curve. In this guideline the structural behavior of composite materials is not appropriately considered, since the imperfection sensitivity and the buckling load of shells made of such materials depend on the lay-up design. Due to the fact that this approach is outdated for preliminary design purposes, several authors are investigating less conservative methodologies. Some authors propose a new lower-bound curve approach based only on statistical analysis of experimental test on composite cylinders. The problem with this approach is that the range of applicability is limited to the database extension. Finite element models are also used by many researchers to characterize the behavior of cylindrical shell considering different types of material and geometrical imperfections. A representative finite element model allows studying a widespread area of possibilities from the design point of view. In this context a numerical investigation about the different methodologies to characterize the behavior of imperfection sensitive composite structures subjected to compressive loads up to buckling is presented in this paper. A comparative study is addressed between new deterministic methodologies, such as the “Single Perturbation Load Approach” proposed by the European project DESICOS and new statistical approaches based on experimental test on composite cylinders. The aim of this work is to define the range of applicability of these methodologies for unstiffened composite cylinders, advantage and disadvantage to use as a design tool, to provide means to calculate less conservative knock-down factors than the obtained with the NASA SP-8007 guideline.

ABSTRACT: The performance of thin-walled structures, which are endangered by buckling, is often strongly influenced by geometrical imperfections. It is impossible to know in advance the imperfections, which will be present in the real structure. Nevertheless, their influence has to be taken into account already at the design process. Attempts to indentify characteristic imperfections due to specific manufacturing processes overcome this difficulty only partly, as they do not consider imperfections coming into existence after fabrication. The remedy is, to build imperfection tolerant structures. For that purpose, a simple means to measure imperfection
tolerance is defined and a multiobjective optimization formulation is proposed to design fiber composite shell structures, which simultaneously exhibit high imperfection tolerance and high buckling load. By example of axially compressed CFRP cylindrical shells first computational and experimental results are given to demonstrate the feasibility of the concept, and to identify needs for further research.

ABSTRACT: Thin-walled, unstiffened and stiffened shell structures made of fibre composite materials are frequently applied due to their high stiffness/strength to weight ratios in all fields of lightweight constructions. One major design criterion of these structures is their sensitivity with respect to buckling failure when subjected to inplane compression and shear loads. This paper describes how the structural analysis program BEOS (Buckling of Eccentrically Orthotropic Sandwich shells) is combined with the optimization procedure SAPOP (Structural Analysis Program and Optimization Procedure) to produce a tool for designing optimum CFRP-panels against buckling. Experimental investigations are used to justify the described procedures.

ABSTRACT: Elastic buckling of stiffened plate with local imperfections were presented in this paper. As its difficult to analysis buckling character of the stiffened plate with local imperfections by using elastic plate theory, this paper used finite element method (FEM) to model 30 different cases of local imperfections in stiffened plate, and analysed how the size, depth and direction of local imperfections affect the critical buckling coefficient of the stiffened plate. Results shown that, the size, depth and direction of local imperfections are have significant impact to the buckling behavior of stiffened plate, the largest decrease of critical buckling coefficient due to the local imperfection reaches 30% in this paper, and the critical buckling coefficient of stiffened plate with smaller stiffness ratio is more susceptible to the local imperfections.

ABSTRACT: We report experimental observations of shell buckling instabilities in free-standing, vertically aligned GaN nanotubes subjected to uniaxial compression. Highly uniform arrays of the GaN nanotubes standing on a GaN template were fabricated and subjected to uniaxial compression using a nanoindenter. The buckling load was found to be of the order of 150 μN for the GaN nanotubes with an outer radius of 40 nm, an inner radius of 20 nm, and heights of 500 and 300 nm. Good agreement was found between the experimental observations, the stress–strain relation equation study findings and the predictions from the cylindrical shell buckling theory.

ABSTRACT: A long, thin, circular, cylindrical shell is subjected to uniform external pressure exerted by a surrounding elastic medium. The stability of equilibrium of the shell is examined by considering possible neighboring equilibrium states. The loading exerted by the elastic medium on the shell in the deformed state is found by solving an associated boundary value problem of the linearized theory of elasticity in the presence of initial stress. Expressions are derived which give the critical pressure for the cases of a bonded and a smooth interface.

ABSTRACT: This article addresses the issue of buckling failure of shell structures. We argue that a good understanding of the shell behavior near the limit state can and should be addressed through sensitivity analysis, that is, the assessment of the impact of individual input parameters (loads, material constants, geometry) or sets
of input parameters on the failure of the structure. A major challenge in most applications lies in the fact that high computational costs have to be faced. Methods have to be developed that admit assertions about the sensitivity of the output with as few computations as possible. This articles presents a number of sensitivity indices based on Monte Carlo simulation techniques. We developed these methods in a project from aerospace engineering with light weight shell structures. We believe that the methods will be useful in composite laminated structures, where equally high computational costs are the rule. A thorough understanding of the sensitivities of a structure can ultimately serve as a robust basis for design guidelines.

ABSTRACT: This paper is the second part of the structure study of double cylindrical shell subjected to hydrostatic external pressure. The author makes researches on the relationship between inner and outer shells of pressurized double cylinders using equilibrium conditions of forces and deformation compatibility conditions with ring plate orthogonally connected to inner and outer shells and puts forward the expressions of longitudinal and circumferential forces of double pressurized cylinder. In this paper, equilibrium equations are established for a double cylindrical shell stiffened longitudinally and transversely and subjected to uniform hydrostatic external pressure by using an adjacent equilibrium method and a solution with high accuracy is presented to calculate theoretically critical pressures of panel buckling and interframe shell buckling. The solution can be applied to both the double and single cylindrical shells without longitudinal stiffeners and therefore, it may be applied widely with higher accuracy. Also, some simplified formulae for the engineering application are given to calculate the panel buckling and the interframe shell buckling strength.

[6] Baruch M, Singer J. Effect of eccentricity of stiffeners on the general instability of stiffened cylindrical shells under hydrostatic

ABSTRACT: The sensitivity of stiffened conical shells to imperfection is considered, via the initial post-buckling analysis. Unlike stiffened cylindrical shells, in the case of generally stiffened conical shells the stiffeners inclination and the distance between the stiffeners vary with the shell coordinates, which complicates the problem considerably. The main objective of the study is to investigate the influence of the stiffeners on the buckling load and on the imperfection sensitivity. Thus, by finding the parameters that influence the shell’s imperfection sensitivity, it is possible to improve the behavior of the whole structure.

ABSTRACT: A hierarchical high-fidelity analysis procedure is adopted for predicting the critical buckling load of filament wound laminated conical shells. This hierarchical procedure includes three levels of fidelity for the analysis. Level-1 assumes that the shell buckling load can be predicted by using simply supported boundary condition with a linear membrane prebuckling solution. Level-2 includes the effects of a nonlinear prebuckling solution and the effects of different boundary conditions. Level-3 includes the nonlinear interaction between pressure. J Mech Eng Sci 1963;5(1):23–7.
nearly simultaneous buckling modes and the effects of boundary imperfections. For the Level-1 analysis a computer code BOLCS had been developed. BOLCS calculates the buckling load of laminated conical shells by a linear bifurcation analysis. The buckling behavior obtained by BOLCS is compared for various load cases with Level-3 solutions calculated by the two-dimensional nonlinear code STAGS-A. The effects of the assumptions and approximations used for the two solutions are discussed. In addition, the influence of the in-plane boundary condition on the buckling behavior of laminated conical shells under axial compression is investigated. It is found that the in-plane boundary condition at the large end of the shell has a major effect on the buckling behavior.

ABSTRACT: Buckling analysis of laminated conical shells under axial compressive load are investigated analytically using high order and Love’s shell theories. Power series are used to solve the developed equations of motion for conical shells with different semi vertex angles, length-to-radius ratio, number of layers and boundary conditions. The validity of the presented procedure is confirmed.

ABSTRACT: The paper identifies and analyzes the so-called ‘beam’ and ‘shell’ modes of buckling of buried pipelines. Such failures have occurred as a result of compressive loads induced to pipelines by large ground movements in seismically active areas. In the beam mode of buckling, the pipeline tears through the ground and lifts off in a characteristic Ω configuration. The shell mode of buckling is a more localized failure characteristic of shell type structures. The two types of instability are simulated numerically using appropriate nonlinear kinematics, inelastic material behaviour and approximate modelling of the soil-structure interaction mechanisms. Parametric sensitivity studies are presented. It is demonstrated that initial geometric imperfections can strongly influence the critical loads and strains of both types of instability. Conditions under which the two modes of buckling interact are also discussed.

ABSTRACT: The buckling of buried pipeline induced by compressive ground failure was investigated. Both the beam mode of buckling and local shell mode of buckling, and their interactions were studied. The pipeline response was analyzed numerically. The results agree qualitatively with past researches and possess satisfactory comparisons with actual case histories. The relations of critical buried depth versus ratio of pipe diameter to thickness for buried pipe with different imperfections and various soil foundations were established.

ABSTRACT: This two-part series of papers is concerned with the response and various instabilities which govern the behavior of circular cylindrical shells under pure bending. Part I describes the experimental part of the study and Part II presents the numerical simulation of the various phenomena observed experimentally. Experiments were conducted on long aluminum 6061-T6 shells with II different diameter-to-thickness ratios ranging from 60.5 to 19.5. For such geometries, the structural response and inherent instabilities are strongly influenced by the plastic characteristics of the material. Thinner shells were found to develop short wavelength periodic ripples on the compressed side of the shell. The shells buckled locally and collapsed soon after the appearance of the ripples. Thicker shells were found to exhibit a limit load instability as a direct consequence of the ovalization of the shell cross-section caused by bending. Following the limit load, the ovalization was found to localize, leading to the eventual collapse of the shells. For shells with intermediate D/t values, short wavelength ripples developed at the same time as localization of ovalization was recorded. The shells buckled locally and catastrophically following the development of a limit load.

ABSTRACT: The second part of this study is concerned with the prediction of the response and various instabilities found in Part I to govern the elastic-plastic flexure of circular cylindrical shells. Sanders' shell kinematics and the principle of virtual work were used to formulate the problem. A Rayleigh-Ritz procedure was used to discretize the problem. The resultant non-linear equations were solved iteratively using Newton's method. The three types of behavior involving bifurcation into short wavelength ripples, localization following the attainment of a natural limit load and interaction of the two were studied. In each case the predicted response was found to be in very good agreement with the experimental result.

ABSTRACT: It is well known that long cylindrical shells used in many practical applications involving external pressure loading collapse catastrophically due to a limit load instability. The limit load is due to interaction between geometric nonlinearities and material nonlinearities due to plasticity. This paper addresses the mechanism of collapse triggered by the limit load instability. It is found that following the limit load the collapse quickly localizes to a section of the shell a few diameters long. The deformations and stresses in the region of localization grow with a decreasing overall pressure whereas the rest of the structure remains intact and retains only a small residual effect from the limit load instability as it unloads. However, under favorable conditions the localized collapse triggers an instability which propagates along the length of the shell and has the potential of catastrophically collapsing the whole structure. The characteristics of the localization are studied parametrically through experiment and analysis.

ABSTRACT: Moderately thick circular tubes under compression crush progressively by axisymmetric folding. The paper presents a combined experimental analytical study of the onset of collapse, its localization and the subsequent progressive folding. Results from four displacement control led crushing experiments are presented on tubes of various radius-to-thickness ratios made of different metal alloys. The experimental results include the crushing response, careful measurements of the geometric characteristics of the folds and the mechanical properties of the alloys. A finite element model of the crushing process has been developed and results from simulations are directly compared with the experiments. The model is found to reproduce the crushing response to a significant degree of accuracy. The mean crushing load is essentially the same as in the experiments; the calculated wavelength of the folds are within a few percent from measured values as are other geometric variables considered. Thus, the crushing energy per unit length of tube is predicted to a very good accuracy. In addition, the model was used to demonstrate that changes in the loading cycles which take place as the number of folds increases, are due to small differences between the inner and outer folds which in turn affect the self contact of the fold walls. Three simpler models taken from the literature in which steady-state folding is modeled by kinematically admissible collapse mechanisms are critically reviewed by comparing predictions of key variables to measured values.

ABSTRACT: Elastic buckling of cylindrical shells due to axial compression results in sudden and catastrophic failure. By contrast, for thicker shells that buckle in the plastic range, failure is preceded by a cascade of events, where the first instability and failure can be separated by strains of 1–5%. The first instability is uniform
axisymmetric wrinkling that is typically treated as a plastic bifurcation. The wrinkle amplitude gradually grows and, in the process, reduces the axial rigidity of the shell. This eventually leads to a limit load instability, beyond which the cylinder fails by localized collapse. For some combinations of geometric and material characteristics, this limit load can be preceded by a second bifurcation that involves a non-axisymmetric mode of deformation. Again, this buckling mode localizes resulting in failure. The problem is revisited using a combination of experiments and analysis. In Part I, we present the results of an experimental study involving stainless steel specimens with diameter-to-thickness ratios between 23 and 52. Fifteen specimens were designed and machined to achieve uniform loading conditions in the test section. They were subsequently compressed to failure under displacement control. Along the way, the evolution of wrinkles was monitored using a special surface-scanning device. Bifurcation buckling based on the J2 deformation theory of plasticity was used to establish the onset of wrinkling. Comparison of measured and calculated results revealed that the wrinkle wavelength was significantly overpredicted. The cause of the discrepancy is shown to be anisotropy present in the tubes used. Modeling of the postbuckling response and the prediction of the limit load instability follows in Part II.

ABSTRACT: In the second part of this study, the evolution of uniform axisymmetric wrinkling in axially compressed cylinders is modeled using the principle of virtual work. A version of this formulation also allows localization of wrinkling. The model domain is assigned an initial axisymmetric imperfection of a chosen amplitude and the wavelength yielded by the first bifurcation check. The solution correctly simulates the growth of wrinkles and results in a limit load instability. The limit strain is influenced by the amplitude of the imperfection. Beyond the limit load, wrinkling tends to localize, eventually leading to local folding. The possibility of bifurcation of the axisymmetric solution to non-axisymmetric buckling modes is examined by using a dedicated bifurcation check. The bifurcation check was found to yield such buckling modes correctly. The evolution of such buckling modes is simulated by a separate non-axisymmetric model assigned imperfections with axisymmetric and nonaxisymmetric components. The domain analyzed is one characteristic wavelength long (2°C). Initially, compression activates mainly axisymmetric deformation. In the neighborhood of the bifurcation point, non-axisymmetric deformation starts to develop, eventually leading to a limit load instability. Experimental responses were simulated with accuracy by assigning appropriate values to the two imperfection amplitudes. Prediction of the limit strains for the whole range of diameter-to-thickness ratios (D/t) considered in the experiments was achieved by making the amplitude of the non-axisymmetric imperfection proportional to (D/t)2/m3 (m is the circumferential wavenumber). Matching all aspects of the experiments required inclusion of the anisotropy measured in the tubes tested through Hill's yield criterion in all models.

ABSTRACT: Long cylindrical tubes and pipes under axial compression will usually bend, behaving as beam columns. Shell-type localized buckling occurs mainly when the structure is restrained from lateral movement.
This, for example, is the case for a pipeline buried in a trench or resting on a deformable foundation. Compression can be caused by the passage of hot hydrocarbons carried from the well to a central gathering point by buried flowlines in offshore operations. Foundation motion caused by fault movement, landslides, ground subsidence, permafrost melting, or soil liquefaction can also result in severe compression of the lines. Both loading scenarios can impose compressive strains high enough to result in shell type buckling…

ABSTRACT: In the present paper the behaviour of cylindrical elastic tubes under pure bending is discussed. This behaviour is characterised by a smooth global maximum on the load-deflection curve which is due to the well-known von Kármán effect, that is to the progressive flattening of the cross section of the tube under bending moment. However, during the loading process another type of failure may also occur before the limit load is reached, that is, at a certain stage the compressed region of the bent tube wrinkles axially and can give origin to a localised instability. Even if these phenomena have been extensively investigated in many classical works, nevertheless the analysis of experimental data shows that there are still some points which seem to be worthy of further considerations, especially from an engineering standpoint and for design purposes. To this aim, a straightforward treatment of the problem is presented which can be employed to give clear reason for several experimental findings by means of plain expressions and with a clear physical meaning. Finally, the results are compared to those obtained by means of a commercially available non-linear finite element code.

ABSTRACT: This paper discusses the dynamic pre-buckling of finite cylindrical shells in the propagation and reflection of axial stress waves. By introducing the Hamiltonian system into dynamic buckling of structures, the problem can be described mathematically in a symplectic space. The solutions of Hamiltonian dual equations shown in canonical variables are obtained. The problem is reduced to the determination of eigenvalues and eigensolutions, with the former indicating critical buckling loads and the latter buckling modes. Numerical example presented shows phenomena of axisymmetric and non-axisymmetric dynamic buckling subject to impacts of axial load.

ABSTRACT: This paper investigates the prebuckling dynamics of transversely isotropic thin cylinder shells in the context of propagation and reflection of axial stress waves. By constructing the Hamiltonian system of the governing equation, the symplectic eigenvalues and eigenfunctions are obtained directly and rationally without the need for any trial shape functions, such as the classical semi-inverse method. The critical loads and buckling models are reduced to the problem of eigenvalues and eigensolutions, in which zero-eigenvalue solutions and nonzero-eigenvalue solutions correspond to axisymmetric buckling and nonaxisymmetric buckling, respectively. Numerical results reveal that energy is concentrated at the unconstrained free ends of the shell and the buckling modes have bigger bell-mouthed shapes at these positions.

ABSTRACT: In this paper, the local and global buckling of cylindrical shells under axial, compressive impact loads is studied. A Hamiltonian system is introduced in the problem. The fundamental problem in the system can be described mathematically by the Hamiltonian dual equations, which are expressed in four pairs of dual variables. The problem is reduced to a problem of eigenvalues and eigensolutions for critical loads and buckling modes, respectively. The buckling modes can be described by their respective orders and they are grouped into two classes, the short-wave or local buckling and the long-wave or global buckling. The solutions are obtained analytically and numerically, and some rules observed are indicated.

ABSTRACT: The paper deals with the thermal buckling of cylindrical shells in a uniform temperature field based on the Hamiltonian principle in a symplectic space. In the system, the buckling problem is reduced to an eigenvalue problem which corresponds to the critical temperatures and buckling modes. Unlike the classical approach where a predetermined trial shape function satisfying the geometric boundary conditions is required at the outset, the symplectic eigenvalue approach is completely rational where solutions satisfying both geometric and natural boundary conditions are solved with complete reasoning. The results reveal distinct axisymmetric buckling and nonaxisymmetric buckling modes under thermal loads. Besides, the influence for different boundary conditions is discussed.

Symplectic Methods in Dynamic and Thermal Buckling of Elastic Cylindrical Shells
Pubdate:2009-12-28 (no publisher, no author given. Found in “Latest-Science-Articles”)  
ABSTRACT: The stability of structure is an important research subject in modern solid mechanics and much attention has been focused on the problem in industry equipments. Since cylindrical shell is a basic structure, its buckling problems play an important role in the theories of structural stability. Many researches have been carried out and great progress has been made in solving many practical problems. Some phenomena which deal with local buckling of a cylindrical shell in experiments are reported. To explain these, it is necessary to consider basic theories and a new method is needed. It is well known that an object can be impacted or heated. The buckling phenomena of a cylindrical shell subjected to an impact load or a thermal load are not the same because of their different characters. When a shell is impacted, the internal forces caused by the impact will be propagated and reflected in a stress wave form. Because stress waves are affected locally, the shell will be overall bucked and accompanied with local wrinkles, if both loads are applied. High-order partial differential equations often occur when one solves problems which deal with pre-buckling of a cylindrical shell. Sometimes traditional separation of variables is not work anymore if the problem is presented in a Lagrangian system. When this happens, it is necessary to introduce a new system. This paper deals with pre-buckling of a shell
subjected to thermal load, impact load or coupling load. By introducing a Hamiltonian function, the Hamiltonian system for the problem is established. This means that the transformation from a Lagrangian system to a Hamiltonian system is finished. In a symplectic space, eigenvalues and eigenfunctions take the place of the critical buckling loads and buckling modes of the problem. The zero-eigenvalues describe axisymmetric buckling and non-zero eigenvalues mean non-axisymmetric bucking. In pre-buckling problems, small deformation theories are used, while larger deformation theories are applied in solving post-buckling problems. Based on the complete solutions obtained in the pre-buckling problems, a symplectic eigenfunction expansion method is developed and the whole progress from prebuckling to postbuckling are described. A new method for solving such nonlinear problems is presented. Stress waves play an important role in the local buckling of a shell when the waves propagate, reflect and transmit in the shell. After studying these effects, critical loads and buckling modes of a shell subjected to impact loads, thermal loads and coupling loads with different boundary conditions are presented. Numerical results show that when a shell is impacted, local buckling is unavoidable due to the local effects of the stress waves. There will be overall buckling if a shell is heated. When a shell is impacted, a big open is tend to occur at the impact end in the beginning and when the stress waves are reflected, the big open may appear at the reflect end. If a pulse is imposed, a bamboo-node type will come up in the middle of the shell. The pulse usually is produced by the propagation, reflection and transmission of the stress waves in the bullet. In fact, local buckling of a shell is a type of energy concentration in the shell. It can be concluded that local buckling in a shell are mainly caused by the propagation, reflection and transmission of stress waves. Local buckling have something to do with not only the physical properties of the shell but also its geometric feature parameters. The length of a pulse and the wave impedance are of major significance on a bamboo node-type. In post-buckling problems, an initial mode which is in the form of prebuckling solutions is adopted, and the effects of the initial mode to the post-buckling are discussed in three ways, that is, its amplitudes, circular orders and axial branches. It is found that the shell is not sensitive to the initial mode. In post-buckling process, a thinner shell is inclined to a higher circular order and a longer shell tends to a higher axial order. These provide important rules for structure stability design in engineering.

ABSTRACT: Based on Hamilton's principle, a new accurate solution methodology is developed to study the torsional bifurcation buckling of functionally graded cylindrical shells in a thermal environment. The effective properties of functionally graded materials (FGMs) are assumed to be functions of the ambient temperature as well as the thickness coordinate of the shell. By applying Donnell's shell theory, the lower-order Hamiltonian canonical equations are established, from which the eigenvalues and eigenvectors are solved as the critical loads and buckling modes of the shell of concern, respectively. The effects of various aspects, including the combined in-plane and transverse boundary conditions, dimensionless geometric parameters, FGM parameters and changing thermal surroundings, are discussed in detail. The results reveal that the in-plane axial edge supports do have a certain influence on the buckling loads. On the other hand, the transverse boundary conditions only affect extremely short shells. With increasing thermal loads, the material volume fraction has a different influence on the critical stresses. It is concluded that the optimized FGM mixtures to withstand thermal torsional buckling are Si3N4/SUS304 and Al2O3/SUS304 among the materials studied in this paper.

ABSTRACT: This article focuses on analytical solutions for bifurcation buckling of FGM cylindrical shells under thermal and compressive loads. A new solution methodology is established based on Hamilton's principle. The fundamental problem is subsequently transformed into the solutions of symplectic eigenvalues and eigenvectors, respectively. Then, by applying a unidirectional Galerkin method, imperfection sensitivity of an imperfect FGM cylindrical shell is discussed in detail. The solutions reveal that boundary conditions, volume fraction exponent, FGM properties, and temperature rise distribution significantly influence the buckling behavior. Critical stresses are reduced greatly due to the existence of initial geometric imperfections.

ABSTRACT: In this article, the elastic buckling behavior of cylindrical shells under external pressure is studied by using a symplectic method. Based on Donnell’s shell theory, the governing equations which are expressed in stress function and radial displacement are re-arranged into the Hamiltonian canonical equations. The critical loads and buckling modes are reduced to solving for symplectic eigenvalues and eigenvectors. The buckling solutions are mainly grouped into four categories according to the natures of the buckling modes. The effects of geometrical parameters and boundary conditions on the buckling loads and modes are examined in detail.

ABSTRACT: The effect of two localized axisymmetric initial imperfections on the critical load of elastic cylindrical shells subjected to axial compression is studied through finite element modelling. This was carried out by means of the specialized shell buckling package Stanlax. First, a single defect having a triangular geometry is considered in order to determine the most adverse defect configuration, then two defects having this arrangement and which are symmetrically distributed along the shell length are introduced in the problem in order to assess their global interacting effect on the buckling load reduction. A statistical approach which is based on full factorial design of experiment tables and analysis of variance is used to quantify the relative influence of all the intervening factors. It is shown that two interacting defects yield further reduction of the shell critical load.

ABSTRACT: The creep buckling behavior of a geometrically imperfect complete spherical shell subjected to a uniform external pressure is examined using Sanders' equilibrium and kinematic equations appropriately modified to include the influence of initial stress-free imperfections in the radius. The Norton-Bailey constitutive equations are used to describe the secondary creep behavior and elastic effects are retained. The initial imperfections have the same shape as the classical axisymmetric elastic buckling mode and the initial elastic response is obtained analytically for external pressures smaller than the corresponding static collapse pressure. Numerical finite-difference procedures are used to obtain the axisymmetrical creep buckling behavior and to determine when a bifurcation or loss of uniqueness into a non-axisymmetric deformation state occurs. The numerical results for the creep buckling behavior of complete spherical shells are similar for hydrostatic and deadweight-type external pressures, at least for the particular parameters examined herein, and demonstrate that initial imperfections exercise an important influence on the critical times. It turns out from a practical viewpoint that axisymmetric creep buckling governs the behavior of the spherical shells examined in this article. It was observed from the present results that the creep buckling times of externally pressurised complete spherical shells are longer than those for “equivalent” axially loaded cylindrical shells.

ABSTRACT: A perturbation method of analysis has been used to examine the dynamic plastic buckling of a stringer-stiffened cylindrical shell subjected to an axial impact. It transpires that it is more efficient to place stiffeners on the outer shell surface rather than on the inner surface. Various results are presented to demonstrate the influence of the second moment of area, eccentricity, cross-sectional area and number of stiffeners on the dynamic plastic response.

ABSTRACT: The dynamic elastic buckling behavior of a geometrically imperfect complete spherical shell that is subjected to a uniform external step pressure is examined using Sander's equilibrium and kinematic equations, appropriately modified to include the influence of inertia forces and initial stress-free imperfections.
in the radius. A finite-difference procedure with either the Houbolt or Park methods of time integration is used to predict the axisymmetric dynamic elastic buckling pressures and associated critical mode numbers. The dynamic buckling pressure is significantly smaller than the corresponding static value for small initial imperfections, but is less imperfection.

ABSTRACT: The dynamic axisymmetrical behaviour of a perfect complete spherical shell made from a bilinear or work hardening material and subjected to a uniform external step pressure loading is investigated. A perturbation method of analysis leads to a Mathieu equation which gives the dynamic buckling pressure and associated mode for a complete spherical shell. The influence of the plastic parameter and damping on the dynamic buckling pressure and mode number are also discussed.

ABSTRACT: Eighty-four dynamic tests on thin-walled square steel tubes having two different cross-sections with c/h = 30.25 and c/h = 32.18 and various lengths were crushed axially on a drop hammer rig. Approximate theoretical predictions were developed for the axial progressive crushing of square box columns using a kinematically admissible method of analysis. This theoretical study predicts four deformation modes which govern the behaviour for different ranges of the parameter c/h. New asymmetric deformation modes were predicted theoretically and confirmed in the experimental tests. These asymmetric modes cause an inclination of a column which could lead to collapse in the sense of Euler even for relatively short columns. The effective crushing distance is considered in the approximate theoretical analysis together with the influence of material strain rate sensitivity, which is important for steel even when the loadings are quasi-static. The simple equations presented herein for the design of axially crushed square box columns give reasonable agreement with the corresponding experimental results.

ABSTRACT: A series of axial crushing tests on steel circular cylindrical shells loaded either statically or dynamically is reported and compared with various theoretical predictions and empirical relations. A modified version of Alexander's theoretical analysis for axisymmetric, or concertina, deformations gives good agreement with the experimental results when the effective crushing distance is considered and provided that the influence of material strain rate sensitivity is retained in the dynamic crushing case.

ABSTRACT: A series of over 120 axial crushing tests were conducted on circular and square steel tubes loaded either statically or dynamically. Approximate theoretical predictions for static and dynamic progressive buckling are developed. Fair agreement with the experimental results is achieved provided the effective crushing distance is taken into account and the influence of material strain rate sensitivity is retained for dynamic loads.

ABSTRACT: The equilibrium equations for elastic circular arches are established using the principle of virtual work. The nonlinear partial differential equations of motion are solved using a finite difference method (Park's method for time difference). The dynamic stability of a hinged and a clamped elastic circular arch with a uniform step load is analysed with finite deformations and initial geometric imperfections. Results show that the buckling mode varies with the value of the arch half angle, theta0. The boundary condition and initial imperfection amplitude also affect the buckling mode. A nearly perfect arch usually buckling with a “direct” buckling form, while an imperfect arch with an “indirect” buckling form. The effect of theta0 on the ratio pd/ps (pd is the dynamic critical load and ps the static critical load) is shown for different initial imperfections and different boundary conditions.

ABSTRACT: The axial impact of cylindrical tubes, which incorporate axial stiffeners, is examined in this paper. For comparison purposes, the effect of static loading is also studied. An examination is made into the influence of stiffener depth (T), number of stiffeners (N) and the effect of placing the stiffeners externally or internally. The experimental results on mild steel specimens show that there are considerable differences between the static and dynamic modes of failure, and that an optimum T/D ratio may exist for a given value of N.

ABSTRACT: The structural members examined in the previous chapters responded in a stable manner when subjected to dynamic loads. However, in practice, dynamic loads may cause an unstable response. This chapter examines the dynamic progressive buckling phenomenon [4.1], which is illustrated in figure 4.1 for a circular tube.

ABSTRACT: The use of a simple imperfection-sensitive elastic-plastic model for studying the non-linear buckling of short columns and cylindrical shells under dynamic axial compression is discussed in this paper. The axial impact loading of the model by a mass with an initial velocity is considered as a particular example. The critical impact velocities are determined for wholly elastic and elastic-plastic materials with linear strain hardening characteristics. The results show that the maximum initial kinetic energy at the transition between stable and unstable behaviour after impact is sensitive to the magnitude of the material strain hardening
parameter. It is also evident from the results that impact due to larger masses leads to larger lateral displacements at buckling and that the instability of a column is more sensitive to the presence of initial imperfections at higher impact velocities. Some guidance is offered on the choice of the various parameters in the idealized model for the analysis of practical engineering structures.

ABSTRACT: The present study is concerned with the dynamic anomalous response of an elastic-plastic column struck axially by a mass $m$ with an initial velocity $v_0$. This simple example is considered in order to clarify the influence of the impact characteristics and the material plastic properties on the dynamic buckling phenomenon and particularly on the final vibration amplitudes of the column when it shakes down to a wholly elastic behaviour. The material is assumed to have a linear strain hardening with a plastic reloading allowed. These material properties are the reason a number of elastic-plastic cycles to be realized prior to any wholly elastic stable behaviour, which causes different amounts of energy to be absorbed due to the plastic deformations. The column exhibits two types of behaviour over the range of the impact masses — a quasi-periodic and a chaotic response. The chaotic behaviour is caused by the multiple equilibrium states of the column when any small changes in the loading parameters cause small changes in the plastic strains which result in large changes in the response behaviour. The two types of behaviour are represented by displacement-time and phase-plane diagrams. The sensitivity to the load parameters is illustrated by the calculation of a Lyapunov-like exponent. Poincaré maps are shown for three particular cases.

“Strain-rate effects in the dynamic buckling of a simple elastic-plastic model”, Journal of Applied Mechanics, 03/1997, Vol. 64, No. 1, DOI: 10.1115/1.2787272

ABSTRACT: The phenomenon of dynamic buckling is examined when the influence of material strain-rate sensitivity is retained in the basic equations for a simple elastic-plastic model with linear strain hardening when subjected to an impact by a mass. Two approaches are proposed for taking into account the material strain-rate effects and both use the Cowper-Symonds constitutive equation. The critical impact velocities depend on the impact mass and are determined for a wholly elastic material, a strain-rate insensitive elastic-plastic material and an elastic-plastic material with a dynamic yield force together with linear or nonlinear hardening due to the strain-rate effects. The results obtained show that both strain-rate sensitive models predict impact velocities which are higher than those predicted by the strain-rate insensitive idealization and that the influence of any initial imperfections is important for the three material models considered.

PARTIAL ABSTRACT: Dynamic axisymmetric buckling of cylindrical shells, loaded dynamically by a Kolsky bar, is studied in order to analyse the influence of stress wave propagation on the initiation of buckling. The considered specimens are made of an aluminium alloy which has linear strain hardening and displays the Bauschinger effect. The acceleration wave speeds are obtained assuming the Tresca yield criterion. The deformation process is analysed by a numerical simulation using a discrete model for the shell and the theoretical predictions are compared with some published experimental data. It is shown that the different modes of...

ABSTRACT: Dynamic axisymmetric buckling of circular cylindrical shells struck axially by a mass is studied in order to clarify the initiation of buckling and to provide some insight into the buckling mechanism as a transient process. It is assumed that the material is elastic–plastic with linear strain hardening and displaying the Bauschinger effect. The deformation process is analysed by a numerical simulation using a discrete model. Particular attention is paid to the influence of stress wave propagation on the initiation of buckling. It is found that the development of the buckling shape depends strongly on the inertia properties of the striker and on the geometry of the shell. The theoretical method is used to clarify some experimental data and good agreement is obtained with results on aluminium alloy tubes.

ABSTRACT: The axisymmetric buckling of elastic–plastic cylindrical shells subjected to axial impact are studied using a finite element analysis. This study reveals that shells, subjected to axial impact, are both velocity and mass sensitive, so that larger energies can be absorbed by a shell for high-velocity impacts when decreasing the striking mass. It is shown that the inertia characteristics of the shell, together with the material properties, determine particular patterns of the axial stress wave propagation, thus, causing either dynamic plastic or dynamic progressive buckling to develop during the initial phase of the shell response. Domains of the load parameters, where the different buckling phenomena develop, are obtained for two particular shells. Strain rate effects are also considered when discussing the energy absorbing properties of the shells.

ABSTRACT: The crushing behaviour of aluminium and steel cylindrical shells, when subjected to an axial impact, is examined using a numerical simulation. The influence of the material properties, shell geometry, boundary conditions and loading techniques on the energy absorbed and the buckling shapes is explored. Various shell response characteristics, such as the peak load, fold lengths, axial compression and energy absorption are studied. An examination is also made of the influence of filtering on the accuracy of data obtained usually in dynamic tests.

ABSTRACT: A new concept is presented for the dynamic elastic–plastic axisymmetric buckling of circular cylindrical shells under axial impact. The phenomena of dynamic plastic buckling (when the entire length of the shell wrinkles before the development of large radial displacements) and dynamic progressive buckling (when the shell folds form sequentially) are analysed from the viewpoint of stress wave propagation resulting from an axial impact. The conditions for the development of dynamic plastic buckling are obtained. A numerical analysis of the buckling phenomena reveals that the material properties together with the geometrical characteristics of the shell determine the particular type of response for high velocity impacts. It is concluded
that shells made of strain rate insensitive materials can respond either by dynamic plastic buckling or dynamic progressive buckling, depending on the inertia properties of the shell, while those shells made of strain rate sensitive materials respond always by dynamic progressive buckling. It is shown that the prediction for the peak load, which can develop in a shell for a high velocity impact, depends on the particular yield criterion used in the analysis.

ABSTRACT: Some characteristic features of the dynamic inelastic buckling behaviour of cylindrical shells subjected to axial impact loads are discussed. It is shown that the material properties and their approximations in the plastic range influence the initial instability pattern and the final buckling shape of a shell having a given geometry. The phenomena of dynamic plastic buckling (when the entire length of a cylindrical shell wrinkles before the development of large radial displacements) and dynamic progressive buckling (when the folds in a cylindrical shell form sequentially) are analysed from the viewpoint of stress wave propagation resulting from an axial impact. It is shown that a high velocity impact causes an instantaneously applied load, with a maximum value at t=0 and whether or not this load causes an inelastic collapse depends on the magnitude of the initial kinetic energy.

ABSTRACT: This article discusses the dynamic plastic instability of various basic structural members, subjected to large axial impact loads, which is relevant to the fields of structural impact and structural crashworthiness. In particular, studies on the dynamic axial response of idealised elastic–plastic models, rods, cylindrical shells and square tubes, is discussed in some detail. The analyses for some of the rods, shells and tubes retain the simultaneous influence of elastic and plastic stress waves (axial inertia) and the structural response (lateral inertia). The predictions reveal the profound influence of stress wave propagation phenomena which explain the characteristics of many of the experimental results obtained in laboratories over the years. These more complete analyses are vital for the higher velocity impact scenarios encountered increasingly in designs and for comparing properly the relative merits of different ductile materials in potential energy absorbing systems.

“Counterintuitive response of long circular tubes to axial impact”, XXI ICTAM, 15-21 August 2004, Warsaw, Poland
Summary: The dynamic transition from progressive buckling to global bending collapse of a long circular tube under an axial impact is studied in order to obtain the energy absorption characteristics. The developed theoretical modes are used to analyse the influence of various parameters on the buckling transition. The analysis reveals a specific impact velocity, which causes a counterintuitive response of a tube. An empirical criterion for the lower and upper bounds to the critical lengths for buckling transition is proposed.

ABSTRACT: This paper deals with the evaluation of the crashworthiness of thin-walled sandwich box structures for automotive applications. Quasi-static crushing simulations are carried out to estimate the energy absorption of prismatic box columns made from sandwich sheets. The sandwich sheets have perforated cores of different densities with staggered holes perpendicular to the panel faces. It is found that the specific energy absorption of columns made of sandwich sheets is approximately the same as that of conventional columns composed of homogeneous sheets of the same total wall thickness. Furthermore, theoretical analysis indicates that by increasing the core thickness, sandwich structures could be up to 50% lighter while providing the same mean crushing force. However, these gains may not be achieved in practical applications since increasing the core thickness also increases the likelihood of premature face sheet fracture during crushing.

Vivek B. Mariyanna (Department of Mechanical Engineering, College of Engineering, Wichita State University, Wichita, Kansas, USA), “Energy absorption characteristics of stitched corrugated sandwich panels”, Master’s Thesis, December 2005, URI: http://hdl.handle.net/10057/762
ABSTRACT: The tailorable of composite sandwich structure with their strength-to-weight ratio interests in all field of crashworthiness application. An investigation of sandwich structure under static and high speed condition will provide useful information for wide variety of applications. In this present thesis, the characteristics of stitched corrugated sandwich panels as an energy absorption mechanism are evaluated, using
experimental and numerical methods. Edgewise compression tests under static and dynamic loading conditions are performed on unstitched and stitched corrugated sandwich specimens made of glass/epoxy face sheets and polyurethane foam core. Parameters affecting the instability of specimens under compressive edge loads are studied for different ply orientations, corrugation wavelengths, and ply material. The local buckling phenomena are then characterized for a particular corrugation configuration. The parametric studies of this thesis using experimental methods indicate a strong dependence of the different instability modes on the stitch configuration and the test rate on the sandwich panels.

ABSTRACT: Energy absorbers are used to reduce accident induced damages. Thin-walled energy absorbers are widely used in modern industries due to their high efficiency and ease of manufacturing. In this study, thin-walled stainless steel structures in quasi-hemisphere geometry were subjected under quasi-static loading using Santam 150KN apparatus. Experimental results were compared with the results of numerical simulations by LSDYNA and it was shown that there is a good agreement between experimental and numerical results. Two different collapse types in radial and circumferential directions were observed. Also, the multi-cell quasi-hemisphere specimens from 3 to 6 cells were numerically investigated and it is observed that increasing the number of cells increases the absorbed energy. Increasing the thickness of the quasi-hemisphere sample in smaller diameter specimens is more effective. The results showed that Six-cell specimen with the largest diameter and the minimum thickness has the most increase of Specific Absorbed Energy (SAE) with respect to simple section.

In this paper, the effects of tapering and introducing axisymmetric indentations on the crash performances of thin-walled tubes are investigated. The crash performances of the tubes are evaluated using two metrics: the crush force efficiency (CFE, the ratio of the average crushing load to the peak load), and the specific energy absorption (SEA, absorbed energy per unit mass). The optimum values of the number of the axisymmetric indentations, the radius of the indentations, the taper angle and the tube thickness are sought for maximum CFE and maximum SEA using surrogate based optimization. In addition, multi-objective optimization of the tubes is performed by maximizing a composite objective function that provides a compromise between CFE and SEA. The CFE and SEA values at the training points of surrogate models (metamodels) are computed using the finite element analysis code LS-DYNA. Polynomial response surfaces, radial basis functions, and Kriging are the different surrogate models used in this study. Surrogate based
optimization of the tubes showed that the tubes with indentations have better crush performance than tubes without indentations. It is found that maximum CFE requires large number of indentations with high radius, small thickness, and medium taper angle, while maximum SEA requires small number of indentations with low radius, large thickness and small taper angle. It is also found that the globally most accurate surrogate model does not necessarily lead to the optimum.

Shujuan Hou, Xu Han, Guangyong Sun, Shuyao Long, Wei Li, Xujing Yang and Qing Li, “Multiobjective optimization for tapered circular tubes”, Thin-Walled Structures, Vol. 49, No 7, pp 855-863, July 2011
ABSTRACT: As more and more new functional requirements are placed, some novel development of sectional configurations of the structural members has been increasingly introduced. This paper presents the optimal design for tapered tubes of three different configurations, namely hollow single, foam-filled single and collinear double tubes. To represent complex crashworthiness objective functions, a surrogate model method, more specifically, response surface method (RSM), was adopted in this study. The design of experiments (DoEs) of the factorial design and Latin Hypercube Sampling techniques is employed to construct the response surface models of specific energy absorption (SEA) and the maximum impact load (MaxL), respectively. In this paper, the linearly weighted average, geometrical average and particle swarm optimization methods are utilized in the multiobjective optimization for these three different tapered tube cases, respectively. A comparison is made among the different tapered profiles with the different optimization algorithms, and the crashworthiness merits of foam-filled tapered tubes are identified

ABSTRACT: Foam-filled thin-wall structures exhibit significant advantages in light weight and high energy absorption. They have been widely applied in automotive, aerospace, transportation and defense industries. Quasi-static tests were done to investigate the crash behavior of the empty and polyurethane foam-filled end-capped conical tubes. Non-linear dynamic finite element analyses were carried out to simulate the quasi-static tests. The predicted numerical crushing force and fold pattern were found to be in good agreement with the experimental results. The energy absorption capacities of the filled tubes were compared with the empty end-capped conical tubes. The results showed that the energy absorption capability of foam-filled tube is somewhat higher than that of the combined effect of the empty tube and the foam alone. Finally, the crash performance of the empty and foam filled conical and cylindrical tubes were compared. Results from this study can assist aerospace industry to design sounding rocket carrier payload based on foam-filled conical tubes.

ABSTRACT: Open cross-section, thin-walled, cold-formed steel columns have at least three competing buckling modes: local, distortional, and Euler (i.e., flexural or flexural-torsional) buckling. Closed-form prediction of the buckling stress in the local mode, including interaction of the connected elements, and the distortional mode, including consideration of the elastic and geometric stiffness at the web/flange juncture, are provided and shown to agree well with numerical methods. Numerical analyses and experiments indicate postbuckling capacity in the distortional mode is lower than in the local mode. Current North American design specifications for cold-formed steel columns ignore local buckling interaction and do not provide an explicit
check for distortional buckling. Existing experiments on cold-formed channel, zed, and rack columns indicate inconsistency and systematic error in current design methods and provide validation for alternative methods. A new method is proposed for design that explicitly incorporates local, distortional and Euler buckling, does not require calculations of effective width and/or effective properties, gives reliable predictions devoid of systematic error, and provides a means to introduce rational analysis for elastic buckling prediction into the design of thin-walled columns.

DOI: 10.1016/j.tws.2012.07.001

ABSTRACT: In this paper, a summary of the available imperfection measurements for cold-formed steel members is presented. Three methods to simulate imperfection fields are introduced: the first is the classical approach employing a superposition of eigenmode imperfections, but scaled to match peaks in the measured physical measurements. The second is a method based on the multi-dimensional spectral representation method, in which imperfections are considered as a two-dimensional random field and simulations are performed taking a spectra-based approach. The third is a novel combination of modal approaches and spectral representation that directly considers the frequency content of the imperfection field, but employs a spectral representation method driven by the cross-sectional eigenmode shapes to generate the imperfection fields. The effect of these different approaches on the simulated strength and collapse behavior of members is investigated using material and geometric nonlinear finite element collapse modeling. The third imperfection generation method, termed the 1D Modal Spectra Method, provides an intriguing new tool in the simulation of thin-walled members.

Nursafarina, A., Hanizah, A.H., Nurbaiah, M.N. and Clotilda, P. (Faculty of Civil Engineering, Universiti Teknologi Mara Malaysia, 40450 Shah Alam, Selangor, Malaysia), “Buckling profile on thin walled steel columns”, International Conference on Business, Engineering and Industrial Applications (ICBEIA), 2011

ABSTRACT: Thin-walled steel sections are usually fabricated with flat plates which are welded along the connection between the plates. Hence, this process of welding can extremely introduce geometric imperfection and residual stresses which can affect the structural behaviour of a loaded thin walled steel structure. This paper presents an experimental study on the buckling profile of thin-walled steel tube columns due to welding. A measuring of buckling profile has been developed with zigzag method using a Web Deflection Transducer Bar on six thin-walled columns. This investigation consists of two different weld patterns. Three of which are with full weld and the remaining are with intermittent weld. The patterns of buckling profile due to welding were measured and the results are presented in this paper.

ABSTRACT: Based on the compression characteristics of the concrete-filled thin-walled square steel tube short columns, the U-shaped tie bars are designed in this paper. The U-shaped tie bars and steel pipe walls are connected with each other in T-shape in order to enhance the local stability of the walls under pressure. According to the concrete strength C30/C35/C40 and the thickness of the steel plates 1.25mm/1.75mm/2.5mm, 42 short-column specimens are made, and the size of all specimens is 200mm×200mm×690mm. The bearing capacity test is done by the 500-ton electro-hydraulic serve testing machine. The strain of U-shaped tie bar and thin-walled steel are tested, and then the whole curve of compression process is obtained. The results show that the U-shaped tie bar has a very good role in bonding, and has good effects on improving buckling mode and the ductility of the components significantly. Concrete-filled thin-walled square steel tube short column fixed U-shaped tie bar has advantages on stronger post-deformability and more applicable to configuration compared with existing research achievements, and can provide a reference for engineering design.

ABSTRACT: This paper investigates the behaviour of axially loaded stiffened concrete-filled steel composite (CFSC) stub columns using the finite element software LUSAS. Modelling accuracy is established by comparing results of the nonlinear analysis and the experimental test. The CFSC stub columns are extensively developed using different special arrangements, number, spacing, and diameters of bar stiffeners with various steel wall thicknesses, concrete compressive strengths, and steel yield stresses. Their effects on the columns behaviour are examined. Failure modes of the columns are also illustrated. It is concluded that the parameters have considerable effects on the behaviour of the columns. An equation is proposed based on the obtained results to predict the ultimate load capacity of the columns. Results are compared with predicted values by the design code EC4, suggested equation of other researchers, and proposed equation of this study which is concluded that the proposed equation can give closer predictions than the others.

ABSTRACT: For the problem of square concrete-filled steel tube (CFST) under the action of axial pressure, concrete received local compression and buckling occurred in the application of thin-walled steel pipe. Using built-in spiral reinforcement to strengthen the constraints of thin-walled square steel tube to core concrete. And by using ANSYS program established the built-in spiral reinforcement of thin-walled square steel tube concrete composite column 3 d finite element model, and the results show that spiral reinforcement strengthen the
constraint effect, increase the ultimate bearing capacity of the composite columns of square steel tube by 7.41%; And with stiffening rib and rod measures were compared, built-in spiral ripe construction is convenient, easily applied.

ABSTRACT: The transition between global and progressive buckling is explored in this paper for three different open cross-section shells. The shells were simply supported or clamped at the bottom and were submitted to axial quasi-static loads and to the impact of different drop masses. The experiments were complemented by a detailed finite element analysis, which required a quasi-static material characterisation based on tensile and three point bending tests. It was found that buckling transition from a global to a progressive mode cannot be clearly characterised for these open shells by considering only the overall final bucking shape. Using the finite element analysis, a more meaningful parameter to indicate the collapse mode, the specific energy, was calculated, allowing a better distinction among the most crashworthy profiles.

“Impact And Crash Modelling Of Composite Structures: A Challenge For Damage Mechanics”, (publisher and date of publication is not given in the pdf file)

ABSTRACT: The paper describes recent progress on the materials modelling and numerical simulation of the impact and crash response of fibre reinforced composite structures. The work is based on the application of explicit finite element (FE) analysis codes to composite aircraft structures under both low velocity crash and high velocity impact conditions. Detailed results are presented for the crash response of helicopter subfloor box structures using a strain based damage and failure criterion for fabric reinforced composites. In order to obtain better agreement with measured impact response, an improved composites damage mechanics model with damage parameters as internal state variables is presented. Improved models for predicting delamination are also considered and a novel approach is presented in which a composite laminate is modelled numerically by stacked shell elements with contact interfaces whose delamination is controlled by fracture mechanics criteria.

ABSTRACT: The axial crushing and crashing of thin-walled high-strength steel tubes is performed using 3D-shell finite elements and an implicit time integration scheme. The calculated results are compared with published experimental data and results obtained using explicit time integration. The objective is to show that, while for such analyses generally explicit time integration is used, with the current state of the art also an implicit time integration solution should be considered, and such solution approach can provide an effective alternative for a simulation.

[21] Nia AA, Hamedani JH. Comparative analysis of energy absorption and deformations of thin walled tubes with various section
ABSTRACT: Twenty-five quasi-static and forty-three dynamic axial crushing tests have been performed on square and circular stainless steel type 304 specimens in order to investigate the transitions between dynamic progressive buckling and global bending of thin-walled tubes. The columns consisted of three different circular (mean diameter/ thickness, 2R/H = 7.5, 22, 47) and three different square (mean width/ thickness, C/H = 7.7, 24, 42) cross-sections, which are representative of ‘thick’, ‘intermediate’ and ‘thin’ shells, and have a range of different lengths, L, (3.38 < L/2R < 15.45 and 3.37 s L/C < 20.8) that encompass the two failure modes. Standard collapse modes were identified for the structures and the associated energy absorbing characteristics have been examined and compared with previous studies on mild steel tubes. Empirical formulae for the critical slenderness ratios for the transition between modes are suggested and the material properties of the stainless steels obtained by standard static and dynamic tensile tests are also reported.

ABSTRACT: Quasi-static and dynamic axial crushing tests have been performed on circular thin-walled sections made of three materials: 304 stainless steel, aluminium alloy 6063-T6, and mild steel. The tests were arranged to investigate the mode transitions during the impact crushing of thin-walled tubes and the three materials were chosen for their distinctive individual characteristics, such as strain rate sensitive properties, pronounced strain hardening, etc. The stainless steel, aluminium alloy and mild steel shells have moderate diameter-to-thickness ratios, $2R/H$, of 22, 33 and 26, respectively, and were examined over a range of different axial lengths that encompassed both classical progressive buckling and the global bending modes of failure. The tests were conducted at a standardised energy of 9 kJ, approximately, with a few tests repeated at a higher energy of 18 kJ. The shells were impacted at velocities up to 13.4 m/s with masses up to 502 kg. Standard collapse modes developed in the tubes and the associated energy absorbing characteristics have been examined and compared with previous studies on mild steel. Quasi-static and dynamic tensile test results on the materials are also reported and the critical slenderness ratios at the transition between the two principal modes of failure are identified. The effects of strain hardening, strain rate as well as inertia effects due to the individual characteristics of the three materials are explored.

ABSTRACT: An experimental programme is reported which examines the progressive collapse behaviour of some thin-walled closed-section structural sections made from high-strength steels under quasi-static and impact axial loads. A comparison is made with theoretical formulae, which have been used successfully for predicting the behaviour of mild steel thin-walled structures. Ten quasi-static crush tests and 46 impact tests were conducted on spot-welded top-hat and laser-welded square sections. The thin-walled sections were made from two different types of high-strength steel and one mild steel, the mechanical properties of which were determined experimentally from quasi-static and dynamic tensile tests. Although no specific change in the collapse mode was observed, the limited weight-specific energy absorption efficiency of the high-strength steels under dynamic loadings hinders the weight-reduction potential of crashworthy designs. An unexpected difference in the structural effectiveness of spot-welded top-hat sections made from mild steels and high-strength steels was identified, but was not present for similar square sections. This difference further accentuated the loss in the advantage of high-strength steels over mild steels, especially for spot-welded top-hat sections, and led to differences in the agreement between the experimental results and the theoretical predictions.

ABSTRACT: The common features of the deformation of long circular tubes made from different aluminium alloys and subjected to various axial impact loadings are established and used to develop simplified structural models for global bending collapse and progressive buckling. A two-phase deformation model for axially loaded structural elements is proposed, which retains the characteristic features of the initial compression and subsequent bending/buckling phases. It is shown that the velocity histories in the two principal collapse modes of long tubes play an important role for the formation of the particular deformation pattern. The simplified structural models are verified with some numerical finite-element results and their behaviour is shown to be adequate. A parametric analysis of the models is further performed in order to divulge the major factors, which influence the dynamic buckling transition. The analysis reveals that there is a specific impact velocity associated with the particular geometric and material properties of a circular tube, which causes a counterintuitive response. An empirical criterion for the lower and upper bounds to the critical impact velocity for a
buckling transition is proposed. Further, the upper bound to the impact velocity is used to formulate a criterion for the dynamic buckling transition.

“Dynamic crushing of thin-walled spheres: An experimental study”, International Journal of Impact
ABSTRACT: Experimental studies on dynamic behavior of thin-walled spheres and sphere arrays in response to different impact velocity are presented. Ping pong balls are selected to study the collapse of thin-walled spheres. The tests were carried out by a modified Split Hopkinson Pressure Bar (SHPB) test system. The experimental results show that the deformation of thin-walled spherical shells depends on the impact velocity. The dynamic force in the range of small elastic deformation is larger than its quasi-static counterpart, but significantly below the latter after snap-through of the shell. The deformation and buckling mode are sensitive to the loading rate. It is noted that the strain rate effect of the materials and the inertia effect of the shell should be considered in the analysis of the shells response to dynamic loading.

ABSTRACT: Plastic crushing behavior of thin-walled spheres under various loading cases is studied using Finite Element Method. The entire plastic deformation process is tracked during the post-buckling process. The results are compared with the experimental results reported in literature [13], and very good agreements between the numerical simulation and the experimental result are achieved.

ABSTRACT: A theoretical analysis of the observed stable collapse mechanism of thin-walled circular frusta and tubes, crushed under axial static and/or dynamic loading, for calculating crushing loads and the energy absorbed during collapse, is reported. The analysis is based on experimental observations regarding the energy-absorbing collapse mechanisms developed during the crushing process. The proposed theoretical model was experimentally verified and proved to be very efficient for theoretically predicting the energy-absorbing capability of the conical shells.

ABSTRACT: The flexural properties, collapse modes and crushing characteristics of various types of composite sandwich panels – that were candidate materials for the manufacture of the front-end bumper of transportation vehicles – were investigated in a series of three-point bending tests that were performed in accordance with the American Society for Testing and Materials International Standard D790. The tested hybrid composites were constructed trying four types of polymer foam core (more specifically polymethacrylimide foam, cross-linked and linear polyvinyl chloride foam and polyurethane foam) and two types of fibreglass reinforced polyester faceplate laminates made of glass fibre reinforcements impregnated in modified acrylic resin, in eight different material combinations. Two modes of collapse were recorded in the series of flexural tests: the first was foam core shear failure and the second was local indentation collapse mode. The influence of the most important material properties of the faceplate laminates and foam core and the sandwich construction geometry on the flexural response and the crushing characteristics of the tested sandwich panels such as the peak load, crash
energy absorption and collapse modes is extensively analysed. Particular attention is paid to the analysis of the mechanics of progressive deformation and crumpling of the sandwich panels in each of the collapse modes emphasising the mechanisms related to the crash energy absorption during the bending of the sandwich panels.

ABSTRACT: Crashworthy structural elements may be subjected to various types of loading, such as axial or lateral compression and bending; consequently, extensive theoretical and experimental research work has been performed exploring the collapse mechanisms occurred under such loading conditions. However, the designer needs theoretical tools ranging from simple analytical calculations to full finite element analysis using non-linear, large deformation codes. The main objective of this paper is to apply the explicit FE code LS-DYNA through a Grid computing platform in order to simulate the crash behaviour of thin-walled cylindrical steel tubes subjected to three-point bending test in various cases of the position and direction of the imposed load. The simulation has been carried out through the GRIA computing platform that advances the computational performance of the executed tests, and additionally enables the remote and collaborative conduction of the experiments. The results taken from the simulation allow in drawing useful concluding remarks pertaining to the design of the crushing process.

“Finite Element Modeling of Composite Tubular Crash Structures with an Explicit Code”, (no publisher or date given in the pdf file; most recent reference is 2006)

ABSTRACT: As emissions regulations tighten worldwide, automotive manufacturers must look for ways to reduce structural vehicle weight. While employing alloys and exotic metals may provide a degree of weight reduction, a more significant reduction can be achieved through the use of composite materials. Importantly, composites have shown an ability to improve vehicle crashworthiness through higher levels of specific energy absorption and almost ideal crush characteristics. These advantages have not been exploited in mass-produced vehicles, due primarily to the high cost of component manufacture and lack of computational methods for simulation of the crash behavior of such materials. While development of rapid, inexpensive production processes can increase the production volume and reduce cost, manufacturers will still be required to prototype components. The provision of accurate computational models for the failure behavior of composite materials will reduce the demand on manufacturers to prototype designs and ultimately result in structures of higher performance. Herein, a phenomenological Finite Element (FE) modeling methodology is presented, the development of which focused on the accurate consideration of the experimentally observed failure mechanisms typical of the splaying mode of failure. LS-DYNA has been employed to validate a multi-shell model of Continuous Filament Random Mat (CFRM) glass/polyester tubes. This modeling approach utilizes a spotweld approach to modeling delamination with deformable beam elements. Typical constraint-type delamination approaches do not allow shear deformation prior to delamination and result in an inaccurate representation of laminate stiffness. Spotweld validation simulations were performed on 3-point-bend, Double Cantilever Beam (DCB) and End Notch Flexure (ENF) tests with excellent correlation before application in full-tube simulations. Initiation of the splaying mode of failure was accomplished by pre-definition of a debris wedge, the geometry of which was based on micrograph images of the experimental crush zone. Additionally, the methodology was
applied to simulations of plug initiator tube crush experiments and the results are presented. In general, the load-displacement correlation of full-tube simulations is poor demonstrating the difficulty with representing the continuous fracture and delamination processes with discrete elements. Future work will be aimed at improving the simulated delamination behavior to enhance the observed failure mechanisms.

ABSTRACT: Non-linear finite element software LS-DYNA is used to analyze the axial compression behavior and energy absorption of a high-strength thin-walled member under an impact load. To elucidate the effect of dynamic impact on the strain rate, the Cowper–Symonds equation is applied to analyze the plastic state of stress and the onset of dynamic yielding under different strain rates, such that the modeled deformation behavior of the member is consistent with the actual situation. Results for the thin-walled members made of mild steel and dual phase steel are compared. Assuming two different materials with equal sectional areas, an analysis confirms that the energy absorption of high-strength thin-walled component is better than the mild steel thin-walled component. Hence, thin-walled tubes made of high-strength steel are investigated using a series of analysis. The relationships between displacement and load, average load and energy absorption properties are obtained.

ABSTRACT: Light weight thin walled cylindrical shells subjected to external loads are prone to buckling rather than strength failure. In this paper, buckling investigation of thin walled cylindrical shells under axial compression is presented. Buckling failure is studied using analytical, numerical and semi empirical models. Analytical model is developed using Classical Shell small deflection theory. A Semi empirical model is obtained by employing experimental correction factors based on the available test data to the theoretical model. A finite elements model is built using ANSYS FEA Code for the same shell. Finally, the different results obtained using the three analysis methods are compared. The comparison reveals that analytical and numerical linear model results match closely with each other but are higher than the empirical values. To investigate this discrepancy, non linear buckling analysis with large deflection effect, is carried out. The effect of geometric imperfection is also studied through a nonlinear model. These nonlinear analyses show that the effects of nonlinearity and geometric imperfections are responsible for the difference between theoretical and experimental results.

ABSTRACT: The influence of impact velocity and material characteristics on the dynamic buckling response of circular shells subjected to axial impact loads is studied. It is shown experimentally that the critical buckling length, which marks the transition between progressive and global buckling of aluminium alloy circular tubes, is significantly influenced by the axial impact velocity. A finite element analysis is undertaken to further explore the effects of material yield stress, strain hardening and strain rate sensitivity on the transition phenomenon. It is observed that circular tubes made of ductile alloys with a high yield stress and low strain hardening characteristics have a better performance as energy absorbers than tubes made of alloys with a low yield stress and high strain hardening characteristics. Theoretical analysis of some particular features of the dynamic buckling transition is presented in Part II [International Journal of Solids and Structures (2004)].

ABSTRACT: This is the second paper of a two-part paper investigating the complex phenomenon of the dynamic transition from progressive buckling to global bending collapse of a long circular cylindrical shell subjected to an axial impact. The paper focuses on the theoretical analysis of the phenomenon. The two-phase concept for the deformation of ‘Type II’ structures is employed to explore the influence of the loading parameters and the material and geometrical characteristics of a shell on the critical length that marks the transition between the two collapse modes. Simple models for the initial compressive phase in the case of global bending and for the development of a single axisymmetric wrinkle in a circular shell, are used to analyse some numerical results presented in Part I of this study [International Journal of Solids and Structures 41 (2004) 1565].

ABSTRACT: Two typical buckling patterns of circular cylindrical shells, which can occur due to axial impact loadings, are discussed. The phenomena of “dynamic plastic” buckling (when the entire length of a cylindrical shell wrinkles before the development of large radial displacements) and “dynamic progressive” buckling (when the folds in a cylindrical shell form sequentially) are analyzed from the viewpoint of stress wave propagation resulting from an axial impact. It is shown that the particular impact velocity, which instantaneously causes stresses that exceed the elastic limit of the material at the proximal end of a shell, and therefore can cause the initial instability pattern within a sustained axial plastic flow, depends on the material properties. The present analysis reveals that “dynamic plastic” buckling can develop for relatively low impact velocity, too provided that a shell has certain inertia characteristics. The latter conclusion is in contrast with the established perception that the high impact velocity is a necessary condition for the initial shell instability within a sustained axial plastic flow. A phenomenological approach is used to predict the buckling mode of a circular shell under axial impact with a given initial velocity.

References listed at the end of the paper:

ABSTRACT: Several experiments were performed with a Kolsky Bar (Split Hopkinson Pressure Bar) device to investigate the dynamic axial buckling of cylindrical shells. The Kolsky Bar is a loading as well as a measuring device which can subject the shells to a fairly good square pulse. An attempt is made to understand the interaction between the stress wave and the dynamic buckling of cylindrical shells. It is suggested that the dynamic axial buckling of the shells, elastic or elasto-plastic, is mainly due to the compressive wave rather than the flexural or bending wave. The experimental results seem to support the two critical velocity theory for plastic buckling, with $V_{c1}$ corresponding to an axisymmetric buckling mode and $V_{c2}$ corresponding to a non-symmetric buckling mode.

“A Consistent Nonlinear Shell Element Based On A Corotational Formulation For Hyperelastic Material Models”, 20th International Congress of Mechanical Engineering November 15-20, 2009, Gramado, RS, Brazil

ABSTRACT: The corotational (CR) kinematic description is the most recent of the formulations proposed for geometrically nonlinear structural analysis. Because of this novelty, it has not reached the same level of maturity of the older Lagrangian formulations (Total and Updated). Much work remains to be done, particularly in material nonlinearities. Therefore, the aim of this paper is to develop an efficient shell element for hyperelastic analysis with two important assumptions: (i) strains from a corotated configuration are small while (ii) the magnitude of rotations from a base configuration is not restricted. The assumed natural deviatoric strain (ANDES) three nodes triangular shell element is implemented for hyperelastic material models and its application to different constitutive models is discussed. Results provided by the proposed shell element are compared with the results presented by other authors in the literature in order to show the adequacy of the presented theory and the effectiveness of the numerical procedure and shell element employed in this work.

Wang Ren, Han Mingbao, Huang Zhuping and Yan Qingchun (Department of Mechanics, Peking University, Beijing, China), “An experimental study on the dynamic axial plastic buckling of cylindrical shells”,

ABSTRACT: This paper deals with an experimental study on the dynamic plastic post-buckling behaviour of a stationary AM_i aluminium alloy cylindrical shell under axial impact. According to current theory, it is believed that within a certain velocity range, the shell will buckle in a uniform axisymmetrical sinusoidal mode. However, we found that when the impact velocity is less than a certain critical value Vc1, the shell will exhibit only uniform plastic deformation in both the axial and radial directions and does not produce the sinusoidal waves. On the other hand, when the impact velocity exceeds another critical value Vc2, the shell will change from the axisymmetric mode into a nonuniform type of large deformation, the number of waves decreases slightly and the shell begins to lose its load-carrying capacity. Experimental results on cylinders with three different thicknesses are presented and discussed. An approximate theoretical formula for estimating Vc2 based on strain rate reversal is also given.

ABSTRACT: This paper presents a unified theoretical framework for the corotational (CR) formulation of finite elements in geometrically nonlinear structural analysis. The key assumptions behind CR are: (i) strains from a corotated configuration are small while (ii) the magnitude of rotations from a base configuration is not restricted. Following a historical outline the basic steps of the element independent CR formulation are presented. The element internal force and consistent tangent stiffness matrix are derived by taking variations of the internal energy with respect to nodal freedoms. It is shown that this framework permits the derivation of a set of CR variants through selective simplifications. This set includes some previously used by other investigators. The different variants are compared with respect to a set of desirable qualities, including self-equilibrium in the deformed configuration, tangent stiffness consistency, invariance, symmetrizability, and element independence. We discuss the main benefits of the CR formulation as well as its modeling limitations.

[38] B. Haugen and C. A. Felippa, A unified formulation of small-strain corotational finite elements: II. Applications to shells and mechanisms, in preparation.

ABSTRACT: The variational formulation for thin elastic shells undergoing large deflections is discussed. No restrictions are imposed on the magnitude of the rotational part of the deformation gradient, yet it is assumed that the strains remain small everywhere in the shell. Ten functional and associated variational principles are derived, including the Hu-Washizu, the Hellinger-Reissner, the generalized complementary energy and the stationary potential energy principles. The total Lagrangian description (TLD) is exclusively used.

ABSTRACT: The paper presents a comparatively simple method for assessing the global stability of single- and double-layer reticulated shells, assuming rigid connections between the bars. With knowledge of the rigidities of the reticulated shell, a statically equivalent replacement solid shell is established, the buckling of which is extensively treated in the literature. The critical load of this replacement continuum is determined by taking into account the influences of geometric imperfections (eccentricity), plasticity, (local) bar buckling and – in the case of double-layer reticulated shells – of transverse shear deformation. All these are presented in detail for isotropic shells, but the method can also be used for anisotropic ones. Finally, for dimensioning reticulated shells, a unique safety factor based on the theory of probabilities is recommended, which depends on the uncertainties of the various effects. Numerical values for the safety factor are also given. The method proposed...
provides a transition from shells to plane plates, from surface to bar structures, and from reticulated to solid shells, thus ensuring identical safety levels for all these structures.

A talk by: Emeritus Prof Chris Calladine (CUED), “Understanding The Buckling of Cylindrical Shells”, Friday 19 January 2007, 15:00-16:00, Engineering Department – LR6. This talk is part of the Engineering Department Structures Research Seminars series.

INITIAL REMARKS: The classical theory of buckling of axially-loaded thin cylindrical shells predicts that the buckling stress is directly proportional to the thickness t, other things being equal. But empirical data show clearly that the buckling stress is actually proportional to t^{1.5}, other things being equal. As is well known, there is wide scatter in the buckling-stress data, ranging from one half to twice the mean value. Current theories of shell buckling attribute both the scatter and the low buckling stress – in comparison with the classical – to “imperfection-sensitive”, non-linear structural behaviour. But those theories always take the classical analysis of an ideal, perfect shell as their point of reference. My aim in this talk is to explain directly the observed t^{1.5} law, including the scatter, without the need to invoke the misleading classical theory.

Li Zhi-min (School of Ocean and Civil Engineering, Shanghai Jiao Tong University, Shanghai 200030, China), “Buckling analysis of three dimensional braided composite cylindrical shells under axial compression”, Structure & Environment Engineering, 2007-04, doi: CNKI:SUN:QDHJ.0.2007-04-003

ABSTRACT: A buckling and postbuckling analysis of clamped supported 3D braided shells of finite length subjected to axial compression is presented. The governing equations are based on Reddy’s higher order shear deformation shell theory with von Kármán-Donnell type of kinematic nonlinearity, which includes the effects of nonlinear prebuckling deformations, large deflections in the postbuckling range and initial geometric imperfections of the shell. Asymptotic solutions of a boundary layer theory of shell buckling are analyzed by singular perturbation method. The influence exercised by the fiber volume fraction, and the shell geometric parameter of the cylindrical shell on the buckling behavior of the braided composite shell is investigated. It is concluded that the fiber volume fraction and the shell geometric parameter have a significant effect on the buckling load and postbuckling behavior of braided composite cylindrical shells.

ABSTRACT: A simplified theoretical method is presented for analyzing the buckling behavior of a 3D braided composite cylindrical shell. The method is based on the refined anisotropic plate model. The buckling load with different values of geometric parameter is described. In order to verify the proposed model, the finite element package ANSYS is used to calculate the buckling load. Predictions from the proposed model correlate well with the simulation results. The results reveal that geometric parameters and braid angle have a significant effect on the buckling load.

ABSTRACT: Thermal postbuckling analysis is presented for 3D braided composite cylindrical shell of finite length subjected to a uniform temperature rise. Based on a micro-macro-mechanical model, a 3D braided composite may be as a cell system and the geometry of each cell is deeply dependent on its position in the cross-section of the cylindrical shell. The material properties of epoxy are expressed as a linear function of temperature. The governing equations are based on Reddy's higher order shear deformation shell theory with a von Kármán-Donnell-type of kinematic nonlinearity and including thermal effects. A singular perturbation technique is employed to determine the buckling temperatures and postbuckling behaviors of 3D braided composite cylindrical shells. The numerical illustrations concern the postbuckling behavior of perfect and imperfect, braided composite cylindrical shells with different values of geometric parameter and of fiber volume fraction. The results show that the shell has lower buckling temperatures and postbuckling equilibrium paths when the temperature-dependent properties are taken into account. The results reveal that the fiber volume fraction, braiding angle and the shell geometric parameter have a significant effect on the thermal buckling and postbuckling behavior of braided composite cylindrical shells.

ABSTRACT: Nonlinear buckling and postbuckling behavior for a 3D braided composite cylindrical shell of finite length subjected to lateral pressure, hydrostatic pressure, or external liquid pressure in thermal environments have been presented in this paper. Based on a new micromacromechanical model, a 3D braided composite may be treated as a cell system and the geometry of each cell is deeply dependent on its position in the cross section of the cylindrical shell. The material properties of the epoxy are expressed as a linear function of temperature. The governing equations are based on Reddy’s higher order shear deformation shell theory with a von Kármán–Donnell type of kinematic nonlinearity and including thermal effects. A singular perturbation technique is employed to determine the buckling pressure and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling behavior of perfect and imperfect braided composite cylindrical shells with different values of geometric parameter and of fiber volume fraction in different cases of thermal environmental conditions. The results show that the shell has lower buckling pressures and postbuckling paths when the temperature-dependent properties are taken into account. The results reveal that the temperature changes, the fiber volume fraction, and the shell geometric parameter have a significant effect on the buckling pressure and postbuckling behavior of braided composite cylindrical shells.

Nonlinear buckling behavior of 3D-braided composite cylindrical shells subjected to internal pressure loads in thermal environments. The nonlinear buckling behavior of a 3D-braided composite cylindrical shell of finite length subjected to internal pressure in thermal environments is considered. According to a new micromacromechanical model, a 3D-braided composite may be treated as a cell system where the geometry of each cell strongly depends on its position in the cross section of the cylindrical shell. The material properties of the epoxy matrix are expressed as linear functions of temperature. The governing equations are based on Reddy’s higher-order shear deformation theory of shells with a von Karman–Donnell-type kinematic nonlinearity and include thermal effects. The singular perturbation technique is employed to determine the buckling pressure and the postbuckling equilibrium paths of the shell.

ABSTRACT: This paper investigates numerically and experimentally the influence of initial geometric imperfections on the critical loads of initially stretched thick hyperelastic cylindrical shells under increasing uniform internal pressure. Imperfections in shells can have a global or local character. First, two types of local imperfections are considered: (1) a local axially symmetric imperfection in the form of a ring and (2) a small rectangular imperfection. The influence of the imperfection thickness, position and size are analysed in detail. Results show that the critical load decreases as the imperfections increase in size or thickness and as they move from the boundaries to the centre of the shell. The influence of multiple local imperfections is also studied in the present paper. Finally, the influence of global imperfections is considered with the imperfections described as a variation of the shell curvature in the axial direction. The results show that thick hyperelastic shells may be sensitive to local and global imperfections. In all cases the experimental results are in good agreement with the numerical ones, corroborating the conclusions.

ABSTRACT: A post-buckling analysis is presented for a stiffened braided thin shell subjected to combined loading of external pressure and axial compression. The effects of the nonlinear large deflection and the initial geometrical imperfection are considered in the formulations. The analysis uses perturbation method to determine the interactive buckling loads and the post-buckling equilibrium paths and a three-cell model are used to obtain the elastic constants of braided shell. Some effects such as imperfection parameter, stiffened and Braiding parameters on the post-buckling path are discussed in the article.

ABSTRACT: The nonlinear strain-displacement relations in general cylindrical coordinates are simplified by Sander’s assumptions for the cylindrical shells and substituted into the total potential energy function for thermoelastic loading. … An improvement is observed in the resulting equations as no length limitations are imposed on a thin cylindrical shell…. Based on the improved equilibrium and stability equations, the magnitude of thermoelastic buckling of thin cylindrical shells under deferrent thermal loading is obtained. The results are extended to short and long thin cylindrical shells.

ABSTRACT: In this paper, the elastic axisymmetric buckling of a thin, isotropic and simply supported cylindrical shell with an elastic core under axial compression has been analyzed using energy method. The nonlinear strain-displacement relations in general cylindrical coordinates are simplified using Sanders kinematic relations (Sanders, 1963) for axial compression. Equilibrium equations are obtained by using minimum potential energy together with Euler equations applied for potential energy function in cylindrical shell. To acquire stability equation of cylindrical shell with an elastic core, minimum potential energy theory and Trefftz criteria are implemented. Stability and compatibility equations for an imperfect cylindrical shell with an elastic
core are also obtained by the energy method, and the buckling analysis of shell is carried out using Galerkin method. Critical load curves versus the aspect ratio are obtained and analyzed for a cylindrical shell with an elastic core. It is concluded that the application of an elastic core increases elastic stability and significantly reduces the weight of cylindrical shells.

ABSTRACT: Electro-thermo-torsional buckling response of a double-walled boron nitride nanotube (DWBNNT) has been investigated based on nonlocal elasticity and piezoelectricity theories. The effects of surrounding elastic medium such as the spring constant of the Winkler-type and the shear constant of the Pasternak-type are taken into account. The van der Waals (vdW) forces are considered between inner and outer layers of nanotube. According to the relationship between the piezoelectric coefficient of armchair boron nitride nanotubes (BNNTs) and stresses, the first order shear deformation theory (FSDT) is used. Energy method and Hamilton’s principle are employed to obtain coupled differential equations containing displacements, rotations and electric potential terms. The detailed parameter study is conducted to investigate the effects of nonlocal parameter, elastic foundation modulus, temperature change, piezoelectric and dielectric constants on the critical torsional buckling load. Results indicate that the critical buckling load decreases when piezoelectric effect is considered.

“Nonlinear vibration and instability analysis of functionally graded-CNT-reinforced cylindrical shells conveying viscous fluid resting on orthotropic Pasternak medium”, Mechanics of Advanced Materials and Structures, in press, Accepted May 2015, DOI: 10.1080/15376494.2015.1029170
ABSTRACT: In this study, nonlinear vibration and instability of embedded temperature-dependent cylindrical shell conveying viscous fluid resting on temperature-dependent orthotropic Pasternak medium are investigated. The equivalent material properties of nanocomposite are estimated using rule of mixture. Both cases of uniform distribution (UD) and functionally graded (FG) distribution patterns of reinforcements are considered. Based on orthotropic Mindlin shell theory, the governing equations are derived. Generalized differential quadrature method (GDQM) is applied for obtaining the frequency and critical fluid velocity of system. The effects of different parameters such as distribution type of SWCNTs, volume fractions of SWCNTs and Pasternak medium are discussed.

ABSTRACT: A method for the calculation of the critical load for a semi-ellipsoidal shell with a stiffening rib at the edge is presented. The external and internal buckling energy of the shell is described. The Rayleigh quotient
is used as the static buckling criterion, assuming the deflection function to depend on four shape parameters. Some numerical examples are presented showing the influence of the rib stiffness and the shell dimensions on the critical pressure value.

ABSTRACT: The paper is devoted to stability problem of an axially compressed open elastic circular cylindrical shell. Two curvilinear edges of the open cylindrical shell are simply supported while two straight edges are free. Two load cases of the shell are assumed. The first load case - was the invariable axially normal force intensity, and the second load case - the linearly varying axially normal force intensity. Critical loads of the shell for both load cases are determined. These critical loads are compared with a classical load for closed circular cylindrical shell.

ABSTRACT: The subject of the paper is a simply supported sandwich beam with a metal foam core. Mechanical properties of the core vary through its depth. A nonlinear hypothesis of deformation of a plane cross section of the beam is assumed and described. The elastic potential energy and the work of the load are formulated. The system of differential equations of the equilibrium is derived on the basis of the theorem of minimum total potential energy. The system of equations is analytically solved. The stress state and the critical force for the beam are determined. The optimal dimensionless parameters of the beam are calculated. Results of the numerical investigations are presented in figures.

ABSTRACT: The study is devoted to a radial compressed metal foam circular plate. Properties of the plate vary
across its thickness. The middle plane of the plate is its symmetry plane. First of all, a displacement field of any cross-section of the plate was defined. Afterwards, the components of strain and stress states were found. The Hamilton principle allowed one to formulate a system of differential equations of dynamic stability of the plate. This basic system of equations was approximately solved. The forms of unknown functions were assumed and the system of equations was reduced to a single ordinary differential equation of motion. The equation was then numerically processed that allowed one to determine critical loads for a family of metal foam plates. The results of studies are shown in figures. They show the effect of porosity of the plate on the critical loads. The results obtained for porous plates were compared to homogeneous circular plates.

ABSTRACT: The paper is devoted to a simply supported thin-walled beam. The critical state of the beam under uniformly distributed transverse load, an axial force and two different moments located at its both ends is analytically studied. The elastic potential energy and the work of loads for the beam are described. Basing on the stationary of the total potential energy the general algebraic equation of the critical state for the beam is obtained. The equation describes a convex hyper-surface. Particularly simple load cases are studied. Based on the general equation of the critical state numerical investigations are realized. The results are shown in Figures.

ABSTRACT: The present paper deals with an influence of the axial extension mode on static and dynamic interactive buckling of a thin-walled channel with imperfections subjected to uniform compression when the shear lag phenomenon and distortional deformations are taken into account. A plate model is adopted for the channel. The structure is assumed to be simply supported at the ends. Equations of motion of component plates were obtained from Hamilton’s principle taking into account all components of inertia forces. In the frame of first order nonlinear approximation, the dynamic problem of modal interactive buckling is solved by the transition matrix using the perturbation method and Godunov’s orthogonalization.

ABSTRACT: The problem of buckling and initial post-buckling equilibrium paths of thin-walled structures built of plate and/or shell elements subjected to compression and bending has been solved. Plate and shell elements can be made of multi-layer orthotropic materials. A method of the modal solution to the coupled buckling problem within the first-order approximation of Koiter’s asymptotic theory, using the transition matrix method, has been presented. In the solution obtained, the effect of cross-sectional distortions and a shear lag phenomenon is included. The calculations are carried out for a few thin-walled structures.

ABSTRACT: The paper concerns theoretical, numerical and experimental analysis of the stability and ultimate
load of multi-cell thin-walled columns of rectangular and square cross-sections subjected to axial compression (uniform shortening of the column). The theoretical analysis deals with the local and global stability of multi-cell orthotropic columns of a rectangular profile with rectangular cells. It has been shown that for a multi-cell column made of the same material and having the same cross-section area, the value of local buckling stress of the column walls grows rapidly with an increase of the cell number. The experiment conducted for isotropic columns has also proved a significant growth of the ultimate load with the increase of the cell number. The paper gives some conclusions which can be useful in design of thin-walled box columns.

ABSTRACT: This paper deals with local dynamic buckling of thin-walled girder segments (short beam-columns) subjected to bending. Various shapes of pulse loading (triangle, trapezoid and rectangle) with a duration corresponding to the fundamental period of vibration were taken into account. Assumed boundary conditions correspond to a simple support, this agrees with conditions that exist in the place of the diaphragm in a long spar. The problem was solved by finite element method. In order to determine the critical load pulse amplitudes Volmir, Budiansky–Hutchinson, Ari–Gur and Simonetta criteria were employed.

ABSTRACT: Thin–walled structure, by its nature, is subjected to loss of stability. In addition, the shell has a cutout, which reduces the critical load. The aim of this study is to determine critical stress of the shell under pure bending. The goal was achieved in two ways: experimentally and analytically. Experimental studies were carried out on a specially designed test bench with the use of a resistive strain gauge. In the analytical solution the form of buckled shell was assumed, and then Bubnov–Galerkin method was applied.

References listed at the end of the paper:

ABSTRACT: The work deals with the problem a straight beam of a rectangular cross-section pivoted at both ends and loaded with a lengthwise compressive force. The beam is made of an isotropic porous material. Its properties vary through thickness of the beam. The modulus of elasticity is minimal on the beam axis and assumes maximum values at its top and bottom surfaces. The principle of stationarity of the total potential energy enables one to define a system of differential equations that govern the beam stability. The system is analytically solved, which leads to an explicit expression for the critical load of the compressed beam. Results of the solution are verified on an example beam by means of the Finite Element Method (COSMOS).

ABSTRACT: The aim of the paper is to present a procedure for design of a family of shells of revolution of constant mass and, as a next step, of constant volume. As a reference a cylindrical shell is taken into consideration. By decreasing the value of the meridional radius of curvature R1, which for cylindrical shell equals infinity, barrelled shells are created up to the spherical shell for which both meridional and circumferential radii of curvature are equal (R1=R2). A numerical example of using the presented procedure is
considered. Then for the family of shells of revolution of constant mass a buckling analysis using FEM method is carried out. Results of the analysis show the relationship between the radius of curvature of the shell $R_1$ and the critical load $p_{cr}$ in the case of uniform external pressure.

SUMMARY: The present work is devoted to the elastic stability of shells of revolution in the pure bending state. Buckling shapes are presented and the dependency between the shape of a shell and its critical stress is described. The ABAQUUS system based on the finite elements method was used to obtain the results. Examples of works concerning stability of shells under bending can be easily found in the literature. However they are usually limited to cylindrical shells. Brush and Almroth [1] and Volmir [2] present analytical solutions of the problem and a state of the art in this field. In the paper presented here the authors extend the investigation to shells of revolution other than cylindrical ones including a cylinder as a reference point. A family of shells of revolution of the same volume and length is investigated including shells with positive (barrel) and negative Gaussian curvature. The model of a shell is simply supported at both ends. To introduce a pure bending conditions a non-uniform axial load is applied to the edge of the shell. The results obtained from the analyses confirm the advantages of barrelled shells presented for example by Blachut [3]. A barrelled shell can bear about 75% higher load than a cylinder if pure bending conditions are assumed. The gain in buckling strength grows monotonically with decreasing the meridional radius of curvature $R$. The buckling shape is of the form of short wrinkles concentrated near the edge of the shell where the load is applied. Shells with negative Gaussian curvature buckle in a global way and the buckling load decreases with decreasing radius $R$. Since buckling of thin, middle-length bending shells is caused by compressive stresses the buckling analysis under axial compression was also carried out. The results are similar to those obtained for bending load. Critical stresses are slightly higher, up to 5.5%, for bending.

ABSTRACT: The paper is devoted to shells of revolution with positive and negative Gaussian curvature. The meridian of shells is a plane curve in the Cassini oval form. Geometrical properties of the middle surface of the shell of revolution based on this curve are presented. The membrane state of stress of a family of shells with constant capacity and mass under uniform pressure is described analytically and numerically with the use of the FEM (the ANSYS system). The critical pressure, buckling modes and equilibrium paths of analysed shells are calculated numerically. The advantages of a pressure vessel made in the form of Cassini ovaloidal shell, such as the lack of edge effect and a stable post-buckling behaviour, are pointed out. The results of the analytical and numerical investigations are compared and presented in tables and figures.

ABSTRACT: The main goal of this paper is a solution of the problem of buckling and deflection. A circular porous plate with simply supported edge under radial uniform compression and uniformly distributed load (pressure) is considered. Mechanical properties of the isotropic porous material vary across the thickness of the plate. Middle plane of the plate is its symmetry plane. A field of displacements (geometric model of nonlinear hypothesis) is described. The principle of stationarity of the total potential energy allowed to get a system of differential equations that govern the plate stability. A critical load and a deflection are determined. The results obtained for porous plates are compared to homogeneous circular plates.

**ABSTRACT:** This paper considers an isotropic porous shell loaded by axial compression shown in Figure 53.1. The effects of varying porous material and geometric parameters of the cylindrical shell, on the elastic buckling load are studied. The shell is made of an isotropic porous material which varies only across the thickness of the shell wall. Banhart [1] reviewed the possibilities of manufacturing metal foams or other porous metallic structures as well as ways for characterizing the properties of cellular metals. In the present paper the porous shell is a generalization of a sandwich construction.

**ABSTRACT:** The paper is devoted to five different flanges of cold-formed thin-walled beams. Mathematical models of each of the flanges are formulated and solved. The theory of elastic stability of plates and cylindrical shallow shells is applied for this purpose. Critical stress for each flange of the beam is determined. Results of analytical solutions are discussed and compared with numerical (FEM) and experimental investigations. The formulas of critical stresses may be used in practical applications.

ABSTRACT: By the aid of differential geometry analysis on the initial buckling of shell element, a set of new and exact buckling bifurcation equations of the spherical shells is derived. Making use of Galerkin variational method, the general stability of the hinged spherical shells with the circumferential shear loads is studied. Constructing the buckling mode close to the bifurcation point deformations, the critical eigenvalues, critical load intensities and critical stresses of torsional buckling ranging from the shallow shells to the hemispherical shell are obtained for the first time.

1965 (Chinese version)

ABSTRACT: A thin-walled spherical shell is pivoted at both edges. One of the edges may rotate around the shell axis. Moreover, it is loaded with a torque. The problem of shell stability is considered. The system of equations characterizing the problem consists of a non-linear equation of equilibrium and non-linear compatibility equation. Both equations are solved with Bubnov-Galerkin’s method, assuming beforehand the form of deflection and force-functions. As a result of the solution, an algebraic equation is obtained, with respect to a dimensionless load parameter. The critical load parameter corresponding to the minimal critical load value is determined from this equation. The number m at which the load parameter has the minimum value determines the mode of stability loss. The paper is supplied with a numerical example.

ABSTRACT: A thin-walled spherical shell is pivoted at both ends. The upper edge of the shell, loaded with a torque, may rotate around the shell axis. The problem of the loss of stability of the shell is solved with an energetic method. The change in the total energy of the shell while losing stability is determined. This requires
the forms of the deflection and force functions to be assumed, according to actual boundary conditions. Coefficients of the force function are determined from the solution to the inseparability equation with the Bubnov-Galerkin method. The stability equation of the shell is formulated as a result of application of the Ritz method to the total energy variation. It is an algebraic equation serving for determination of the critical load. It is equal to the minimal value of the load. The work ends with a numerical example.

ABSTRACT: The subject of the study are open circular cylindrical thin shells with two edges supported and two edges free. The elastic buckling and limit load of these shells in pure bending state are investigated. The study includes simple analytical description, numerical analysis with the use of the Finite Element Method (FEM), and laboratory tests for shells. The results of these three investigation methods are compared and presented in figures. The critical load and limit load for these shells are described in detail. Moreover, an analytical formula of critical stresses for open circular cylindrical thin shells in pure bending state is proposed. The main goal of the paper is comparison of the results of critical load values obtained by analytical, numerical (FEM), and experimental methods.

ABSTRACT: A limit load analysis of a vessel nozzle with pressure and external force loading was conducted. The limit load was defined by increasing the pressure and the nozzle external loads proportionally until collapse occurred. The evaluation of the limit load analysis was conducted in accordance with ASME BPVC Section VIII Division 2 [1]. The limit load analysis provides insight into the collapse load and failure mode. The results of the limit load analysis and a plastic analysis are compared to the results obtained by linear and nonlinear shell and plate element analyses of the same nozzle. The authors discuss the comparison of the results as there is some variance between the different methodologies.

ABSTRACT: The problem of elastic buckling of an open sandwich cylindrical thin-walled panel with three edges simply supported and one edge free under axial compression is considered in the paper. The classical broken line hypothesis is replaced by its modified generalized version. On the basis of force and moment equilibrium conditions for the shell element, a set of the fundamental equations is derived. The set is solved with the help of the orthogonalizational Bubnov–Galerkin method. The nonlinear algebraic equation is obtained. Physical and geometrical parameters of the shell, deflection factor and loading are connected in the equation. It is possible, among others, to obtain from here the critical load value.

ABSTRACT: In this paper, the authors consider the influence of axial load on the stability of shells of revolution subjected to external pressure. Shells of different geometry are investigated with emphasis to barrelled shells. The variable quantities are length L and meridional radius of curvature R1 of a shell. The constant parameters are: thickness of the shell h, mass ms and reference radius r0. The material of shells is steel. Numerical calculations were performed in the ABAQUS system. All the shells considered in this paper were subjected to axial compression to determine the force corresponding to the loss of stability in such conditions. A part of this force is then used to preload shell before the buckling analysis in the conditions of external pressure.
is started. The buckling shapes for shells of different geometry are presented with and without the influence of axial load. The ability of controlling the buckling strength and shape is discussed.

ABSTRACT: The paper is devoted to sandwich beams under pure bending. The local buckling problem is analysed. The analytical description of the upper face wrinkling is proposed. From the principle of stationary total potential energy, formulae describing critical stresses in the faces of the beam are derived. The algorithm for determining the critical stresses is shown. Two particular cases of the solution following the core properties are mentioned. The finite element model of the sandwich beam is formulated. The comparison of the results obtained from the proposed analytical model and from FEM analysis is shown for a family of sandwich beams with different thicknesses and core properties.

ABSTRACT: The paper is devoted to the analytical, numerical and experimental studies of the global and local buckling–wrinkling of the face sheets of sandwich beams and sandwich circular plates. A mathematical model of displacements, which includes a shear effect, is presented. The governing differential equations of sandwich plates are derived. The equations are analytically solved and the critical loads are obtained. Finite element models of the plates are formulated and the critical loads and buckling modes are calculated. Moreover, experimental investigations are carried out for the family of sandwich beam-plates. The values of the critical load obtained by the analytical, numerical (FEM), and experimental methods are compared.

ABSTRACT: The subject of the paper is a sandwich beam with a crosswise or lengthwise corrugated core. The beam is made of an aluminium alloy. The plane faces and the corrugated core are glued together. Geometrical properties and rigidities of the beams are described. The load cases investigated in the work are pure bending and axial compression. The relationship between the applied bending moment and the deflection of the beam under four-point bending is discussed. The analytical and numerical (FEM) calculations as well as experimental results are described and compared. Moreover, for the axial compression, the elastic global buckling problem of the analysed beams is presented. The critical loads for the beams with the crosswise and lengthwise corrugated core are determined. The comparison of the analytical and FEM results is shown.

ABSTRACT: Cohesive zone model to capture the failure behaviour and strength of CFRP skinned cantilever sandwich beam with delamination is carried out and verified through test. The inputs required to represent the interfacial behaviour between the skin and honeycomb core in cohesive zone model are determined by standard tests. Acoustic emission was monitored during the test. Comparison of the load-displacement response obtained shows a good agreement with the experimental result. Both the test and analysis show a buckling induced delamination resulting earlier buckling failure of the specimen. Prediction of failure load based on nonlinear buckling analysis with CZM and without CZM approach shows a deviation of 6% and 9% respectively with the test. The present study reveals that coupled buckling induced delamination failure of bonded sandwich structures can be accurately predicted by cohesive zone model which incorporates debond growth and buckling simultaneously. Parametric study reveals that the interfacial strength plays a key role in failure load of adhesively bonded sandwich structures in comparison to the delamination fracture toughness.

ABSTRACT: The subject of numerical research is a seven-layer cylindrical shell subjected uniformly distributed external pressure. The shell is thin-walled sandwich structure composed of main corrugated core (made of a thin metal sheet) and two three-layer faces. The cores of the faces are porous and made of isotropic metal foam. The corrugation of the main core is along longitudinal axis of the shell. The shell is simply supported at its all outer edges. Numerical FEM model of the shell is elaborated. Critical pressure for the family of these shells are calculated. Furthermore, developed a model of an equivalent single-layer shell wherein diameter, and weight are the same as the seven-layer shell. It has been shown several times higher resistance to buckling of a seven-layer shell compared to the single-layer shell.

ABSTRACT: We manufactured sandwich-walled cylindrical shells with aluminum pyramidal truss core of constant curvature employing an interlocking fabrication technique for the metallic core. The skins were made of carbon-fiber reinforced composites and co-cured with the metallic truss core. Thereafter, we carried out axial compression tests on some representative samples to investigate the failure modes of these structures and compared with an analytical failure map developed to account for Euler buckling, shell buckling, local buckling between reinforcements and face-crushing. The experimental data closely matched the analytically predicted behavior of the cylinders. In particular, we found that local buckling and face crushing modes can exist together and are the most important modes of failure of the fabricated structure.

ABSTRACT: A plate model for analysis and design of laminated composite structures subjected to large deflections is considered. The model is based on a facet approximation of the midsurface and Reissner–Mindlin–Von Kármán type plate equations. The potential energy functional where the linearized strain tensor has been replaced by nonlinear functions, i.e., the Von Kármán model for large deformation is formulated. The nonlinear equations are solved iteratively by Riks’ method with Crisfield’s elliptical constraint for arc length. The linearized equations are discretized by the finite element method. Load–displacement behavior of the structure as well as failure prediction and identification of critical areas of the FE-model are illustrated with a numerical example.

ABSTRACT: In this paper post-buckling analysis of carbon fibre reinforced plastic cylindrical shells under axial compression is considered. Reissner–Mindlin–Von Kármán type shell facet model is used in the computations. The effect of geometric imperfection shape and amplitude on nonlinear analysis results is discussed. Numerical–experimental correlation is performed using the results of experimental buckling tests found in the literature. Results show that bringing the diamond shape geometric imperfection in the model significantly improves the correlation and gives good accuracy in simulating cylindrical shell post-buckling behaviour.

ABSTRACT: Design of thin-walled cylindrical shells fabricated from composite materials leads to the requirement of validated simulation procedures for the buckling simulation of realistic, geometrically imperfect shells. In this work, the simulation is performed with a geometrically nonlinear analysis using Reissner-Mindlin-Von Kármán type shell facet model. A diamond shaped geometric imperfection pattern is applied in the computational model. Based on the simulation, limits of buckling loads are estimated for the cylindrical CFRP shells and compared to the test results from the literature.

ABSTRACT: Postbuckling behaviour of laminated composite structures using Reissner-Mindlin-Von Kármán type plate model is considered. The potential energy functional where the linearized strain tensor has been replaced by nonlinear Von Kármán model for large deformation is formulated. The stabilized MITC-technique is used to discretize the problem by finite elements. Load-displacement behaviour of the structure as well as the failure prediction and the identification of the critical areas of the model are illustrated with numerical examples.

ABSTRACT: In this paper, the static buckling of especially orthotropic stringer-stiffened composite cylindrical shells subjected to combined axial compression and external pressure is investigated, based on geometrical nonlinear analysis with considering pre-buckling deformations. The kinematic relation of shells is based on the Donnell non-linear theory and First Order Shear Deformation (FOSD) is adopted for both shell and stiffeners. Displacements, rotations and interacting forces are expressed in terms of Fourier series expansions as independent approximate solution functions. Unknown coefficients of shell and stringers are related by satisfying continuity conditions of displacements at their contact areas using Lagrange multipliers. The nonlinear equilibrium equations are obtained using the Ritz method. The effects of sensitivity parameters, e.g., shell lay-ups, different numbers of stringers in the circumference, location of stiffeners (outside vs. inside) and the discrete versus smeared approach on interaction buckling curves are considered. Results indicate remarkable differences between outside and inside stringer-stiffened cylinder buckling loads and also illustrate the fundamental role of shell stacking sequences and stiffened shell geometry on the applicability range of the smeared stiffener approach.

ABSTRACT: Optimum laminate configuration for minimum weight of filament wound laminated conical shells subject to buckling load constraint is investigated. In the case of a laminated conical shell, the thickness and the ply orientation (the design variables) are functions of the shell coordinates, influencing both the buckling load
and its weight. These effects complicate the optimization problem considerably. The first level of complexity is attributed to the correlation between the volume and the buckling load and their dependence on the fiber configuration. The second level of complexity is associated with the high computational cost involved in calculation of the buckling load. Thus, the main objective of this study is to solve the optimization problem as well as to reduce the computational cost associated with it. Based on the characteristic buckling behavior of laminated conical shells, the usual penalty function method is used.

ABSTRACT: In this paper a new technique was proposed for the repair of defected metal columns. The finite element method was chosen to find out the adequacy of the proposed method, regarding, the load carrying capacity of two types of thin walled cylindrical columns with L=D = 10 and 20 along with circumferential and longitudinal cracks. The study considers the non linearity behavior in both material as well as geometrical characteristics. Various configurations of the composite patches made from carbon-epoxy were assumed on the cracked region and the influence of a patch on the load carrying capacity of the columns was examined. The obtained results indicate that composite material can not only compensate the effect of damage on column buckling load, but also increase buckling strength to a level even greater than in an intact one.

ABSTRACT: Although, for homogeneous columns, the differences between Engesser’s and Haringx’s formulas for shear buckling have been explained in 1971 by the dependence of shear modulus on the axial stress, for soft-core sandwich columns the choice of the correct formula has baffled engineers for half a century. Recently, Bazˇant explained this difference by a variational analysis which showed that an agreement is achieved if the shear modulus of the light core is considered to depend on the compressive stress in the skins even when small-strain elasticity applies. To clarify this paradoxical dependence, first the variational framework is briefly reviewed. Subsequently, the mathematical results from Bazˇant’s recent study are physically reinterpreted, with the conclusion that only the Engesser-type theory (rather than Haringx-type theory) corresponds to constant shear moduli as obtained, for example, by the torsional test of a tube made from the foam. This is a rather fundamental point for applications because the discrepancy between these two theories can be very large in the case of short columns with thin skins. The implications for standard finite element programs are then explored by computing the critical loads of several sandwich columns with different material and geometric properties. The finite element computations show agreement with the Engesser-type formula predictions, while the Haringx-type prediction can be obtained with the finite element program somewhat artificially—by updating the core modulus as a function of the axial stress in the skins.

ABSTRACT: This paper investigates torsional buckling of an individual multi-walled carbon nanotubes. The multiple shell model is adopted and the effect of van der Waals forces between adjacent nanotubes is taken into account. According to the ratio of radius-to-thickness, multi-walled carbon nanotubes discussed here are classified into three cases: thin, thick, and nearly solid. The critical shear stress and the torsional buckling mode are calculated for various radius-to-thickness ratios. Results carried out show that the buckling mode (m, n) corresponding the critical shear stress is sole, which is obviously different from the axially compressed buckling of an individual multi-walled carbon nanotubes. The investigation on torsional buckling of multi-walled carbon nanotubes in this paper may be used as a useful reference for the designs of nano-oscillators, nano-drive devices and actuators in which multi-walled carbon nanotubes act as basic elements.

ABSTRACT: This paper reports the results of an investigation on combined torsional buckling of an individual multi-walled carbon nanotube (MWNT) under combined torque and axial loading. Here, a multiple shell model is adopted and the effect of van der Waals forces between two adjacent tubes is taken into account. According to the ratio of radius to thickness, MWNTs discussed in this paper are classified into three types: thin, thick and nearly solid. The critical shear stress and the combined buckling mode are calculated for three types of MWNTs under combined torque and axial loading. Results carried out show that the buckling mode (m, n) corresponding to the critical shear stress is unique, which is obviously different from the purely axial compression buckling of an individual MWNT. Numerical results also show that the critical shear stresses and the corresponding buckling modes of MWNTs under combined torque and axial loading are dependent on the axial loading form and the types of MWNTs. The new features and meaningful numerical results in the present work on combined buckling of MWNTs under combined torque and axial loading may be used as a useful reference for the designs of nano-drive devices and rotational actuators in which MWNTs act as basic elements.

ABSTRACT: This paper describes an investigation into elastic buckling of an embedded multi-walled carbon nanotube under combined torsion and axial loading, which takes account of the radial constraint from the surrounding elastic medium and van der Waals force between two adjacent tube walls. Depending on the ratio of radius to thickness, the multi-walled carbon nanotubes discussed here are classified as thin, thick, and nearly solid. Critical buckling load with the corresponding mode is obtained for multi-walled carbon nanotubes under combined torsion and axial loading, with various values of the radius to thickness ratio and surrounded with different elastic media. The study indicates that the buckling mode \((m, n)\) of an embedded multi-walled carbon nanotube under combined torsion and axial loading is unique and it is different from that with axial compression only. New features for the buckling of an embedded multi-walled carbon nanotube under combined torsion and axial loading and the meaningful numerical results are useful in the design of nanodrive device, nanotorsional oscillator and rotational actuators, where multi-walled carbon nanotubes act as basic elements.

ABSTRACT: This paper investigates the bending stability of a multi-wall carbon nanotube (MWNT) embedded in an elastic medium, based on a multiple shell model. The effects of the surrounding elastic medium and the van der Waals forces between two adjacent tubes are taken into account. The critical bending moment and the corresponding buckling mode for three types of MWNTs with different layer numbers and ratios of radius to thickness are calculated. Results obtained show that the bending buckling mode corresponding to the critical bending moment is unique, which is obviously different from the purely axial compression buckling of an individual MWNT. On the other hand, a simplified method is applied to calculate the bending stability of MWNTs with larger layers, embedded in an elastic medium, by substitution of a multiple shell with fewer layers. The new features of the bending stability of MWNTs embedded in an elastic medium and some meaningful results in this paper are helpful for the application and the design of nanostructures in which MWNTs act as basic elements.

ABSTRACT: This paper investigates torsional buckling of a multi-wall carbon nanotube embedded in an elastic medium. The effects of surrounding elastic medium and van der Waals forces from adjacent nanotubes are taken into account. Using continuum mechanics, an elastic laminated shell model is presented to study the torsional buckling of a multi-wall carbon nanotube embedded in an elastic medium. A laminated cylinder composed of a multi-wall carbon nanotube and a surrounding elastic medium is used to describe the effect of elastic medium on the multi-wall carbon nanotubes. According to the ratio of radius-to-thickness, multi-wall carbon nanotubes discussed here are classified into three cases: thin, thick, and nearly solid. The critical shear stress and the torsional buckling mode are calculated for various radius-to-thickness ratios and elastic medium
effects. Results carried out show that the buckling mode \((m,n)\) corresponding the critical shear stress is sole, which is obviously different from the axially compressed buckling of multi-wall carbon nanotubes. The investigation on torsional buckling of multi-wall carbon nanotubes embedded in an elastic medium in this paper may be used as a useful reference for the designs of nano-oscillators and actuators in which multi-wall carbon nanotubes act as torsional springs.

ABSTRACT: The torsional buckling of an individual multi-walled carbon nanotube under two different loading conditions is studied in this article. The multiple shell model is adopted and the effects of van der Waals forces between adjacent nanotubes are taken into account. An examination with an individual double-walled carbon nanotube shows that the effect of the change of interlayer spacing on the torsional buckling force can be neglected if only the innermost radius is larger than a certain value. Under this condition, single buckling equations are derived and explicit formulas for the critical torsional loads in terms of the buckling modes are obtained. It is found that the critical torsional load of a multi-walled carbon nanotube with torque exerted on the outermost tube is higher than that of the same multi-walled carbon nanotubes under the torques being proportionally applied to each individual layer of the multi-walled carbon nanotubes. For thin multi-walled carbon nanotubes with large radii, the critical shear force (per unit length) of the multi-walled carbon nanotubes uniformly twisted along the cross section does not increase as its layer number (thickness) increases, which is due to the interlayer slips between adjacent nanotubes.

ABSTRACT: Individual multiwalled carbon nanotubes with a range of aspect ratios are subjected to cyclic axial compression to large strains using atomic force microscopy. Distinct elastic buckling and postbuckling phenomena are observed reproducibly and are ascribed to Euler, asymmetric shell buckling (i.e., kinking), and symmetric shell buckling. These show agreement with continuum theories that range from approximate to remarkable. Shell buckling yields reproducible incremental negative stiffness in the initial postbuckled regime. ABSTRACT: Beams made from thin walled elements, while very efficient in terms of the structural strength and stiffness to weight ratios, can be susceptible to highly complex instability phenomena. A nonlinear analytical formulation based on variational principles for the ubiquitous I beam with thin flanges under uniformly bending is presented. The resulting system of differential and integral equations are solved using numerical continuation techniques such that the set of bifurcation points, and the consequent buckling ranges can be portrayed. The interaction between global lateral-torsional buckling of the beam and local buckling of the flange plate is found to oblige the buckling deformation to localize initially at the beam midspan with subsequent cellular buckling (snaking) being predicted.

ABSTRACT: An analytical pilot model for interactive buckling in sandwich struts with cores made from a functionally graded material based on total potential energy principles is presented. Using a Timoshenko beam
approach, a system of nonlinear differential and integral equations is derived that predicts critical and secondary instabilities. These are validated against numerical simulations performed within the commercial finite-element package *Abaqus*. Good agreement is found, and this offers encouragement for more elaborate models to be devised that can account for face-core delamination—a feature where functionally graded materials are known to offer distinct advantages.

**ABSTRACT:** An analytical model based on variational principles for a thin-walled stiffened plate subjected to axial compression is presented. A system of nonlinear differential and integral equations is derived and solved using numerical continuation. The results show that the system is susceptible to highly unstable local–global mode interaction after an initial instability is triggered. Moreover, snap-backs in the response showing sequential destabilization and restabilization, known as cellular buckling or snaking, arise. The analytical model is compared to static finite element models for joint conditions between the stiffener and the main plate that have significant rotational restraint. However, it is known from previous studies that the behaviour, where the same joint is insignificantly restrained rotationally, is captured better by an analytical approach than by standard finite element methods; the latter being unable to capture cellular buckling behaviour even though the phenomenon is clearly observed in laboratory experiments.

ABSTRACT: Five aluminium blade stiffened panels of three different geometries were tested in compression in a displacement controlled loading apparatus. Panel designs were achieved using VICONOPT, a fast-running optimization package based on linear eigenvalue buckling theory, and include two different design philosophies. The panels were loaded beyond initial buckling to collapse, and the effects of initial overall imperfections were monitored. In all cases the final failure showed evidence of significant interaction between buckling modes. The tests draw particular attention to a violently unstable and unpredictable form of failure, involving a combination of overall and stiffener buckling, which can occur even when initial buckling in the skin has the effect of pushing the panel in the opposite sense.

ABSTRACT: We investigate the cross-sectional buckling of multi-concentric tubular nanomaterials, which are called multiwalled carbon nanotubes (MWNTs), using an analysis based on thin-shell theory. MWNTs under hydrostatic pressure experience radial buckling. As a result of this, different buckling modes are obtained depending on the inter-tube separation d as well as the number of constituent tubes N and the innermost tube diameter. All of the buckling modes are classified into two deformation phases. In the first phase, which corresponds to an elliptic deformation, the radial stiffness increases rapidly with increasing N. In contrast, the second phase yields wavy, corrugated structures along the circumference for which the radial stiffness declines with increasing N. The hard-to-soft phase transition in radial buckling is a direct consequence of the core-shell structure of MWNTs. Special attention is devoted to how the variation in d affects the critical tube number Nc,
which separates the two deformation phases observed in N -walled nanotubes, i.e., the elliptic phase for N < Nc and the corrugated phase for N > Nc. We demonstrate that a larger d tends to result in a smaller Nc, which is attributed to the primary role of the interatomic forces between concentric tubes in the hard-to-soft transition during the radial buckling of MWNTs.

Irene Arias and Marino Arroyo (Dept. Applied Mathematics 3, LaCaN, Universitat Politècnica de Catalunya (UPC), Barcelona 08034, Spain), “Size–Dependent Nonlinear Elastic Scaling of Multiwalled Carbon Nanotubes”,
ABSTRACT: We characterize through large-scale simulations the nonlinear elastic response of multiwalled carbon nanotubes (MWCNTs) in torsion and bending. We identify a unified law consisting of two distinct power law regimes in the energy-deformation relation. This law encapsulates the complex mechanics of rippling and is described in terms of elastic constants, a critical length scale, and an anharmonic energy-deformation exponent. The mechanical response of MWCNTs is found to be strongly size dependent, in that the critical strain beyond which they behave nonlinearly scales as the inverse of their diameter. These predictions are consistent with available experimental observations.

ABSTRACT: In many applications, one would like to perform calculations on smooth manifolds of low-dimension $d$ embedded in a high-dimensional space of dimension $D$. Often, a continuous description of such manifold is not known, and instead it is sampled by a set of scattered points in high dimensions. This poses a serious challenge. In this thesis, we approximate the point-set manifold as an overlapping set of smooth parametric descriptions, whose geometric structure is revealed by statistical learning methods, and then parametrized by meshfree methods. This approach avoids any global parameterization, and hence is applicable to manifolds of any genus and complex geometry. It combines four ingredients: (1) partitioning of the point set into subregions of trivial topology, (2) the automatic detection of the geometric structure of the manifold by nonlinear dimensionality reduction techniques, (3) the local parameterization of the manifold using smooth meshfree (here local maximum-entropy) approximants, and (4) patching together the local representations by means of a partition of unity. We show the generality, flexibility, and accuracy of the method in four different problems. First, we exercise it in the context of Kirchhoff-Love thin shells, ($d = 2, D = 3$). We test our methodology against classical linear and non linear benchmarks in thin-shell analysis, and highlight its ability to handle point-set surfaces of complex topology and geometry. We then tackle problems of much higher dimensionality. We perform reduced order modeling in the context of finite deformation elastodynamics, considering a nonlinear reduced configuration space, in contrast with classical linear approaches based on Principal Component Analysis ($d = 2, D = 10, 000$’s). We further quantitatively unveil the geometric structure of the motility strategy of a family of micro-organisms called Euglenids from experimental videos ($d = 1, D \approx 30,000$’s). Finally, in the context of enhanced sampling in molecular dynamics, we automatically construct collective variables, which characterize molecular conformations ($d = 1 \ldots 6, D \approx 30$ to $1,000$’s).

ABSTRACT: A finite element formulation is presented for modelling geometrically nonlinear thin shells which exploits standard Lagrange finite element basis functions without introducing rotation degrees of freedom. The classical regularity requirements associated with thin bending problems are circumvented by introducing special integrals over inter-element edges. The use of Lagrange finite element basis functions and the absence of rotation degrees of freedom make the formulation relatively simple, and discontinuities in material properties and non-smooth shell geometry can be incorporated trivially. The variational problem can be exactly linearised, leading to an efficient Newton–Raphson solution process. The performance of the approach is demonstrated via a range of numerical benchmarks for both geometrically linear and nonlinear problems. It is shown that cubic elements perform particularly well.

SUMMARY: Calculations on general point-set surfaces are attractive because of their flexibility and simplicity in the preprocessing but present important challenges. The absence of a mesh makes it nontrivial to decide if two neighboring points in the three-dimensional embedding are nearby or rather far apart on the manifold. Furthermore, the topology of surfaces is generally not that of an open two-dimensional set, ruling out global parametrizations. We propose a general and simple numerical method analogous to the mathematical theory of manifolds, in which the point-set surface is described by a set of overlapping charts forming a complete atlas. We proceed in four steps: (1) partitioning of the node set into subregions of trivial topology; (2) automatic detection of the geometric structure of the surface patches by nonlinear dimensionality reduction methods; (3) parametrization of the surface using smooth meshfree (here maximum-entropy) approximants; and (4) gluing together the patch representations by means of a partition of unity. Each patch may be viewed as a meshfree macro-element. We exemplify the generality, flexibility, and accuracy of the proposed approach by numerically approximating the geometrically nonlinear Kirchhoff–Love theory of thin-shells. We analyze standard benchmark tests as well as point-set surfaces of complex geometry and topology.

ABSTRACT: The study of novel materials produces many challenges in the areas of synthesis, modeling and characterization. For the latter, one would like to be able to determine mechanical, electrical and dynamical properties, and correlate them with structure. In the following chapter, we describe work performed at the University of North Carolina-Chapel Hill (UNC) in the development of microscopy instrument systems, including a natural interface for scanned probe microscopy we call the nanoManipulator. We describe the principle design features of the instrument system including the visual display of data, the haptic (force-feedback) control and display capabilities. Second, we describe the combination of microscopy and manipulation in a joint Scanning Electron Microscopy/Scanning Probe Microscopy system. These systems have been used for studies of nanotube mechanical dynamical and electrical properties and for the study of biological macromolecular structures such as viruses, fibers (pili, fibrin, microtubules, etc.) and molecules (DNA). We describe examples of these studies drawn from our work on nanotubes and viruses.

ABSTRACT: A model, based on the theory of nonlocal continuum mechanics, on the column buckling of multiwalled carbon nanotubes is presented. The present analysis considers that each of the nested concentric tubes is an individual column and that the deflection of all the columns is coupled together through the van der Waals interactions between adjacent tubes. Based on this description, a condition is derived in terms of the parameters that describe the van der Waals forces and the small internal length scale effects. In particular, an explicit expression is derived for the critical axial strain of a double walled carbon nanotube which clearly
demonstrates that small scale effects contribute significantly to the mechanical behavior of multiwalled carbon nanotubes and cannot be ignored.

ABSTRACT: An elastic model is presented for column buckling of a multiwalled carbon nanotube embedded within an elastic medium. The emphasis is placed on the role of interlayer radial displacements between adjacent nanotubes. In contrast to an existing model which treats the entire multiwalled nanotube as a single column, the present model treats each of the nested tubes as an individual column interacting with adjacent nanotubes through the intertube van der Waals forces. Based on this model, a condition is derived in terms of the parameters describing the van der Waals interaction, under which the effect of the noncoincidence of all deflected column axes is so small that it does not virtually affect the critical axial strain. In particular, this condition is met for carbon multiwalled nanotubes provided that the half-wavelength of the buckling mode is much larger than the outermost diameter. In this case, the critical axial strain can be predicted correctly by the existing single-column model. On the other hand, the existing model could overestimate the critical axial strain when the half-wavelength of the buckling mode is close to or smaller than the outermost radius.

ABSTRACT: A multiple-shell model is presented for infinitesimal axially compressed buckling of a multiwalled carbon nanotube embedded within an elastic matrix. In contrast to an existing single-shell model which treats the entire multiwalled nanotube as a singlelayer elastic shell, the present model assumes that each of the nested concentric tubes is an individual elastic shell and the deflections of all shells are coupled through the van der Waals interaction between adjacent nanotubes. By examining a doublewalled carbon nanotube, it is found that the change in interlayer spacing has a negligible effect on the axial buckling strain provided that the innermost radius is at least a few nanometers. Under this condition, a single equation is derived which determines the deflection of the multiwalled carbon nanotube, and it is shown that infinitesimal axial buckling of a N-walled carbon nanotubes is equivalent to that of a single layer elastic shell whose bending stiffness is approximately N times the effective bending stiffness of a single walled carbon nanotube. As a result, the axial buckling strain of a N-walled carbon nanotube is about 5 N times lower than that predicted by the existing single-shell model. The degraded axial buckling strain is attributed to the interlayer slips between adjacent nanotubes, which represents an essential feature of mechanical behavior of multiwalled carbon nanotubes.

ABSTRACT: Motivated by structural heterogeneity and thickness nonuniformity of protein shells (such as microtubules and viral capsids), a refined elastic shell model is suggested to study the effect of transverse shear and effective bending thickness on buckling of an empty spherical viral shell under external pressure. A key feature of the model is that the transverse shear modulus of viral shells is allowed to be much lower than the in-plane shear modulus, in accordance with the weak resistance of two-dimensional protein assemblies to transverse shear. The results show that the transverse shear-induced critical pressure drop could be as big as 50%–70% for smaller-radius viral shells when the transverse shear modulus is about one order of magnitude smaller than the in-plane shear
modulus, although the effect of transverse shear is negligible if the transverse shear modulus is equal to or larger than the in-plane shear modulus. These results suggest that the classical homogeneous shell model widely used in the literature would overestimate the strength of viral shells against buckling under external pressure. The refined model suggested here could extend the applicability of homogeneous elastic shell models from larger-radius viral shells to small-radius ones.

ABSTRACT: This work complements recent developments concerning the buckling of beams lying on a nonlinear (non-convex) elastic foundation, and also reports on some investigations on the role of material nonlinearity. Two structural models are studied using a simple elasto-plastic constitutive relationship, and buckling problems are formulated as reversible fourth-order differential equations. It is demonstrated that modulated responses are possible under certain circumstances. Some numerical simulations are presented supporting the analytical findings.

ABSTRACT: A thin annular plate is subjected to a uniform tensile field at its inner edge which leads to compressive circumferential stresses. When the intensity of the applied field is strong enough, elastic buckling occurs circumferentially, leading to a wrinkling pattern. Using a linear non-homogeneous pre-bifurcation state, the linearised eigenvalue problem describing this instability is cast as a fourth-order linear differential equation with variable coefficients. This problem is investigated numerically and it is shown that the simple application of the Galerkin technique reported in the literature leads to gross errors in the corresponding approximations. Several novel mathematical features of the eigenvalue problem are included as well.

ABSTRACT: This work addresses a generalization of Dean's classical problem, which sought to explain how an annular thin elastic plate buckles under uniform shearing forces applied around its edges. We adapt the original setting by assuming that the outer edge is radially stretched while the inner rim undergoes in-plane rotation through some small angle. Boundary-layer methods are used to investigate analytically the deformation pattern which is set up and localized around the inner hole when this angle reaches a well-defined critical wrinkling value. Linear stability theory enables us to identify both the critical load and the preferred number of wrinkles appearing in the deformed configuration. Our asymptotic results are compared with a number of direct numerical simulations.

ABSTRACT: This work investigates the edge-buckling experienced by a sectorial plate in a uniform bi-axial state of stress and subject to in-plane bending. Since the governing differential equations have variable coefficients, it turns out that the neutrally stable eigenfunctions can be qualitatively quite different as the mode number varies. Our interactive boundary-layer analysis succeeds in capturing the most dangerous mode associated with the global minimum of the marginal stability curve, while a complementary WKB route supplies an explanation for the morphological transitions experienced by the eigenmodes. The validity of our analysis is confirmed by direct numerical simulations of the full fourth-order buckling equation, which are in excellent agreement with the theoretical considerations.

ABSTRACT: The problem of inflation for a thick-walled compressible, isotropic, hyperelastic, spherical shell is considered. First we give a new class of strain–energy functions for which analytic solutions to the spherically symmetric problem can be obtained. These solutions are compared with the existing solutions for harmonic materials. Secondly we obtain numerical results for the aspherical bifurcation problem. A number of different strain–energy functions are considered and all show the same qualitative features as those demonstrated by incompressible materials. We show that a decrease in the bulk modulus of the material has a stabilizing effect, in that critical values of the deformation are increased.

SUMMARY: We investigate a pre-stressed annular thin film subjected to a uniform displacement field along its inner boundary. This loading scenario leads to a variable stress distribution characterized by an orthoradial component that may change sign along a concentric circle within the annular domain. When the intensity of the applied field is strong enough, elastic buckling occurs circumferentially, leading to a localized wrinkling pattern near the inner edge. Using a linear non-homogeneous pre-bifurcation state, the eigenvalue problem describing this instability is cast as a singularly-perturbed fourth-order linear differential equation with variable coefficients. The dependence of the lowest eigenvalue on various non-dimensional quantities is numerically investigated using the compound matrix method. These results are complemented by a WKB analysis which suggests that the qualitative and quantitative features of the full model can be described by a simplified second-order eigenvalue problem which takes into account the finite stiffness of the system.

ABSTRACT: Singular perturbation techniques are used to investigate the linear eigenvalue problem that describes the partial wrinkling of a pre-stressed rectangular thin elastic plate under in-plane bending. The dependence of the critical load and the wavelength of the localised oscillatory pattern on the non-dimensional bending rigidity of the plate is captured with a higher-order boundary-layer analysis. Comparisons with direct
numerical simulations of the original eigenproblem confirm the accuracy and versatility of the asymptotic technique explored in this work.

ABSTRACT: This work complements the first author’s recent asymptotic investigations on a class of boundary-eigenvalue problems for tensile buckling of thin elastic plates. In particular, it is shown here that the approximations for the critical buckling load can be improved by using a modified energy method that relies directly on the asymptotic results derived previously. We also explore a number of additional mathematical features that have an intrinsic interest in the context of multi-parameter eigenvalue problems.

ABSTRACT: Analogy between the post-buckling equilibrium form of complete spherical shells with the mandrel inside and the form of living spherical honeycomb structures is investigated. The primary aim of this paper is to describe the typical topological-geometrical properties of the multi-dimple buckling pattern of a complete spherical shell on the basis of this analogy. It was found that, although the sphere itself is the most symmetrical form, the buckling pattern on it (consisting of pentagons, hexagons and heptagons) is asymmetric.

ABSTRACT: We show that the icosahedral packings of protein capsomeres proposed by Caspar and Klug for spherical viruses become unstable to facetting for sufficiently large virus size, in analogy with the buckling instability of disclinations in two-dimensional crystals. Our model, based on the nonlinear physics of thin elastic shells, produces excellent one-parameter fits in real space to the full three-dimensional shape of large spherical viruses. The faceted shape depends only on the dimensionless Foppl - von Karman number $y=AY^2/\kappa$, where $Y$ is the two-dimensional Young’s modulus of the protein shell, $\kappa$ is its bending rigidity, and $R$ is the mean virus radius. The shape can be parametrized more quantitatively in terms of a spherical harmonic expansion. We also investigate elastic shell theory for extremely large $y$, $10^3< y <10^8$, and find results applicable to icosahedral shapes of large vesicles studied with freeze fracture and electron microscopy.

package DNA against a large internal force”, Nature 413, 748 (2001).
ABSTRACT: The shape and mechanical properties of viral capsids play an important role in several biological processes during the virus life cycle. In particular, to become infective, many viruses require a maturation stage where the capsid undergoes a buckling transition, from an initial spherical procapsid into a final icosahedral faceted shell. Here we study, using a minimal physical model, how the capsid shape and the buckling transition depend on the triangulation number T and the icosahedral class P of the virus structure. We find that, for small shells, capsids with P = 1 are most likely to produce polyhedral shapes that minimize their energy and accumulated stress, whereas viruses with P = 3 prefer to remain spherical. For big capsids, all shells are more stable adopting an icosahedral shape, in agreement with continuum elastic theory. Moreover, spherical viruses show a buckling transition to polyhedral shells under expansion, in consonance with virus maturation. The resulting icosahedral shell is mechanically stiffer, tolerates larger expansions and withstands higher internal pressures before failing, which could explain why some dsDNA viruses, which rely on the pressurization of their genetic material to facilitate the infection, undergo a buckling transition. We emphasize that the results are general and could also be applied to non-biological systems.

Antonio Siber (Institute of Physics, P.O. Box 304, 10001 Zagreb, Croatia), “Buckling transition in icosahedral shells subjected to volume conservation constraint and pressure: Relations to virus maturation”, Phys. Rev. E 73, 061915 (2006) [10 pages], doi: 10.1103/PhysRevE.73.061915

ABSTRACT: Minimal energy shapes of closed, elastic shells with 12 pentagonal disclinations introduced in otherwise hexagonally coordinated crystalline lattice are studied. The geometry and the total energy of shells are studied as a function of the elastic properties of the material they are made of. Particular emphasis is put on the buckling transition of the shells, that is, a strong preference of the shell shapes to “buckle out” in spatial regions close to the pentagonal disclinations for a certain range of the elastic parameters of the problem. The transition effectively increases the mean square aspherity of shapes, making them look more like an icosahedron rather than a sphere, which is a preferred shape prior to the onset of the transition. The properties of the buckling transition are studied in cases when (i) the total volume enclosed by the elastic shell has to be fixed and when (ii) there is an internal pressure acting on the shell. This may be related to the maturation process in nonenveloped dsDNA viruses, where the insertion of the genetic material in a preformed protein shell (viral coating) may effectively impose the fixed volume and/or pressure constraint. Several scenarios that may explain the experimentally observed feature of mature viruses being more aspherical (facetted) from their immature precursors are discussed, and predictions for the elastic properties of viral coatings are obtained on the basis of the presented studies.

ABSTRACT: Recent atomic force microscopy (AFM) nanoindentation experiments measuring mechanical response of the protein shells of viruses have provided a quantitative description of their strength and elasticity. To better understand and interpret these measurements, and to elucidate the underlying mechanisms, this paper adopts a course-grained modeling approach within the framework of three-dimensional nonlinear continuum elasticity. Homogeneous, isotropic, elastic, thick-shell models are proposed for two capsids: the spherical cowpea chlorotic mottle virus (CCMV), and the ellipsocylindrical bacteriophage phi29. As analyzed by the finite-element method, these models enable parametric characterization of the effects of AFM tip geometry, capsid dimensions, and capsid constitutive descriptions. The generally nonlinear force response of capsids to indentation is shown to be insensitive to constitutive particulars, and greatly influenced by geometric and kinematic details. Nonlinear stiffening and softening of the force response is dependent on the AFM tip dimensions and shell thickness. Fits of the models capture the roughly linear behavior observed in experimental measurements and result in estimates of Young’s moduli of approximately 280–360 MPa for CCMV and approximately 4.5 GPa for phi29.

ABSTRACT: A series of recent nanoindentation experiments on the protein shells (capsids) of viruses have established atomic force microscopy (AFM) as a useful framework for probing the mechanics of large protein
assemblies. Specifically these experiments provide an opportunity to study the coupling of the global assembly response to local conformational changes. AFM experiments on cowpea chlorotic mottle virus, known to undergo a pH-controlled swelling conformational change, have revealed a pH-dependent mechanical response. Previous theoretical studies have shown that homogeneous changes in shell geometry can play a significant role in the mechanical response. This article develops a method for accurately capturing the heterogeneous geometry of a viral capsid and explores its effect on mechanical response with a nonlinear continuum elasticity model. Models of both native and swollen cowpea chlorotic mottle virus capsids are generated from x-ray crystal structures, and are used in finite element simulations of AFM indentation along two-, three-, and fivefold icosahedral symmetry orientations. The force response of the swollen capsid model is observed to be softer by roughly a factor of two, significantly more nonlinear, and more orientation-dependent than that of a native capsid with equivalent elastic moduli, demonstrating that capsid geometric heterogeneity can have significant effects on the global structural response.

INTRODUCTION: By “spherical shell”, we mean complete spherical configurations, hemispherical heads (such as pressure vessel heads), and shallow spherical caps. In analyses, a spherical cap may be used to model the behavior of a complete spherical vessel with thickness discontinuities, reinforcements, and penetrations. Although the response of a spherical shell to external pressure has received considerable attention from analysts, the calculation of collapse pressure still presents substantial difficulties in the presence of geometrical discontinuities and manufacturing imperfections. The bulk of the theoretical work carried out so far has had a rather limited effect on the method of engineering design, and therefore much experimental support is still needed. At the same time, the application of spherical geometry to the optimum vessel design has continued to be attractive in many branches of industry dealing with submersibles, satellite probes, storage tanks, pressure domes, diaphragms, and similar systems. This chapter deals with the mechanical response and working formulas for spherical shell design in the elastic and plastic ranges of collapse, which could be used for underground and aboveground applications. The material presented is based on state-of-the-art knowledge in pressure vessel design and analysis.

Shahin Nayyeri Amiri (Dept. of Civil Engineering, Kansas State University), “Elastic and plastic buckling of spherical shells under various loading conditions”, Ph.D dissertation, Dept. of Civil Engineering, Kansas State University, Advisor Hayder A. Rasheed, August 2011, URL: http://hdl.handle.net/2097/10855

ABSTRACT: Spherical shells are widely used in aerospace, mechanical, marine, and other industrial applications. Accordingly, the accurate determination of their behavior becomes more and more important. One of the most important problems in spherical shell behavior is the determination of buckling loads either experimentally or theoretically. Therefore, in this study some elastic and plastic buckling problems associated with spherical shells are investigated. The first part of this research study presents the analytical, numerical, and experimental results of moderately thick and thin hemispherical metal shells into the plastic buckling range illustrating the importance of geometry changes on the buckling load. The hemispherical shell is rigidly supported around the base circumference against horizontal translation and the load is vertically applied by a rigid cylindrical boss (Loading actuator) at the apex. Kinematics stages of initial buckling and subsequent propagation of plastic deformation for a rigid-perfectly plastic shell models are formulated on the basis of Drucker-Shield's limited interaction yield condition. The effect of the radius of the boss used to apply the
loading, on the initial and subsequent collapse load is studied. In the numerical model, the material is assumed to be isotropic and linear elastic perfectly plastic without strain hardening obeying the Tresca or Von Mises yield criterion. Finally, the results of the analytical solution are compared and verified with the numerical results using ABAQUS software and experimental findings. Good agreement is observed between the load-deflection curves obtained using three different fundamental approaches. In the second part, the Southwell’s nondestructive method for columns is analytically extended to spherical shells subjected to uniform external pressure acting radially. Subsequently finite element simulation and experimental work shown that the theory is applicable to spherical shells with an arbitrary axi-symmetrical loading too. The results showed that the technique provides a useful estimate of the elastic buckling load provided care is taken in interpreting the results. The usefulness of the method lies in its generality, simplicity and in the fact that, it is non-destructive. Moreover, it does not make any assumption regarding the number of buckling waves or the exact localization of buckling.

ABSTRACT: Axisymmetric buckling analysis is presented for moderately thick laminated shallow annular spherical cap under transverse load. Buckling under central ring load and uniformly distributed transverse load, applied statically or as a step function load is considered. The central circular opening is either free or plugged by a rigid central mass or reinforced by a rigid ring. Annular spherical caps have been analysed for clamped and simple supports with movable and immovable inplane edge conditions. The governing equations of the Marguerre-type, first order shear deformation shallow shell theory (FSDT), formulated in terms of transverse deflection \( w \), the rotation \( \omega \) of the normal to the midsurface and the stress function \( U \), are solved by the orthogonal point collocation method. Typical numerical results for static and dynamic buckling loads for FSDT are compared with the classical lamination theory and the dependence of the effect of the shear deformation on the thickness parameter for various boundary conditions is investigated.

is assumed to be temperature dependent. Governing partial differential equation of motion is solved analytically by using Laplace transform for time domain and power series for spacial domain. The results in Laplace domain is transferred to time domain by employing the fast inverse Laplace transform (FLIT) method. Accuracy of present approach is assessed by comparing the the numerical results with the results of published work in literature. Furtheremore, the effects of non-local parameter and wall thickness on the dynamic characteristics of the nano-sphere are studied.

ABSTRACT: The nonlinear response of multi-layered composite cylindrical shell panels subjected to thermomechanical loads are studied in this article. The structural model is based on the first order shear deformation theory incorporating geometric nonlinearities. The nonlinear equilibrium paths are traced using the arc-length control algorithm within the framework of finite element method. Hashin’s failure criterion has been adopted to predict the first-ply failure of cylindrical laminates. Both temperature independent and temperature dependent elastic properties are considered in the analysis. Specific numerical results are reported to show the effect of radius-to-span ratio, thickness-to-span ratio, laminate stacking sequence, and boundary condition on stability characteristics of laminated cylindrical shell panels subjected to combined thermal and mechanical transverse loads.

ABSTRACT: Stability characteristics of composite skew plates subjected to in-plane compressive load are investigated here using the shear deformable finite element approach. The influences of high prebuckling stresses at the corner regions of isotropic and composite skew plates on their stability characteristics are emphasized for different load direction, boundary condition and laminate stacking sequence. The non-linear governing equations based on von Kármán's assumptions are solved by Newton–Raphson technique to get the hitherto unreported postbuckling equilibrium paths of composite skew plates loaded between two rigid flat platens. The variation of out-of-plane deformation and end-shortening with compressive in-plane load are examined for simply supported and clamped skew plates made of isotropic, symmetric and unsymmetric laminates. Marguerre's shallow shell theory is employed to study the effect of sinusoidal imperfection on the non-linear behavior of composite skew plates.

ABSTRACT: Stability characteristics of isotropic and composite plates subjected to partial or concentrated compressive edge loads are investigated here using a four-noded shear-flexible quadrilateral high-precision plate-bending element. A complete cubic polynomial shape function is used to interpolate the in-plane displacements for better accuracy in capturing the high-stress zone near the locally distributed edge load. The influences of location and distribution of in-plane edge compression on the buckling load of composite plates are studied. The nonlinear governing equations based on von Kármán's assumptions are solved by Newton–Raphson technique to get the hitherto unreported postbuckling equilibrium paths of partially loaded plates made of isotropic, symmetric, and unsymmetric laminates. Marguerre's shallow-shell theory is employed to study the effect of sinusoidal imperfection on the nonlinear behavior of composite plates under partial in-plane load.

ABSTRACT: This paper first compares the writers’ results of static and dynamic analyses of plates, cylindrical and spherical shells employing four-, eight-, and nine-noded elements with different integration rules with those of earlier investigators and including some of the recent composite theories. Thereafter, the nonlinear transient responses of laminated composite cylindrical and spherical shell panels with cutouts are investigated taking up additional examples that are yet to appear in the published literature. For these, the finite-element model is employed using eight-noded C0 continuity, an isoparametric quadrilateral element considering von Karman large deflection assumptions. In the time integration, the Newmark average acceleration method is used in conjunction with a modified Newton–Raphson iteration scheme. Important conclusions with respect to nonlinear transient responses are summarized for cylindrical and spherical shells with and without cutouts.

ABSTRACT: The nonlinear transient response of composite shells with/without cutouts and initial geometric
imperfection is investigated using the finite element method. The present formulation considers doubly curved shells incorporating von Kármán type nonlinear strains into the first order shear deformation theory. The analysis is carried out using quadratic C0 eight-noded isoparametric element. The governing nonlinear equations are solved by using the Newmark average acceleration method in the time integration in conjunction with modified Newton–Raphson iteration scheme. The validity of the model is demonstrated by comparing the present results with those available in the literature. Parametric studies are carried out varying the radius of curvature to width ratio and amplitude of initial geometric imperfection of laminated composite cylindrical, spherical and hyperbolic paraboloid shells with/without cutouts.

ABSTRACT: The concept of functionally graded (FG) materials was first introduced in 1984 by a group of material scientists in Japan, as ultrahigh temperature resistant materials for aircraft, space vehicles and other engineering applications. FG materials are a class of composites that have a continuous variation of material properties from one surface to another and thus eliminate interface problems found in laminated composites. The gradation in properties of the material reduces thermal stresses, residual stresses and stress concentration factors. The gradual variation results in a very efficient material tailored to suit the needs of the structure and, therefore, designated as a FG material. FG materials are typically manufactured from isotropic components such as metals and ceramics since they are used as thermal barrier structures in environments with severe thermal gradients. FG materials have the advantage of heat and corrosion resistance typical of ceramics and mechanical strength and t...

ABSTRACT: A C0 finite element formulation using a higher-order shear deformation theory (HSDT) is developed and used to analyse the buckling behaviour of laminated hypar and conoids. Higher order terms in the Taylor's series expansion are used to represent the higher-order transverse cross-sectional deformation modes. The formulation includes Sanders' approximation for doubly curved shells considering the effect of transverse shear. A realistic parabolic distribution of transverse shear strains through the shell thickness is assumed and the use of shear correction factor is avoided. The accuracy of the formulation is validated by carrying out convergence study and comparing the results with those available in the literature.

ABSTRACT: Nonlinear transient analysis of functionally graded curved panels is carried out employing a higher-order C0 finite element formulation. The element consists of nine degrees-of-freedom per node with higher-order terms in the Taylor’s series expansion which represents the higher-order transverse cross sectional deformation modes. The formulation includes Sanders’ approximation for doubly curved shells considering the effects of rotary inertia, transverse shear and moderately large rotations in the von Kármán sense. A realistic parabolic distribution of transverse shear strains through the shell thickness is assumed and the use of shear correction factor is avoided. The accuracy of the formulation is validated by comparing the results with those available in the literature. The transient dynamic responses of the functionally graded shell panels are investigated by varying the volume fraction index using a simple power law distribution. Material properties are assumed to be temperature-independent and graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents. Heat conduction between ceramic and metal constituents is neglected. Effects of different panel geometry parameters, boundary conditions and loadings are studied.

ABSTRACT: This paper investigates the free vibration and buckling behavior of singly and doubly curved shell panels made of functionally graded materials (FGMs). A higher-order shear deformation theory is used for the analysis of five shell panels, namely, cylindrical (CYL), spherical (SPH), hyperbolic paraboloid (HPR), hypar (HYP), and conoid (CON). The shell panels are subjected to a temperature field and in the case of buckling analysis, the shell panels are also subjected to a uniaxial compressive load. The properties of FGMs are considered to be temperature dependent and graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents. The accuracy of the formulation is validated by comparing the results with those available in the literature. The effects of geometric properties, material composition, and boundary conditions on the free vibration and buckling are studied.

ABSTRACT: This paper reports the dynamic instability behavior of functionally graded (FG) shells subjected to in-plane periodic load and temperature field using a higher-order shear deformation theory in conjunction with the finite-element approach. Properties of FG materials are assumed to be temperature dependent and graded in the thickness direction according to the power-law distribution in terms of volume fraction of the constituents. Five forms of shells considered in this investigation are singly curved cylindrical, doubly curved spherical, and hyperbolic paraboloid having two principal curvatures, doubly curved hypar having twist
curvature only, and doubly curved conoid having one curvature and twist curvature. The boundaries of dynamic instability regions are obtained using Bolotin’s approach. The structural system is considered to be undamped. The correctness of the formulation is established by comparing the writers’ results with those of problems available in the published literature. Effects of material composition and geometrical parameters are studied on the dynamic instability characteristics of the aforementioned five forms of shells having practical applications in many engineering disciplines.

ABSTRACT: In the present paper the postbuckling response of symmetrically and antisymmetrically laminated composite plates subjected to a combination of uniform temperature distribution through the thickness and in-plane compressive edge loading is presented. The structural model is based on a higher-order shear deformation theory incorporating von Karman nonlinear strain displacement relations. Adopting the Galerkin procedure, the governing nonlinear partial differential equations are converted into a set of nonlinear algebraic equations, which are solved using the Newton–Raphson iterative procedure. The critical buckling temperature is obtained from the solution of the linear eigenvalue problem. Postbuckled equilibrium paths are obtained for symmetrically laminated cross-ply, quasi-isotropic and antisymmetric angle-ply composite plates with and without initial geometric imperfections. Modal participation of each mode in the postbuckling deflection is reported using a multi-term Galerkin procedure.

ABSTRACT: The purpose of this paper is to study the nonlinear forced vibration response of delaminated composite shells in hygrothermal environments. Finite element method using an eight-noded C⁰ continuity, isoparametric quadrilateral element is employed. The theoretical formulations are based on the first-order shear deformation theory and von Kármán type nonlinear kinematics. For modeling the delamination, multipoint constraint algorithm is incorporated in the finite element code. The paper finds that the effect of presence of delaminations on the nonlinear transient response of composite shells is dependent not only on the size, but also on the location of the delaminations and the hygrothermal environments. The present study is limited to cylindrical and spherical shells having rectangular planform containing single delamination. Studies on different shell forms having non-rectangular planforms containing multiple delaminations can be taken up for future research. The value in this paper lies in that nonlinear transient response of delaminated shells in hygrothermal environments is studied for the first time. It will assist researchers of nonlinear dynamic behavior of elastic systems.

ABSTRACT: In the present paper the postbuckling and postbuckled vibrations of symmetrically laminated composite plate subjected to a uniform temperature distribution through the thickness is presented. The structural model is based on a higher-order shear deformation theory incorporating von Kármán nonlinear strain–displacement relations and initial geometric imperfections. Adopting a multi-term Galerkin's approximation, the governing nonlinear partial differential equations are converted into a set of nonlinear algebraic equations in the case of postbuckling analysis and nonlinear ordinary differential equations in the case of free vibration analysis. The critical buckling temperatures are obtained from the solution of the corresponding linear eigenvalue problems. Postbuckled equilibrium paths are traced by solving the nonlinear algebraic equations, via the Newton–Raphson iterative procedure. The free vibration frequencies of a thermally postbuckled plate are reported by solving the eigenvalue problem for different postbuckled deflections.

ABSTRACT: The postbuckling analysis of symmetric and antisymmetric cross-ply laminated cylindrical shell panels subjected to thermomechanical loading is examined in this paper. The formulation is based on an extension of Reissner’s shallow shell simplifications and accounts for parabolic distribution of transverse shear strains. Adopting a multiterm Galerkin’s method, the governing nonlinear partial differential equations are reduced into a set of nonlinear algebraic equations. The nonlinear equilibrium paths through limit points are traced using the Newton–Raphson method in conjunction with Riks approach. Numerical results are presented for symmetric and antisymmetric cross-ply laminated cylindrical shell panels, that illustrate the influence of mechanical edge loads, lateral distributed load, initial imperfection, and temperature field on the limit loads and snap-through behavior.

ABSTRACT: The nonlinear static response and vibration behavior of cross-ply laminated cylindrical shell panels subjected to axial compression combined with other secondary loading are examined. The shell theory adopted in the present case is based on a higher-order shallow shell theory, includes geometric imperfection and von Kármán-type geometric nonlinearity. The solutions to the governing nonlinear partial differential equations are sought using the multiterm Galerkin technique. The nonlinear equilibrium paths through limit points and bifurcation points are traced using the Newton–Raphson method coupled with the Riks approach. The free vibration frequencies of post-buckled cylindrical panels about the static equilibrium state are reported by solving the associated linear eigenvalue problem. Results are presented for simply supported cross-ply laminated cylindrical shell panels, which illustrates the influence of initial geometric imperfection, temperature field, lateral pressure loads, and mechanical edge loads on the static response and vibration behavior of the shell panel.

ABSTRACT: The present investigation deals with the nonlinear stability behavior of cross-ply laminated composite circular cylindrical shells subjected to partial and complete edge loading along with uniform external pressure. The shell is modeled using Donnell’s shell theory including the first-order shear deformation theory (FSDT). The analysis uses the simply supported boundary condition (at x=0, \( LN_{xx} = 0 \), \( w = M_{xx} = v = \varphi_0 = 0 \)). The equations governing the nonlinear stability behavior of cylindrical shells are derived in terms of displacements (\( u \), \( v \), \( w \)) and rotations (\( \varphi_x \), \( \varphi_\theta \)). The applied partial edge loading is expressed in terms of Fourier series, and stress distributions within the cylindrical shell are determined by prebuckling analysis. The study uses multiterm Galerkin's method along with the Newton-Raphson method to solve the governing partial differential equations of the shell nonlinear stability. With the help of numerical investigations, the authors present the number of modes required for the postbuckling analysis and the influence of initial geometric imperfections on the equilibrium path in the presence of partial edge loading. They have developed a simple algorithm based on potential theory to locate the exact location of bifurcation and limit points on the equilibrium path using the bisection method.

ABSTRACT: Linear and nonlinear dynamic instability behavior of cylindrical sandwich panels subjected to combined static and dynamic nonuniform in-plane loadings is studied in this article. The core compressibility effects are considered in the model by assuming fourth and fifth order expansions for the transverse and tangential displacement of the core. The exact stress distributions within the panel are determined by panel prebuckling analysis for the applied parabolic and partial edge loadings. Galerkin's method is used to reduce the governing partial differential equations of the shell panel into a set of nonlinear ordinary differential equations. Dropping the nonlinear term, dynamic instability regions are obtained by solving the Mathieu-type differential equation by the method of Fourier series. The characteristics feature of the stable and unstable regions are investigated by linear and nonlinear time history responses and phase plots of the shell panel in those regions using Newmark's time integration. Incremental harmonic balance (IHB) method is used to study the nonlinear frequency amplitude responses of the cylindrical sandwich panels.

Ramachandra (Department of Civil Engineering, Indian Institute of Technology Kharagpur, Kharagpur 721302, India), “Static and dynamic instability analysis of composite cylindrical shell panels subject to partial edge loading”, International Journal of Non-Linear Mechanics, Vol. 64, pp 46-56, September 2014, DOI: 10.1016/j.ijnonlinmec.2014.03.014

ABSTRACT: The postbuckling and dynamic instability behavior of simply supported composite cylindrical shell panels subjected to dynamic partial edge loadings and transverse patch loadings is studied in this paper considering von Kármán type of non-linearity. The stress distribution within the panel due to the applied partial edge loadings is evaluated by panel's membrane analysis. Subsequently using these stress distribution and via Hamilton’s variational principle, the equations governing the instability behavior of shell panel are derived. Neglecting inertia terms, governing equations for the postbuckling analysis of panel are obtained. Galerkin’s method is used in the solution procedure. It is observed from the postbuckling analysis that the cylindrical shell panel subjected to partial edge compression behaves as an imperfect shell panel as the partial edge compression
in the $x$-direction induces tensile stress in the $y$-direction which makes the shell panel to deflect out-of-plane. It is also observed that by suitably adjusting the lamina number and lamina layup, the snap through behavior of shells can be altogether avoided. Dynamic instability regions of simply supported composite shell panels are traced by the method suggested by Bolotin. The linear and non-linear dynamic responses of the shell in stable and unstable regions are studied. This brings out various features of the instability problem such as, existence of beats and its dependence on forcing frequency and initial conditions, and effect of non-linearity on the response. It is found that for certain value of dynamic partial edge loading, the panel exhibits chaotic behavior.

ABSTRACT: The problem of stability and buckling of plates under creep conditions has been studied in the fundamental papers [1–4]. In the papers [5, 6], the theory of buckling of rods and plates is developed in the framework of the dominating bending model [7], where the forces in the midplane of the plate were determined independently of the solution of the bending problem. In what follows, we use the Kármán scheme [8] to derive two basic differential equations of the coupled theory of the plane stress state and bending. We solve the problem of buckling of a rectilinear plate for linearly viscous (Newtonian) medium and show that the Kármán scheme gives an essential correction to the solution of the bending problem for initial deflections comparable with the plate thickness.

ABSTRACT: This paper discusses the structural optimization problem of finding the optimal wall thickness of
an axisymmetric cylindrical shell so as to maximize the buckling load when the volume of material is fixed. An optimality condition is derived and then the method of truncated Fourier series is used to find an optimal design which indicates an 83% increase in buckling load over the classical critical buckling load for the case of uniform thickness.

ABSTRACT: Eigenvalue buckling of cylindrical shells with various boundary conditions under hydrostatic load is examined, using an energy method. Results are compared to known solutions, where these solutions exist. It is found that, for shells of intermediate length, buckling loads for different end conditions may be determined by applying a simple, scalar multiplier to the pin-ended case. This does not apply to long shells, where the circumferential wave number $n\leq 3$. For $n=2$, the ring equation may be applied to all cases, as the boundary conditions no longer influence the solution. It is seen for the case of a shell with one end pinned and the other end free that the buckling solution collapses to the long shell solution, for geometries of practical interest. The effect of radial elastic restraint at the open end is also examined, as an intermediate case between pinned and free ends. The work has application to the design of suction caissons, where cylinder dimensions are usually in the range of intermediate length shells.

ABSTRACT: Suction caissons are a type of foundation which is penetrated into the seabed using net external water pressure rather than more conventional techniques. The geometry of these foundations is such that, structurally, they fall into the category of shell structures. Due to the type of loading experienced by these foundations, which is predominantly hydrostatic, buckling of the caisson shell during suction installation becomes a consideration. This paper examines the factors influencing the buckling load of the caisson, including the boundary conditions of the shell, geometric imperfections, material plasticity, embedment ratio and the amount of lateral restraint offered by the surrounding soil. Results are obtained from three dimensional finite element analyses. (References not available.)

ABSTRACT: Shell eigen buckling behaviour is investigated for combined axial and lateral pressure loading and with various end conditions. In addition to the more common pinned (P) and clamped (C) end conditions, particular emphasis is placed on shells where one or both of the ends are free (F). The physical behaviour in different geometry ranges is used to develop simple, approximate eigenvalue formulae, which are verified against the predictions of linear shell buckling theory using the method of variations. The different end conditions are treated through multipliers to the well-known pin-ended (P–P) case. It is found that, for practical geometries, P–F shells are very much weaker than C–F shells due to the lack of warping restraint. The results have application to the design of suction caisson foundations for offshore platforms.

Ronalds (The University of Western Australia, School of Oil & Gas Engineering, 35 Stirling Hwy, Crawley, Western Australia, 6009, Australia), “Buckling and postbuckling of cylindrical shells with one end pinned and the other end free”, Thin-Walled Structures, Vol. 41, No. 6, June 2003, pp. 507-527, doi:10.1016/S0263-8231(03)00006-5

ABSTRACT: Using finite element analysis, this paper examines the linear bifurcation buckling loads, and nonlinear collapse loads, of cylindrical shells with one end pinned and the other end free, under a variety of axial and pressure load combinations. The pinned end is formulated so as to provide no axial restraint. For the bifurcation analysis, loads are related back to the classical solutions for cylinder buckling loads, to explain the very low values found for this set of boundary conditions. The nonlinear analysis includes both imperfections and material plasticity. In this analysis, it is found that cylindrical shells with pinned-free boundary conditions are notably imperfection insensitive, and for a range of geometries are able to reach collapse loads significantly greater than their bifurcation load. For other geometries, collapse loads very close to the bifurcation load are found. This unusual imperfection insensitivity for a cylindrical shell is explained in terms of the large flexibility engendered by the pinned-free boundary conditions and the oval buckling mode.

Ronalds (School of Oil & Gas Engineering, The University of Western Australia, 35 Stirling Hwy, Crawley 6009, Australia), “Buckling and collapse of cylinders with one end open and one end simply supported with varying axial restraint”, International Journal of Mechanical Sciences, Vol. 46, No. 4, April 2004, pp. 541-559, doi:10.1016/j.ijmecsci.2004.05.002

ABSTRACT: This paper examines the buckling and collapse of cylindrical shells under axial load with one end radially and tangentially fixed, with varying axial fixity, and the other end free. The bifurcation loads are found
for elastic cylinders, while collapse loads are found for both elastic and elastic-perfectly plastic cylinders. The varying axial restraint is applied in the form of linear springs. The eigenvalue buckling loads are calculated with conditions matching those of a classical analysis. Bifurcation loads are shown to be a function of the axial restraint; as the axial restraint is increased, the bifurcation load increases dramatically, until it reaches that of a semi-infinite, open ended cylinder. A non-dimensional form of the axial spring stiffness is proposed, and shown to be applicable across a range of geometries. The collapse load and imperfection sensitivity of cylinders with the boundary conditions examined here is also found to be a function of the axial restraint. Cylinders with low axial restraint are shown to be imperfection insensitive, with collapse loads above, or close to, the bifurcation load. As the amount of axial restraint increases, the collapse behaviour displays a degree of imperfection sensitivity associated with more usual boundary conditions.

ABSTRACT: This paper presents the results of physically and geometrically nonlinear analyses of the load-bearing capacity of slender wind-loaded cylindrical shells. These structures do not, even though their geometry is beam-like, behave as beams. The reason for this behaviour deviating from classic beam theory lies in the non-uniform wind pressure along the circumference, which leads to an ovalization of the cross section. There are two global and one local failure modes. The global failure modes are fundamentally different from those of squat shells with h/r<15. The top-stiffened shell in the geometrical transition range of shell-beam does not present the worst case. Additional ring-stiffeners lead to a loss of load baring capacity. Some conclusions are drawn from nonlinear parameter studies for the design practice.
Fourth Int. Colloquium on Computation of Shell & Spatial Structures, Chania-Crete, Greece

ABSTRACT: Despite of the intensive research effort of the last decades there are considerable gaps of knowledge concerning the imperfection sensitivity of steel shell structures, even with regard to the basic buckling cases. It is explained in the presented paper why the most unfavourable imperfection pattern does not exist for shell structures but only different unfavourable patterns depending on the imperfection amplitude. This amplitude-depending pattern cannot be determined with certainty because of the substantial influence of the material non-linearity and because of the numerous post-buckling paths which cross each other. However, the method of quasi-collapse-affine imperfections allows a reasonable approximation to the most unfavourable imperfection pattern. The basic thoughts of this concept are presented. The application of the concept to slender wind-loaded shells illustrates its capability.

ABSTRACT: A geometrically and materially nonlinear analysis with imperfections included (GMNIA) is currently the most sophisticated and perspective the most accurate method of a numerical buckling strength verification. By this way, equivalent geometric imperfections, which have to cover the influence of all deviations from the nominal data of the resistance parameters, are fundamental. The problem of consistent equivalent geometric imperfections includes the problems of their shape and size. It is recommended to start from the failure modes of the perfect structure in order to get imperfection patterns, which are unfavourable with respect to buckling resistance, relevant referring to manufacture and easy to use. The influence of the imperfection length is not sufficiently attended in the present design codes. It is proposed to use the full wave length of the ideal ring buckling mode as the imperfection length of the equivalent geometric imperfection for the basic buckling case of the axially compressed cylindrical shell. Finally, proposals are made for consistent equivalent geometric imperfection amplitudes of this buckling case.
ABSTRACT: The strong load drop in the post buckling area and the huge number of possible buckling modes at almost the same load level cause a considerable imperfection sensitivity of thin-walled shell structures. Thus, the inevitable deviations from the nominal resistance parameters have to be explicitly included in the numerical simulation. Because of the big dimensions of the structures of civil engineering and plant engineering, experiments at original structures are very expensive and are only exceptionally maintainable. Data from buckling experiments are available only for some basic buckling cases of fundamental shell geometries. However in the most cases, only the buckling loads but not the imperfections are documented well.

In order to assess the carrying capacity of buckling cases which are not yet sufficiently investigated, the new shell buckling code EN 1993-1-6:2007 allows numerical buckling strength verifications. Bearing in mind the complexity, diversity and sensitivity of shell buckling phenomena, it is not astonishing, that a number of application problems have not been solved yet [4]. Existing regulation deficiencies may be explored best at the basic buckling cases because of the available comparative experimental data. In the presentation, experiences and research needs are presented which result from performing geometrically and materially nonlinear calculations with imperfections included for the basic buckling case of a circular cylindrical shell subject to hoop compression. The mentioned Eurocode advises the use of equivalent geometric imperfections in order to cover the effect of different accidental imperfections in a safe manner.

In the first part of the presentation, the challenge of equivalent geometric imperfections is discussed. This problem divides up into the questions about the imperfection pattern and the imperfection size. Imperfection modes which have the most detrimental effect should be used according to the Eurocode. It is reasoned in the presentation, that eigenmode-affine imperfections are not appropriate for the buckling case hoop compression. Moreover, the most unfavourable imperfection pattern does not exist for shell structures but only different unfavourable patterns depending on the imperfection amplitude [3]. This amplitude-depending pattern can not be determined with certainty because of the substantial influence of the material non-linearity and because of the numerous postbuckling paths which cross each other. However, the method of quasi-collapse-affine imperfections allows a reasonable approximation to the most unfavourable imperfection pattern [3]. Single longitudinal predeformations resulting from this concept are well suited as equivalent imperfections. Regarding the imperfection amplitude, the question is addressed, what imperfection amplitudes are necessary to gain numerically the experimentally based lower bound buckling resistance of the stress design. Using the imperfection amplitudes recommended in the Eurocode, partly considerable discrepancies result from a numerical analysis of the circular cylindrical shell subject to hoop compression [2]. In order to overcome the knowledge gaps and to relate the accidental imperfections to the buckling resistance, for the first time extensive experimental series of test cylinders with the same nominal data have been performed at the Gdansk University of Technology. The geometric imperfections and the buckling process are well documented.

The numerical simulation of these experiments is dealt with in the second part of the contribution. Using static analyses, only the imperfection parts which initiate the buckling process may be reliably detected. In contrast, this statement is not valid for the buckling pattern. The inert forces must not be neglected performing a numerical simulation of the buckling process, because the collapse takes place with high velocities even though the load is increased very slowly. Therefore, a dynamic analysis is necessary in order to simulate the buckling in a mechanically consistent manner [1]. By means of a dynamic analysis, the arising buckling pattern is closely captured. Dynamic analyses are especially reasonable at the basic buckling case hoop compression, because the buckling process takes place by a sequence of several local buckling phenomena. The succession of stable and
unstable areas of the load-displacement path of a static analysis, which is connected with loading and unloading, does not correspond to mechanical reality. Finally, the minor differences between experiments and numerical simulations, which underline the high imperfection sensitivity of shell buckling, are discussed in detail. Summarising, conclusions are drawn concerning the imperfection parts initiating the buckling process as well as concerning the equivalent imperfection modes and amplitudes which should be used for performing a numerical buckling strength verification.

ABSTRACT: Although edge-wave and centre-buckles in rolled strip are believed to be largely self-equilibrated, the result of residual stress, formation of herringbone and quarter-buckles in hot- or cold-rolled strip is believed to require application of external stress. It is verified here that stress distributions such as those indicated by Roberts are possible causes of quarter-buckling and herringbone buckling. Quarter-buckling is believed to result from stress in the sheet or strip produced by non-parabolic bending of the work rolls. Herringbone buckling is attributed to local regions of axial tension and compression in the transverse stress distribution, caused by misalignment, which effectively produces a shear in the sheet that may manifest itself in diagonal buckling.

ABSTRACT: A personal overview of the buckling process is given, based on more than 30 years research experience. A fundamental distinction is drawn between structures that tend to distribute their pattern of buckling over the entire available length, and those that favour limiting it to a localized portion. Difficulties are compounded by the fact that localized solutions typically are shadowed by distributed counterparts. The difference is found to depend primarily on the stability of the system at the point of buckling. When an unstable localized form shows a tendency to restabilize, a pattern known as cellular buckling can develop, taking place sequentially in both space and time. The paper focuses particularly on the buckling of the axially-compressed cylindrical shell, and shows how the circumferential periodicity coupled with axial localization has special but hidden characteristics. In particular, the circumferential wavenumber is picked at an early stage of buckling and remains locked, while localization in the axial sense permits extensive change to the post-buckling shape.

ABSTRACT: Basic mechanisms for the buckling of a thin cylindrical shell under torsional loading are reviewed from a post-buckling perspective. Deflections are considered so far into the large-deflection range that the shell is allowed to fold to a flat two-dimensional form, in a mechanism reminiscent of a deployable structure. Critical and initial post-buckling effects are explored through concepts of energy minimization and hidden symmetries. For comparisons with the final large-deflection folded shape, a truss element program is employed. It is shown...
that, as buckling develops, the mode shape must change to accommodate both the symmetry-breaking aspects of the predominately inwards deflection, and the rotation of peak and valley lines of the buckle pattern necessary to accommodate the geometry of the final folded shape.

ABSTRACT: This paper focuses on rigid foldability of the cylindrical origami with Kresling pattern. The theory of quaternion representing spatial fixed-point rotation and the rotating vector model were proposed by some researchers to obtain the quaternion rotation sequence method (QRS method) to study the foldability of origami, but the method is limited definitely and not suitable for cylindrical foldable structures. In order to solve the problem, the method was improved in this paper. The single-vertex origami model with six creases was firstly introduced and the motion of this origami pattern was studied. Then the QRS method is improved by taking the geometry relationship into consideration. The results show the cylindrical origami with Kresling pattern is not rigid foldable.

INITIAL WORDS: “For each of us, it is a great pleasure to come together in this tribute to Michael Thompson's remarkable contributions to nonlinear statics and dynamics over the best part of half a century. Although having been friends and colleagues for many years, we have never written anything together, so it is entirely fitting that this should be happening for the first time in this piece. Each of us had Michael as an inspirational research supervisor over a different period in his research career: between us we must span, as close colleagues and collaborators, most of his lifetime of research. . .”

Mark Schenk and Simon D. Guest, “Origami folding: a structural engineering approach”, (publisher and date not given in the pdf file; 2010?)

ABSTRACT: In this paper we present a novel engineering application of Origami, using it for both the flexibility and the rigidity the folding patterns provide. The proposed Folded Textured Sheets have several interesting mechanical properties. The folding patterns are modeled as a pin-jointed framework, which allows the use of established structural engineering methods to gain insight into the kinematics of the folded sheet. The kinematic analysis can be naturally developed into a stiffness matrix approach; by studying its softest eigenmodes, important deformations of a partially folded sheet can be found, which aids in the understanding of Origami sheets for engineering applications.

ABSTRACT: This paper presents a theory for predicting the wavelength and amplitude of the wrinkles that form in a membrane in pure shear. Predictions from this theory are compared to experimental measurements and a finite element simulation and are found to be very accurate.
References listed at the end of the paper:
distribution of residual stresses induced by plastic bending. The basic mechanics of the bistability are explained, along with details of the plastic forming. A comprehensive analytical model is developed which predicts the residual stress distribution and bistable configurations of the shell. Good correlation has been found between experimental results and predictions from this model.

ABSTRACT: This is the third and final part of a study of wrinkles in thin membrane structures. High-fidelity, geometrically nonlinear finite element models of membrane structures, based on thin-shell elements, are used to simulate the onset and growth of wrinkles. The simulations are carried out with the ABAQUS finite element package. The accuracy of the results is demonstrated by computing the characteristics of the wrinkles in two specific membrane structures that were investigated experimentally and analytically in the first two papers in this series.

ABSTRACT: Thin-shell deployable reflector structures that are folded elastically in a nearly inextensional mode have been recently realized, exploiting the recent availability of high-modulus, ultrathin composite materials. An inherent and significant limitation of this approach is that these structures remain “floppy” in their deployed configuration. This paper presents a general concept for increasing the deployed stiffness of such structures, through the addition of a collapsible edge stiffener around the rim of a reflector dish. An analytical expression of the frequency/stiffness related to the softest deformation mode of a thin-shell reflector structure is presented, both with and without the stiffener. During folding, the stiffener collapses elastically, and this behavior is facilitated by the introduction of suitable discontinuities within the stiffener, or between the dish and the stiffener. A detailed study of a range of different options is presented, and one particular scheme is selected and optimized. For a specific example, a stiffness increase by a factor of 31 and a fundamental frequency increase by a factor of 4 are achieved, with a mass increase of only 16%.

ABSTRACT: Thin cylindrical shell structures can show interesting bistable behaviour. If made unstressed from
isotropic materials they are only stable in the initial configuration, but if made from fibre-reinforced composites they may also have a second, stable configuration. If the layup of the composite is antisymmetric, this alternative stable configuration forms a tight coil; if the layup is symmetric the alternative stable configuration is helical. A simple two-parameter model for these structure is presented that is able to distinguish between these different behaviours.

ABSTRACT: This paper presents a computational study of the critical buckling pressure of pumpkin balloons, which consist of a thin, compliant membrane constrained by stiff meridional tendons. The n-fold symmetric shape of a pumpkin balloon with n identical lobes is exploited by adopting a symmetry-adapted coordinate system, which leads to the tangent stiffness matrix in an efficient block-diagonal form; the smallest eigenvalue of a particular block leads to the buckling pressure for the balloon. Two different types of balloon design are considered. Extensive results are obtained for the buckling pressures of a set of 10 m diameter experimental balloons and also for an 80 m diameter flight balloon. The key findings are as follows: the same type of buckling mode, forming four circumferential waves is critical for most of the balloons that have been analysed; balloons with flatter lobes are more stable, and the buckling pressure varies with an inverse power-law of the number of lobes; increasing the Young’s modulus, the Poisson’s ratio of the membrane, or the diameter of the end fitting has the effect of increasing the buckling pressure; but increasing the axial stiffness of the tendons has the effect of decreasing the buckling pressure.

ABSTRACT: This thesis presents an experimental, numerical and analytical study of the behavior of thin fiber composites with a silicone matrix. The main difference with respect to traditional composites with epoxy matrix is the fact that the soft matrix allows the fibers to microbuckle without breaking. This process acts as a stress relief mechanism during folding, and allows the material to reach very high curvatures, which makes them
particularly interesting as components of space deployable structures. The goal of this study is to characterize the behavior and understand the mechanics of this type of composite.

Experimental testing of the bending behavior of unidirectional composites with a silicone matrix shows a highly non-linear moment vs. curvature relationship, as well as strain softening under cyclic loading. These effects are not usually observed in composites with an epoxy matrix. In the case of tension in the direction transverse to the fibers, the behavior shows again non-linearity and strain softening, as well as an initial stiffness much higher than what would be expected based on the traditional estimates for fiber composites.

The micro mechanics of the material have been studied with a finite element model. It uses solid elements and a random fiber arrangement produced with a reconstruction process based on micrographs of the material cross section. The simulations capture the macroscopic non-linear response, as well as the fiber microbuckling, and show how microbuckling reduces the strain in the fibers. The model shows good agreement for the bending stiffness of specimens with low fiber volume fraction, but it overestimates the effect of the matrix for more densely packed fibers. This is due to the high matrix strain that derives from the assumption of perfect bonding between fiber and matrix. In the case of tension transverse to the fibers, the model shows a much better agreement with experiments than traditional composite theory, and shows that the reason for the observed high stiffness is the incompressibility of the matrix. In order to capture the strain softening due to fiber debonding, cohesive elements have been introduced between the fibers and the matrix. This allows the model to capture quantitatively the non-linear behavior in the case of loading transverse to the fibers, and the damage due to cyclic loading. A single set of parameters for the cohesive elements produce good agreement with the experimental results for very different values of the fiber volume fraction, and could also be used in the analysis of more complicated loading cases, such as bending or biaxial tension. In addition to the simulations, a homogenized analytical model has also been created. It extends previous analysis of composites with a soft matrix to the case of very thin composites. It provides a good qualitative description of the material behavior, and it helps understand the mechanics that take place within the material, such as the equilibrium of energy terms leading to a finite wave length, as opposed to microbuckling under compression.

Francisco Lopez Jimenez (University of Colorado Boulder) and Sergio Pellegrino (California Institute of Technology), “Folding of thin-walled composite structures with a soft matrix”, AIAA/ASME Structures, Structural Dynamics and Materials Conference, May 2009

ABSTRACT: The paper presents detailed micromechanical finite element simulations of composite materials with soft materials undergoing large macroscopic bending deformation. The simulations allow the study of fibre microbuckling under bending, including the kinematics of the fibres, as well as the strains in the matrix. These simulations lead to a simple analytical model that allows a quite accurate estimation of the buckling wavelength. It also provides the moment-curvature relationship. Finally, the model is also able to predict the maximum strain in the fibres for a given curvature.

ABSTRACT: This paper is concerned with the optimization of the cutting pattern of n-fold symmetric super-
pressure balloons made from identical lobes constrained by stiff meridional tendons. It is shown that the critical buckling pressure of such balloons is maximized if the unstressed surface area of the balloon is minimized under a stress constraint. This approach results in fully stressed balloon designs that in some cases have a smaller unstressed surface area than the corresponding axisymmetric surface that is in equilibrium with zero hoop stress. It is shown that, compared to current designs, the buckling pressures can be increased by up to 300% without increasing the maximum stress in the lobe.

ABSTRACT: This paper presents a simplified simulation technique for orthotropic viscoelastic membranes. Wrinkling is detected by a combined stress-strain criterion and an iterative scheme searches for the wrinkle angle using a pseudo-elastic material stiffness matrix based on a non-linear viscoelastic constitutive model. This simplified model has been implemented in ABAQUS/Explicit and is able to compute the behavior of a membrane structure by superposition of a small number of response increments. The model has been tested against a published solution for a time-independent isotropic membrane under simple shear and also against experimental results on StratoFilm 420 under simple shear.

ABSTRACT: The rapid growth in direct digital manufacturing technologies has opened the challenge of designing optimal micro-structures for high-performance components. Current topology optimization techniques do not work well for this type of problems and hence in this paper we propose a technique based on an implicit representation of the structural topology. The detailed microstructure is designed by a continuous variable, the size distribution field, defined over the design domain by chosen shape functions. We can optimize the structural topology by optimizing only the weights of the size distribution and, for any given size distribution, we use standard meshing software to determine the actual detailed microstructure. We have implemented the optimization loop using commercial CAD and FEA software, running under a genetic algorithm in MATLAB. Application this novel technique to the design of a sandwich beam has produced designs that are superior to any standard solid beam or even optimized truss structure.

ABSTRACT: The buckling of axially compressed cylindrical shells and externally pressurized spherical shells is extremely sensitive to even very small geometric imperfections. In practice this issue is addressed by either using overly conservative knockdown factors, while keeping perfect axial or spherical symmetry, or adding closely and equally spaced stiffeners on shell surface. The influence of imperfection-sensitivity is mitigated, but the shells designed from these approaches are either too heavy or very expensive and are still sensitive to imperfections. Despite their drawbacks, these approaches have been used for more than half a century. This thesis proposes a novel method to design imperfection-insensitive cylindrical shells subject to axial compression. Instead of following the classical paths, focused on axially symmetric or high-order rotationally symmetric cross-sections, the method in this thesis adopts optimal symmetry-breaking wavy cross-sections (wavy shells). The avoidance of imperfection sensitivity is achieved by searching with an evolutionary
algorithm for smooth cross-sectional shapes that maximize the minimum among the buckling loads of geometrically perfect and imperfect wavy shells. It is found that the shells designed through this approach can achieve higher critical stresses and knockdown factors than any previously known monocoque cylindrical shells. It is also found that these shells have superior mass efficiency to almost all previously reported stiffened shells. Experimental studies on a design of composite wavy shell obtained through the proposed method are presented in this thesis. A method of making composite wavy shells and a photogrammetry technique of measuring full-field geometric imperfections have been developed. Numerical predictions based on the measured geometric imperfections match remarkably well with the experiments. Experimental results confirm that the wavy shells are not sensitive to imperfections and can carry axial compression with superior mass efficiency. An efficient computational method for the buckling analysis of corrugated and stiffened cylindrical shells subject to axial compression has been developed in this thesis. This method modifies the traditional Bloch wave method based on the stiffness matrix method of rotationally periodic structures. A highly efficient algorithm has been developed to implement the modified Bloch wave method. This method is applied in buckling analyses of a series of corrugated composite cylindrical shells and a large-scale orthogonally stiffened aluminum cylindrical shell. Numerical examples show that the modified Bloch wave method can achieve very high accuracy and require much less computational time than linear and nonlinear analyses of detailed full finite element models. This thesis presents parametric studies on a series of externally pressurized pseudo-spherical shells, i.e., polyhedral shells, including icosahedron, geodesic shells, and triambic icosahedra. Several optimization methods have been developed to further improve the performance of pseudo-spherical shells under external pressure. It has been shown that the buckling pressures of the shell designs obtained from the optimizations are much higher than the spherical shells and not sensitive to imperfections.

ABSTRACT: This paper presents an efficient computational method for predicting the onset of buckling of axially loaded, corrugated or stiffened cylindrical shells. This method is a modification of the Bloch wave method which builds on the stiffness matrix method. A numerical method and an efficient algorithm have been developed to implement the proposed method in the commercial finite element package Abaqus. Numerical examples have shown that, compared to the nonlinear buckling analyses based on detailed full finite element models, the proposed method can obtain highly accurate buckling loads and buckling modes and can achieve very significant reductions in computational time.

Bloch wave method for infinitely periodic structures. We modified the traditional Bloch wave method in order to analyze the buckling of rotationally periodic shell structures. We have developed an efficient algorithm to perform our modified Bloch wave method. The buckling behavior of composite corrugated cylindrical shells with a range of numbers of corrugations was analyzed. Linear and nonlinear buckling analyses of detailed full finite element models were also performed and compared to our method. Comparisons showed that our modified Bloch wave method was able to obtain highly accurate buckling loads and it was able to capture both global and local buckling modes. It was also found that the computational time required by our modified Bloch wave method did not scale up as the number of corrugations increased.

Pellegrino writes: “Last year I gave a series of lectures on the folding and deployment of thin shell structures, as part of a course at CISM (in Udine, Italy) on Extremely Deformable Structures organized by Davide Bigoni. These lectures provided an opportunity to revisit the work that I had done over a period of about 15 years, with many students and collaborators. My write-up of the lectures will appear as a book to be edited by Davide. There is also a downloadable pdf file on my website (http://pellegrino.caltech.edu/publications.html)”

ABSTRACT: Thin shells made of high modulus material are widely used as lightweight deployable space structures. The focus of this chapter is the most basic deployable thin shell structure, namely a straight,
transversely curved strip known as a tape spring. Following a review of the materials used for the construction of deployable thin shell structures, including constitutive models and failure criteria developed specifically for this type of structures, this chapter provides an introduction to the mechanics of tape springs and tape spring hinges. Finite element techniques to model deployable structures containing tape springs are presented and the ability of these models to accurately simulate experimentally observed behavior is demonstrated. These tools can be used to design structures able to achieve specific behaviors. As an example, the design of a two-hinge boom that can be wrapped around a small spacecraft without any damage, and can dynamically deploy and smoothly latch into the deployed configuration is presented.

ABSTRACT: This study is concerned with the equilibrium shapes of orthotropic, elliptical plates and shells deforming elastically without initial stresses. The aim is to explore potential bistable configurations and their dependencies on material parameters and initial shape for elucidating novel morphing structures. A strain energy formulation gives way to a compact set of governing equations of deformation, which can be solved in closed form for some isotropic and orthotropic conditions. It is shown that bistability depends on the change in Gaussian curvature of the shell, in particular, for initially untwisted shells, isotropy precludes bistability, where there is negative initial Gaussian curvature, but orthotropic materials yield bistability irrespective of the sign of the initial Gaussian curvature. This improved range of performance stems from increasing the independent shear modulus, which imparts sufficient torsional rigidity to stabilize against perturbations in the deformed state. It is also shown that the range of bistable configurations for initially twisted shells generally diminishes as the degree of twist increases.

ABSTRACT: Thin sheet materials of low bending stiffness but high membrane stiffness are often corrugated in order to achieve improvements of several orders of magnitude in bending stiffness with only minimal increases in weight and cost. If these corrugated sheets are initially curved along the corrugations, much of this stiffness gain is lost. In return, the sheets are then capable of significant elastic changes in shape overall, including large changes in overall Gaussian curvature. These shape changes are described here by non-linear and coupled kinematical relationships, which are verified against experiment and finite-element simulations. It is found that gross simplifications can be made about the large displacement behaviour of such shells without a loss of accuracy.

ABSTRACT: This study deals with prestressed shells, which are capable of “morphing” under large deflexions between very different load-free configurations. Prestressing involves plastically curving a flat, thin shell in orthogonal directions either in the opposite or same sense, resulting in two unique types of behavior for isotropic shells. Opposite-sense prestressing produces a bistable, cylindrically curved shell provided the prestress levels are large enough and similar in size: This effect forms the basis of a child's “flick” bracelet and is well known. On the other hand, same-sense prestressing results in a novel, neutrally stable shell provided the levels are also sufficiently large but identical: The shell has to be made precisely, otherwise, it is monostable and is demonstrated here by means of a thin, helically curved strip. The equilibrium states associated with both effects are quantified theoretically and new expressions are determined for the requisite prestress levels. Furthermore, each stability response is revealed in closed form where it is shown that the neutrally stable case occurs only for isotropic materials, otherwise, bistability follows for orthotropic materials, specifically, those, which have a shear modulus different from the isotropic value. Finally, prestressing and initial shape are considered together and, promisingly, it is predicted that some shells can be neutrally stable and bistable simultaneously.

ABSTRACT: Creasing in thin shells admits large deformation by concentrating curvatures while relieving stretching strains over the bulk of the shell: after unloading, the creases remain as narrow ridges and the rest of the shell is flat or simply curved. We present a helically creased unloaded shell that is doubly curved everywhere, which is formed by cylindrically wrapping a flat sheet with embedded fold-lines not axially aligned. The finished shell is in a state of uniform self-stress and this is responsible for maintaining the Gaussian curvature outside of the creases in a controllable and persistent manner. We describe the overall shape of the shell using the familiar geometrical concept of a Mohr’s circle applied to each of its constituent features—the creases, the regions between the creases, and the overall cylindrical form. These Mohr’s circles can be combined in view of geometrical compatibility, which enables the observed shape to be accurately and completely described in terms of the helical pitch angle alone.

ABSTRACT: We consider the axial buckling of a thin-walled cylinder fitted onto a mandrel core with a prescribed annular gap. The buckling pattern develops fully and uniformly to yield a surface texture of regular diamond-shaped buckles, which we propose for novel morphing structures. We describe experiments that operate well into the postbuckling regime, where a classical analysis does not apply; we show that the size of buckles depends on the cylinder radius and the gap width, but not on its thickness, and we formulate simple relationships from kinematics alone for estimating the buckle proportions during loading.

ABSTRACT: This paper presents research on the calculating analysis and experimental observations of shell buckling in individual gallium nitride hollow nanocolumns using nanoindentation. By using the experiment results of critical buckling strain under compression, we investigated the stiffness of hollow nanocolumns which were vertically aligned on a template by using linear elastic shell buckling theory. In addition, more studies of various possible nanomechanical behavior modes of gallium nitride hollow nanocolumns by shall model are provided. Furthermore, there was a comparison between nanocolumns by molecular dynamics simulation (one dimensional structure) and thin film by nanoindentation experiment (two dimensional structures). Finally, the buckling energy of compression for an individual gallium nitride hollow nanocolumn was also discussed.

ABSTRACT: Buckling considerations arise in the design of steel silos and tanks because the slender shell wall is subjected to compressive stresses, most commonly from the action of wind on the empty structure causing circumferential stresses, and combinations of wall friction forces, roof loads, non-uniform filling and discharge, and non-uniform settlement of the foundation causing meridional stresses. In this paper, recent research work of the author and graduate students relevant to buckling behaviour is briefly reviewed. Problems relevant to buckling behaviour, and which arose in several major tanks and silos with which the author was concerned either at the design stage or arising from operational problems, are discussed. The buckling behaviour and design of slender steel silos and tanks has been reviewed, with particular reference to buckling under wind loading, and under meridional compression. The benefits to be obtained by refined finite element analysis at the design stage have been emphasised, and several examples of buckling phenomena in the design of major structures reviewed. The occurrence of uplift of large empty tanks under severe wind loadings has been detected. A simplified design method for wind buckling has been given, which includes an approximate consideration of the effects of imperfections, meridional end restraints and form of the wind pressure distributions. Situations under which meridional compression can govern the design have been explored. The beneficial effects of a bulk solid content against buckling have been investigated.

PARTIAL INTRODUCTION: In Chapter 5, cylindrical shells under uniform external pressure with particular reference to short, medium-long and long cylinders, boundary conditions, stepped wall thicknesses and ring stiffeners were discussed. This chapter deals with buckling under non-uniform external pressure, examples of which abound in civil/mechanical engineering, marine, ballistic and aerospace structures. Earlier work on the stability of cylinders under external pressure was based on the Donnell stability equations, modified by Batdorf (1947)…. 

Peter Ansourian, “Shell Structures”, Center for Advanced Structural Engineering – CASE, Department of Civil Engineering, The University of Sidney, 2002

ABSTRACT: This project is concerned with the buckling failure of metal structures generally formed of curved plates. These structures are typically used in the liquid and bulk material storage industries, pressure vessels, aerospace vehicles, and in many other contexts. The analysis and design of pressure vessel closures may surprisingly sustain buckling failure under internal pressure. This is followed by a consideration of buckling under external pressure, firstly in the context of the Donnell stability equations which provide solutions of good accuracy in many cases, but secondly using the more rigorous and generally more accurate Flügge equations in coupled form. The latter theory is applied to cases of uniform and non-uniform pressure such as wind and patch loading. A further advantage of the theory is that solutions are possible for non-classical boundary conditions. Solutions are tabulated for uniform, hydrostatic, wind and patch loadings. Buckling under in-plane compressive forces is also briefly considered. Experimental and prototype responses under several loading regimes are examined and the significance to design considered; included are buckling problems associated with corrugated plates. When tank structures are supported on soils of non-uniform stiffness, differential settlement may occur, causing possible overstress or even buckling failure. Analyses based on inextensional theory are valid at low harmonic number in open-top tanks, while finite element analysis is the most general and accurate tool for the linear and non-linear stress and buckling response. The non-linear behaviour and coupled instabilities of steel cylindrical tank shells subjected to meridional edge deformation of harmonic pattern are investigated. The harmonic number n is shown to have a strong influence on the shear and meridional buckling interaction.
Practical applications are related to the design and maintenance of storage tanks and silos. The shear buckling mode is observed at small harmonic number \( n < 5 \) in shells of uniform thickness; with increasing \( n \), the mode is dominated by axial buckling. As the shell deforms in the shear buckling mode, it continues to carry higher load until local buckling occurs near the base. In tapered shells, shear buckling occurs in the upper region of the shell at high \( n \). (No references are given.)

Eiichi Watanabe, Kunitomo Sugiura and Takeshi Yamaguchi (Kyoto University, Japan), “Strength and ductility of thin-walled beam-columns with low yield steel”, Earthquake Engineering. Tenth World Conference, Rotterdam, 1992

ABSTRACT: Discussed herein is the load-deformation relationship of bridge piers considering the local failure characteristics. Firstly, the strength and ductility of thin tubular beam-column segments are investigated by two series of experiments keeping a focus on the cross sectional shape and inelastic characteristics of material. Assuming bridge piers subjected to strong ground motions, monotonic bending tests under the constant axial compressive force are carried out. The effect of the yield ratio and use of round corners on the strength and ductility is evaluated. It is found that the box section with round corners and the use of structural steel with low yield ratio is desirable for the ductility improvement. Secondly, by modeling the plastic hinge behavior considering the local instability based on the experimental observation, the deformation characteristic of steel bridge piers are investigated by numerical simulation. It is concluded that the effect of local instability on the strength deterioration is significant and the P-delta effect accelerates the degradation.

ABSTRACT: This paper presents an estimation of global elastic shear buckling strength of corrugated plates considering the influence of elastically rotational restraint on boundary edges. The corrugated plate possesses higher shear buckling strength compared to a flat one and it has been used to replace concrete web in PC box girder in recent bridge construction in Japan. In this study, the corrugated plate is considered as an orthotropic flat plate. Thick rectangular plate theory is used and Rayleigh-Ritz method is utilized in extracting eigenvalues. Elastically rotational restraint on boundary edges is taken into account in the form of rotational spring in the analysis. Prediction of buckling strengths of corrugated plates is carried out using the Rayleigh-Ritz method, which was proved to be consistent with those as predicted by a proposed formula using a design manual and was found also to cover the more general cases of elastically rotational restraint on the boundary edges showing transition curve of plate buckling strengths from the case of simple support to the case of clamped support. A finite element analysis was also carried out to verify the accuracy of the proposed method. As a result, a discrepancy is found between the buckling strength by the finite element analysis and that by the proposed analysis; however, the formula adopted in the design manual may be thought to be conveniently used because it can lead to the conservative design.

ABSTRACT: Abstract. Based on both molecular mechanics and computational structural mechanics, a three-dimensional (3D) equivalent beam element is developed to model a C-C covalent bond on carbon nanotubes (CNTs) whereas the van der Waals forces between atoms in the different walls of multi-walled CNTs are described using a rod element. The buckling characteristics of CNTs are conveniently analyzed by using the traditional finite element method (FEM) of a 3D beam and rod model, termed as molecular structural mechanics approach (MSMA). Moreover, to model the CNTs with large length or large diameter, the validity of Euler’s beam buckling theory and a shell model with proper properties defined from the results of MSMA is investigated. The predicted results by this simple continuum mechanics approach agree well with the reported experimental data.

ABSTRACT: In this paper, the buckling of carbon nanotubes, modeled as nonlocal one dimensional continua within the framework of Euler–Bernoulli beams, is considered. Both a stress gradient and a strain gradient approach are considered and a variational approach is adopted to obtain the variationally consistent boundary conditions. The dependence of the buckling load on the nonlocal parameter has been determined using the boundary conditions obtained from the variational analysis. Results indicate significant dependence of nonlocal parameter on buckling load for particular types of boundary conditions. These findings are important in mechanical design considerations of devices that use carbon nanotubes.

ABSTRACT: The natural frequencies of isotropic and composite laminates are presented. The forced vibration analysis of laminated composite plates and shells subjected to arbitrary loading is investigated. In order to overcome membrane and shear locking phenomena, the assumed natural strain method is used. To develop a laminated shell element for free and forced vibration analysis, the equivalent constitutive equation that makes the computation of composite structures efficient was applied. The Mindlin-Reissner theory which allows the shear deformation and rotary inertia effect to be considered is adopted for development of nine-node assumed strain shell element. The present shell element offers significant advantages since it consistently uses the natural co-ordinate system. Results of the present theory show good agreement with the 3-D elasticity and analytical solutions. In addition the effect of damping is investigated on the forced vibration analysis of laminated composite plates and shells.

ABSTRACT: To demonstrate the solutions of linear and geometrically non-linear analysis of laminated composite plates and shells, the co-rotational non-linear formulation of the shell element is presented. The combinations of an enhanced assumed strain (EAS) in the membrane strains and assumed natural strains (ANS) in the shear strains improve the behavior of 4-node shell element. To secure computational efficiency in the incremental non-linear analysis, the present element uses the form of the resultant forces pre-integrated through the thickness. The transverse shear stiffness of the laminates is defined by an equilibrium approach instead of the shear correction factor. Numerical examples of this study show very good agreement with the references.

ABSTRACT: The formulation of a non-linear composite 4-node co-rotational resultant shell element is presented for the solution of bending, free vibration, critical buckling and postbuckling analysis of composite plates and shells. Using the ANS (assumed natural strain) method the present shell element generates shear locking behavior, and such element performs very well as much as shells get thin. The formulation of the geometrical stiffness presented here is exactly defined on the mid-surface and is efficient for analyzing stability problems of thin and thick laminated plates, and shells by incorporating bending moment and transverse shear resultant forces. The transverse shear stiffness is defined by an equilibrium approach instead of using the shear correction factor. The adoption of a second-order co-rotational formulation makes it computationally efficient compared to the most existing composite shell elements. The proposed formulation is computationally efficient and the test results showed good agreement.

ABSTRACT: In order to solve the nonlinear problem in analyzing the buckling of thin-walled structures, an updated Lagrangian co-rotational method for the nonlinear analysis of shell structures was presented. A program based on this method was developed, and two numerical examples of the buckling analysis of shell structures were given. In this method, an updated Lagrangian formulation is adopted to build the equilibrium equation of shell elements under large displacements, and then the tangent stiffness matrix is obtained with the energy theory. The polar decomposition theory is applied in the computations of the new co-rotational coordinates of elements and the rigid body rotations of nodes, and the finite rotation theory is introduced to separate rigid displacements from total displacements to get deformations of the nodes. As a result, stresses of an element can be calculated based on the deformations by using the small-strain theory to obtain the element state for the current load step. The numerical examples indicate that the nonlinear analysis method based on co-rotational (CR) formulation is efficient and accurate in solving the buckling of shell structures. ABSTRACT: In this paper, the recently-developed solid-shell element SHB8PS is used for the analysis of a
representative set of popular limit-point buckling benchmark problems. For this purpose, the element has been implemented in Abaqus/Standard finite element software and the modified Riks method was employed as an efficient path-following strategy. For the benchmark problems tested, the new element shows better performance compared to solid elements and often performs as well as state-of-the-art shell elements. In contrast to shell elements, it allows for the accurate prescription of boundary conditions as applied to the actual edges of the structure.

This paper deals with the convergence acceleration of iterative nonlinear methods. An effective iterative algorithm, named the three–point method, is applied to nonlinear analysis of structures. In terms of computational cost, each iteration of the three–point method requires three evaluations of the function. In this study the effective functions have been proposed to accelerate the convergence process. The proposed method has a convergence order of eight, and it is important to note that its implementation does not require the computation of higher order derivatives compared to most other methods of the same order. To trace the equilibrium path beyond the limit point, a normal flow algorithm is implemented into a computer program. The three–point method is applied as an inner step in the normal flow algorithm. The procedure can be used for structures with complex behavior, including: unloading, snap–through, elastic post–buckling and inelastic post–buckling analyses. Several numerical examples are given to illustrate the efficiency and performance of the new method. Results show that the new method is comparable with the well–known existing methods and gives better results in convergence speed.

ABSTRACT: The paper presents the inelastic post-buckling analysis of truss structures by the Dynamic Relaxation (DR) method. A simplified inelastic finite element formulation for truss element and new algorithms are proposed for Elastic Post-Buckling (EPB) analysis and Inelastic Post-Buckling (IEPB) analysis using the DR method. The post-buckling paths for elastic, EPB and IEPB analyses are completely traced using the variable-arc-length method. Four numerical examples are presented to illustrate the application of the proposed algorithms.

Glenn A. Hrinda (NASA Langley Research Center, Hampton, Virginia, USA), “Snap-through instability patterns in truss structures”, Presented at one of the AIAA Structures (SDM) meetings; date not given in the pdf file; the most recent reference is 2009)

ABSTRACT: Geometrically nonlinear truss structures with snap-through behavior are demonstrated by using an arc length approach within a finite element analysis. The instability patterns are equilibrium paths that are plotted throughout the snap-through event. Careful observation of these patterns helps to identify weak designs in large space structures, as well as identify desirable snap-through behavior in the miniaturization of electronic devices known as microelectromechanical systems (MEMS). Examples of highly nonlinear trusses that show snap-through behavior are examined by tracing their equilibrium paths.

ABSTRACT: This paper presents a new co-rotational approach for the large displacement analysis of plates employing 4-noded quadrilateral flat shell elements. The proposed approach benefits from (i) a simple local co-
rotational system invariant to the element nodal ordering, (ii) the choice of the two smallest components of the nodal normal vector as global rotational degrees of freedom, and (iii) the use of hierarchic freedoms, that are unaffected by the co-rotational transformations, for higher-order accuracy. Important additional benefits that arise from the aforementioned features include symmetry of the tangent stiffness matrix and complete insensitivity of the large displacement transformations to the size of the incremental step. The applicability of the new approach to moderately thick as well as thin plates is illustrated by considering two alternative local formulations based on the Reissner–Mindlin and discrete Kirchhoff hypotheses. Several examples are finally presented which demonstrate the accuracy, step-insensitivity and computational benefits of the proposed co-rotational approach for large displacement analysis of plate structures.

ABSTRACT: A new 9-node co-rotational curved quadrilateral shell element formulation is presented in this paper. Different from other existing co-rotational element formulations: (1) Additive rotational nodal variables are utilized in the present formulation, they are two well-chosen components of the mid-surface normal vector at each node, and are additive in an incremental solution procedure; (2) the internal force vector and the element tangent stiffness matrix are respectively the first derivative and the second derivative of the element strain energy with respect to the nodal variables, furthermore, all nodal variables are commutative in calculating the second derivatives, resulting in symmetric element tangent stiffness matrices in the local and global coordinate systems; (3) the element tangent stiffness matrix is updated using the total values of the nodal variables in an incremental solution procedure, making it advantageous for solving dynamic problems. Finally, several examples are solved to verify the reliability and computational efficiency of the proposed element formulation. References listed at the end of the paper:

“ A stabilized co-rotational curved quadrilateral composite shell element”, International Journal for Numerical
ABSTRACT: A new curved quadrilateral composite shell element using vectorial rotational variables is presented.
An advanced co-rotational framework defined by the two vectors generated by the four corner nodes is employed to
extract pure element deformation from large displacement/rotation problems, and thus an element-independent
formulation is obtained. The present line of formulation differs from other co-rotational formulations in that (i) all
nodal variables are additive in an incremental solution procedure, (ii) the resulting element tangent stiffness is
symmetric, and (iii) is updated using the total values of the nodal variables, making solving dynamic problems
highly efficient. To overcome locking problems, uniformly reduced integration is used to compute the internal force
vector and the element tangent stiffness matrix. A stabilized assumed strain procedure is employed to avoid spurious
zero-energy modes. Several examples involving composite plates and shells with large displacements and large

ABSTRACT: Based on the boundary layer theory for the buckling of thin elastic shells suggested in ref. [14], the buckling and postbuckling behavior of clamped circular cylindrical shells under lateral or hydrostatic pressure is studied applying singular perturbation method by taking deflection as perturbation parameter. The effects of initial geometric imperfection are also considered. Some numerical results for perfect and imperfect cylindrical shells are given. The analytical results obtained are compared with some experimental data in detail, which shows that both are rather coincident.

plates under uniaxial compression, Appl. Math. and Mech., 9, 8 (1988), 793–804

ABSTRACT: In this paper, applying perturbation method to von Kármán nonlinear large deflection equations of plates by taking deflection as perturbation parameter, the postbuckling behavior of simply supported rectangular plates under uniaxial compression is investigated. Two types of in-plane boundary conditions are now considered and the effects of initial imperfections are also studied. It is found that the theoretical results are in good agreement with experiments. The method suggested in this paper which has not been found in previous papers is rather simple and easy for the postbuckling analysis of rectangular plates.

ABSTRACT: Buckling and postbuckling behaviour of perfect and imperfect cylindrical shells of finite length subject to combined loading of external pressure and axial compression are considered. Based on the boundary layer theory which includes the edge effect in the buckling of shells, a theoretical analysis for the buckling and postbuckling of circular cylindrical shells under combined loading is presented using a singular perturbation technique. Some interaction curves for perfect and imperfect cylindrical shells are given. The analytical results obtained are compared with some experimental data in detail, and it is shown that both agree well. The effects of initial imperfection on the interactive buckling load and postbuckling behaviour of cylindrical shells have also been discussed.

ABSTRACT: A new approach is extended to investigate the buckling and postbuckling behaviour of perfect and imperfect, stringer and ring stiffened cylindrical shells of finite length subject to combined loading of external pressure and axial compression. The formulations are based on a boundary layer theory which includes the edge effect in the postbuckling analysis of a thin shell. The analysis uses a singular perturbation technique to determine the buckling loads and the postbuckling equilibrium paths. Some interaction curves for perfect and imperfect stiffened cylindrical shells are given and compared well with experimental data. The effects of initial imperfection on the interactive buckling load and postbuckling behaviour of stiffened cylindrical shells have also been discussed.

ABSTRACT: A post-buckling analysis is presented for a stiffened laminated cylindrical shell of finite length subject to combined loading of external pressure and axial compression. The formulations are based on a boundary layer theory of shell buckling which includes the effects of the nonlinear pre-buckling deformation, the nonlinear large deflection in the post-buckling range and the initial geometrical imperfection of the shell. The “smeared stiffener” approach is adopted for the stiffeners. The analysis uses a singular perturbation technique to determine the interactive buckling loads and the post-buckling equilibrium paths. Numerical examples cover the performances of perfect and imperfect, stiffened and unstiffened cross-ply laminated cylindrical shells. Typical results are presented in dimensionless graphical form.

ABSTRACT: A postbuckling analysis is presented for a circular cylindrical shell of finite length which is subjected to combined loading of external liquid pressure and axial compression. The formulations are based on a boundary layer theory which includes effects of the nonlinear prebuckling deformation, the nonlinear large deflection in the postbuckling range and the initial geometrical imperfection of shells. The analysis uses a singular perturbation technique to determine interactive buckling loads and postbuckling equilibrium paths. Numerical examples are presented that relate to the performances of perfect and imperfect cylindrical shells. Typical results are presented in dimensionless graphical form.

ABSTRACT: A thermal postbuckling analysis is presented for a stiffened laminated cylindrical shell of finite length subjected to a uniform or non-uniform parabolic temperature distribution varying in the circumferential or axial direction. The formulations are based on a boundary layer theory of shell buckling which includes the effects of non-linear prebuckling deformations, non-linear large deflections in the postbuckling range, and initial geometrical imperfections of the shell. The “smeared stiffener” approach is adopted for the stiffeners. The analysis uses a singular perturbation technique to determine thermal buckling loads and postbuckling equilibrium paths. Numerical examples are presented that relate to the performances of perfect and imperfect, stiffened and unstiffened cross-ply laminated cylindrical shells. Typical results are presented in dimensionless graphical form and exhibit two different types of thermal postbuckling response.

ABSTRACT: A postbuckling analysis is presented for a stiffened laminated cylindrical shell of finite length subjected to combined axial compression and uniform temperature loading. The two cases of compressive
postbuckling of initially heated shells and of thermal postbuckling of initially compressed shells are considered. The formulations are based on a boundary layer theory of shell buckling, which includes the effects of the nonlinear prebuckling deformation, the nonlinear large deflection in the postbuckling range and the initial geometrical imperfection of the shell. The “smeared-stiffener” approach is adopted for the stiffeners. The analysis uses a singular perturbation technique to determine buckling loads and postbuckling equilibrium paths. Numerical examples cover the performances of perfect and imperfect, stiffened and unstiffened cross-ply laminated cylindrical shells with or without initial thermal or compressive stress. Typical results are presented in dimensionless graphical form, and they indicate that the postbuckling response of initially compressed laminated cylindrical shells under thermal load is different from that of mechanically loaded shells with and without initial thermal stress.

ABSTRACT: A postbuckling analysis is presented for a stiffened laminated cylindrical shell of finite length subjected to combined loading of external pressure and a uniform temperature rise. The formulation is based on a boundary layer theory of shell buckling which includes the effects of nonlinear prebuckling deformations, nonlinear large deflections in the postbuckling range and initial geometrical imperfections of the shell. The “smeared stiffener” approach is adopted for the stiffeners. The analysis uses a singular perturbation technique to determine the interactive buckling loads and the postbuckling equilibrium paths. Numerical examples are presented that relate to the performance of perfect and imperfect, stiffened and unstiffened cross-ply laminated cylindrical shells. Typical results are presented in dimensionless graphical form for different parameters and loading conditions.

ABSTRACT: A postbuckling analysis is presented for a stiffened, laminated, thin cylindrical shell of finite length subjected to combined loading of external liquid pressure and axial compression. The formulations are based on a boundary layer theory of shell buckling, which includes the effects of nonlinear prebuckling deformations, nonlinear large deflections in the postbuckling range and initial geometrical imperfections of the shell. The ‘smeared stiffener’ approach is adopted for the stiffeners. The analysis uses a singular perturbation technique to determine the interactive buckling loads and postbuckling equilibrium paths. Numerical examples cover the performances of perfect and imperfect, stiffened and unstiffened cross-ply laminated cylindrical shells. Typical results are presented in dimensionless graphical form.

Hui-Shen Shen (School of Civil Engineering and Mechanics, Shanghai Jiao Tong University, 1954 Hua Shan Road, Shanghai 200030, People's Republic of China), “Hygrothermal effects on the postbuckling of composite laminated cylindrical shells”, Composites Science and Technology, Vol. 60, No. 8, June 2000, pp. 1227-1240, doi:10.1016/S0266-3538(00)00062-2

ABSTRACT: The influence of hygrothermal effects on the buckling and post-buckling of composite laminated cylindrical shells subjected to combined loading of external pressure and axial compression has been investigated by using a micro-to-macro-mechanical analytical model. The material properties of the composite are affected by the variation of temperature and moisture, and are based on a micro-mechanical model of a laminate. The governing equations are based on the classical laminated-shell theory, including hygrothermal effects. The non-linear prebuckling deformations and initial geometric imperfections of the shell were both taken into account. A boundary layer theory of shell buckling is extended to the case of laminated cylindrical shells under hygrothermal environments and a singular perturbation technique is employed to determine the interactive buckling loads and post-buckling equilibrium paths. The numerical illustrations concern the postbuckling behaviour of perfect and imperfect, cross-ply laminated cylindrical shells under different sets of environmental conditions. The results show that the hygrothermal environment has a significant effect on the interactive buckling load as well as post-buckling response of the shell. In contrast, it has a small effect on the imperfection sensitivity.

A boundary layer theory of shell buckling is extended to the case of shear deformable laminated cylindrical shells under hygrothermal environments and a singular perturbation technique is employed to determine the interactive buckling loads and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling behaviour of perfect and imperfect, moderately thick, cross-ply laminated cylindrical shells under different sets of environmental conditions. The results show that the hygrothermal environment has a significant effect on the interactive buckling load as well as postbuckling response of the shell. In contrast, it has a small effect on the imperfection sensitivity of the shell with a very small geometric imperfection.

ABSTRACT: Thermal postbuckling analysis is presented for a cross-ply laminated cylindrical shell with piezoelectric actuators subjected to the combined action of thermal and electric loads. The temperature field considered is assumed to be a uniform distribution over the shell surface and through the shell thickness and the electric field is assumed to be the transverse component EZ only. The material properties are assumed to be independent of the temperature and the electric field. The governing equations are based on the classical shell theory with von Kármán–Donnell-type of kinematic nonlinearity. The nonlinear prebuckling deformations and initial geometric imperfections of the shell are both taken into account. A boundary layer theory of shell buckling, which includes the effects of nonlinear prebuckling deformations, large deflections in the postbuckling range, and initial geometric imperfections of the shell, is extended to the case of hybrid laminated cylindrical shells. A singular perturbation technique is employed to determine buckling temperatures and postbuckling load-deflection curves. The numerical illustrations concern thermal postbuckling behavior of perfect and imperfect, cross-ply laminated cylindrical thin shells with fully covered or embedded piezoelectric actuators under thermal and electric loads. The results show that the control voltage has a significant effect on the buckling temperature as well as thermal postbuckling response of the shell. In contrast, it has a very small effect on the imperfection sensitivity of (0/90)2S laminated cylindrical shells with piezoelectric actuators.

ABSTRACT: A postbuckling analysis is presented for a cross-ply laminated cylindrical shell with piezoelectric actuators subjected to the combined action of external pressure and heating and under electric loading cases. The temperature rise considered is assumed to be a uniform distribution over the shell surface and through the shell thickness and the electric field is assumed to be the transverse component EZ only. The material properties are assumed to be independent of the temperature and the electric field. The governing equations are
based on the classical shell theory with von Kármán–Donnell type of kinematic nonlinearity. ABSTRACT: Large deflection and postbuckling responses of functionally graded rectangular plates under transverse and in-plane loads are investigated by using a semi-analytical approach. Material properties are assumed to be temperature-dependent, and graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents. The plate is assumed to be clamped on two opposite edges and the remaining two edges may be simply supported or clamped or may have elastic rotational edge constraints. The formulations are based on the classical plate theory, accounting for the plate-foundation interaction effects by a two-parameter model (Pasternak-type), from which Winkler elastic foundation can be treated as a limiting case. A perturbation technique in conjunction with one-dimensional differential quadrature approximation and Galerkin procedure are employed in the present analysis. The numerical illustrations concern the large deflection and postbuckling behavior of functionally graded plates with two pairs of constituent materials. Effects played by volume fraction, the character of boundary conditions, plate aspect ratio, foundation stiffness, initial compressive stress as well as initial transverse pressure are studied.

The influences played by temperature rise, volume fraction distributions, transverse shear deformation, panel geometric parameters, as well as initial geometric imperfections, are studied.

ABSTRACT: An elastic double-shell model is presented for the buckling and postbuckling of a double-walled carbon nanotube subjected to external hydrostatic pressure. The analysis is based on a continuum mechanics model in which each tube of a double-walled carbon nanotube is described as an individual elastic shell and the interlayer friction is negligible between the inner and outer tubes. The governing equations are based on higher order shear deformation shell theory with a von Kármán–Donnell-type of kinematic nonlinearity. The van der Waals interaction between the inner and outer nanotubes and the nonlinear prebuckling deformations of the shell are both taken into account. A boundary layer theory of shell buckling is extended to the case of double-
walled carbon nanotubes under hydrostatic pressure. A singular perturbation technique is employed to
determine the buckling loads and postbuckling equilibrium paths. Numerical results reveal that the single-
walled carbon nanotube has a stable postbuckling path, whereas the double-walled carbon nanotube has an
unstable postbuckling behavior due to the presence of van der Waals interaction forces.

“Postbuckling of Axially Loaded Functionally Graded Cylindrical Panels with Piezoelectric Actuators in
ABSTRACT: A compressive postbuckling analysis is presented for a functionally graded cylindrical panel with
piezoelectric actuators subjected to the combined action of mechanical, electrical, and thermal loads. The
temperature field considered is assumed to be of uniform distribution over the panel surface and through the
panel thickness and the electric field considers only the transverse component EZ. The material properties of the
presently considered functionally graded materials (FGMs) are assumed to be temperature-dependent, and
graded in the thickness direction according to a simple power law distribution in terms of the volume fractions
of the constituents, whereas the material properties of the piezoelectric layers are assumed to be independent of
the temperature and the electric field. The governing equations are based on a higher-order shear deformation
theory with a von Kármán–Donnell-type of kinematic nonlinearity. A boundary layer theory for shell buckling is
extended to the case of hybrid FGM cylindrical panels of finite length. The nonlinear prebuckling deformations
and initial geometric imperfections of the panel are both taken into account. A singular perturbation technique is
employed to determine the buckling loads and postbuckling equilibrium paths. The numerical illustrations
concern the compressive postbuckling behavior of perfect and imperfect FGM cylindrical panels with fully
covered piezoelectric actuators, under different sets of thermal and electrical loading conditions. The effects due
to temperature rise, volume fraction distribution, applied voltages, panel geometric parameters, in-plane
boundary conditions, as well as initial geometric imperfections are studied.

ABSTRACT: A boundary layer theory for the buckling and postbuckling of anisotropic laminated thin shells is developed. The material of each layer of the shell is assumed to be linearly elastic, anisotropic and fiber-
reinforced. It is also assumed that the well-known von Kármán nonlinear strain–displacement relationships are valid. The governing equations with transverse displacement and stress function as independent variables are deduced to a boundary layer type, which includes the effects of nonlinear prebuckling deformations, large deflections in the postbuckling range, and initial geometric imperfections of the shell. A postbuckling analysis is presented for axially loaded, perfect and imperfect, anisotropic laminated cylindrical shells with different values of shell parameters and stacking sequence. A singular perturbation technique is employed to determine the buckling loads and postbuckling equilibrium paths. The joint effects played by anisotropy, nonlinear prebuckling deformations, as well as initial geometric imperfections are studied. The new finding is that there exists a compressive stress along with an associate shear stress and twisting when the anisotropic laminated cylindrical shell is subjected to axial compression, and all the results published previously need to be re-examined.

ABSTRACT: A boundary layer theory for the buckling and postbuckling of anisotropic laminated thin shells is extended to the loading case of external pressure. A singular perturbation technique is employed to determine the buckling pressure and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling behavior of pressure-loaded, perfect and imperfect, anisotropic laminated cylindrical shells with different values of shell parameters and stacking sequence. The new finding is that there exists a circumferential stress along with an associate shear stress and twisting when the anisotropic shell is subjected to lateral pressure, and all the results published previously need to be re-examined. The results confirm that the effect of the boundary layer on the solution of a pressurized shell is of the order $\mu^{3/2}$. The postbuckling equilibrium path is stable for the moderately long shell under external pressure and the shell structure is virtually imperfection-insensitive, whereas the postbuckling equilibrium path is unstable for a very short cylindrical shell under the same loading case.

ABSTRACT: A postbuckling analysis is presented for an anisotropic laminated cylindrical shell of finite length subjected to combined loading of axial compression and torsion. The governing equations are based on classical shell theory with von Kármán–Donnell-type of kinematic nonlinearity and including the extension–twist, extension–flexural and flexural–twist couplings. The nonlinear prebuckling deformations and initial geometric imperfections of the shell are both taken into account. A singular perturbation technique is employed to determine interactive buckling loads and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling response of perfect and imperfect, anisotropic laminated cylindrical shells for different values of load-proportional parameters. The results show that the postbuckling characteristics depend significantly upon the load-proportional parameter. The results reveal that in combined loading cases the postbuckling equilibrium path is unstable and the shell structure is imperfection-sensitive.

ABSTRACT: Compressive post-buckling under thermal environments and thermal post-buckling due to uniform temperature field or heat conduction are presented for a shear deformable functionally graded cylindrical shell with piezoelectric fiber reinforced composite (PFRC) actuators. The material properties of functionally graded materials (FGMs) are assumed to be graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents, and the material properties of both FGM and PFRC layers are assumed to be temperature-dependent. The governing equations are based on a higher order shear deformation shell theory that includes thermopiezoelectric effects. The nonlinear prebuckling deformations and initial geometric imperfections of the shell are both taken into account. A singular perturbation technique is employed to determine buckling loads (temperature) and postbuckling equilibrium paths. The numerical illustrations concern the compressive and thermal post-buckling behavior of perfect and imperfect FGM cylindrical shells with fully covered PFRC actuators under different sets of thermal and electric loading conditions, from which results for monolithic piezoelectric actuators are obtained as comparators. The results reveal that, in the compressive buckling case, the control voltage only has a small effect on the postbuckling load-deflection curves of the shell with PFRC actuators, whereas in the thermal buckling case, the effect of control voltage is more pronounced for the shell with PFRC actuators, compared with the results of the same shell with monolithic piezoelectric actuators.

ABSTRACT: This paper presents a study on the post-buckling response of an anisotropic laminated cylindrical shell of finite length embedded in a large outer elastic medium and subjected to internal pressure in thermal environments. The surrounding elastic medium is modelled as a tensionless Pasternak foundation reacting in compression only. The governing equations are based on higher-order shear deformation shell theory with von Kármán–Donnell kinematic non-linearity and including extension–twist, extension–flexural, and flexural–twist couplings. The thermal effects are also included, and the material properties are assumed to be temperature dependent. Non-linear prebuckling deformations and the initial geometric imperfections of the shell are both taken into account. A singular perturbation technique is employed to determine the post-buckling response of the shells, and an iterative scheme is developed to obtain numerical results without using any assumption concerning the shape of the contact region between the shell and the elastic medium. Numerical illustrations concern the buckling and post-buckling response of cross-ply and symmetric angle-ply laminated shells surrounded by an elastic medium of tensionless foundation of the Pasternak type, from which results for conventional elastic foundations are obtained as comparators. The results reveal that unilateral constraints have a significant effect on the post-buckling response of shells subjected to internal pressure in thermal environments when the foundation stiffness is sufficiently large.

ABSTRACT: A version of nonlocal elasticity theory is employed to develop a nonlocal shear deformable shell model. The governing equations are based on higher order shear deformation shell theory with a von Kármán-type of kinematic nonlinearity and include small scale effects. These equations are then used to solve buckling problems of microtubules (MTs) embedded in an elastic matrix of cytoplasm subjected to bending. The surrounding elastic medium is modeled as a Pasternak foundation. The thermal effects are also included and the material properties are assumed to be temperature-dependent. The small scale parameter $e_0a$ is estimated by matching the buckling curvature of MTs observed from measurements with the numerical results obtained from the nonlocal shear deformable shell model. The numerical results show that buckling loads are decreased with the increasing small scale parameter $e_0a$. The results reveal that the lateral constraint has a significant effect on the buckling moments of a microtubule when the foundation stiffness is sufficiently large.

ABSTRACT: Based on theory of nonlocal elasticity, a nonlocal double-elastic beam model is developed for the free transverse vibrations of double-walled carbon nanotubes. The effect of small length scale is incorporated in the formulation. With this nonlocal double-elastic beam model, explicit expressions are derived for natural frequencies and associated amplitude ratios of the inner to the outer tubes for the case of simply supported double-walled carbon nanotubes. The effect of small length scale on the properties of vibrations is discussed. It is demonstrated that the natural frequencies and the associated amplitude ratios of the inner to the outer tubes are dependent upon the small length scale. The effect of small length scale is related to the vibrational mode and the aspect ratio.

ABSTRACT: Elastic buckling of a long double-walled carbon nanotube embedded in an elastic medium and subjected to a far-field hydrostatic pressure is analyzed using the energy method. The study is on the basis of elastic-shell models at nano-scale, and the effect of van der Waals forces on the buckling is considered. The double-walled carbon nanotube is assumed to be thin and the tube is taken to be perfectly bonded to the surrounding medium. Both normal and shear stresses at the outer tube-medium interface are included. The difference between the Poisson's ratio of the tube and that of the elastic medium is taken into account. An expression is derived relating the external pressure to the buckling mode number, from which the critical pressure can be obtained. As a result, the critical pressure is dependent on the inner radius-to-thickness ratio, the material parameters of the elastic medium, and the van der Waals force.

ABSTRACT: A nonlocal multiple-shell model is developed for the elastic buckling of multi-walled carbon nanotubes under uniform external radial pressure on the basis of theory of nonlocal elasticity. The effect of small length scale is incorporated in the formulation. An explicit expression is derived for the critical buckling pressure for a double-walled carbon nanotube. The influence of the small length scale on the buckling pressure is examined. It is concluded that the critical buckling pressure for a carbon nanotube could be overestimated by the classic (local) shell model due to ignoring the effect of small length scale.

ABSTRACT: Buckling and post-buckling analysis is presented for axially compressed double-walled carbon nanotubes (CNTs) embedded in an elastic matrix in thermal environments. The double-walled carbon nanotube is modeled as a nonlocal shear deformable cylindrical shell, which contains small scale effects and van der Waals interaction forces. The surrounding elastic medium is modeled as a tensionless Pasternak foundation. The post-buckling analysis is based on a higher order shear deformation shell theory with the von Kármán–Donnell-type of kinematic nonlinearity. The thermal effects are also included and the material properties are assumed to be temperature-dependent and are obtained from molecular dynamics (MD) simulations. The nonlinear prebuckling deformations of the shell and the initial local point defect, which is simulated as a dimple on the tube wall, are both taken into account. A singular perturbation technique is employed to determine the post-buckling response of the tubes and an iterative scheme is developed to obtain numerical results without
using any assumption on the shape of the contact region between the tube and the elastic medium. The small scale parameter $e_0a$ is estimated by matching the buckling loads of CNTs observed from the MD simulation results with the numerical results obtained from the nonlocal shear deformable shell model. Numerical solutions are presented to show the post-buckling behavior of CNTs surrounded by an elastic medium of conventional and tensionless Pasternak foundations. The results show that buckling and post-buckling behavior of CNTs is very sensitive to the small scale parameter $e_0a$. The results reveal that the unilateral constraint has a significant effect on the post-buckling response of CNTs when the foundation stiffness is sufficiently large.

ABSTRACT: A postbuckling analysis is presented for nanocomposite cylindrical shells reinforced by single-walled carbon nanotubes (SWCNTs) subjected to lateral or hydrostatic pressure in thermal environments. The multi-scale model for functionally graded carbon nanotube-reinforced composite (FG-CNTRC) shells under external pressure is proposed and a singular perturbation technique is employed to determine the buckling pressure and postbuckling equilibrium path. Numerical results for pressure-loaded, perfect and imperfect, FG-CNTRC cylindrical shells are obtained under different sets of thermal environmental conditions. The results for uniformly distributed CNTRC shell, which is a special case in the present study, are compared with those of the FG-CNTRC shell. The results show that the linear functionally graded reinforcements can increase the buckling pressure as well as postbuckling strength of the shell under external pressure. The results reveal that the carbon nanotube volume fraction has a significant effect on the buckling pressure and postbuckling behavior of CNTRC shells.

ABSTRACT: There has been a growing interest in the active suppression of noise in aircraft interiors in the recent past. While there are already many different technical solutions available in the form of active noise controllers using loudspeakers and structural sources, there is a need for low-profile acoustic sources that could be used for generating large volume velocities with high efficiency and low control effort. This paper presents an investigation into the potential usage of shallow-spherical-shell actuators (also known as RAINBOW actuators), made of piezoelectric materials supported on a flexible foundation along the edge, for such applications. The actuators have been modeled analytically and the effects of curvature, mount stiffness, mass and other parameters on the natural frequencies, linear stroke and volume velocity have been studied. Simulation results are presented and the potential for using the actuator as an efficient acoustic source has been discussed.

ABSTRACT: We probe the local mechanical properties of microtubules at the nanometer scale by radial indentation with a scanning force microscope tip. We find a linear elastic regime that can be described by both thin-shell theory and finite element methods, in which microtubules are modeled as hollow tubes. We also find a nonlinear regime and catastrophic collapse of the microtubules under large loads. The main physics of protein shells at the nanometer scale shows simultaneously aspects of continuum elasticity in their linear response, as well as molecular graininess in their nonlinear behavior.

ABSTRACT: This paper presents an investigation on the buckling and postbuckling of double-walled carbon nanotubes (CNTs) subjected to torsion in thermal environments. The double-walled carbon nanotube is modeled as a nonlocal shear deformable cylindrical shell which contains small scale effects and van der Waals interaction forces. The governing equations are based on higher order shear deformation shell theory with a von Kármán–Donnell-type of kinematic non-linearity and including the extension/twist, extension/flexural and flexural/twist couplings. The thermal effects are also included and the material properties are assumed to be temperature-dependent and are obtained from molecular dynamics (MD) simulations. The small scale parameter e0a is estimated by matching the buckling torque of CNTs observed from the MD simulation results with the numerical results obtained from the nonlocal shear deformable shell model. The results show that buckling torque and postbuckling behavior of CNTs are very sensitive to the small scale parameter e0a. The results reveal that the size-dependent and temperature-dependent material properties have a significant effect on the torsional buckling
and postbuckling behavior of both single-walled and double-walled CNTs.

ABSTRACT: This paper presents an investigation on the buckling and postbuckling of microtubules (MTs) subjected to a uniform external radial pressure in thermal environments. The microtubule is modeled as a nonlocal shear deformable cylindrical shell which contains small scale effects. The governing equations are based on higher order shear deformation shell theory with a von Kármán-Donnell-type of kinematic nonlinearity and include the extension-twist and flexural-twist couplings. The thermal effects are also included and the material properties are assumed to be temperature-dependent. A singular perturbation technique is employed to determine the buckling pressure and postbuckling equilibrium paths. The small scale parameter \( e(0)a \) is estimated by matching the buckling pressure of MTs measured from the experiments with the numerical results obtained from the nonlocal shear deformable shell model. The numerical results show that buckling pressure and postbuckling behavior of MTs are very sensitive to the small scale parameter \( e(0)a \). The results reveal that the 13_3 microtubule has a stable postbuckling path, whereas the 13_2 microtubule has an unstable postbuckling behavior due to the presence of skew angles.

ABSTRACT: Numerical simulations for local buckling and postbuckling behavior of plant stems are presented under two combined loading cases: (1) axial compression (caused by axial grains) combined with wind pressure; and (2) bending moment (caused by eccentric axial grains) combined with wind pressure. Based on its microstructure, a hollow plant stem is modeled as a stringer stiffened multiwalled shell. The material properties of the stem are assumed to be orthotropic. The nonlinear governing equations for buckling and postbuckling of plant stems are solved through arc-length method along with Newton–Raphson technique. The numerical calculations are carried out using the finite element package ABAQUS. The results show that the postbuckling equilibrium path is unstable for plant stems subjected to axial compression or bending combined with relatively low values of wind pressure. Large reduction in buckling load and in postbuckling strength can be found even if the applied wind pressure is relatively small, which results in the easy occurrence of stem lodging.

D. Dinkler and J. Pontow (Instutüt für Static, Technische Universität, Braunschweig, Germany), “A Model to Evaluate Limit Loads of Imperfection Sensitive Shells”, Computational Mechanics, WCCM VI in conjunction with APCOM'04, Sept 5-10, 2004, Beijing, China, published by Tsinghua Universityhy Press and Springer-Verlag

ABSTRACT: The paper deals with the development and application of stability estimates for structures under time-dependent loads. Applications to bars and shell structures show the variety of the phenomena in dynamic buckling behaviour of elastic structures in case of impulsive loading. The judgement of the stability is based on energy norms, that may be used for investigation of safety against loss of stability by buckling. Static analysis is used to compute the critical strain energy which is necessary to effect the transition from the pre{ to the postbuckling range. Starting from a stable state of equilibrium the presented
procedure allows to decide whether the structure stays for a certain load history within the critical bounds, which separate the motion around the prebuckling state from the motion in a postbuckling region. The stability is proved by comparing the load induced energy and the critical strain energy.

References listed at the end of the paper:

Summary: The paper deals with the stability of perturbation sensitive shells. The perturbation energy concept developed by Dinkler/Kroplin [2] is applied to estimate the static and kinetic limit loads of different perturbation sensitive shells by a single energy value, the perturbation energy. The material behaviour is described by a rate-independent model for elasto-plasticity.

ABSTRACT: The paper presents a procedure for computation of the limit loads of imperfection-sensitive shells including plastic deformations. On the basis of strain energy of shells, the worst case scenario for critical perturbations at fixed load levels is investigated. Limit loads of cylindrical and conical shells under combined actions are compared to European design rules. The concept is applied to more general buckling cases of combined shell structures.

ABSTRACT: The paper deals with the perturbation energy concept and its application to stability of imperfection sensitive structures under time-dependent loads. The evaluation of the stability is based on energy norms, which may be used for investigation of safety against buckling. Starting from a stable state of equilibrium the presented procedure allows to decide whether the structure stays for a certain load history within critical bounds, which separate the motion round the prebuckling state from a motion in the postbuckling region. The stability is proved by comparing the critical energy calculated by a static analysis and the load induced energy. Applications to a truss and a spherical shell illustrate the variety of the phenomena in dynamic buckling behaviour of elastic structures in case of impulsive loading and the accuracy of the proposed method.

Eyassu Woldesenbet, “Buckling analysis of Grid stiffened composite cylinders”, ICCEMCE-03, International

ABSTRACT: Due to their high stiffness to mass ratio, stiffened cylindrical composite shells are major components of Aerospace and Aircraft industries. These structures are employed in fuselage and fuel tank applications, and are usually subjected to combinations of compressive, shear or transverse loads. Usually the failure mode associated with these structures is buckling. This failure mode is further subdivided into ‘local skin and/or stiffener buckling’, and ‘universal buckling’.

ABSTRACT: This paper discusses the recent experimental and analytical studies related to buckling of fabricated steel cylinders subjected to combinations of axial compression load and external pressure. The effects of initial imperfections and residual stresses are being investigated. A description of the test facilities and model geometries are given. The D/t ratios of the models range from 48 to 1000. The test programs include ring and stringer stiffened as well as ring stiffened cylinders.

ABSTRACT: This paper discusses the recent experimental and analytical studies related to buckling design of fabricated steel shells. The effects of initial imperfections and residual stresses on buckling are under investigation. The test programs include ring and stringer stiffened as well as ring stiffened cylinders subject to combinations of axial compression and external pressure. Proposed modifications to ASME Code Case N-284, “Metal Containment Shell Buckling Design Methods,” as well as the need for additional research, are discussed.

ABSTRACT: Buckling of freestanding nuclear steel containment buildings from dynamic base excitation was investigated in a combined experimental/numerical program. A polycarbonate scale model of a containment building was excited with scaled earthquake transients and single-frequency harmonic transients to determine the peak base acceleration levels required to induce buckling. Buckling was identified using recorded signals from strain gages and accelerometers, with high-speed video records, and by audibility. Experimental results are compared with numerical results obtained by using a freezing-in-time technique. The results are preliminary, since several more tests are to be performed. However, the limited data obtained indicate that the freezing-in-time technique approximates the required acceleration levels reasonably well, although not conservatively. Additional experiments are described that will take containment asymmetries into account, as well as use instrumentation that will provide more accurate measures of the occurrence of buckling.

ABSTRACT: Two aspects of buckling of a free-standing nuclear steel containment building were investigated in a combined experimental and analytical program. In the first part of the study, the response of a scale model of a containment building to dynamic base excitation is investigated. A simple harmonic signal was used for preliminary studies followed by experiments with scaled earthquake signals as the excitation source. The experiments and accompanying analyses indicate that the scale model response to earthquake-type excitations is very complex and that current analytical methods may require that a dynamic capacity reduction factor be incorporated. The second part of the study quantified the effects of framing at large penetrations on the static buckling capacity of scale model containments. Results show little effect from the framing for the scale models constructed from the polycarbonate, Lexan. However, additional studies with a model constructed of the prototypic steel material are recommended.

ABSTRACT: Buckling test and linear buckling analysis has been performed on the spherical steel shell structure. Measured buckling loads are less than the values obtained by analysis and the knock-down factors are usually defined as the ratios of the experimental buckling load to the analytical values. The knock-down factors derived from the study are: for horizontal direction: 0.47 ~ 0.57 and for vertical direction: 0.40 ~ 0.60. The allowable buckling stress can be evaluated by using a knock-down factor and a safety factor. A simple and practical method for evaluating the allowable buckling stress for spherical shell has been proposed as a result of the study.

ABSTRACT: A simplified method is presented for evaluating the seismic buckling capacity of unstiffened, free-standing steel containment structures. The method is consistent with current US Nuclear Regulatory Commission seismic design standards and with containment buckling interaction equations given in the American Society of Mechanical Engineers Boiler and Pressure Vessel Code which includes the influence of geometrical imperfections of the shell on buckling. Stresses to be considered in the interaction equations are determined from beam theory using standard response spectrum analysis. An empirical correction factor is developed to account for hoop stresses that are not explicitly represented in the beam theory. As the results of these analyses are very sensitive to the damping that is assumed, the extensive three-dimensional finite element analyses that were performed to develop the hoop stress reduction factor were also used to study the sensitivity of containment buckling to the assumed damping. Experiments on model containment structures were then performed to further investigate the damping properties exhibited by these structures. The study in concluded by showing that the simplified method reasonably predicts seismic buckling capacities when compared with independently determined predictions from detailed finite element analyses.

PARTIAL INTRODUCTION: The special feature of pool type fast breeder reactor is the usage of very large sized thin shell structures for its reactor vessels. Due to the large diameter to thickness ratio (around 700 to 900), design of these vessels poses challenging structural mechanics problems particularly under seismic loading. An important threat to structural integrity of reactor vessels is the buckling risk during seismic events…

ABSTRACT: This paper presents the results of an experimental study on the buckling of scaled-down models of the inner vessel used in nuclear reactor structures. The inner vessel, a shell of composite geometry, consists of two cylindrical shells connected by conical and torus shells. There are six stand-pipes on the conical portion of the vessel carrying heat exchangers and pumps. Scaled-down models of the inner vessel are made by the conventional fabrication methods (rolling, welding) and are tested in the present study. The test setup consists of a loading system for applying concentrated load on the stand-pipes, an air compressor for applying internal pressure and the related instrumentation. Imperfection scans are carried out in a specially fabricated experimental setup using linear variable differential transformers (LVDTs) before and during loading. Using the scanned raw data, the initial geometric imperfections and eccentricity between the LVDTs and the specimen axes at different axial locations are calculated. The results show that the maximum initial imperfections are on the order of 1.75 times the wall thickness; generally, the growth of deformation patterns with loading resembles the shapes of initial imperfections, and the growth is predominant on lower cylinder and torus regions. The general purpose, finite element-based software, ABAQUS, is used to obtain the analytical values. The initial imperfections measured on the experimental models are incorporated into the finite element models. The agreement between experimental and analytical buckling loads is within about 30 percent error.

transmitted appropriately to 3D shell geometries for the buckling analysis. In view of high computational time needed for carrying out buckling analysis at every time increment, the elastoplastic analysis is carried out only at a few critical time steps which are identified based on strain energies that are associated with the shear and compressive stresses developed at the portions of the vessels prone to buckle. The shear buckling of main vessel straight portion and buckling of toroidal portion of inner vessel and thermal baffles are found to be important. The possible randomness of support excitation time histories is accounted for by compressing as well as expanding the nominal time histories by 10%. Buckling strength reduction factors due to the initial geometrical imperfections are adopted from the literature. The inner vessel is found to be the most critical component which buckles under seismic forces induced by a safe shutdown earthquake with a load multiplier of 1.52, which is higher than the minimum factor of safety of 1.3 required as per the design code RCC-MR [RCC-MR: edition, 2002. Design and construction rules for mechanical components for FBR nuclear islands, vol. 1, section I, subsection B. AFCEN, Paris, in press] for service level D conditions.

ABSTRACT: This document is described as the 5th Edition of the ECCS European Recommendations for the Buckling of Steel Shells. It is the successor to the 4th Edition, published in 1988. In the 20 years since the publication of the 4th Edition in 1988, much has changed in the field of metal shell buckling. Extensive research has been undertaken, much new knowledge has been developed, and powerful computational modelling has transformed the field, though much design is still conducted by hand calculation. These changes are reflected in this 5th Edition. The 5th Edition quotes extensively from the Eurocode EN 1993-1-6 (2007) and is completely compatible with that standard. However, the Eurocode has no commentary, so the meaning, limitations and origins of many rules are not always clear. This 5th Edition provides an extensive commentary on the existing rules related to buckling in the Eurocode, but extends far beyond it in giving recommendations, expansions, advice and warnings, explanations and examples, all of which should give the user considerably more insight and confidence in applying the rules of EN 1993-1-6.

ABSTRACT: Plastic zone method of advanced analysis, which uses shell elements to model the entire structure, is the most accurate method available to predict the ultimate strength and behavior of steel frames. The disadvantage of such full shell plastic zone models is that it is computationally expensive and hence its use is limited to small structures. Beam elements in commercial finite element packages can model residual stress and capture spread of plasticity, but cannot model local buckling of plates that the member is made up of, which leads to unloading and failure in steel frames. A hybrid model using shell elements only in the regions vulnerable to elastic or inelastic local buckling and beam elements in other locations could overcome this limitation of full beam element model. The issues in using this hybrid model are, knowing a priori the location and length of the shell element region and connecting the beam and shell regions without any artificial stress concentrations or incompatible displacements. In this study, in addition to addressing these issues, the hybrid model is systematically evaluated by studying its performance in structural elements. It is seen that the hybrid
model strength predictions has an average error of only 0.91% but requires on an average 83% less computational time when compared to the full shell plastic zone models.

ABSTRACT: The availability of high strength steels and concrete leads to the use of thin steel plates in concrete-filled steel tubular beam–columns. However, the use of thin steel plates in composite beam–columns gives a rise to local buckling that would appreciably reduce the strength and ductility performance of the members. This paper studies the critical local and post-local buckling behavior of steel plates in concrete-filled thin-walled steel tubular beam–columns by using the finite element analysis method. Geometric and material nonlinear analyses are performed to investigate the critical local and post-local buckling strengths of steel plates under compression and in-plane bending. Initial geometric imperfections and residual stresses presented in steel plates, material yielding and strain hardening are taken into account in the nonlinear analysis. Based on the results obtained from the nonlinear finite element analyses, a set of design formulas are proposed for determining the critical local buckling and ultimate strengths of steel plates in concrete-filled steel tubular beam–columns. In addition, effective width formulas are developed for the ultimate strength design of clamped steel plates under non-uniform compression. The accuracy of the proposed design formulas is established by comparisons with available solutions. The proposed design formulas can be used directly in the design of composite beam–columns and adopted in the advanced analysis of concrete-filled thin-walled steel tubular beam–columns to account for local buckling effects.

“Behaviour and design of high strength steel-concrete filled columns”, The 2013 World Congress on Advances in Structural Engineering and Mechanics (ASEM13), Jeju, Korea, September 8-12, 2013

ABSTRACT: This paper considers the behaviour and design of high strength steel-concrete composite columns used in major infrastructure engineering systems. The paper will highlight the major applications where high strength steel has been used in Australia and internationally. Current codes of practice will then be considered, highlighting the latest developments in Australian and International Standards for the use of high strength steel and high strength concrete in composite structural forms of construction. This paper also presents the results of an experimental study of the use of high strength steel-concrete composite columns which evaluates the in-plane residual stresses. This study uses high strength steel with nominal yield stress of 690 MPa coupled with high strength concrete of characteristic compressive strength of 100 MPa. The concrete used in this study adopts a reduction of 30% of the use of cement content by using high volume fly ash. The use of both of these high strength materials satisfies the Green Building Council of Australia objectives to reduce materials and the impact of construction materials on carbon emissions. This paper focuses on a number of the technical aspects which the combination of these two materials allows. The improved local buckling resistance of the use of steel in contact with concrete is taken into account. Furthermore, the effect of increased confining effect due to the larger elastic range of steel is also considered.

ABSTRACT: This paper is based on a study that was done by utilising construction and demolition debris that had been effectively recycled, in structural members. The steel tubular columns were filled with different types of waste material, as well as recycled aggregate concrete, instead of normal conventional concrete. The results were subsequently analysed. The behaviour of circular and square concrete-filled steel tubular sections (CFSTs) under axial load, in which coarse aggregate had been partially replaced by recycled aggregates, is presented. The effects of steel tube dimensions, shapes and the confinement of concrete are also examined. Measured column strengths are compared with the values predicted by Eurocode 4, Australian Standards and American Codes. Twelve specimens were tested with 20 MPa concrete and steel sections with diameter-to-thickness ratios of 18.5, 25.3 and 36.0. The columns were of two different shapes - a circular-shaped set with diameters of 76 mm and 89 mm, and a square-shaped set with sizes 72 mm and 91 mm. The circular-shaped columns of 76 mm diameter and the square-shaped columns with 72 mm diameter are 900 mm long. The circular columns with a diameter of 89 mm and the square columns of 91 mm diameter are 350 mm long. Eurocode 4 (EC4) gives the best estimation for both conventional and recycled aggregate concrete. However, the American Concrete Institute (ACI) / Australian Standards (AS) equation predicted lower values than measured during the experiments. Hence the ACI/AS equation has been modified by introducing a multiplying factor ‘k’ to predict good results for columns of L/D < 12. The values of k factor for L/D ratio varying from 4 to 12 are suggested in this study. From the results it has been noted that square columns save 30% of steel when compared with circular columns. It was also observed that the ultimate load of steel tubular columns filled with recycled aggregate concrete is higher than that of conventional concrete and columns filled with recycled aggregate concrete, and can result in a 10% saving in the cost of concrete. This research therefore proposes a solution for effective solid waste management, which will also prove to be cost effective.

ABSTRACT: With the wide application of high-strength concrete and thin-wall steel tube in concrete-filled steel tube, it is essential to study the post-local buckling behavior of rectangle steel plates. Based on large deflection theory of plate, the post-local buckling behavior of steel plates in concrete-filled steel tube is analyzed in this paper. At the same time, the post-local stress of steel plates is obtained. The results indicate that the post-local buckling behavior of steel plates can be effectively utilized in large width-to-thickness ratios of steel plates.

ABSTRACT: Buckling behavior of thin circular cylindrical shells stiffened by one or two rings has been studied in a wind tunnel. Both the prebuckling deflection and the buckling load were measured with a variety of specimens in a smooth flow, and the effects of the stiffeners on them were examined. For comparison purposes, the buckling load of each specimen under hydrostatic pressure was also measured. The results indicate that the prebuckling deflection and ovalling oscillation can be significantly suppressed by relatively light stiffeners. As the flexural rigidity, EsIs, of the ring increases, the axial buckling mode changes from a symmetric one accompanied by ring deflection to another one with the rings acting as nodes, at a critical value of EsIs. This critical value was found to be nearly equal to that for the hydrostatic pressure. On the other hand, contrary to the hydrostatic pressure case, the buckling load gradually increases with an increase in EsIs, even for values of EsIs greater than the critical value.

Portela Gauthier, Genock, Ph.D., University Of Puerto Rico, Mayaguez , 2004, 526 pages; 3141791 (dissertation?), “Wind pressures and buckling of metal cantilever tanks”, Department of Civil Engineering, DAI-B 65/08, p. 4174, Feb 2005

ABSTRACT: This thesis reports work done to evaluate wind pressure distributions on aboveground tanks formed by a cylinder and a roof, and to assess shell buckling due to such pressures. First, wind tunnel experiments were performed to obtain wind pressure distributions developed on the wall and on the roof of circular short steel tanks, including different geometries and group configurations. The geometries considered were selected from typical cylindrical tanks located in the Caribbean Region (including Puerto Rico), with conical, shallow-dome, and deep-dome roofs. The pressure distributions measured on the cylinder of the isolated tanks were similar to pressure values on silos obtained by other authors. However, shielding arrays revealed increments in windward pressures on the cylinder, and group arrays generated changes to the pressure distributions with respect to the isolated tanks. Second, linear bifurcation and nonlinear step-by-step buckling analyses were performed on tanks using the pressure distributions measured from the wind tunnel experiments, in order to obtain buckling loads and their associated modes of deformation. Changes to the initial geometry of tanks using the first mode of deformation obtained from an eigenvalue analysis were investigated to compute the sensitivity due to imperfections. The magnitudes of the imperfections applied varied from 10% to 200% the thickness of the shell. From the results, it seems that bifurcation analyses represent adequately the buckling behavior of isolated tanks with conical roofs, but not of tanks with dome roofs based on the selected dimensions of short tanks. Results also showed that corrosion effects reduce the buckling capacity of steel tanks. On the other hand, ring stiffeners around the cylinder of the tanks provide additional buckling capacity that depends on the elevations at which they are located. About imperfections, it seems that tanks with roofs have higher buckling loads but at the same time are more sensitive to imperfections than open-top tanks.

“Numerical simulation on buckling of combined multilayered unequal-thickness cylindrical shell”, Journal of Zhejiang University (Engineering Science), 2009 –09

ABSTRACT: The influence of the characteristic factor of unequal-thickness on critical buckling load was
analyzed by numerical simulation method based on geometric features of large vertical combined cylindrical shell. The character of unequal-thickness was considered as geometrical defect, which decreases the critical stress of classical shell buckling to some extent. Finite element analysis (FEA) models of combined multilayered unequal-thickness cylindrical shell were built to analyze the buckling of combined cylindrical shell under different loadings. Critical loads of instability buckling under different loadings were obtained to verify the influence regularity of hoop stress on the buckling of combined cylindrical shell. Results show that the characteristic factor of unequal-thickness can largely decrease the critical load of classical shell buckling. And the number of layers and the thickness difference of adjacent shell courses have the biggest influence on critical buckling load.

ABSTRACT: Experimental and numerical work was conducted to better understand composite shell response to transverse loadings which simulate damage-causing impact events. The quasi-static, centered, transverse loading response of laminated graphite/epoxy shells in a [+/-45(sub n)/O(sub n)](sub s) layup having geometric characteristics of a commercial fuselage are studied. The singly curved composite shell structures are hinged along the straight circumferential edges and are either free or simply supported along the curved axial edges. Key components of the shell response are response instabilities due to limit-point and/or bifurcation buckling. Experimentally, deflection-controlled shell response is characterized via load-deflection data, deformation-shape evolutions, and the resulting damage state. Finite element models are used to study the kinematically nonlinear shell response, including bifurcation, limit-points, and postbuckling. A novel technique is developed for evaluating bifurcation from nonlinear prebuckling states utilizing asymmetric spatial discretization to introduce numerical perturbations. Advantages of the asymmetric meshing technique (AMT) over traditional techniques include efficiency, robustness, ease of application, and solution of the actual (not modified) problems. The AMT is validated by comparison to traditional numerical analysis of a benchmark problem and verified by comparison to experimental data. Applying the technique, bifurcation in a benchmark shell-buckling problem is correctly identified. Excellent agreement between the numerical and experimental results are obtained for a number of composite shells although predictive capability decreases for stiffer (thicker) specimens which is attributed to compliance of the test fixture. Restraining the axial edge (simple support) has the effect of creating a more complex response which involves unstable bifurcation, limit-point buckling, and dynamic collapse. Such shells were noted to bifurcate into asymmetric deformation modes but were undamaged during testing. Shells in this study which were damaged were not observed to bifurcate. Thus, a direct link between bifurcation and atypical damage could not be established although the mechanism (bifurcation) was identified. Recommendations for further work in these related areas are provided and include extensions of the AMT to other shell geometries and structural problems.

ABSTRACT: A benchmark, geometrically nonlinear, shell-buckling problem is reviewed and the correct solution is identified and discussed vis-à-vis the incorrect solution from the open literature. The problem is that of a hinged, thin, isotropic cylindrical shell section, point-loaded transversely at the center, undergoing large deformations (5 x thickness). This benchmark problem and solution were introduced in 1972 and have been reproduced in at least 30 journal articles and books in the more than three decades since that time. The benchmark problem is of interest because it demonstrates many features possible in shell buckling, including a
load-limit point (snap-through buckling) and a deflection-limit point (snap-down, or snap-back). The benchmark problem is typically used to demonstrate the capability of commercial/private finite element codes to traverse such complicated nonlinear load paths. The existing incorrect benchmark solution involves the nonlinear growth of only symmetric deformation modes. The correct solution to this benchmark problem involves bifurcation from the nonlinear load path into a simple asymmetric deformation mode. Experimental data do not exist for verification of the calculated benchmark response, and so a similar problem using a laminated composite shell is suggested as an alternative benchmark problem for shell stability analysis.

ABSTRACT: In this paper, buckling analysis of cylindrical shells with a circumferential crack is presented. The analyses were performed both numerically using FEM and experimentally. The numerical analyses and experiments were conducted for several crack lengths and radius of curvature, and two different boundary conditions were applied, i.e. simply support and clamp in all sides. The results show the effect of the presence of crack to the critical buckling load of the shells. There are good agreements between experimental and numerical results.

ABSTRACT: A long circular cylindrical shell subjected to external pressure may collapse through the development of a propagating buckle. In this work a method has been developed for the theoretical prediction of the smallest propagation pressure in the case of path-dependent material descriptions. The method is illustrated by comparing predictions of the propagation pressure based on J2 flow theory with predictions based on J2 deformation theory for two different radius to thickness ratios. The modelling is based on thin shell theory and small strain approximations, allowing for large deformations. Results for two different non-linear bending strain measures are compared, and the effect of using a finite strain J2 flow theory is investigated.

ABSTRACT: Failure by steady state kink band broadening in uni-directional fibre composites or layered materials is analysed. An incremental scheme for calculation of kink band broadening stresses and lock-up conditions in the band for arbitrary material behaviour is presented. The method is illustrated by material data which are representative for polymer matrix composites for which experimental work exists.

ABSTRACT: Compressive failure of fibre reinforced or layered materials by fibre kinking, matrix splitting and fibre/matrix debonding is analysed. The main focus is on brittle matrix composites, however, the analysis of effects due to debonding is carried out in a general framework allowing for arbitrary time-independent plasticity of the layers. Fibre kinking and matrix splitting are regarded as competing failure modes with the conditions governing the active mode depending on the biaxial stress state in the composite and a combination of micro mechanical parameters. Two criteria for matrix splitting, and two models for the evolution of micro cracks in the matrix have been discussed.

ABSTRACT: An analysis of buckling-driven delamination of a layer in a spherical, layered shell has been carried out. The effects of the substrate having a double curvature compared to previous studies of delamination on cylindrical substrates turn out to be non-trivial in the sense that additional to the effect of the shape of the substrate, a new non-dimensional geometrical parameter enters the conditions for steady-state delamination. It is shown that this additional geometrical parameter in most cases of practical relevance has insignificant influence on the fracture mechanical parameters involved for the problem. The consequence is that solutions need to be mapped as a function of one rather than two dimensionless parameters. Furthermore, the shape of the substrate has profound influence especially on initiation of delamination growth.

ABSTRACT: The main objective of this work was to investigate and predict the behaviour of damaged structural elements (skin-stringer panels). The study combined characterisation through testing with fractographic analysis, and analysis of delamination using the finite element method. The experimental studies entailed investigation of damage growth from embedded skin defects in panels under compressive load, and the subsequent structural failure. Parameters such as defect size, location with respect to sub-structure and through-thickness position were studied. Local delamination and global panel buckling were modelled, and the resulting delamination growth was simulated using a moving mesh technique. The results illustrated the importance of the location of the 90° plies to the damage evolution, and the criticality of global buckling and stringer detachment in the structural failure. The understanding gained from both the experimental investigations and numerical simulations have led to guidelines for realistic modelling and rules for designing damage tolerant structures.

PARTIAL ABSTRACT: In this paper a damage tolerance model based on the assumption of delamination criticality in compression-loaded slender composite panels is outlined. In particular, the verification of the model by comparison between numerical predictions and experimental results is reviewed. Growth of shallow delaminations in slender panels is shown to be promoted by the global buckling of the panel. Consequently, care must be taken if structures with delaminations are to be allowed to buckle.…

ABSTRACT: This report describes an in-depth finite element simulation of a spent fuel canister for geological disposal loaded in iso-static pressure until plastic collapse. The canister consists of a copper overpack and a ductile cast iron insert with steel cassettes where the spent fuel is placed. The highly non-linear finite element analysis is based on the explicit formulation and includes large deformations, non-linear material behaviour and
contact between the canister components. The analysis includes comparison between two- and three-dimensional models and assessment of the different geometrical features such as corner radius of the cassette, cassette offset, different bonding/dedonding conditions between insert and steel cassette. The analysis shows that the bonding cassette/insert has a large impact on the collapse load. Two large-scale mock-ups test that had been performed earlier are also simulated by the developed finite element models. There is a very good agreement between measured and computed deformations versus applied load and collapse load.

ABSTRACT: This paper deals with the computational modeling of delamination and the prediction of delamination growth in laminated composites. In the analysis of post-buckled delaminations, an important parameter is the distribution of the local strain-energy release rate along the delamination front. A study using virtual crack closure technique is made for three-dimensional finite-element models of circular delaminations embedded in woven and non-woven composite laminates. The delamination is embedded at different depths along the thickness direction of the laminates. The issue of symmetry boundary conditions is discussed. It is found that fibre orientation of the plies in the delaminated part play an important role in the distribution of the local strain-energy release rate. This implies that the popular use of quarter models in order to save computational effort is unjustified and will lead to erroneous results. Comparison is made with experimental results and growth of the delamination front with fatigue cycling is predicted. A methodology for the prediction of delamination areas and directions using evolution criteria derived from test coupon data is also described. It is found that evolution criteria based on components of the strain-energy release rate predict the rate of delamination growth much better than evolution criteria based on the total strain energy release rate.

ABSTRACT: This paper presents the results of a buckling and postbuckling analysis and modeling of embedded delaminations, and the prediction of delamination growth in laminated composites with consideration for residual thermal stresses. The distribution of the local strain energy release rate along the delamination front is obtained via the virtual crack closure technique applied to three-dimensional (3D) finite element models of circular delaminations embedded in woven and non-woven composite laminates. In each case, the delamination is embedded at a different depth along the thickness direction of the laminates. The fibre orientation of the plies bounding the delamination significantly influences the distribution of the local strain energy release rate. There is general qualitative agreement between the predicted directions of delamination growth and C-scan results of the embedded delaminations. It is found that residual thermal stresses have a significant effect on the onset of buckling of the delaminated sublaminate, but negligible influence on the distribution of the local strain energy release rate in the postbuckled regime. Furthermore, the effect of residual thermal stresses is more pronounced for delaminations that are closer to the surface. A method for the prediction of delamination areas and directions using fatigue growth criteria derived from test coupon data is also presented. It is found that growth criteria based on components of the strain energy release rate predict the rate of delamination growth much better than those based on the total strain energy release rate.
INTRODUCTION: Egg shell quality is of considerable economic significance for commercial egg production. Eggs with shell defects lead to a direct reduction in yield and damage the image of eggs with the end user. Possible causes of these quality reductions are age, housing conditions, feeding, egg handling technology and genetic predisposition. The shell is the outer covering of the egg and performs several important functions and tasks. Each individual egg is unique with its own microstructure which provides a wealth of information about the environment in which it was created. The shell protects the contents of the egg from mechanical impact to some extent and allows a controlled exchange of fluid and gas through the pores. The egg shell also provides protection against microbial entry from the environment and serves as a source of calcium for the development of the embryonal skeleton. Because of its central importance for the egg as a commercial product, breeders and producers are continuously seeking to improve the quality and consistency of the egg shell. In this paper we propose to concentrate on breeding approaches and alternative measuring techniques which have a direct impact on product quality at the producer level and which indicate possibilities for improving shell stability.

ABSTRACT: Dextran-covered PLA nanoparticles have been formulated by two strategies. On one hand, dextran-g-PLA copolymers have been synthesized by click-chemistry between azide-multifunctionalized dextran (DexN3) and alkyne end-functionalized PLA chains (α-alkyne PLA); then nanoprecipitated without any additional surfactants. On the other hand, DexN3 exhibiting surfactant properties have been emulsified with unfunctionalized or α-alkyne PLA, which are dissolved in organic phase with or without CuBr. Depending on the o/w emulsion/evaporation process experimental conditions, dextran-g-PLA copolymers have been produced in situ, by click chemistry at the liquid/liquid interface during the emulsification step. Whatever the process, biodegradable core/shell polymeric nanoparticles have been obtained, then characterized. Colloidal stability of these nanoparticles in the presence of NaCl or SDS has been studied. While the physically adsorbed polysaccharide based shell has been displaced by SDS, the covalently-linked polysaccharide based shell ensures a permanent stability, even in the presence of SDS.

ABSTRACT: The similarity in stability characteristics between multiscale circular cylindrical structures is
revealed. Two detailed structures are explored. One is the circular cylindrical shell on an engineering scale, and another is the circular cylindrical lipid bilayer vesicle on a micro- or nanoscale. The critical stability of the vesicle acted on by uniformly distributed radial pressure is analysed. The critical load of the vesicle is derived and compared with that of the thin shell. The astonishing similarity between them is disclosed. The possible applications of such similarity to biophysics, biology and biomedicine are presented.

“Application and Analysis of Sandwich Elements in the Primary Structure of Large Wind Turbine Blades”,  
Journal of Sandwich Structures and Materials, November 2007, vol. 9, no. 6, pp. 525-552,  
doi: 10.1177/1099636207069071  
ABSTRACT: The present work studies the advantages of applying a sandwich construction as opposed to traditional single skin composites in the flanges of a load carrying spar in a future 180 m wind turbine rotor. A parametric finite element model is used to analyze two basic designs with single skin and sandwich flanges, respectively. Buckling is by far the governing criterion for the single skin design. Introducing a sandwich construction results in a globally more flexible structure making tower clearance the critical criterion. Significant weight reduction up to 22.3% and increased buckling capacity is obtained. Moreover, the study showed that proper choice of core material is important to prevent face wrinkling. Geometric nonlinear analysis showed sensitivity to imperfections. A consistent submodeling technique is presented for verifying the response from the global model in any section of interest.

“Buckling Optimization of Laminated Hybrid Composite Shell Structures Using Discrete Material Optimization”, 6th World Congress on Structural and Multidisciplinary Optimization Rio de Janeiro, 30 May - 03 June 2005, Brazil  
ABSTRACT: The design problem of maximizing the buckling load factor of laminated hybrid composite shell structures is investigated using the so-called Discrete Material Optimization (DMO) approach. The design optimization method is based on ideas from multi-phase topology optimization where the material stiffness is computed as a weighted sum of candidate materials, thus making it possible to solve discrete optimization problems using gradient based techniques and mathematical programming. The potential of the DMO method to solve the combinatorial problem of proper choice of material, stacking sequence and fiber orientation simultaneously is illustrated for two benchmark plate examples, and ongoing work on buckling optimization of a wind turbine blade test section is outlined.

[7] A.P. Seyranian, E. Lund and N. Olhoff, Multiple eigenvalues in structural optimization problems, Structural Optimization, 8, 207–
ABSTRACT: The design of composite structures such as wind turbine blades is a challenging problem due to the need for pushing the material utilization to the limit in order to obtain light and cost effective structures. As a consequence of the minimum material design strategy the structures are becoming thin-walled, such that buckling problems must be addressed, and in this work the aim is to obtain buckling optimized multi-material designs of wind turbine blades. The design problem consists of distributing multiple materials within a given design domain, and the candidate materials may be fiber-reinforced materials, oriented at given discrete fiber angles, together with isotropic materials like foam materials used for sandwich structures. The discrete design optimization problem is converted to a continuous problem using the so-called Discrete Material Optimization (DMO) approach based on ideas from multi-phase topology optimization where interpolation functions with penalization are introduced. In this way traditional gradient based optimization techniques including efficient methods for design sensitivity analysis and mathematical programming can be used for solving the multi-material distribution problem. The multi-material topology optimization approach is demonstrated for buckling optimization of a 9 m generic wind turbine blade test section.

ABSTRACT: The design problem of maximizing the buckling load factor of laminated multi-material composite shell structures is investigated using the so-called Discrete Material Optimization (DMO) approach. The design optimization method is based on ideas from multi-phase topology optimization where the material stiffness is computed as a weighted sum of candidate materials, thus making it possible to solve discrete optimization problems using gradient based techniques and mathematical programming. The potential of the DMO method to solve the combinatorial problem of proper choice of material and fiber orientation simultaneously is illustrated for multilayered plate examples and a simplified shell model of a spar cap of a wind turbine blade.

doi: 10.1007/s00158-010-0593-8

ABSTRACT: This paper focuses on criterion functions for gradient based optimization of the buckling load of laminated composite structures considering different types of buckling behaviour. A local criterion is developed, and is, together with a range of local and global criterion functions from literature, benchmarked on a number of numerical examples of laminated composite structures for the maximization of the buckling load considering fiber angle design variables. The optimization formulations are based on either linear or geometrically nonlinear analysis and formulated as mathematical programming problems solved using gradient based techniques. The developed local criterion is formulated such it captures nonlinear effects upon loading and proves useful for both analysis purposes and as a criterion for use in nonlinear buckling optimization.

ABSTRACT: The paper presents an approach to nonlinear buckling fiber angle optimization of laminated composite shell structures. The approach accounts for the geometrically nonlinear behaviour of the structure by utilizing response analysis up until the critical point. Sensitivity information is obtained efficiently by an estimated critical load factor at a precritical state. In the optimization formulation, which is formulated as a mathematical programming problem and solved using gradient-based techniques, a number of the lowest buckling factors are included such that the risk of “mode switching” during optimization is avoided. The presented optimization formulation is compared to the traditional linear buckling formulation and two numerical examples, including a large laminated composite wind turbine main spar, to clearly illustrate the pitfalls of the traditional formulation and the advantage and potential of the presented approach.

ABSTRACT: Nonlinear buckling optimization is introduced as a method for doing laminate optimization on
generalized composite shell structures exhibiting nonlinear behaviour where the objective is to maximize the
buckling load. The method is based on geometrically nonlinear analyses and uses gradient information of the
nonlinear buckling load in combination with mathematical programming to solve the problem. Thin-walled
optimal laminated structures may have risk of a relatively high sensitivity to geometric imperfections. This is
investigated by the concepts of “worst” imperfections and an optimization method to determine the “worst”
shape imperfections is presented where the objective is to minimize the buckling load subject to imperfection
amplitude constraints. The ability of the nonlinear buckling optimization formulation to solve the laminate
problem and determine the “worst” shape imperfections is illustrated by several numerical examples of
composite laminated structures and the application of both formulations gives useful insight into the interaction
between laminate design and geometric imperfections.

ABSTRACT: A unified approach to nonlinear buckling fiber angle optimization of laminated composite shell
structures is presented. The method includes loss of stability due to bifurcation and limiting behaviour. The
optimization formulation is formulated as a mathematical programming problem and solved using gradient-
based techniques. Buckling of a well-known cylindrical shell benchmark problem is studied and the solutions
found in literature are proved to be incorrect. The nonlinear buckling optimization formulation is benchmarked
against the traditional linear buckling optimization formulation through several numerical optimization cases of
a composite cylindrical shell panel which clearly illustrates the advantage and potential of the presented
approach.

Esben Lindgaard and Jonas Dahl (Department of Mechanical and Manufacturing Engineering, Aalborg
University, Fibigerstraede 16, DK-9220, Aalborg East, Denmark), “On compliance and buckling objective
functions in topology optimization of snap-through problems”, Structural and Multidisciplinary Optimization,

ABSTRACT: This paper deals with topology optimization of static geometrically nonlinear structures
experiencing snap-through behaviour. Different compliance and buckling criterion functions are studied and
applied for topology optimization of a point loaded curved beam problem with the aim of maximizing the snap-
through buckling load. The response of the optimized structures obtained using the considered objective
functions are evaluated and compared. Due to the intrinsic nonlinear nature of the problem, the load level at
which the objective function is evaluated has a tremendous effect on the resulting optimized design. A well-
known issue in buckling topology optimization is artificial buckling modes in low density regions. The typical
remedy applied for linear buckling does not have a natural extension to nonlinear problems, and we propose an
alternative approach. Some possible negative implications of using symmetry to reduce the model size are
highlighted and it is demonstrated how an initial symmetric buckling response may change to an asymmetric
buckling response during the optimization process. This problem may partly be avoided by not exploiting
symmetry, however special requirements are needed of the analysis method and optimization formulation. We
apply a nonlinear path tracing algorithm capable of detecting different types of stability points and an
optimization formulation that handles possible mode switching. This is an extension into the topology
optimization realm of a method developed, and used for, fiber angle optimization in laminated composite structures. We finally discuss and pinpoint some of the issues related to buckling topology optimization that remains unsolved and demands further research.

ABSTRACT: Elastic buckling, which occurs in shell structures, is a major design issue because it can cause failures of structures. In particular, the variation in buckling load caused by a decrease in the thickness of the walls of structures is a key issue for safe design. The arc-length method, which is a finite element method, is generally applied to solve this type of problem. However, it has been reported that there are some cases in which the path of the buckling load cannot be solved using this method. We verified the problem by applying the arc-length method to elastic buckling that occurs in a shallow partial spherical shell. To solve the problem, we formulated a novel algorithm used in the explicit finite element method for estimating minimum strength of thin-walled structures. In this algorithm, initial deformation is given by pressing a rigid wall to the vertical direction of buckling mode. We anticipate that the proposed method will prove to be a practical way of calculating the minimum load for partial elastic buckling that occurs in a general shell structure under pressure.

ABSTRACT: The arc-length method has become a widely established solution technique for studying nonlinear structural behavior. By augmenting the set of nonlinear equilibrium equations with a constraint equation, which is a function of both the displacements and load increment, it is capable of traversing limit points. Numerous investigations have shown that highly nonlinear behavior such as sharp “snap-backs” can still lead to numerical difficulties. Two practical examples are presented to assess the effectiveness of this solution technique in capturing secondary instabilities in postbuckling structures, which present themselves as abrupt mode jumps. Although the first example poses no special difficulties, in the second case the nonlinear procedure fails to converge. An improvement to the method’s formulation is suggested, which accounts for the residual forces that are usually neglected, which proceeding to the next increment once convergence is reached on the current increment. The choice of a correct load increment at the first iteration, within a predictor-corrector scheme, is central to the method’s effectiveness. Current strategies for a choice of this load increment are discussed and are shown to be no longer consistent with the modified formulation; therefore, a new approach is proposed.

ABSTRACT: In this article, the buckling and post-buckling behaviours of a laminated composite spherical shallow shell panel embedded with shape memory alloy (SMA) fibres are studied under a thermal environment. System equations for a laminated composite spherical shell panel embedded with SMA fibres are for the first time derived by modelling the geometric non-linearity in the Green–Lagrange sense and the material non-linearity in SMA fibres in the framework of the higher-order shear deformation theory. The shell panel model is discretized by using a non-linear finite-element approach. The governing algebraic equations are then derived by the variational approach and solved using a direct iterative technique. Influences of the thickness ratio, boundary condition, aspect ratio, curvature ratio, lamination scheme, SMA volume fraction, percentage of prestrain, and amplitude ratio on the buckling and post-buckling temperatures of a laminated composite shell panel with and without SMA have been examined in detail. The results are computed using the present model and compared with those available in the literature.

ABSTRACT: A ring-stiffened slightly conical shell is optimized for external pressure according to the design rules of Det Norske Veritas. The whole length and the different two end radii are given. The shell is divided into \( n \) equidistant segments with one stiffener in each segment. Each segment has a different shell thickness determined using a buckling constraint, and each ring-stiffener of welded square box section is designed by means of the required moment of inertia. The optimal number of shell segments (\( n_{opt} \)) is determined by means of costs calculated for a series of \( n \). The cost function includes the material, fabrication and painting costs. The shell normal stresses are determined also by finite element method.

References listed at the end of the paper:

ABSTRACT: In this overview of loaded a longitudinally stiffened welded circular cylindrical steel shell is investigated. The halved rolled I-section stringers are welded outside to the shell. The simply supported belt-conveyor bridge is loaded by bending with a uniformly distributed normal load. The design constraints are related to the shell buckling, panel stiffener buckling and the maximum deflection of the bridge. The optimum shell thickness as well as the dimensions and number of stringers are sought, which minimize the cost function. The cost function includes the material, fabrication and painting costs. For the comparison an unstiffened shell is also optimized. The cost comparison shows that the cost of stiffened version is smaller than that of the unstiffened one only in those cases when the allowable deflection is strict enough.

ABSTRACT: This study examines free and parametric vibrations of cylindrical shells subjected to axial loads. In the case of free vibrations, the loading is static. Parametric vibrations are excited by a combined load consisting of one static and two periodic load components. The load is assumed to be nonuniform in the circumferential direction, and the shell is noncircular so that vibrations are concentrated near the “weakest” generatrix on the shell surface. By using Tovstik’s asymptotic method in combination with the multiple scale method with respect to time, the solutions of the governing equations are found in the form of functions.
localized near the “weakest” line and growing with time in the case of dynamic instability. The dependence of fundamental frequencies upon the static nonuniform axial force is studied. For the weak parametric excitation, the region of instability of a cylinder is determined directly in terms of its geometry, load intensity, and frequency.

ABSTRACT: Low-frequency vibrations of an elastic noncircular cylindrical shell in a nonstationary temperature field is investigated. By using the method of multiple scales, the solutions of the shell equations are constructed in the form of functions localized near “the weakest” generatrix. The equations for definition of the vibration amplitude are derived. The main region of instability of the shell equilibrium is established.

ABSTRACT: Low-frequency parametric vibrations of a viscoelastic cylindrical shell subjected to axial static and additional periodic loads are studied. It is assumed that the shell is noncircular and the load is non-uniform in the circumferential direction. It is supposed that for the weak parametric excitation the shell vibrations are localized near the weakest generatrix on the shell surface. By using Fourier transformations over the circumferential coordinate and the multiple scale method with respect to time, the solutions of the shell equations are constructed in the form of functions that decrease quickly outside a small neighbourhood of the weakest line. The region of instability of the shell is determined with regard to the viscosity.

ABSTRACT: The problem of local buckling of a thin composite laminated cylindrical shell under external pressure is studied. Each layer of the shell is assumed to be isotropic. The special case of the shell being non-circular and/or having no plane edges is considered here. Presupposing that buckling takes place in the neighborhood of some so-called “weakest” generator, the asymptotic Tovstik’s method is applied finding the critical pressure and the eigenmodes. As an example, buckling of a three-layered circular thin cylinder with a sloped edge is investigated. Besides the asymptotic approach the finite element simulation is applied to facilitate the estimation of the range to which the results obtained can be applied. (13 References)

ABSTRACT: The problem of parametric instability is studied for a thin conical shell subjected to nonuniform pulsating pressure. The edges of the shell (not necessary planar curves) are simply supported. The excitation frequency is assumed to be close to the twice the fundamental natural frequency of the shell. By using the WKB method combined with the method of multiple time scales we construct solutions of the governing equations as
functions decreasing away from a certain "most weak" generatrix and slowly increasing in time in the case of parametric resonance. Taking into account the viscous friction, we find the boundaries of the principal domain of local parametric instability.

ABSTRACT: The present work discusses the problem of dynamic stability of a viscoelastic circular cylindrical shell, according to revised Timoshenko theory, with an account of shear deformation and rotatory inertia in the geometrically nonlinear statement. Proceeding by Bubnov-Galerkin method in combination with a numerical method based on the quadrature formula the problem is reduced to a solution of a system of nonlinear integro-differential equations with singular kernel of relaxation. For a wide range of variation of physical mechanical and geometrical parameters, the dynamic behavior of the shell is studied. The influence of viscoelastic properties of the material on the dynamical stability of the circular cylindrical shell is shown. Results obtained using different theories are compared.

ABSTRACT: Approximate elasticity relations are derived for the axially symmetric deformation of a thin shell of revolution made of a nonlinearly elastic material using the three-dimensional equations of the theory of elasticity. The deformations are assumed to be of the order of a small parameter which is proportional to the square root of the dimensionless thickness of the shell. Terms of the second order of smallness with respect to the deformations are retained in the elasticity relations, as a result of which the equations obtained have an error of the order of the dimensionless thickness of the shell, which is customary in the linear theory of shells. The Kirchhoff-Love hypotheses are satisfied only in the first approximation. The axial compression of a shell, assuming that one of the extreme parallels can freely slide along a plane of support, which is perpendicular to the axis of revolution, is considered as an example. A formula is obtained for the limiting load, which physically and geometrically takes account of nonlinear effects in the first approximation.

ABSTRACT: Stability of a complete spherical shell under concentrated load was first considered by D. Bushnell (1967) by means of a finite difference method. In the present paper the effect of the internal pressure on the critical value of a concentrated load is studied by means of a combination of asymptotic and numerical methods.

ABSTRACT: We consider the stability of a thin transversally isotropic circular cylindrical shell under axial compression. We use a local approach according to which the buckling deflection is sought in the form of a doubly periodic function of curvilinear coordinates and the boundary conditions are ignored. We compare the solutions obtained according to the two-dimensional Kirchhoff-Love (KL) and Timoshenko-Reissner (TR) models with the solutions constructed according to the three-dimensional theory. Attention is mainly paid to the case of very small shear stiffness in the transverse direction.

ABSTRACT: The buckling modes of a homogeneously compressed elastic plate on a soft elastic substrate are studied. The critical compression is uniquely determined by the bifurcation equation, but this compression is associated with a wide set of buckling modes. It was proved that any solution of the Helmholtz equation satisfies the bifurcation equation. At the same time, in microelectronics, it is required to know which buckling mode is realized. Experimental and theoretical investigations show that the chessboard-like buckling mode should be expected. In what follows, this problem is discussed theoretically. The expected buckling mode can be found by analyzing the energy of the initial postcritical deformation, and the desired mode is determined from the condition of its minimum. The analytic expression of this energy is obtained. Its minimization results in the chessboard-like buckling mode.

and the corresponding behavior of the functions $\lambda(q, g)$ is investigated. The role of the fifth boundary condition in the TR model, which does not exist in the Kirchhoff–Love (KL) model is studied. It is shown that, if the boundary condition $H = 0$ holds and $g \to 0$, then the results based on the TR and KL models coincide. If the restraint $\phi_2 = 0$ is imposed and $g \to 0$, then the TR model produces new results as compared with the KL model.

ABSTRACT: We have conducted molecular dynamics simulations on compressing behaviors of single-walled carbon nanotubes (SWCNTs) with a large variaty of aspect ratios. It is found that SWCNTs with large aspect ratios experience column buckling behavior at low strain levels, in contrast to commonly observed shell buckling of short SWCNTs. Further compression leads to a transition to a shell buckling mode, which is distinct from those of short SWCNTs under compression. It originates from the column buckling induced bending loadings. We extract the scaling law with respect to the aspect ratio of SWCNTs based on an analytical model of bending buckling.

ABSTRACT: Using molecular dynamics simulations, we study axial compressive behavior of single-walled carbon nanotubes (SWCNTs) with a wide range of aspect ratios (length to diameter ratio). It is shown that the difference in aspect ratio leads to distinct buckling modes in SWCNTs. Small-aspect-ratio SWCNTs primarily exhibit shell buckling; they switch to a column buckling mode with increasing aspect ratio. Further compression of the already column buckled large-aspect-ratio SWCNTs results in a shell buckling. This shell buckling mode is distinct from that of small-aspect-ratio SWCNTs in that it originates from the column buckling induced bending deformation. The transition strain from column buckling to shell buckling of large-aspect-ratio SWCNTs is predicted using an analytical expression. The underlying mechanism is discussed by analyzing the variation of C-C bond lengths and angles.

ABSTRACT: Postbuckling and vibration analyses considering large thermopiezoelectric deflections are performed for fully symmetric and partially eccentric piezolaminated composite plates. Non-linear finite element equations based on the layerwise displacement theory are formulated for piezolaminated plates subject to thermal piezoelectric loads. The results demonstrate a methodology for raising the thermal buckling temperature and decreasing the thermal postbuckled deflection. Vibration characteristics under complex thermopiezoelectric loads are investigated in the prebuckling and postbuckling regions. For fully distributed piezolaminates, this study shows that excessive bending moments for the suppression of thermally buckled deflection may cause another type of structural instability. In addition, the effective placement of piezoceramic patches is studied to improve suppression of thermally buckled deflection for the partially segmented piezolaminates.

ABSTRACT: In this paper, the sensitivity of randomness in material parameters on the thermal buckling of conical shells embedded with and without piezoelectric layer is examined. A higher order shear deformation theory is used to model the system behaviour of the conical shell. The lamina material properties are modelled as basic random variables. A deterministic finite element method in conjunction with the first-order perturbation technique is employed to handle the randomness in the material properties. Typical numerical results for the second order statistics of the linear thermal buckling load of the composite conical shells/panels with and without piezoelectric layer are obtained. Mean value results are validated with those available in the literature and standard deviation results are also validated with an independent Monte Carlo simulation.

ABSTRACT: This report constitutes a synthesis of different results of numerical analysis of thin shell problems. The first part involves a general geometric definition of thin shells which is illustrated by different concrete examples. Next, one records the mechanical and the mathematical formulations of the problems and one gives some existence results. The second part presents some results obtained or under study concerning the approximation of these problems by finite element methods. They include conforming methods, flat plate element methods, mixed methods and D.K.T. methods. Finally, the third part contains basic results to solve the optimal design problem of a thin shell (joint work with F. Palma and B. Rousselet).

This paper is concerned with the analysis of optimized plates for buckling. The Rayleigh-Ritz
A computer program has been developed, based on both the linear and nonlinear theories of shells, which obtains numerical solutions for the most commonly used types of pressure vessels, namely those with spherical, ellipsoidal or conical heads and also flat-end pressure vessels. A multisegment integration technique has been used to obtain the solutions of the governing equations. The computed solutions are found to be highly accurate when compared with the known results of simple shells, as no nonlinear analysis is reported in the literature on the shell junctions in pressure vessels.

ABSTRACT: The present work is devoted to the investigation of stability of general spherical shells under external pressure with various end-conditions. The governing non-linear differential equations for the axisymmetric deformations of spherical shells, which defines the unique states of lowest potential energy under given pressures, are solved exactly by using the method of multisegment integration, developed by Kalnins and Lestingi [J. appl. Mech. 34, 59 (1967)]. The critical pressure for a particular shell is interpreted from the fact that any further increase in pressure, no matter how small, will cause enormous shell deformation indicating that the state of lowest potential energy for any increase in pressure is far from that at the critical pressure. Numerical results for a few shells, ranging from shallow to hemispherical, are presented here as examples and compared with others, where available.

ABSTRACT: This paper describes the nonlinear analysis of pressure vessels necessary for taking into account the large deformations that take place at the junctions of shells of different geometries. Specifically, a computer program has been developed, based on both the linear and nonlinear theories of shells, which obtains numerical solutions for the most commonly used types of pressure vessels, namely those with spherical, ellipsoidal or conical heads and also flat-end pressure vessels. A multisegment integration technique has been used to obtain the solutions of the governing equations. The computed solutions are found to be highly accurate when compared with the known results of simple shells, as no nonlinear analysis is reported in the literature on the shell junctions in pressure vessels.

The critical pressure for a particular shell is interpreted from the fact that any further increase in pressure, no matter how small, will cause enormous shell deformation indicating that the state of lowest potential energy for any increase in pressure is far from that at the critical pressure. Numerical results for a few shells, ranging from shallow to hemispherical, are presented here as examples and compared with others, where available.
ABSTRACT: This paper deals with the analysis of axisymmetric elastic buckling of semi-ellipsoidal shells under external pressure. Reissner's non-linear equations for the axisymmetric deformations of shells of revolution are specialized here for ellipsoidal shells and used in this analysis. The geometric singularity of these equations at the apex of shells is avoided through further modifications by imposing the conditions of continuity of the shell parameters and other variables across the apex. A multisegment method of integration, as developed by Kalnins and Lestringi, has been used to solve the non-linear equations of ellipsoidal shells. The critical pressure of a shell is interpreted from the fact that the mode of primary deformation along the fundamental equilibrium path of a structure cannot change without a change in its status of stability. The appearance of a secondary deformation on the fundamental equilibrium path is always hinted by a substantial increase in the deformation rate with respect to the load parameter. Specifically, for shells at the critical equilibrium, any further increase in loading, however small, causes the shell enormous deformation indicating that the state of deformation of the shell which corresponds to the lowest potential energy is far from that at critical pressure. Extensive numerical results on the buckling of semi-ellipsoidal shells with completely restrained edges and for varying thickness ratios have been obtained. It is observed that the critical pressure increases with an increase in the ratio of minor to major axes of the ellipsoidal shell and decreases with an increase in its thickness ratio.

ABSTRACT: This paper summarizes the major computer programs in existence for the analysis of shells of revolution by numerical integration and finite difference procedures. The report describes programs for (1) linear and nonlinear analysis of shells subjected to axisymmetric and asymmetric static loads, (2) buckling and vibration behavior including effects of axisymmetric nonlinear prestress, and (3) transient response. Extensions of these programs which are currently underway and some of the primary assets of both the numerical integration and finite difference procedures are discussed. In addition, a summary of the shell theory formulation, the numerical approximation, and the solution techniques of a set of programs denoted SALORS (Structural Analysis of Layered Orthotropic Ring-Stiffened Shells), developed at the NASA Langley Research Center, are described. Stress, vibration, and buckling results from the SALORS program are given for several shell configurations having a variety of structural complexities that illustrate the current capability of shell of revolution programs.

ABSTRACT: Test results and related structural instability analyses are presented for a 10-ft-diam, 37-in. -long cylinder, and a 10-ft-diam, 40-in. -long, 45-deg. conical frustum. Both structures are based upon flanged isogrids and are fabricated in 2024-T851 aluminum. Peak edge load intensities at failure were 1,654 lb/in. for the cylinder and 1,457 lb/in. at the small diam of the frustum. General instability cylindrical-monocoque-structure equivalent knockdown factors for both were in good agreement ( gamma equals 0. 48). Design analysis is also derived for estimating critical cylinder instability edge loads from the performance of two tandem isogrid members. Evaluation is made of effective skin contributing to isogrid load-carrying cross-section.

Walter L. Heard, Jr. (1), Melvin S. Anderson (1), and Paul Slysh (2)
ABSTRACT: An engineering procedure is presented for calculating the compressive buckling strength of isogrid cylinders using shell-of-revolution techniques and accounting for loading beyond the material proportional limit and/or local buckling of the skin prior to general buckling. A general nondimensional chart (based on a nonlinear postbuckling analysis of a typical skin element) is presented which can be used in conjunction with formulas based on simple deformation plasticity theory to calculate postbuckling stiffnesses of the skin. The stiffening grid system is treated as an equivalent isotropic grid layer. Stiffnesses are determined for this grid layer, when loaded beyond the proportional limit, by the same plasticity theory used for the skin and a nonlinear stress-strain curve constructed from simple isogrid-handbook formulas and standard-reference-manual stress-strain curves for the material involved. Comparison of prebuckling strains and buckling results obtained by this procedure with data from a large isogrid-cylinder test is excellent, with the calculated buckling load no more than 4 percent greater than the test value.

ABSTRACT: This paper investigated reliability of a postbuckled composite isogrid stiffened shell structure under a compression load. The outside diameter of the isogrid cylinder was 624.8 mm, the length was 368.3 mm and the total weight of the cylinder was 3.24 kg. A finite element buckling analysis result was compared with the axial compression experimental data. The average critical buckling load of 186.56 kN was obtained by using the Patran finite element analysis (FEA). The isogrid shell was modeled using 3-node triangular elements and the stiffeners were modeled using 4-node quad elements with a total of 504 nodes and 900 elements. The postbuckled isogrid cylinder was compression tested to the failure load of 177.35 kN. The postbuckled cylinder continued to resist compression loading even after one or more stiffeners had fractured. The testing evaluation revealed that the stiffener buckling was the critical failure mode and it has been demonstrated to be tolerant to structural damage due to the multiplicity of load paths. The lower experimental bucking load was due to the small imperfections in the cylinder but this problem can be overcome by advancement in the manufacturing methods.

ABSTRACT: The problem of determining the snap and snap back pressures of thin shallow shells of revolution subject to uniform loading is considered. The deformation is modelled using Marguerre's equations and bifurcation and postbuckling analyses are undertaken. A finite element model of the deformation is given and results for snap and snap back are presented.

ABSTRACT: An efficient substructuring analysis method is presented for predicting the natural frequencies of shells of revolution which may have arbitrary shape of meridian, general type of material property and any kind of boundary condition. This method is developed in the context of first order shear deformation shell theory as well as the classical thin shell theory. The vibrational behaviours of a circular cylinder, an elliptic hyperboloid shell (modelling a cooling tower) and a complete spherical shell are investigated using this method.

Li Jun and Hua Hongzing (Institute of Vibration, Shock & Noise, Shanghai Jiao Tong University, 800 Dongchuan Road, Shanghai, 200240, People’s Republic of China), “Free vibration analyses of axially loaded laminated composite beams based on higher-order shear deformation theory”, Meccanica, Vol. 46, No. 6, pp 1299-1317, December 2011

ABSTRACT: The dynamic stiffness matrix method is introduced to solve exactly the free vibration and buckling problems of axially loaded laminated composite beams with arbitrary lay-ups. The Poisson effect, axial force, extensional deformation, shear deformation and rotary inertia are included in the mathematical formulation. The exact dynamic stiffness matrix is derived from the analytical solutions of the governing differential equations of the composite beams based on third-order shear deformation beam theory. The application of the present method is illustrated by two numerical examples, in which the effects of axial force and boundary condition on the natural frequencies, mode shapes and buckling loads are examined. Comparison of the current results to the existing solutions in the literature demonstrates the accuracy and effectiveness of the present method

ABSTRACT: This paper deals with the development and application of reliable, creative and efficient computational tools for the structural optimisation of variable thickness axisymmetric and prismatic shells and folded plates using computer-aided analysis and design procedure. The problem of finding optimal forms and thickness variations for such structures is solved by integrating computer aided geometry modelling tools, automatic mesh generation, structural analysis, sensitivity evaluation and mathematical programming methods. The shape and thickness variation of the structures are defined using parametric cubic splines and the structural analysis is carried out with either finite element or finite strip methods in which Mindlin-Reissner assumptions are adopted. In static situations, the composition of the strain energy is monitored during the optimisation process to obtain insight into the energy distribution for the optimum structures. This allows us to demonstrate that, in the majority of cases, the optimum shells are membrane energy dominated as might be expected. For the vibrating structures, the mode shapes of the initial and optimum solutions are presented. A set of carefully defined, unambiguous benchmark examples is presented and studied with independent verification to test the various features of the structural optimisation process.
ABSTRACT: In this paper, the problem of optimal design of shells against instability is considered. A thin-walled shell is loaded, in general, by overall bending moment, constant or varying along an axis of a shell, by the appropriate shearing force and by an axial force and a constant torsional moment. We look for the shape of middle surface as well as the thickness of a shell, which ensures the maximum critical value of the loading parameter. The volume of material and the capacity of a shell are considered as equality constraints. The concept of a shell of uniform stability is applied.

1. Optimal design of rotationally symmetric shells for buckling under thermal loadings
ABSTRACT: In the present paper the problem of optimal design of a rotationally symmetric shell with immovable supports loaded by a uniform elevated temperature is investigated. We look for the variable thickness and the shape of the middle surface which lead to the maximal increment of the temperature causing buckling of the wall of this shell. The concept of the shell of uniform stability is applied.

2. Influence of a shearing force on optimal design of shells against buckling under overall bending
ABSTRACT: The present article is devoted to optimization of shells with a double positive curvature against buckling under overall bending moment which varies along an axis of the shell and under an appropriate shearing force which is associated with that variable bending moment. It seeks the shape of the meridian (only the axially symmetrical shape of the middle surface is allowed for here) as well as the thickness of the shell, which ensure the minimal volume of material. As equality constraints the critical value of the loading parameter and the capacity of a shell are considered. The hypothesis of the locality of buckling is utilized and the optimal structure is sought in the class of shells of uniform stability applying the Shirshov local stability condition.

ABSTRACT: The subject of the present paper is shells of revolution subjected to the external pressure. A family of shells of revolution, with positive and negative Gaussian curvature, were taken into consideration. The volume Vs and length L of the shell were constant. Three different rc/t ratios were investigated: 300, 504 and 700. The goal is to investigate elastic stability of shells of revolution. For that reason two kinds of analyses were performed using ABAQUS system. These are linear eigenvalue buckling prediction and non-linear post-buckling analysis. As a result of the linear analysis the influence of a meridional radius of curvature on the critical load was determined and presented on the graph. Non-linear analysis allowed to create equilibrium paths showing the behaviour of shells in a post-critical state. As can be seen from a number of plots convex barrelled shells are not stable after exceeding the critical load. Some concave barrelled shells on the contrary have stable equilibrium paths in the post-critical range.

The purpose of this report's analysis is to develop a numerical method and computer program for the calculation of the large deflection dynamic response of simply supported shallow spherical shells subjected to a class of spatially asymmetric and timewise step loadings. The program is then used to calculate asymmetric dynamics buckling loads for a few geometries and load durations, which is of importance in the design of spacecraft structures.

ABSTRACT: An investigation of the stability of the roof of an 85-ft diameter cylindrical prestressed concrete wastewater treatment tank is presented. The roof of the tank is a very thick, shallow spherical dome. With a 1/16 rise to span ratio, 2 ft thickness, and an 18 ft diameter central opening at its pole, the dome falls outside the range of parameters for which the thickness design equation for domes in the ACI 350 code applies. The shallowness parameter of the dome is in the range where axisymmetric snap-through buckling can be expected. A finite-element model was used to compute the nonlinear axisymmetric deflection of the dome up to its limit point, the snap-through to its inverted configuration, and the post snap-through load deflection. Bifurcation from the symmetric deformation to a nonsymmetric buckling mode below the limit point was investigated with a different finite-element model than was used for the evaluation of the snap-through. The finite-element results are compared to a form of the design equation for dome thickness in ACI 350. The dome thickness equation in ACI 350 was used to calculate dome load capacity, given the thickness, and was found to be significantly higher
than the capacity computed with the finite-element model.

ABSTRACT: On the basis of nonlinear theory, the axisymmetric dynamic deformations produced in viscoelastic clamped shallow spherical shells by transient pressure loading are analyzed. Two types of loading condition, that is, a step loading and a graded loading, are considered and the three-element model is used to describe the viscoelastic characteristics of the material considered. The governing equations derived by the authors are solved numerically, and the critical loads and the effects of viscoelasticity and loading speed on the dynamic behavior of the shell are discussed. And it is pointed out that Che buckling phenomena have to be analyzed paying an attention to the connection with the time, because the dynamic, static and creep bucklings are related with one another as a function of time. From the results of the present numerical solution, the quasi-static buckling load also is obtained immediately, which differs little from the static buckling load reported so far. The procedure adopted in the present analysis can be applied easily to the problems of elastic shells. The dynamic behavior of elastic shallow spherical shell obtained, by the present procedure is compared with the previous results and an excellent agreement between them is seen.

ABSTRACT: If it is assumed that, during its forced vibrations which lead to dynamic axisymmetric snap-through buckling, a dynamically loaded spherical cap passes through one of its corresponding static, unstable equilibrium configurations, then it is possible to estimate the dynamic axisymmetric snap-through buckling load from a simple static analysis only, without resorting to an elaborate dynamic analysis. It is shown, through numerical analysis of the spherical cap subjected to a timewise step load, that dynamic axisymmetric snap-through buckling loads obtained from the static approach are comparable to those obtained from the dynamic approach.

ABSTRACT: The dynamic axisymmetric behaviour of clamped orthotropic shallow spherical shell subjected to instantaneously applied uniform step-pressure load of infinite duration, is investigated here. The available modal equations, based on an assumed two-term mode shape for the lateral displacement, for the free flexural vibrations of an orthotropic shallow spherical shell is extended now for the forced oscillations. The resulting modal equations, two in number, are numerically integrated using Runge-Kutta method, and hence the load-deflection curves are plotted. The pressure corresponding to a sudden jump in the maximum deflection (at the apex) is considered as the dynamic buckling pressure, and these values are found for various values of geometric parameters and one value of orthotropic parameter. The numerical results are also determined for the isotropic case and they agree very well with the previous available results. It is observed here that the dynamic buckling load increases with the increase in the orthotropic parameter value. The effect of damping on the dynamic buckling load is also studied and this effect is found to increase the dynamic buckling load. It is further observed that this effect is more pronounced with increase in the rise of the shell.

ABSTRACT: The dynamic axisymmetric behavior of clamped laminated composite spherical caps subjected to suddenly applied loads is investigated using an eight-noded quadrilateral doubly curved shear flexible shell element based on the field-consistency approach. Geometric nonlinearity is considered using von Karman’s strain-displacement relations. The solution is obtained using the Wilson-Π numerical integration scheme. The pressure corresponding to a sudden jump in the maximum average deflection in the time history of the shell structure is taken as dynamic buckling pressure. A detailed parametric study is carried out to bring out the effects of shell geometries and material properties, number of layers, lamination schemes, and type of loading on a dynamic buckling load.

ABSTRACT: The dynamic instability analysis of a joined conical and cylindrical shell subjected to periodic in-plane load is investigated using C0 two-noded shear flexible shell element. The formulation is based on first-order shear deformation theory. The present model accounts for in-plane and rotary inertia effects. The instability regions are determined based on the principle of Bolotin’s method. The boundaries of the principal instability region obtained here are conveniently represented in the non-dimensional excitation frequency - non-dimensional load amplitude plane. The influence of various parameters such as orthotropy, cone angle, lay-up, combinations of different sections, thickness ratio, circumferential wave number, static load, and external pressure on the dynamic stability regions of cross-ply laminates is brought out.

ABSTRACT: Here, the nonlinear axisymmetric dynamic behavior of clamped laminated angle-ply composite spherical caps under suddenly applied loads of infinite duration is studied. The formulation is based on first-order shear deformation theory and it includes the in-plane and rotary inertia effects. Geometric nonlinearity is introduced in the formulation using von Kármán’s strain–displacement relations. The governing equations obtained are solved employing the Newmark’s integration technique coupled with a modified Newton–Raphson iteration scheme. The load corresponding to a sudden jump in the maximum average displacement in the time history of the shell structure is taken as the dynamic buckling pressure. The performance of the present model is validated against the available analytical/three-dimensional finite element solutions. The effect of shell geometrical parameter and ply angle on the axisymmetric dynamic buckling load of shallow spherical shells is brought out.

ABSTRACT: Here, free vibrations and transient dynamic response analyses of laminated cross-ply oval cylindrical shells are carried out. The formulation is based on higher order theory that accounts for the transverse shear and the transverse normal deformations, and includes zig-zag variation in the in-plane displacements across the thickness of the multi-layered shells. The contributions of inertia effect due to in-plane and rotary motions, and the higher order function arising from the assumed displacement models are included. The governing equations obtained using Lagrangian equations of motion are solved through finite element approach. A detailed parametric study is conducted to bring out the influence of different shell geometry, ovality parameter, lay-up and loading environment on the vibration characteristics related to different modes of vibrations of oval shell.

ABSTRACT: Here, linear elastic stability behavior of laminated cross-ply oval cylindrical shells under axial compression is studied through finite element approach. The formulation is based on higher-order theory that accounts for the transverse shear and transverse normal deformations, and incorporates realistic through the thickness approximations of the in-plane displacements. The strain–displacement relations are accurately introduced in the formulation. The contributions of work done by applied loads due to the higher-order function arising from the assumed displacement models are also included. The governing equations are obtained using the principle of minimum potential energy. The combined influence of higher-order shear deformation, shell geometry and ovality, and lay-up on the buckling loads of cylindrical shells is examined.

ABSTRACT: Here, the free vibration characteristics of functionally graded elliptical cylindrical shells are analyzed using finite element formulated based on the theory with higher-order through the thickness approximations of both in-plane and transverse displacements. The power law variation of properties is assumed in the thickness direction. The finite element employed in the study is based on field-consistency approach and free from shear and membrane locking problems. The strain–displacement relations are accurately introduced in the formulation without making any approximation in the thickness co-ordinate to radius ratio terms. The detailed parametric studies are carried out to study the influences of non-circularity, radius-to-thickness ratio, material composition and material profile index on the free vibration frequencies and mode shape characteristics of functionally graded elliptical shells. The significance of thickness stretch/contraction terms is highlighted through the mode shape study.

ABSTRACT: Interaction of clamped orthotropic shallow spherical shells with nonlinear elastic foundations is studied under transient loads. The effect of softening and hardening foundation nonlinearities on the response behaviour of shallow shells has been investigated. Detailed analysis depicting the influence of hardening type foundation nonlinearity on the maximum response of orthotropic shallow spherical shells has been conducted. The numerical results suggest that for the shell-foundation interaction problems undergoing moderately large deformations, the nonlinear model for the foundation must be considered.

ABSTRACT: The axisymmetric moderately thick laminated shallow spherical shells undergoing moderately large deflection subjected to dynamic loading are analyzed. Including the effects of transverse shear and rotatory inertia, the equations of dynamic equilibrium are formulated in terms of normal deflection, slope and stress function. Nonlinear governing equations of motion are linearized using quadratic extrapolation technique and the resulting linear differential equations are discretized in space and time domain using fast converging Chebyshev polynomials and the implicit Houbolt time marching scheme, respectively. Considering step function and sinusoidal loadings, both clamped and simply supported immovable laminated spherical shells are analyzed. The effect of control space variables, viz., transverse shear, rotatory inertia, material properties, shell parameter, base radius to thickness ratio, boundary conditions, number of layer and damping on the central response have been studied.

ABSTRACT: The stability and dynamic characteristics of laminated plates (rectangular, sector) and shells (cylindrical/conical/circular/noncircular) are studied using analytical solutions employing chebyshev polynomials and finite element method. The detailed parametric studies are carried out to highlight the effects of geometrical parameters, lamination schemes, loading and boundary conditions on the stability and dynamic response characteristics of plates and shells undergoing large deformation. Few results are presented.

ABSTRACT: The stability of postbuckled equilibrium configurations and the nonlinear dynamic characteristics of cross-ply laminated heated cylindrical shells are investigated employing semi-analytical shell finite element. The presence of asymmetric perturbation in the form of small magnitude load spatially proportional to the linear buckling mode shape is considered to initiate the bifurcation of the shell deformation from axisymmetric mode to asymmetric one. The frequencies of small oscillations about equilibrium configuration are obtained by solving the eigenvalue problem formulated using tangent stiffness matrix of the converged equilibrium configuration and mass matrix. The study reveals that the prediction of the postbuckling equilibrium configuration from nonlinear static analysis depends on the nature (longitudinally symmetric/antisymmetric) of initial disturbance. The longitudinally antisymmetric postbuckled equilibrium configuration is stable whereas the longitudinally symmetric one is unstable. The nonlinear dynamic response shows that the shell with longitudinally symmetric disturbance jumps from symmetric mode to antisymmetric mode and the predicted equilibrium configuration is of antisymmetric nature irrespective of the type of initial disturbance. The nonlinear forced dynamic response of the heated shell in the prebuckling region differs significantly from that in the postbuckling region.

ABSTRACT: Here, the thermo-elastic buckling characteristics of angle-ply laminated elliptical cylindrical shells subjected to uniform temperature rise are studied to highlight the combined influences of non-circularity and ply-angle on the critical temperature parameter and buckling mode shapes. It is brought out that the rate of change of the critical temperature parameter with respect to ply-angle reduces significantly with the increase in the non-circularity parameter. Further the shells in the optimum ply-angle range are found to be highly sensitive to non-circularity whereas their sensitivity is very less away from the optimum ply-angle range.

ABSTRACT: Here, the dynamic stability behavior of a clamped functionally graded materials spherical shell
structural element subjected to external pressure load is studied. The material properties are graded in the thickness direction according to the power-law distribution in terms of volume fractions of the constituents of the material. The effective material properties are evaluated using a homogenization method. The structural model is based on shear deformation theory and geometric non-linearity is considered in the formulation using von Karman’s assumptions. The governing equations obtained are solved employing the Newmark’s integration technique coupled with a modified Newton–Raphson iteration scheme. The load corresponding to a sudden jump in the maximum average displacement in the time history of the shell structure is taken as the dynamic buckling pressure. The present model is validated against the available isotropic cases. A detailed numerical study is carried out to bring out the effects of power-law index of functional graded material on the axisymmetric dynamic stability characteristics of shallow spherical shells.

PARTIAL INTRODUCTION: Recent research works on improved performance materials have addressed new materials, known as functionally graded materials [1] (FGMs), in which the material properties vary smoothly and continuously from one surface of the material to the other surface. These are high-performance, heat-resistant materials that are able to withstand the ultrahigh temperatures and extremely large thermal gradients that are used in fusion reactors and aerospace industries. They maintain their structural integrity and avoid the interface problem that exists in homogeneous composites. Thin-walled structural members of aerospace and defense that are subjected to dynamic load could encounter deflections of the order of the shell thickness. The dynamic response of such shells may lead to the phenomenon of dynamic snapping or dynamic buckling. Hence, the nonlinear behavior of thin structural members, in particular, spherical shells that form an important
class of structural components, has to be understood for their optimum design.

ABSTRACT: The non-linear buckling strength of clamped spherical caps under uniform step loading was investigated. To simplify the finite element formulation of the geometrically non-linear behavior of snap-through buckling, the geometric coordinates of spherical caps are updated at every time step. Thus, a linearized finite element incremental equation based on the principle of virtual work can be derived. A three-dimensional shell element with arbitrary geometry was used in the finite element formulation, and the whole process was accomplished according to the Newmark method as the time integration scheme. Two alternative criteria of critical load, the apex displacement and the average deflection, were utilized to determine the dynamic buckling loads. The results agree well with previously published work.

ABSTRACT: Random vibrations are considered for the cases of shear-deformable plates with initial curvature and of elastically buckled plates. The nontrivial generalization of the flat plate vibrations is expressed by the fact that “small amplitude” vibrations exist about the curved equilibrium position together with the snap-through and snap-buckling type large amplitude vibrations about the flat position. The problem of snap-buckling in the large deflection random response, i.e., the loss of stability accompanied in simple and regular structures by the change from a symmetric to an antimeric configuration, is studied in detail. The geometrically nonlinear panel vibrations are treated by applying Berger’s approximation to the generalized von Karman-type
plate equations considering hard hinged supports of the straight boundary segments of skew or even more generally shaped polygonal plates. Shear deformation is considered by means of Mindlin’s kinematic hypothesis. A distributed lateral force loading is applied, and additionally, the influence of thermal prestress is taken into account as well as a randomly fluctuating temperature. A multi-mode approach and the Galerkin procedure are applied to the boundary value problem. The result of the projection and of a transformation is a set of nonlinearity coupled ordinary differential equations (ODEs) driven effectively by random forces and with potential restoring forces. For reasons of convergence, a light viscous modal damping is added at this stage. By means of a nondimensional formulation and introducing the eigen-time of the basic mode of the associated linearized problem renders a unifying result with respect to the planform of the panel. With the simplifying approximation of the action of the random environment by effective forces modeled by uncorrelated, zero-mean wide-band noise processes, and by considering the set of modal equations to be finite, the Fokker-Planck-Kolmogorov (F.P.K.) equation for the transition probability density of the generalized coordinates and velocities is derived. The probability of first dynamic snap-through is derived for a single mode approximation with the influence of higher modes taken into account. Using the two-mode expansion, the probability distribution of the asymmetric snap-buckling is also evaluated. All probabilistic results obtained for the complex panel structures to be considered hold independently (in the sense of similitude) of their special planform. They are cast in the form of graphs with a structural parameter varying in a wide range.

ABSTRACT: An analytical method for the elasto/visco-plastic dynamic problems of axisymmetrical thin shells subjected to mechanical or thermal loads or both is developed. The equations of motion and the relations between the strains and displacements are derived by extending Sanders' elastic-shell theory. For the constitutive relations, Perzyna's elasto/visco-plastic equations, including the temperature effect, are employed. The derived fundamental equations are numerically solved by the finite-difference method. As numerical examples, simply supported cylindrical shells made of mild steel are treated, and the following two cases are analyzed: a non-uniformly heated cylindrical shell subjected to impulsive internal pressure, and an internally pressurized cylindrical shell subjected to impulsive thermal load. In both cases, the variations of displacements and internal forces with time are discussed.

ABSTRACT: In this paper, by means of combining non probabilistic convex modeling with perturbation theory, an improvement is made on the first order approximate solution in convex models of uncertainties. Convex modeling is extended to largely uncertain and non-convex sets of uncertainties and the combinational convex modeling is developed. The presented method not only extends applications of convex modeling, but also improves its accuracy in uncertain problems and computational efficiency. The numerical example illustrates the efficiency of the proposed method.

Xu Han, Chao Jiang, LiXin Liu, Jie Liu and XiangYun Long (State Key Laboratory of Advanced Design and Manufacturing for Vehicle Body, College of Mechanical and Vehicle Engineering, Hunan University, Changsha, 410082, China), “Response-surface-based structural reliability analysis with random and interval mixed uncertainties”, Science China Technological Sciences, Vol. 57, No. 7, pp 1322-1334, July 2014

ABSTRACT: Traditional reliability analysis requires probability distributions of all the uncertain parameters. However, in many practical applications, the variation bounds can be only determined for the parameters with limited information. A complex hybrid reliability problem then will be caused when the random and interval variables coexist in a same structure. In this paper, by introducing the response surface technique, we develop a new hybrid reliability method to efficiently compute the interval of the failure probability of the structure due to the probability-interval hybrid uncertainty. The present method consists of a sequence of iterations. At each step, a response surface model is constructed for the limit-state function by using a quadratic polynomial and a modified axial experimental design method. An approximate hybrid reliability problem is created based on the response surface model, which is subsequently solved by an efficient decoupling approach. An updating strategy is suggested to improve the quality of the response surface and whereby ensure the reliability analysis precision. A computational procedure is then summarized for the whole iterations. Four numerical examples and also a practical application are provided to demonstrate the effectiveness of the present method.

ABSTRACT: Functionally graded materials (FGM) are composite materials with microstructure gradation optimized for the functioning of engineering components. For the case of fibrous composites, the fibre density is varied spatially, leading to variable material properties tailored to specific optimization requirements. There is an increasing demand for the use of such intelligent materials in space and aircraft industries. The current preferred methods to study engineering components made of FGM are mainly modelling particularly those that
are finite element (FE) based as experimental methods have not yet sufficiently matured. Hence this thesis reports the development of a new Mindlin-type element and new Reissner-type element for the FE modelling of functionally graded composite (FGC) structures subjected to various loadings such as tensile loading, in-plane bending and out-of-plane bending, buckling and free vibration. The Mindlin-type element formulation is based on averaging of transverse shear distribution over plate thickness using Lagrangian interpolation. Two types of Mindlin-type element were developed in this report. The properties of the first Mindlin-type element (i.e. Average Mindlin-type element) are computed by using an average fibre distribution technique which averages the macro-mechanical properties over each element. The properties of the second Mindlin-type element (i.e. Smooth Mindlin-type element) are computed by using a smooth fibre distribution technique, which directly uses the macro-mechanical properties at Gaussian quadrature points of each element. The Reissner-type element formulation is based on parabolic transverse shear distribution over plate thickness using Lagrangian and Hermitian interpolation. Two types of Reissner-type element were developed in this report, which include the Average and Smooth Reissner-type elements. There were two types of non-linearity considered in the modelling of the composite structures, which include finite strain and material degradation. The composite structures considered in this paper are functionally graded in a single direction only, but the FE code developed is capable of analysing composite structures with multidirectional functional gradation. This study was able to show that the structural integrity enhancement and strength maximisation of composite structures are achievable through functional gradation of material properties over the composite structures.

ABSTRACT: Equilibrium and stability equations of a moderately thick rectangular plate made of functionally graded materials under thermal loads are derived based on the first order shear deformation theory. It is assumed that the material properties vary as a power form of thickness coordinate variable z. The derived equilibrium and buckling equations are then solved analytically for a plate with simply supported boundary conditions. Two types of thermal loading, uniform temperature rise and gradient through the thickness are considered, and the buckling temperatures are derived. The influences of the plate aspect ratio, the relative thickness, the gradient index and the transverse shear on buckling temperature difference are all discussed.

ABSTRACT: This investigation deals with the static and dynamic axisymmetric buckling of elastic orthotropic thin shallow spherical shells with elastically restrained edge for inplane and rotational displacements. Governing equations in terms of normal displacementw and stress function psi have been employed. Orthogonal point collocation method is used for spatial discretisation and Newmark-beta scheme is used for time-marching.
The uniformly distributed static and step function conservative loadings normal to the underformed surface are considered. The present results are in good agreement with the available results. The influence of orthotropicity parameter beta and the support stiffness parameters on the static and dynamic buckling loads has been investigated.

ABSTRACT: This paper deals with the moderately large dynamic response of a doubly curved shallow spherical shell of rectangular plan form, supported on a two parameter elastic subgrade and subjected to uniformly distributed step and sinusoidal loadings. Von Kármán-Donnell type non-linear partial differential equations of motion are employed and solved by using finite difference and Houbolt time marching techniques. Two boundary conditions are considered. The influence of stiffnesses and mass of the elastic subgrade on the moderately large amplitude of response of the shell has been investigated.

ABSTRACT: This paper deals with the static and dynamic buckling of polar orthotropic antisymmetrically laminated, moderately thick shallow spherical shells under uniformly distributed loading. Considering the effects of transverse shear and rotatory inertia, the governing equations of motion for shells undergoing large deformations are derived and expressed in terms of normal deflection W, slope theta and stress function psi. the Chebyshev series technique is used for spatial discretization and the Houbolt scheme is used for temporal discretization. Considering step function loading, both clamped and simply supported immovable laminated spherical shells are analyzed. The effects of transverse shear, rotatory inertia, shell rise, base-radius-to-thickness ratio and material properties on the static and dynamic snap-through buckling of antisymmetrically laminated shells have been studied.

ABSTRACT: The influence of meridional curvature on the postbuckling behaviour of angle-ply laminated cylindrical shells subjected to external pressure, torsional load, axial compression and uniform temperature rise is investigated using the semi-analytical finite element approach. The nonlinear governing equations are solved using Newton–Raphson iterative technique coupled with the adaptive displacement control method. The presence of asymmetric perturbation in the form of a small magnitude load spatially proportional to the linear buckling mode shape is considered to trace the postbuckling path. The variation of ply-angle and ply-thickness along the meridional direction is considered. The results presented reveal that the imperfection sensitivity of the
cylindrical shells having negative Gaussian curvature decreases with the increase in the magnitude of H/r₀ ratio for all the loading cases considered. The imperfection sensitivity of the positive Gaussian curvature shells increases for external pressure, torsional and thermal loading cases, whereas it decreases for axial loading case with the increase in H/r₀ ratio.

ABSTRACT: Here, the elastic buckling characteristics of laminated cross-ply elliptical cylindrical shells under axial compression is studied through finite element approach. The formulation is based on higher-order theory that accounts for the transverse shear and transverse normal deformations, and incorporates realistic through the thickness approximations of the in-plane displacements. The strain-displacement relations are accurately accounted for in the formulation. The contributions of work done by applied load due to the higher-order function arising from the assumed displacement models are also incorporated. The governing equations obtained using the principle of minimum potential energy are solved through eigenvalue approach. The combined influence of higher-order shear deformation, shell geometry and elliptical cross-sectional parameter, and lay-up on the buckling loads of elliptical cylindrical shells is examined.

ABSTRACT: This paper presents the large deflection elastic curve of buckled bars through perturbation method, and the bifurcation diagrams including the influence of the imperfection at the base by using singular perturbation method of imperfect bifurcation theory. The physical meaning of the bifurcation diagrams is discussed.

ABSTRACT: The present paper deals with an eigenvalue problem for a hemivariational inequality, arising in the study of a mechanical problem: the buckling of a von Kármán plate adhesively connected to a rigid support with delamination effects. For this eigenvalue problem an existence result is obtained by applying a critical point method suitable for nonconvex nonsmooth functions. Further, a result concerning the multiplicity of solutions is proved. The mechanical interpretation of these results is briefly discussed.

ABSTRACT: Most commercial finite-element programs use the Jaumann (or co-rotational) rate of Cauchy stress in their incremental (Riks) updated Lagrangian loading procedure. This rate was shown long ago not to be work-conjugate with the Hencky (logarithmic) finite strain tensor used in these programs, nor with any other finite strain tensor. The lack of work-conjugacy has been either overlooked or believed to cause only negligible errors. Presented are examples of indentation of a naval-type sandwich plate with a polymeric foam core, in which the error can reach 28.8 per cent in the load and 15.3 per cent in the work of load (relative to uncorrected results). Generally, similar errors must be expected for all highly compressible materials, such as metallic and ceramic foams, honeycomb, loess, silt, organic soils, pumice, tuff, osteoporotic bone, light wood, carton and various biological tissues. It is shown that a previously derived equation relating the tangential moduli tensors associated with the Jaumann rates of Cauchy and Kirchhoff stresses can be used in the user’s material subroutine of a black-box commercial program to cancel the error due to the lack of work-conjugacy and make the program perform exactly as if the Jaumann rate of Kirchhoff stress, which is work-conjugate, were used.

References listed at the end of the paper:
ABSTRACT: Most commercial finite element codes, such as ABAQUS, LS-DYNA, ANSYS and NASTRAN, use as the objective stress rate the Jaumann rate of Cauchy (or true) stress, which has two flaws: It does not conserve energy since it is not work-conjugate to any finite strain tensor and, as previously shown for the case of sandwich columns, does not give a correct expression for the work of in-plane forces during buckling. This causes no appreciable errors when the skins and the core are subdivided by several layers of finite elements. However, in spite of a linear elastic behavior of the core and skins, the errors are found to be large when either the sandwich plate theory with the normals of the core remaining straight or the classical equivalent homogenization as an orthotropic plate with the normals remaining straight is used. Numerical analysis of a plate intended for the cladding of the hull of a light long ship shows errors up to 40%. It is shown that a previously derived stress-dependent transformation of the tangential moduli eliminates the energy error caused by Jaumann rate of Cauchy stress and yields the correct critical buckling load. This load corresponds to the Truesdell objective stress rate, which is work-conjugate to the Green–Lagrangian finite strain tensor. The commercial codes should switch to this rate. The classical differential equations for buckling of elastic soft-core sandwich plates with a constant shear modulus of the core are shown to have a form that corresponds to the Truesdell rate and Green–Lagrangian tensor. The critical in-plane load is solved analytically from these differential equations with typical boundary conditions, and is found to agree perfectly with the finite element solution based on the Truesdell rate. Comparisons of the errors of various approaches are tabulated.
not to be associated by work with any finite strain tensor, and the first has often been combined with tangential moduli not associated by work. The error in energy conservation was thought to be negligible, but recently, several papers presented examples of structures with high volume compressibility or a high degree of orthotropy in which the use of commercial software with the Jaumann rate of Cauchy or Kirchhoff stress leads to major errors in energy conservation, on the order of 25–100%. The present paper focuses on the Green–Naghdi rate, which is used in the explicit nonlinear algorithms of commercial software, e.g., in subroutine VUMAT of ABAQUS. This rate can also lead to major violations of energy conservation (or work conjugacy)—not only because of high compressibility or pronounced orthotropy but also because of large material rotations. This fact is first demonstrated analytically. Then an example of a notched steel cylinder made of steel and undergoing compression with the formation of a plastic shear band is simulated numerically by subroutine VUMAT in ABAQUS. It is found that the energy conservation error of the Green–Naghdi rate exceeds 5% or 30% when the specimen shortens by 26% or 38%, respectively. Revisions in commercial software are needed but, even in their absence, correct results can be obtained with the existing software. To this end, the appropriate transformation of tangential moduli, to be implemented in the user's material subroutine, is derived.

ABSTRACT: A new type of composites structural insulated panels (CSIPs) is presented in this article. These panels are proposed for structural floor and wall applications. The developed composite panels are made of low-cost orthotropic thermoplastic glass/polypropylene laminate as facesheets and expanded polystyrene foam as a core. CSIPs have a considerably high facesheet/core moduli ratio. The common mode of failure of these panels is facesheet/core debonding. Accordingly, this investigation presents models for interfacial tensile stress and critical wrinkling in-plane stress associated with debonding of CSIPs. The facesheet in compression was modeled as a beam on a Winkler foundation. The proposed models were validated using full-scale experimental testing for CSIPs floor and wall panels. Both type of panels failed by facesheet/debonding with natural half-wavelength approximately equal to the core thickness.

ABSTRACT: This study examined the structural behaviors of foam insulated concrete sandwich panels subjected to uniform pressure. Finite element models were used to simulate the detailed shear resistance of connectors and the nonlinear behaviors of concrete, foam and rebar components. The models were then validated using data from static tests performed at the University of Missouri. Both composite and non-composite action had a significant effect on the response of the foam insulated concrete sandwich panels, indicating that the simulated shear tie resistance should indeed be incorporated in numerical analyses. The modeling approach used here conveniently simulated the structural behaviors during all loading stages (elastic, yielding, ultimate and post-failure) and was compatible with the American Concrete Institute (ACI) Code and existing design practices. The results of this study will therefore provide useful guidelines for the analysis and
design of foam insulated sandwich panels under both static and dynamic loadings.

ABSTRACT: Buckling analysis of sandwich plate was investigated using layerwise method. The formulation was based on the first-order shear deformation theory, and the Rayleigh-Ritz method was used for approximating and determining the displacement field. The results obtained from layerwise theory was compared with finite element results and showed good agreement. This study demonstrated that layerwise theory could describe buckling behavior of sandwich plates with high accuracy and represents a more realistic and acceptable description of behavior of the plates with much less computational cost.

ABSTRACT: A general analytical model is developed for the stresses and displacements of an assembly of several coaxial laminated hollow circular cylinders made of orthotropic layers, and subjected to internal and external pressure, tensile, torsion and bending loads. Slip and friction conditions at the interfaces are not considered in lieu of perfect bonding. The model results are compared to the experimental tensile test of a composite tube. Displacements and stresses are evaluated for different angle-ply layers and radius-to-thickness ratios.

Ochoa, (Mechanical Engineering Department, Texas A&M University, College Station, TX 77843, USA), “Similitude study for a laminated cylindrical tube under tension, torsion, bending, internal and external pressure Part II: scale models”, Composite Structures, Vol. 44, No. 4, April 1999, pp. 231-236, doi:10.1016/S0263-8223(98)00069-5

ABSTRACT: The aim of this study is to demonstrate the validity of scale model development testing and predict the laminated cylindrical tube behavior under tensile, torsion, bending, internal and external pressure load. Similitude theory is used to develop the necessary similarity conditions. In the amplitude approach, the coefficients of the governing differential equation for the prototype and the model of the prototype are compared to develop scaling laws. For composites, these scaling laws depend not just on geometry, but also on constituent properties and the laminate stacking sequences. The model tubes were loaded under scaled test conditions until catastrophic failure. Data acquired included load, strain measurements and non destructive evaluation of damage mechanisms.

Box 16765-3381, Tehran, Iran), “Transient dynamic response of composite circular cylindrical shells under radial impulse load and axial compressive loads”, Thin-Walled Structures, Vol. 43, No.
ABSTRACT: Free and forced vibration of composite circular cylindrical shells are investigated based on the first love's approximation theory using the first-order shear deformation shell theory. The boundary conditions (BCs) are considered as clamped-free edges. The dynamic response of the composite shells is studied under transverse impulse and axial compressive loads. The axial compressive load was less than critical buckling loads. The modal technique is used to develop the analytical solution of the composite cylindrical shell. The solution for the shell under the given loading conditions can be found using the convolution integrals. The effect of fiber orientation, axial load, and some of the geometric parameters on the time response of the shells has been shown. The results show that dynamic responses are governed primarily by natural period of the structure. The accuracy of the analysis has been examined by comparing results with those available in the literature and experiments.

ABSTRACT: In this paper, the necessary similarity conditions, or scaling laws, for free vibrations of orthogonally stiffened cylindrical shells are developed using the similitude theory. The Donnell-type nonlinear strain–displacement relations along with the smearing theory are used to model the structure. Then the principle of virtual work is used to analyze the free vibration of the stiffened shell. After non-dimensionalizing the derived formulations, the scaling laws are developed, using the similitude theory. Then, different examples are solved to validate the scaling laws numerically and experimentally. The obtained results show the effectiveness of the derived formulations.

ABSTRACT: In this paper, the nonlinear vibration of functionally graded (FGM) cylindrical shells subjected to radial harmonic excitation is investigated. The nonlinear formulation is based on a Donnell’s nonlinear shallow-shell theory, in which the geometric nonlinearity takes the form of von Karman strains. The Lagrange equations of motion were obtained by an energy approach. In order to reduce the system to finite dimensions, the middle surface displacements were expanded by using trial functions. These functions were expressed in terms of Fourier series containing linear mode shapes, which were obtained from free vibration analysis. The large-amplitude response and amplitude frequency curves of shell were computed by using numerical method for both linear and nonlinear analysis.

ABSTRACT: In this paper, a hybrid atomistic-structural element for studying the mechanical behaviour of carbon nanotubes is introduced. Non-linear formulation for this element is derived based on empirical inter-atomic potentials. This hybrid element is capable of taking into account the non-linear nature of inter-atomic forces as well as the non-linearity arising from large deformations. Using these capabilities, the stability analysis of carbon nanotubes under axial compressive loading is performed and the post-buckling behaviour is predicted. Also, the dependence of axial buckling force on nanotube radius is shown.

ABSTRACT: In this study, the influence of nonuniformity of eccentricity of stringers on the general axial buckling load of stiffened laminated cylindrical shells with simply supported end conditions is investigated. The critical loads are calculated using Love’s First-order Shear Deformation Theory and solved using the Rayleigh-Ritz procedure. The effects of the shell length-to-radius ratio, shell thickness-to-radius ratio, number of stringers, and stringers depth-to-width ratio on the buckling load of nonuniformly eccentric shells, are examined. The research demonstrates that an appropriate nonuniform distribution of eccentricity of stringers leads the buckling load to increase significantly.

References listed at the end of the paper:

ABSTRACT: In this research, the general axial and radial buckling optimization of ring-stiffened cylindrical shells is implemented by the genetic algorithm (GA). The stiffened shell is subjected to four constraints including the fundamental frequency, the structural weight, the axial buckling load, and the radial buckling load. In addition, six design variables including shell thickness, number of stiffeners, stiffeners width and height, stiffeners eccentricity distribution order, and stiffeners spacing distribution order are considered. In analytical solution, the Ritz method is applied and stiffeners are treated as discrete elements. The effect of the weighting coefficients of the objective functions on the optimum solution is studied. The results show that optimized stiffening a cylindrical shell leads to a lower structural weight, higher natural frequencies, and larger axial and radial buckling loads, simultaneously. In addition, the upper and lower bounds of the design variables influence the optimum results considerably. It is also found that the distributions of eccentricity and spacing of the stiffeners influence the magnitudes of the axial and radial buckling loads considerably.

ABSTRACT: The problem of stability of shells of positive Gaussian curvature subjected to a concentrated load, internal or external pressure and an accumulating ponding fluid in the depression caused by the load is the subject of this paper. Critical values of the load are calculated by a so called “geometrical method”, using variational Lagrangian principles. The shape of the shell is assumed to be nearly isometrical to the initial shape and its bending rigidity is taken into account. Simple relations for the critical load are obtained and the results presented in graphical form. The expressions and diagrams presented facilitate calculation of critical loads and describe the behaviour of the shell undergoing very large deflections.

ABSTRACT: The present paper gives the results of numerical solutions for non-linear problems concerning transverse bending of flexible shallow hyperbolic paraboloid shells with elastic edge elements and tie-connecting lower corners. Perfect and imperfect shells are analysed. To solve the system of non-linear differential equations, the method of finite differences combined with the method of differentiation with respect to a parameter is used. These methods reduce the boundary value problem to Cauchy's problem which is solved with the use of Runge-Kutta's method. It has been shown that the buckling of a flexible shallow hypar under transverse load occurs in the vicinity of the upper corner zones under the effect of principal compressive membrane forces caused by surface shear. The values of critical loads are given here. They depend significantly on the surface curvature and stiffness of the edge elements and tie. For imperfect shells the position and shape of the initial irregularities influence greatly the value of the critical load.

ABSTRACT: The stability of linearly viscoelastic flexible shallow hyperbolic paraboloid shell is analysed under transverse load. Allowances are made for geometrical nonlinearity and initial imperfections of the surface shape. By application of the method of finite differences with respect to geometrical variables and the method of differentiation with respect to a parameter (time) the solution for the system of equilibrium non-linear integro-differential equations is reduced to Cauchy's problem which can be solved numerically. The critical time was shown to depend on the load, curvature, initial imperfections and edge elements compressibility. Critical loads for an outlying time moment are determined.

ABSTRACT: The stability analysis of stiffened plates by means of the finite strip method is presented. The studies are based on the thin shallow theory, giving nonlinear strain displacement relations, but linear curvature displacement relations. The nonlinear equilibrium equations are obtained by the principle of incremental virtual work, using finite strip discretization. The higher order strip with one internal nodal line is applied. It is shown that considerable improvements can be obtained using this kind of strip. It is especially true for the postbuckling analysis. Numerical examples of the strength of stiffened plates in compression are carried out, covering a range of plate and stiffener slenderness.

ABSTRACT: The purpose of this paper is to examine the two fundamental questions in the finite element analysis of shells; namely, the rates of convergence resulting from different interpolation schemes for the inplane and normal displacements, and the dependence of the condition number of the resulting algebraic
system on the various parameters both of the shell and of the discretization.

ABSTRACT: A cubic-cubic finite element is derived for the thin shell of revolution undergoing large axisymmetrical Kirchhoff deformation. Application is made to the nonlinear elastic distortion of a spherical shell under surface pressure and polar forces.

ABSTRACT: In the present paper the mechanical interpretation of the Berger's hypothesis is considered. Using the geometrical method of Pogorelov and the asymptotic representation of the solutions of the non-linear partial differential equations, the values of the first and second invariants of the strain tensor are evaluated. This method confirms the hypothesis of Berger for the class of non-linear problems of shells under static loading. The result obtained is valid for isotropic and anisotropic shells.

ABSTRACT: The global stability of thin elasto-plastic shells subject to static loading is investigated using the variational principle. With the aid of the assumptions of the geometric method the asymptotic of the energy of deformation on the class of partially-regular surfaces, isometric to the initial ones is obtained. The plastic properties of the material are properly described by the deformation theory of plasticity. The variational principle is applied to cylindrical elasto-plastic shells subject to axial compression. The theoretical results for the minimum critical loading, compared with the experimental ones, show the difference to be not more than 10%

ABSTRACT: This paper presents an attempt to evaluate theoretically the influence of initial geometric imperfections in the shell surface on the value of the upper critical load of a strictly convex shell of revolution which is subjected to uniform pressure. Pogorelov's geometric method for nonlinear stability problems of thin shells is applied to obtain an analytical formula for the upper critical load, dependent on the initial imperfections. A probabilistic solution of the problem is presented. As a result, the stochastic influence of the initial deviations in the shell surface on the probability density function of the critical load and on the shell reliability are estimated and presented graphically. An example is given for an ellipsoidal shell of revolution.

ABSTRACT: A probabilistic method is applied to the problem of stability of a spherical shell with initial imperfections, subjected to uniform external pressure. The distribution law of the normal deflections of the shell is obtained following the Smoluchovsky equation, at a given density of the initial deflections. On this basis the probability for the deflections to be in a given interval is found. A relation for the probability for a jump transition to a new stability form is obtained for a spherical shell with a given probability distribution of the initial imperfections. The relations obtained can be used for solving different kinds of reliability problems, as well as problems for prediction of the shell stability forms together with the probability for their realization.

ABSTRACT: The buckling and post-critical behavior of elastic conservative, shallow shells with very small initial imperfections in the middle-surface shape are investigated for several coincident critical loads. In this case the buckling mode of the shell in the initial post-critical stage is a linear combination of many eigenmodes and a computation of the critical loads is related to the need to solve systems of nonlinear algebraic equations /1,2/. The analysis is on the basis of the Mushtari—Donnell — Vlasov equations /3/ by the Liapunov-Schmidt operator method /4–9/. In the case of shells of arbitrary shape, asymptotic representations are constructed of new equilibria in the initial post-critical stage, a system of bifurcation, equations and formulas to determine its coefficients are obtained, and equations of the critical load surfaces are also derived as functions of the shell imperfection parameters. A complete solution of the problem is given for the non-axisymmetric buckling of the axisymmetric equilibrium of shells of revolution. Computational formulas are written down for the coefficients of the system of bifurcation equations and an algorithm is constructed to determine all its solutions. It is shown that taking account of the connectedness of the eigenmodes yields a substantial reduction in the upper critical pressure. Results of computations are presented for spherical and conical shells in two eigenmodes. According to the computations and experiments, the divergence of the theoretical values of the upper critical loads and the actual snap-through loads of a broad class of elastic shells is related mainly to small initial deviations of their shape from the assumed geometric surface /10–12/. Koiter was the first to investigate the buckling of imperfect shells, and his researches were continued by a number of authors using variational principles (see the surveys /1,2,13–16/, almost all the papers cited in these surveys are limited to a study of buckling in one eigenmode).

Mosch M. Domb (Bombardier Aerospace, Strategic Technology Group, Downsview, Ontario, Canada M3K 1Y5, “Nonlinear buckling predictions of curved panels under combined compression and shear loading”, ICAS2002 Congress, 2002

ABSTRACT: The present work deals with implementation of a nonlinear buckling analysis technique for the prediction of the initial buckling in simply supported curved panels subjected to a combined loading state of compression and shear. Interaction buckling curves are generated for a wide range of curved panels. The curves include the effect of a pre-existing level of imperfection in the panel on the combined buckling characteristics. Good correlation with the parabolic naca interaction curve was obtained for the entire combined loading range
when the model predictions are presented through the buckling stress ratios relative to the nonlinear pure compression and pure shear cases. The results presented in this work show the high sensitivity of curved panel buckling to the degree of initial imperfection in the panel, especially when compression loading is present. The magnitude of imperfection in a given panel would be dependent on the panel configuration parameters and its radius to thickness ratio. Detailed knowledge of this dependency would lead to better prediction of the buckling characteristics of the panel.

ABSTRACT: The load-carrying capability of spherical shells under external pressure has been the subject of a long history and many theoretical and experimental studies have been carried out. However, from a comparative study on the design rules for the minimum thickness of the deep manned spherical shells from various classification societies, significant differences have been found. This indicates that these design rules need to be updated and unified like Common Structural Rules for tankers and bulk carriers. In order to lay a foundation for this target, a systematic study is carried out to develop a consistent calculation method for predicting the ultimate strength of spherical pressure hull under external pressure. This is the first paper of a series of three for reporting this study and in this paper, a critical review on the buckling and ultimate strength of spherical pressure hulls is carried out and further problems to be studied are identified. This could lay a solid foundation for the further study.

ABSTRACT: On the basis of nonlinear strain component formulations of three-dimensional continuum, this paper has derived the nonlinear strain component formulations of shells with initial geometric imperfections. The derivation is not confined to a special shell, therefore they possess general properties. These formulations provide the theoretical basis of the strain analysis for geometric nonlinear problems of shells with initial geometric imperfections.
References listed at the end of the paper:

ABSTRACT: Shell stability in geometrically nonlinear range is considered. Influence of the temperature change on the value of the critical force is examined. The whole analysis is performed numerically using the Finite Element Method. To solve the problem, nonlinear equilibrium paths for given temperature change and various load values must be calculated. These are cross-sections of the nonlinear equilibrium surface. From such paths the critical value of the load for given temperature change can be determined and stability boundary can be found as the main purpose of the procedure. The detailed numerical analysis was performed in reference to the semi cylindrical shell segment subjected to temperature changes and loaded by the concentrated force.

ABSTRACT: The stability phenomenon of elastic, spherical shells is examined numerically by the finite element method. The attention is focused on spherical caps clamped along the periphery and pressurized externally. The stability phenomenon depends on the cap rise. Very shallow shells do not exhibit instability symptoms. Shells of higher rise exhibit typical snap-through buckling. When the rise is greater the bifurcation phenomenon appears as well. The spherical shell of a particular rise is analysed in detail in the paper. The fundamental path and all bifurcation paths splitting from the fundamental one are calculated. Secondary bifurcations are registered in this particular case as well. The most desired forms of geometrical imperfections are indicated. The ‘worst’ imperfections are determined as well.

J. Marcinowski (Institute of Structural Engineering, University of Zielona Góra, Podgora 50, 65-246 Zielona Góra, Poland), “Stability of relatively deep segments of spherical shells loaded by external pressure”, Thin-
ABSTRACT: The buckling of shells in the form of spherical segment depends strictly on its rise. Determination of full equilibrium paths for shells of higher rise is very laborious and evokes many numerical problems. Spherical caps loaded by the external pressure and clamped along the base circle are the subject of a detailed analysis. The stability analysis for shells of relative slenderness of interval $\lambda = 3.5$ - 12 was performed and is presented in the paper. Three critical points, and namely the primary bifurcation point, the primary higher limit point and the primary lower limit point were basis for the plot of relative critical pressure versus slenderness parameter. This plot has big practical significance. One can read off from it the value of critical pressure being the basis of designing procedure, which takes into account stability criterion. The author's program based on FEM and taking into account all singularities characteristic for nonlinear elastic stability, was used in calculations. The correctness of the approach was verified on the example of spherical segment of slenderness $\lambda = 8$ solved before by other authors.

ABSTRACT: The paper deals with some considerations focused on resistance assessment of slender cylindrical shells subjected to the axial compression. The load carrying capacity of such shells is determined by stability criterion. It is not enough to determine the critical load in order to assess the load carrying capacity. It is necessary to apply the whole procedure recommended by designing codes and other design recommendations. Details of this procedure were presented in the paper. The correctness of the resistance assessment was verified experimentally on segments of cylindrical shells made of stainless steel.

References listed at the end of the paper:
buckling capacity curve for the particular class of spherical caps is the principal goal of this work. The method of determination of the critical pressure and the plastic resistance were described by the authors in [1] whereas the worst imperfection mode for the considered class of spherical shells was found in [2]. The determination of buckling parameters defining the buckling capacity curve for the whole class of shells is more complicated task. For this reason the authors focused their attention on spherical steel caps with the radius to thickness ratio of $R/t = 500$, the semi angle phi $= 30^\circ$ and the boundary condition BC2 (the clamped supporting edge). Taking into account all imperfection forms considered in [2] and different amplitudes expressed by the multiple of the shell thickness, sets of buckling parameters defining the capacity curve were determined. These parameters were determined by the methods proposed by Rotter in [3] and [4] where the method of determination of the exponent $\eta$ by means of additional parameter $k$ was presented. As a result of the performed analyses the standard capacity curves for all considered imperfection modes and amplitudes $0.5t$, $1.0t$, $1.5t$.

ABSTRACT: A thermal buckling analysis of symmetric and antisymmetric angle-ply laminated hybrid composite plates with an inclined crack subjected to a uniform temperature rise is presented in this paper. The first-order shear deformation theory in conjunction with the variational energy method is employed in mathematical formulations. The eight-node Lagrange finite-element technique is used for determining the thermal buckling temperatures of hybrid laminates. The effect of crack size and stacking sequences on the temperatures is investigated.

ABSTRACT: A solution to the problem on the stability according to the flexural buckling mode is given for a cylindrical sandwich shell with a transversely soft core of arbitrary thickness. The shell is under the action of a temperature field inhomogeneous across the thickness, and its end faces are fastened in such a way (in the axial direction, the face sections of the external layer are fixed, but of the internal one are free) that an inhomogeneous subcritical stress-strain state arises in the shell across the thickness of its layers. It is shown that, under such conditions, the buckling mode of the shell is mixed flexural. To reveal and investigate this mode, equations of subcritical equilibrium and stability of a corresponding degree of accuracy are needed. References listed at the end of the paper:

ABSTRACT: Problems of the modes of loss of stability of a three-layer spherical shell, consisting of thin external layers and a transversely soft filler of arbitrary thickness, which is under conditions of a uniform external pressure, are considered. The two-dimensional equations of the Kirchhoff-Love theory of the moderate flexure of thin shells are used. These equations are set up for the external layers, taking account of the interaction with the filler and, in the case of the filler, using the geometrically non-linear equations of the theory of elasticity, which correspond to the introduction of the assumption that the stretching deformations are small and the shear deformation are finites, which enables the purely shear modes of loss of stability in the filler to be described correctly. An exact analytical solution is found for the problem of an initial centro-symmetric deformation of a shell, which depends linearly on the external pressure. It is shown that the three-dimensional equations for the filler, which have been linearized in the neighbourhood of this solution, can be integrated with respect to the radial coordinate, and reduce to two two-dimensional differential equations, in addition to the six equations by which the neutral equilibrium of the external layers is described. It is established that the system of eight differential equations of stability, constructed for a shell with isotropic layers, when new unknowns in the form of scalar and vortex potentials are introduced, decomposes into two unconnected systems of equations. The first of these systems has two forms of solutions by which the shear modes of loss of stability are described for the same value of the critical load. A mixed flexural mode, the realization of which is possible for certain combinations of the governing parameters of the shell for high values of the external pressure compared with the shear modes, is described by the second system.

ABSTRACT: We consider the problem of static and dynamic buckling modes of thin shells under external hydrostatic pressure. If the statement of the problem uses the linearized equations of motion obtained in the moderately large bending theory of shells according to the classical or refined model, then part of terms related to the external load in these equations are assumed to be conservative, and the other terms are assumed to be nonconservative. In this connection, we study four statements of the elastic stability problem for a cylindrical shell with hinged faces. The first of them is the statement of the static boundary value problem in the sense of Euler, where the action of external pressure is assumed to be conservative. The second statement is used to study small vibrations near the static equilibrium by a dynamic method for the same conservative load. The third and fourth statements of the problem correspond to the action of a nonconservative load and are similar to the first and second statements, respectively. They use the linearized equations of equilibrium and motion constructed earlier in a consistent version on the basis of a Timoshenko type model and allowing one to reveal all classical and nonclassical shell buckling modes.

ABSTRACT: The buckling of thin-walled shell structures under load is still imperfectly understood, in spite of much research over the past 50 years. In this paper the author traces the history of the ideas which have been deployed in order to shed light on what is often referred to as ‘imperfection-sensitive’ buckling behaviour of shells. The ideas, which recur in various combinations, involve interaction of competing buckling modes, nonlinear behaviour, the growth of initial geometric imperfections under load and the alteration of the distribution of membrane stress as imperfections grow. The author claims that there are strong grounds for supposing that ‘locked in’ initial stresses on account of imperfect initial geometry and the static indeterminacy of boundary conditions of real shells have a pronounced effect on the buckling performance. This effect has been ignored in the past, and is the subject of a current experimental study.

ABSTRACT: The load carrying behaviour of cylindrical thin-walled shell structures under axial load is strongly dependent on imperfections invariably caused by various manufacturing processes. Axisymmetric imperfections have been recognised to result in particularly severe reductions in strength. Imperfections in the vicinity of circumferential welds in steel silos and tanks fall into this category and therefore deserve special attention. A detailed bifurcation and post-buckling finite elements analysis was performed on imperfect cylindrical shells. Special care was taken to model the weld-induced circumferential imperfection. The geometry was calibrated against data gained from measuring such imperfections on existing silos and residual stresses were taken into account. Interaction between neighbouring weld imperfections and the role of the strake height in this interaction was investigated. Weld-induced residual stresses were found to have a small strengthening influence on the buckling load. Interaction between neighbouring imperfections was found to reduce the buckling strength of the structures. A post-buckling analysis was undertaken to investigate the load-carrying behaviour of the
structure after initial bifurcation.

ABSTRACT: Thin-walled shell structures of a circular cylindrical shape are widely used in structural engineering to serve in applications such as silos, tanks or chimneys. The design of such structures poses some considerable challenges to structural engineers as the load carrying behaviour of cylindrical shells is quite complex, especially for non-axisymmetric load cases. Very often a comprehensive analysis causes considerable expenses and the vast amounts of results which are typically generated make it hard to understand the underlying load-carrying principles of the structure. The introduction of an engineering method to handle two typical non-axisymmetric load cases on circular cylindrical thin-walled shell structures is the goal of this paper. The proposed method offers a quick way to generate critical section forces and displacements. The load cases discussed herein are wind-loading and foundation settlement. Ground support for many cylindrical steel structures is often realised by anchoring the lower shell boundary to a concrete foundation. This is accomplished by steel bolts that can be looked at as spring elements providing elastic support for the shell structure. The influence of this type of support on the section forces and displacements under wind loading can be modelled by combining the two abovementioned load cases via an interaction diagram also given in this paper.

ABSTRACT: The strength of thin-walled cylindrical shell structures is highly dependent on the nature and magnitude of imperfections. Most importantly, circumferential imperfections have been reported to have an especially detrimental effect on the buckling resistance of these shells under axial load. Due to the manufacturing techniques commonly used during the erection of steel silos and tanks, specific types of imperfections are introduced into these structures, among them circumferential weld-induced imperfections between strakes of steel plates. A study on several factors influencing the buckling of silos and tanks was carried out using the finite-element method. The interaction between neighboring circumferential weld imperfections was investigated, and it was found that the influence on the buckling behavior depended on the strake height in relation to the linear meridional bending half-wavelength and the depth of the imperfection. The shape of localized circumferential weld imperfections was found to influence the buckling behavior of silos and tanks. The influence of a recently developed shape function on the buckling behavior has been examined. The strengthening effect of weld-induced residual stress fields was also studied, and the extent of the increase in buckling strength was derived for a large range of cylinder geometries.

Axialbelastung.” Der Stahlbau, Berlin, 10, 313–318 (in German).

ABSTRACT: Steel silos and tanks are constructed from plates which are rolled to the correct curvature and welded together to form strakes. Several strakes of curved plates, placed on top of each other then form the completed structure. At each circumferential weld, a slight hourglass depression occurs essentially forming axisymmetric imperfections which are known to be most deleterious. The detrimental influence of this particular type of imperfection on the buckling of axially compressed cylindrical shells such as silos and tanks is well known. Axial compression onto silos or tanks is commonly generated by roof structures, snow loads or, in the case of silos, by friction forces generated by the content. However, very little is known about the post-buckling of thin-walled cylinders with a circumferential weld imperfection. A post-buckling load bearing model was developed and the influence of weld imperfection amplitude, weld-induced residual stress-fields, different boundary-conditions and elastic-plastic material behaviour was studied. Different modelling techniques, taking into account various symmetries of the problem, are also discussed.
ABSTRACT: Steel box sections are usually fabricated from flat plates which are welded at the corners. The welding process can introduce residual stresses and geometric imperfections into the sections which can influence their strength. For some thin-walled sections, large periodic geometric imperfections have been observed in manufactured sections. Subsequent investigations have indicated that the imperfections are in fact buckling deformations i.e. the box section has buckled due to welding residual stresses prior to any application of external load. The welding procedure and the behaviour of the box sections under load has been modelled using a finite element analysis that accounts for both geometric and material non-linearities. Tests have been carried out on box sections with a range of width to thickness ratios for the plate elements. Modelling has been shown to give good correlation with the test results. The conditions for buckling to take place as a result of the welding process have been established. A design method has been proposed.

ABSTRACT: Beams with an I-shaped cross-section (I-sections) are widely used in the building industry throughout Australia and internationally. The Australian Standard AS4100 provides guidelines for the design of such beams. Numerous failure modes are taken into account in these design rules including stability failure modes where such beams buckle out of their plane of loading. Recent failures of beams which have been designed according to the Australian Standard AS4100 have been documented and concerns have been raised that critical out-of-plane failure modes might not be included in the current version of this Australian Standard. A preliminary study on one such I-section was performed at the Centre of Construction Technology and Research (CCTR), University of Western Sydney. This preliminary study revealed that, for short beams, a failure mode exists that is not covered by the current design rules. The current paper documents these findings and proposes a simple failure model which could become the basis for the design against this failure mode.

ABSTRACT: Depending on the geometry of a thin-walled cylindrical structure, three different stability failure modes under wind loading can be observed. In low cylinders, the radial compression at the windward meridian causes a buckling mode similar to cylinders under constant radial compression while very long cylinders display a failure mode characterized by buckling in the lower third of the structure at the side which faces away from the wind. Both of these failure modes have received a certain amount of interest by the research community, and design rules and proposals against both these failure modes exist. The failure of medium-height cylinders is characterized by a number of horizontal ripplelike buckles in an area around the upper half of the windward meridian. Comparatively little attention has been paid to this failure mode in the existing literature. A case study using a finite element model of a cylinder displaying this particular failure mode will be presented in this paper. The governing parameters for this rather unexpected behavior are identified and an explanation for the structural response is given. It is shown that the critical bifurcation mode is strongly dependent on prebuckling deformations. An imperfection sensitivity analysis for various imperfection types is also presented.

ABSTRACT: For particular geometrical constellations of thin-walled cylindrical structures under wind-loading, a peculiar stability failure mode has been observed. This failure mode is characterised by the occurrence of multiple horizontal ripple-like buckles in an area around the upper half of the windward meridian. A recent case
study of a cylinder undergoing this type of buckling revealed the strong influence of localised axi-symmetric imperfections on this particular buckling behaviour. For the present paper a detailed investigation into the nature of this influence of such imperfections on the buckling behaviour under wind loading has been performed using finite elements models. A cylinder with a geometry that displayed the particular buckling pattern in question was considered for this study. The parameters describing the nature of the axi-symmetric weld imperfection were varied and their influence on the buckling of these cylinders was studied in detail. The present study draws from insights gained from similar studies for cylinders under axial loading. Many similarities between the two loading cases can be observed and the influence of weld-induced imperfections on the buckling under the two loading types were compared for this paper.

DOI: 10.1007/s13296-011-3005-z

ABSTRACT: The linear elastic web bend-buckling behavior of I-section girders with a longitudinal stiffener is investigated by a three-dimensional finite element analysis in which the web, top and bottom flanges, and transverse and longitudinal stiffeners are modeled as thin shell elements. After obtaining the bend-buckling moment for an I-section girder by finite element analysis, the buckling stress and subsequently the buckling coefficient of a rectangular web panel with a longitudinal stiffener are calculated and compared with those obtained by AASHTO LRFD and Eurocode 3. To observe the effect of various parameters on the buckling behavior of an I-section girder under pure bending, the following aspects are considered: the non-symmetry of the cross-section, the location of the longitudinal stiffener, the boundary conditions along the transverse and longitudinal stiffeners and flanges, the flexural rigidity of the longitudinal stiffener, the spacing of the transverse web stiffeners, and the slenderness of the web. Based on the numerical results, new design equations for the bend-buckling coefficient of a longitudinally stiffened I-girder are proposed.

ABSTRACT: The desulphurizing tower used in the power plant is the key environmental protection facility to eliminate the air pollution. Multiple cutouts are opened on the tower wall because of the technology requirement. The presence of multiple cutouts will influence the stability of tower under wind loading. On the project background of the large-scale thin-walled cylindrical shells of a practical desulphurizing tower, the investigations are conducted into the buckling mode and buckling capacity of the large-scale thin-walled cylindrical shells with multiple circular cutouts under wind loading by nonlinear finite element methods. The influences a reinvestigated of the cutout position and the number of cutouts on the buckling behavior of cylindrical shells under wind loading. The comparison is conducted between the buckling response of the cylinder with a single cutout and that of the cylinder with multiple cutouts. On the basis of comparison results, the proposal is produced for the buckling check against wind loading of large-scale thin-walled cylindrical shells structure as desulphurizing tower.

ABSTRACT: In this paper the elastic stability and imperfection sensitivity of axially loaded cylindrical shells on narrow discrete supports is explored. This is done by parametric geometrically nonlinear finite element analyses of the perfect and imperfect cylinders up to the critical load maxima. In addition, classical buckling eigenvalues are computed for reference purposes. The obtained numerical results are plotted in a systematic unified way and related curve-fit expressions are developed for the critical load maxima in dependency of the geometrical parameters of the problem. The support width, the shell slenderness and the type of local support, i.e. flexible versus rigid local support conditions, are varied. The present basic investigation is restricted to shells with linear-elastic material behaviour. The study of the buckling behaviour for narrow local supports, including the limiting case of point supports is of special concern. Strictly speaking, point supports exist only in the mathematical limit, since the stress singularities which occur in this case are mere artefacts and have no direct physical significance. But it turns out that the local buckling behaviour, like shape and evolution of buckles, magnitude of buckling loads etc. tends to an invariant typical limiting scenario, which is surprising but understandable at the same time. This typical local mono-modal buckling scenario, which is also investigated and presented in this paper, may be viewed as the counterpart to the well-known multi-modal characteristic global buckling scenario which occurs under uniform axial compression.

ABSTRACT: As the thin-walled structure, the buckling of steel silos is very sensitive to the initial geometric imperfections. However, these imperfections are uncertain to the shape and amplitude, so the studies of the initial geometric imperfections have important practical significance. Over the years, the circumferential imperfections have been known to result in the most important influence on the buckling of steel silos, which is also the most common defect in practical engineering. Using the existing research results, this paper analyzes three different imperfection shape functions and compare to the result of experiment in order to identify a function for the finite element analysis.

ABSTRACT: This paper represents a brief review of the concepts of the reliability of structures. Some closed form solutions, as well as approximate methods are elucidated. Different attempts to describe probabilistically the so-called “safety factor” are described and some instructive counter-examples are given. High sensitivity exhibited by the reliability of the structure is documented in a model structure. The same structure is also analyzed on the basis of non-probabilistic, convex modelling. The latter is complementary to the probabilistic methods when only limited information is available on uncertain variables and functions.

ABSTRACT: This paper focuses on the buckling of cylindrical shells with small thickness variations. Two important cases of thickness variation pattern are considered. Asymptotic formulas up to the second order of the thickness variation parameter $\mu$ are derived by the combination of the perturbation and weighted residual methods. The expressions obtained in this study reduce to Koiter's formulas, when only the first-order term of the thickness variation parameter is retained in the analysis. Results from the asymptotic formulas are compared with those obtained through the purely numerical techniques of the finite difference method and the shooting method.

ABSTRACT: Thin-walled shell structures are likely to buckle under axial loading way below the classical value. In the presence of granular solids (e.g. sand) in cylindrical shells the stiffness of the contents has a positive influence on the buckling load, similar to internal pressure. In practical silo design this effect is not considered. This is because not much is known about the interaction between the shell and the flexible granular contents and about how to handle this in a computational model. The present study will focus on some simple interaction models. It will be seen that the presence of a granular solid can increase the buckling load remarkably, and also that small modifications in the interaction assumptions have a major influence on the buckling loads.

ABSTRACT: The load carrying behaviour of cylindrical thin-walled shell structures under pressure load is strongly dependent on the nature and magnitude of the imperfections invariably caused by various manufacturing processes. The present paper examines instabilities of long homogeneous and isotropic thin elastic tubes, characterized by geometric imperfections like eccentricity or ovality, on the buckling behaviour in conditions for which, at present, a complete theoretical analysis was not found in literature. Moreover, the additional aspect of the influence of the welded joint geometry and position is investigated over a wide range of diameter to thickness ratio, extending the findings of previous works. The problem of buckling for variable load conditions is relevant in the context of NPP applications as, for instance the optimisation of an integrated and innovative LWR Steam Generator (SG) tubes, according to the updated ASME rules. To the purpose, at Pisa University a rather intense research activity is being carried out on the buckling of thin walled metal specimens in the dimensional range suitable for the above mentioned application. Therefore a test equipment (with the
necessary data acquisition facility), suitable for carrying out test series on this issue, as well as numerical models implemented on the MARC FEM code, were set up. The experiments were conducted on test specimens with different materials, e.g. A-316 ASTM (with and without seam weld) and Inconel 690 TT, as well as different loading conditions (lateral and hydrostatic external pressure). A validation of numerical evaluations by comparison with test results is also performed. A good agreement has been observed between the experimental data and the elasto-plastic finite element analyses results, highlighting also the different influence of the mentioned imperfections on the buckling loads.

ABSTRACT: Buckling tests were performed with four tank structures under vacuum pressure with diameters ranging from 10 to 70 m. After discussion of geometric imperfections tolerated by the standards and methods of measuring geometric imperfections of that size the results of the measurements are reported. Some of these results are far beyond the tolerance criteria of standards for stability design of shells. However, the loads where a buckling failure of the tank occurs is underestimated with the application of these standards. Numerical investigations of the buckling behaviour of the shell with geometric imperfections of eigenmode-shape show that with the size recommended for this purpose by standards the analysis will miss the buckling phenomenon. Different shapes of imperfections are investigated in the numerical analysis with a sector model of the tank shell. Only the numerical investigation with a model of the complete tank shell with the measured imperfections gave results which agreed with the buckling phenomenon observed in the tests as well for the loads as for the location of the buckling loads.

ABSTRACT: This paper highlights the discrepancies found in design codes for very long externally pressurized cylindrical shells subjected to uniform external pressure: although the failure is identical to the column buckling of a ring subjected to an external compressive line load, design codes provide far smaller design values of the buckling load for the cylindrical shell in comparison to the ring. Based on the Eurocode 3 (EN 1993-1-6) on shell buckling this situation is pointed out and validated by numerical studies. The results are interpreted and compared to findings from experimental studies for providing an adopted design proposal for very long cylindrical shells subjected to external pressure. The numerical findings are verified by a set of experimental tests with a series of small cylindrical shells subjected to external pressure. The tests provide the fundamental basis for the proposed improved assessment procedure for cylindrical shells.

ABSTRACT: Sandwich panels are modern pre-fabricated construction components used as cladding elements for different types of buildings. Sandwich panels consist of an insulating core material covered by two faces which are typically made of thin metal sheets. In standard applications, the panels are mounted and fixed on a
load-bearing substructure of beams or purlins. Sandwich panels can reduce the problem of lateral torsional buckling of this substructure of beams or purlins by providing stabilization either by shear stiffness or by torsional restraint. The new edition of the German standard for the design of steel structures DIN 18800 gives formulae for the calculation of the stiffness of the torsional spring for restraint of the substructure under vertical downward loading. These new regulations are based on experimental investigations and parametric finite element analyses. These formulae only apply for sandwich panels with steel facings and polyurethane and mineral wool as core material. The paper explains the load-bearing mechanisms of the stabilisation effect by the sandwich panel. A mechanical model is developed for extending the range of application of the design formulae and to include the effects of creep and elevated ambient temperature. It presents the new regulations of DIN 18800 and explains the tests on which these regulations are based. The spectrum of applications not yet examined is investigated by tests and accompanying numerical calculations within the framework of the EASIE project. As a result of these investigations the torsional restraint of panels with facings made of aluminium and glass fibre reinforced plastics (GFRP) and with cores made of EPS are dealt with. The load case wind suction is discussed in addition. The increase of the torsional restraint obtained by fixing roof panels at the upper flange (which is mainly with saddle washers) is also explained and quantified by these investigations.

References listed at the end of the paper:

ABSTRACT: Experimental investigations and parametric finite element analyses show that the moment-rotation characteristic of sandwich panels providing support against the lateral torsional buckling of beams subjected to gravity loading can be represented as tri-linear. Formulae for calculating the parameters of this characteristic are given for different types of beam combined with sandwich panels for roofs and walls. According to available design codes, the torsional restraint coefficient for rotational stiffness required for design against lateral torsional buckling of beams is governed by the rotational stiffness of the connection, which can be obtained from the characteristic mentioned as the secant stiffness for all common types of sandwich panel and different types of structural arrangement. These values allow the maximum spans of beams to be increased and help to improve the economy of lightweight structures.

ABSTRACT: A method is presented for solving the problem of both prelimit and postlimit point behavior of axially loaded stiffened and unstiffened cylindrical shells. The proposed solution makes it possible to obtain postlimit point equilibrium paths for every desired wave number, \( n \) (number of full waves around the circumference). The governing equations are expressed in terms of normal displacement components and Airy stress functions. Numerical results are presented for an unstiffened cylindrical shell and for a ring and stringer-stiffened cylindrical shell.

ABSTRACT: The analysis of imperfect, thin, circular, cylindrical shells, subjected to suddenly applied uniform axial compression, is presented. The concept of dynamic stability is discussed and critical conditions for such configurations are obtained. Results are presented for unstiffened configurations. The effects of several parameters on dynamic critical conditions are assessed.

ABSTRACT: The nonlinear analysis of geometrically imperfect, thin, laminated, circular, cylindrical shells subjected to uniform axial compression, and for various in-plane and transverse supports, is presented. Moreover, the solution methodology is described, and results are generated for imperfect laminated (Boron/Epoxy) cylinders with symmetric, antisymmetric and asymmetric stacking of lamina. The applications deal with imperfection sensitivity studies and investigation of the effect of lamina stacking on the critical conditions. Finally, for some of the chosen geometries, experimental data is available and therefore these geometries serve as (partial) benchmarks for the developed solution scheme.

ABSTRACT: An imperfect, laminated, circular, cylindrical thin shell, simply supported at the boundaries, and subjected to a uniform axial compression and torsion (individually applied and in combination) is analyzed. The analysis is based on nonlinear, Donnell-type, kinematic relations, linearly elastic material behavior, and usual lamination theory. The laminate consists of orthotropic laminae, which typically characterize fiber reinforced composites. Numerical results (critical loads) are generated for several geometries and some of these results are compared to available experimental data. The imperfection sensitivity of the various geometries is studied. It is clearly shown that the laminated shell is more imperfection sensitive under pure axial compression than under pure torsion (same as for the isotropic geometry). The effect of the orientation of the laminae (stacking sequence) on the critical load is also studied.

ABSTRACT: A general analytical and numerical procedure is developed for free and forced vibration of thin-walled shells of revolution made of arbitrarily laminated orthotropic elastic material. The equations of motion are derived with the aid of Hamilton's variational principle. A numerical solution is obtained by expanding the variables in Fourier series in the circumferential direction, and using conical finite elements in the meridional direction. Several examples involving different shell geometries are considered, including the effects of fiber orientation and boundary conditions.

ABSTRACT: The imperfection sensitivity of thin cylindrical shells, made out of fiber-reinforced composite material and subjected to uniform axial compression, and the effects upon it of certain parameters, are investigated. The methodology is based on linear constitutive relations, nonlinear kinematic shell equations (Donnell-type) and the usual lamination theory. The laminate consists of orthotropic laminae, stacked in a general manner (asymmetric laminate). The uniform axial compression is applied eccentrically, and the geometrically imperfect cylindrical shell can be supported in various ways at the boundaries. In this investigation a number of parametric studies are performed. The scope of these studies is to establish the effect of (a) in-plane and transverse boundary conditions and (b) load eccentricity, on the imperfection sensitivity of typical boron/epoxy laminated cylindrical shells with various stacking sequences of laminate. The sensitivity is established by calculating critical loads for various imperfection amplitudes and shapes.

ABSTRACT: The accuracy of Donnell's equations for the buckling analysis of imperfect (limit point instability), circular, cylindrical, thin orthotropic shells under axial compression is investigated. This is accomplished by comparing critical loads obtained by employing Donnell-type kinematic equations with those based on the more accurate Sanders-type. For this purpose, a solution methodology is developed and described in the body of the paper. This methodology is then employed to generate critical loads for several orthotropic geometries, which cover a wide but practical range of parameters. These include cylinder length to radius ratios, radius to thickness ratios, two positions of the strong direction relative to the cylinder axis (\(\Pi=0\) and \(90\)\(^\circ\)) and two shapes of the initial geometric imperfection, axisymmetric and symmetric. Classical simply supported boundaries are used for all configurations for which results are generated.

ABSTRACT: The buckling of axially-loaded, imperfect, circular, cylindrical, thin shells is studied. A solution
methodology, based on two different shell theory approximations to the kinematic relations, is developed and described. The two approximations are those of Sanders and Donnell. Critical loads (limit point loads) are obtained for two shell geometries, one isotropic and one laminated. Several parametric studies are performed in order to establish the accuracy of the Donnell approximation. This is accomplished by comparison to the results obtained by the Sanders kinematic relations, which are considered to be very accurate for thin shells. The parametric studies include the effect of cylinder to radius ratio on the critical loads, as well as the effect of the radius to thickness ratio. Moreover, the imperfection sensitivity of the two geometries is investigated by both shell theory approximations.

ABSTRACT: The nonlinear equations for a stiffened laminated panel, which modeled by plate and beam elements, are derived by applying the variational principle on the potential energy. The equations include the equation for the panel sections between the stiffeners, the continuity requirements and the boundary conditions. These nonlinear equations by which the post-buckling behavior is characterized are exact in terms of Von Karman's kinematic relations.

ABSTRACT: A geometrical nonlinear theory of composite laminated beams is derived with the effect of transverse shear deformation taken into account. The theory is based on a high-order kinematic model, with the nonlinear differential equations solved by Newton's method and a special finite-difference scheme. A parametric study of the shear effect involving several kinematic approaches was carried out for isotropic and anisotropic beams.

ABSTRACT: An analytical-numerical procedure is applied for composite laminated shells of revolution in investigating the coupling effect between symmetric and antisymmetric modes and its overall influence. The numerical solution is based on separating the variables in Fourier series in the circumferential direction and conical finite elements in the meridional direction. The contribution of the coupling effect is examined by means of parametric analysis.

ABSTRACT: A general one-dimensional model of a composite delaminated elongated strip (wide beam) under arbitrary axial and transverse loading and boundary conditions is used for predicting the classical buckling load, with the bending-stretching coupling effect as well as the prebuckling geometrical nonlinearity taken into account. The differential equations are solved by Newton's method, using a finite-difference scheme. The contribution of the coupling effect is examined by means of parametric analysis.

ABSTRACT: This paper presents a parametric study of the effect of delamination, and of initial imperfection, on the overall nonlinear behavior of laminated composite beams. The study is based on geometrical nonlinear analysis with the Von-Karman kinematic approach. It is shown that the bifurcation point provides not more than an indication of the buckling behavior, and that the full nonlinear analysis is needed for predicting the load-carrying capacity. It was also found that the delaminated beam is sensitive to initial imperfection.

ABSTRACT: An analytical solution is presented for the postbuckling behavior of composite laminated stiffened curved panels, whether curved in a longitudinal or lateral direction (not both). The nonlinear equations for the model are based on the Von Karman kinematic approach and consist of equilibrium equations for curved plate, continuity requirements, and boundary conditions. These equations are expressed in terms of the out-of-plane displacement and Airy stress functions. The characteristic behavior in the pre- and postlimit positions is exploited by using an eigenfunction series in the longitudinal direction (direction of the stiffeners) and a finite difference scheme in the other direction. A modified Galerkin procedure is used to minimize errors involved in the truncated series and the nonfulfillment of the boundary conditions. The solution obtained through this procedure proved to be very efficient compared to general purpose finite element codes, especially when mode interactions and parametric studies are involved.

“Nonlinear Analysis of Stiffened Laminated Panels with Various Boundary Conditions”, Journal of Composite
ABSTRACT: A nonlinear analysis of stiffened laminated composite panels under various boundary conditions is presented. The nonlinear differential equations, expressed in terms of the out-of-plane displacement and the Airy stress function, are solved by separating the variables into eigenfunctions in conjunction with a finite-difference scheme. The vibration and buckling eigenfunctions of an isotropic beam are examined as the displacement functions, and a modified Galerkin procedure are used to minimize the error involved in the field equations, the continuity requirements and the boundary conditions. Results are presented for the isotropic and anisotropic cases, with different boundary conditions.

ABSTRACT: An analytical tool for buckling and vibration analysis of laminated shallow curved panels is presented. The equations in terms of transverse displacement and Airy stress function are derived via the Hu-Washizu mixed formulation and solved by the Ritz method, using the eigenfunctions of an isotropic beam. The effect of the prebuckling state and out-of-plane natural boundary conditions is examined. The approximate reduced bending stiffness method is evaluated for cross-ply and angle-ply laminates.

ABSTRACT: An analytical-numerical procedure is applied to investigate the buckling and post-buckling behavior of laminated cylindrical shells with non-circular cross-section of arbitrary closed shape. The buckling and post-buckling analysis are based on Donnell’s nonlinear kinematic relations. The curvature, which is a function of the circumferential coordinate, is expanded in Fourier series. The numerical procedure is based on separation of variables and their expansion into Fourier series. Through the Galerkin procedure, the field and boundary equations, written in terms of the transverse displacement and Airy stress function, are reduced to a system of ordinary differential equations, which are solved by a finite difference scheme. The configuration aspect is investigated parametrically. Unlike the circular cylindrical shells, coupling of the wave number in the circumferential direction is significantly high.

ABSTRACT: The equations, in terms of the normal displacement and Airy stress function, of the Donnell type, are derived via the Hu-Washizu mixed formulation. The curvature, which is a function of the circumferential coordinate, is expanded in Fourier series. The circumferential dependence is eliminated by a combination of Fourier expansion and Galerkin’s method. The resulting ordinary differential equations are then reduced to matrix equations by the use of finite differences. The configurational aspect is investigated parametrically. Unlike the circular cylindrical shells, coupling of the wave number in the circumferential direction is significantly high.

ABSTRACT: The nonlinear analysis of laminated initially imperfect non-circular cylindrical shells is presented. The analytical model is based on Donnell's nonlinear kinematic relations. The equations are derived via the Hu-Washizu mixed formulation, and are expressed in terms of the transverse displacement and the Airy stress function. The curvature of the non-circular cross-section is expanded into a Fourier series, allowing for representation of arbitrary closed cross-sections. The solution procedure is based on expansion of the variables into truncated trigonometric series in the circumferential direction and a finite difference scheme in the longitudinal one. Errors introduced by the truncated series are minimized by the Galerkin procedure and the equations are linearized by the Newton-Raphson method. Solutions beyond the limit point are obtained by Riks' constant arc-length algorithm. Results of both isotropic and laminated, axially loaded oval and elliptic shells are presented. The non-circular configurations are found to be less imperfection sensitive than the circular ones, and for largely eccentric cross-sections the shells are insensitive to initial imperfections.

ABSTRACT: A new simple and efficient algorithm for damage detection and for updating of stiffness and mass matrices is presented, based on minimum static and/or dynamic measured modes and preserving connectivity. A special algorithm was written for grouping uncoupled damage regions, significantly reducing the order of the problem and suitable for any structure size. A mode-scanning procedure is employed for finding the minimum measured modes needed for completing the process. Three illustrative examples are provided.

ABSTRACT: A formulation based on the three-dimensional theory of elasticity is employed to study the buckling of an orthotropic cylindrical shell under combined external pressure and axial compression. A properly defined load interaction parameter expresses the ratio of axial compression and external pressure loading, and critical loads are thus derived for a given load interaction. The results from this elasticity solution are compared with the critical loads predicted by the orthotropic Donnell and Timoshenko nonshallow classical shell formulations. Two cases of orthotropic material are considered with stiffness constants typical of glass/epoxy and graphite/epoxy. Furthermore, two cases of load interaction are considered, representing a relatively high and a relatively low axial load. For both load interaction cases considered and for both materials, the Donnell and the Timoshenko bifurcation points are higher than the elasticity solution, which means that both shell theories are nonconservative. However, the bifurcation points from the Timoshenko formulation is always found to be closer to the elasticity predictions than the one from the Donnell formulation. An additional common observation is that, for a high value of the load interaction parameter (relatively high axial load), the Timoshenko shell theory is performing remarkably well, approaching closely the elasticity solution, especially for thick construction. Finally, a comparison with some available results from higher order shell theories for
pure external pressure indicates that these improved shell theories seem to be adequate for the example cases that were studied.

ABSTRACT: A procedure of total energy release rate and stress intensity factors is developed for general non-homogeneous laminated composite laminates. The total energy release rate is obtained by using the J-integral for a one dimensional model of plane stress, plane strain and cylindrical bending. Decomposition of it into mode I and mode II, by which the mode mixity calculation is carried out, is based on the assumption of equivalent orthotropic properties through the laminate thickness. The process is straightforward and can be used as a criterion for delamination onset and growth of one dimensional structural model under general loading in the pre- and post-buckling states.

ABSTRACT: The delamination growth during the pre- or post-buckling phases in composites with a single delamination (one-dimensional model) is investigated. For that purpose, a general nonlinear analysis, using variational principle, with a new set of relations for the decomposition of the total energy release rate, is used for an arbitrary one-dimensional composite laminate structure. A computer code is developed and used for the parametric study of delamination growth during buckling. The effects of a wide range of parameters, like imperfection, layup, location of delamination, theory type and length-to-thickness ratio, were intensively studied. It is found that a dominant parameter, in terms of the level of energy release rate, is the length-to-thickness ratio.

ABSTRACT: The problem of determining the state of stress in a homogeneous ellipsoidal body (as can be produced by filament winding on a mandrel of elliptical cross-section) is formulated. The material is assumed to possess curvilinear anisotropy, referred to the coordinate system that is inherent to the geometry of the filament wound body. The differential equations that govern the stress functions are derived for the general anisotropy and loading cases. Then the results for the special case of torsion of an orthotropic body are derived.

ABSTRACT: Compression tests on delaminated kevlar/epoxy specimens were conducted in order to determine the buckling and post-buckling behavior of the system and observe the characteristics of the deformation including growth of the delamination. A broad range of geometric configurations, as far as the location of the
delamination through the thickness, was considered. Both the initiation resistance, defined as the applied
displacement per specimen length and the growth resistance, defined as the applied displacement per unit
delamination growth during the postbuckling stage were qualified for each configuration. For the particular
case studied, it was found that the growth resistance is infinite (that is, no growth) for delamination
thickness/total thickness ratio $H/T = 1/15$, becoming 0.52 for $H/T = 2/15$ and dropping to a value of only 0.07
for $H/T = 4/15$. The initiation resistance is also lowered as the delamination is located further away from the
specimen surface and for $H/T = 4/15$ growth initiation occurred before peak load. The experimental program
investigates also the development of the deformation regarding the postbuckled shape, the load-displacement
curve and the corresponding growth of the delamination. Furthermore, a comparison with analytical solutions
for the postbuckling behavior at large applied displacements is performed.

Technology, Atlanta Georgia, USA), “Buckling of orthotropic beam-plates with multiple central
ABSTRACT: A closed form solution is developed for predicting the critical load of a composite beam-plate
with multiple delaminations. The characteristic equation is derived by using non-linear beam theory, performling
proper linearization and by imposing the appropriate kinematical continuity and equilibrium conditions. The
effects of the dimensions and locations of the delaminations on the critical load are investigated and the results
are compared with previously published data.

ABSTRACT: (AIAA format does not permit cutting and pasting)

George A. Kardomeatas and George J. Simitses (Georgia Institute of Technology), “Comparative studies on the
buckling of isotropic, orthotropic, and sandwich columns”, Mechanics of Advanced Materials and Structures,
Vol. 11, pp 309-327, 2004
ABSTRACT: Advanced composite and sandwich construction has raised the issue of accuracy of the column
buckling formulas currently used in structural design. In these advanced material systems, transverse shear
effects are significant and cannot be ignored. The objective of this paper is to answer the question of how
accurate the simple column buckling formulas by Euler or the transverse shear correction formulas by Engesser
and by Haringx or other direct column buckling formulas in the literature are when composite or sandwich
construction and moderate thickness are involved. For this purpose, a three-dimensional elasticity solution
is presented along with finite element results. For the elasticity solution, which is performed for the monolithic
orthotropic material, the column is considered to be in the form of a hollow, circular cylinder and the direct
column buckling formulas are based on the axial modulus. As an example, the cases of an orthotropic material
with stiffness constants typical of glass/epoxy or graphite/epoxy and the reinforcing direction along the
periphery or along the cylinder axis are considered. Finite element results are presented for the sandwich
columns, which are of metallic (aluminum) and laminated (boron/epoxy, graphite/epoxy, and Kevlar/epoxy)
facings and alloy-foam or glass/phenolic honeycomb core. Sandwich columns are especially critical with the
Euler load being, in some cases of typical design, as much as almost five times the critical load from the finite
elements and, therefore, in these cases of sandwich construction, the classical Euler load calculations cannot be
relied upon.

ABSTRACT: The imperfection sensitivity of laminated cylindrical shells is considered—via the initial postbuckling analysis—on the basis of three different shell theories: Donnell in 1933; Sanders in 1963; and Timoshenko in 1961. The procedure involves nonlinear partial differential equations, which are converted into a sequence of three linear sets. The equations are solved with the variables expanded in Fourier series in the circumferential direction and in finite differences in the axial directions. A general code is developed and used in studying the effect of higher exactness of the shell theory on the sensitivity behavior, and in a parametric study of the sensitivity of anisotropic angle-ply cylindrical shells.

ABSTRACT: The sensitivity of isotropic conical shells to imperfection is considered, via the initial postbuckling analysis, on the basis of three different shell theories: Donnell's, Sanders's, and Timoshenko's. The conical shell was chosen as a representative case exhibiting the entire range of imperfection sensitivity. The procedure involves nonlinear partial differential equations, which are converted into a sequence of three linear sets. The latter are solved with the variables expanded in Fourier series in the circumferential direction and in finite differences in the axial directions. A general code is developed and used in studying the effect of higher exactness of the shell theory on the sensitivity behavior and in parametric analyses of the sensitivity of conical shells, especially with respect to the cone semivertex angle.

ABSTRACT: Laminated cylindrical shells are already commonly used in structural engineering, and their buckling and post-buckling behavior is of vital importance in the design of such structures. The validity of linear buckling analysis in this context, has been questioned because of the discrepancy observed between theoretical prediction and test results. The cause of this discrepancy is the fact that the nonlinear behavior of shell-like structures is generally characterized by a limit point rather than by a bifurcation point. For such structures, the load-carrying capacity depends on the level of imperfection (hence the concept “imperfection sensitivity”). The motivation is, therefore, to reduce the sensitivity rather than preventing the imperfection. For that purpose insight into the post-buckling state is called for.

ABSTRACT: A general nonlinear dynamic analysis, based on Donnell's shell-type theory, is developed for an arbitrary imperfect isotropic conical shell. It is used for studying dynamic stability and imperfection sensitivity under dynamic step loading. The nonlinear dynamic time history and the sensitivity behavior are examined in parametric terms over a wide range of aspect ratios. A general symbolic code (using the MAPLE compiler) was programmed to create the differential operators. By this means the Newmark discretization, Galerkin procedure, Newton-Raphson iteration, and finite difference scheme are applied for automatic development of an efficient FORTRAN code for the parametric study, and for examining the correlation of the sensitivity behavior between two different dynamic stability criteria. An extensive parametric study of the effect of the cone semi-vertex angle on the stability and sensitivity to imperfection under dynamic step loading was carried out. It was found that the dynamic buckling can indeed be derived from the nonlinear static solution.

ABSTRACT: A suitable postbuckling analysis, based on geometrically nonlinear behavior, is developed for arbitrary imperfect conical shells. The conical shell was chosen as a representative case exhibiting the entire range of sensitivity to imperfection. A general symbolic code (using the MAPLE compiler) was programmed to create the differential operators of the nonlinear partial differential equations, based on Donnell’s type shell theory. The code then uses the Galerkin procedure, the Newton-Raphson and arc-length procedures, and a finite-differences scheme for automatic development of an efficient FORTRAN code. The code is used for parametric study of the nonlinear behavior and yields the sensitivity characteristic for a wide range of cone semivertex angles. A typical nonlinear behavior of a conical shell is investigated. Comparison with a simpler procedure, based on the initial postbuckling analysis (Koiter’s theory), confirms the need for the present more accurate one, especially for shells with prebuckling nonlinear behavior. The present investigation summarizes the sensitivity behavior with respect to imperfection shapes and amplitudes for the entire range of cone semivertex angles.

ABSTRACT: A general procedure is developed for stability of stiffened conical shells. It is used for studying the sensitivity behavior with respect to the stiffener configurations. The effect of the pre-buckling nonlinearity on the bifurcation point, as well as the limit-point load level, is examined. The unique algorithm presented by the authors is an extended version of an earlier one, adapted for determination of the limit-point load level of imperfect conical shells. The eigenvalue problem is iteratively solved with respect to the nonlinear equilibrium state up to the bifurcation point or to the limit-point load level. A general symbolic code (using MAPLE) was programmed to create the differential operators based on Donnell’s type shell theory. Then the code uses the Galerkin procedure, the Newton–Raphson procedure, and a finite difference scheme for automatic development of an efficient FORTRAN code which is used for the parametric study.

ABSTRACT: The problem of snap-through buckling of a clamped, eccentrically stiffened shallow spherical cap is considered under quasi-statically applied uniform pressure and a special case of dynamically applied uniform pressure. This dynamic case is the constant load infinite duration case (step time-function) and it represents an extreme case of blast loading-large decay time, small decay rate. The analysis is based on the nonlinear shallow shell equations under the assumption of axisymmetric deformations and linear stress-strain laws. The eccentric stiffeners are disposed orthogonally along directions of principal curvature in such a way that the smeared mass, and extensional and flexural stiffnesses are constant. The stiffeners are also taken to be one-sided with constant eccentricity, and the stiffener-shell connection is assumed to be monolithic. The method developed in an earlier paper is employed. In this method, critical pressures are associated with characteristics of the total potential surface in the configuration space of the generalized coordinates. In addition, buckling of the complete thin eccentrically stiffened spherical shell under uniform quasi-statically applied pressure is considered, and these results are used to check the numerical answers. The complete spherical shell is stiffened in the same manner as the shallow cap. The results are presented in graphical form as load parameter vs initial rise parameter. Geometric configurations corresponding to isotropic, lightly stiffened, moderately stiffened and heavily stiffened geometries are considered. By lightly stiffened geometry one means that most of the extensional stiffness is provided by the thin shell. A computer program was written to solve for critical pressures. The Georgia Tech Univac 1108 high speed digital computer was used for this purpose.
ABSTRACT: A procedure is outlined for optimizing stiffened, thin, circular, cylindrical shells under uniform axial compression against general instability, in the presence of initial geometric imperfection. The procedure consists of two parts (a) optimization on the basis of a linear buckling analysis and perfect geometry, and (b) parametric studies on a reasonable region in the design space surrounding the optimum point (as obtained from part (a)) to assess the effect of initial geometric imperfections. This procedure is demonstrated through two design examples, for which it is concluded, that the presence of initial geometric imperfections does not alter the optimum weight and the corresponding design variables appreciably.

ABSTRACT: A solution methodology is described for the complete analysis of a geometrically imperfect, thin, circular, cylindrical shell loaded by a uniform axial compression. The analysis includes pre-limit point behavior, the establishment of critical conditions (limit point) and post-limit point behavior. The solution scheme is then utilized to study the effects of various geometrical parameters (radius to thickness and length to radius ratios) on the response characteristics of an imperfect, unstiffened, thin, cylindrical shell. These effects are assessed for a virtually axisymmetric-type of geometric imperfection.

ABSTRACT: The imperfection sensitivity of thin cylindrical shells, made out of fiberreinforced composite material and subjected to either uniform axial compression or torsion, and the effects upon it of certain parameters, are investigated. The sensitivity is established through plots of critical loads (limit point loads) versus imperfection amplitude. The larger the drop in critical load value with increasing amplitude, the greater the sensitivity. Results are presented for four- and six-ply laminates with simply supported boundaries and various stacking sequences. These sequences lead to symmetric, antisymmetric and asymmetric configurations with respect to the laminate midsurface. The material for all configurations is boron/epoxy. The parametric studies include primarily the effect of lamina stacking and length-to-radius ratio on the critical loads. Among the important findings are that (a) laminated cylindrical shells are more imperfection sensitive under axial compression than under torsion, (b) the imperfection sensitivity decreases as the length-to-radius ratio increases and (c) lamina stacking has a pronounced effect on the imperfection sensitivity of the laminated shell.

ABSTRACT: A model is developed for the study of delamination buckling of axially loaded cylindrical shells. Delamination is assumed to exist before load application, it spans the entire circumference, and it lies on the contact surface of neighboring laminae. The mathematical model employs Donnell-type kinematic relations and linearly elastic material behavior. Furthermore, each lamina is assumed isotropic, and the emphasis is on studying the effect of delamination size and position on the critical load. Two sets of boundary conditions are
used with the model: simply supported and clamped. The study reveals several important conclusions. Among them, one may list the following: (a) the critical load is primarily controlled by the position of the delamination from the reference surface, provided that the delamination is not very close to the boundaries; and (b) for long delaminations (relative to the cylinder length), the critical load is not appreciably affected by the boundary conditions.

ABSTRACT: Delamination buckling of long complete cylindrical shells and curved panels, when acted upon by uniform lateral loading, is being investigated. The geometry is such that it covers a wide range of length to radius ratios, as well as panels of different widths. Results, though, are presented only for very long configurations and a limited number of widths. The boundaries of the panels are either clamped or simply supported, along the straight edges. Finally, the geometry is free of initial geometric imperfections, and all parts of the shell are assumed to be virtually isotropic. The emphasis of the investigation concerns the effect of several factors and parameters on the critical load. These include, load behavior during buckling, width of delamination, position of delamination and panel width.

ABSTRACT: Delamination is one of the basic defects inherent to laminar materials. The investigation of the buckling characteristics of delaminated cylindrical shells or panels, when subjected to external pressure, is presented herein. The geometry is such that it covers a wide range of length to radius ratios as well as panels of different widths. Results are presented only for very long cylinders and panels. The boundaries are either simply supported or clamped. Furthermore, the material is such that it leads to (quasi) isotropic laminates for all
sections involved, the overall as well as the ones separated by the delamination. Finally, the geometry is free of
initial geometric imperfections. Because of the last two assumptions, a primary membrane state exists and
bifurcational buckling is possible. Buckling loads are calculated for a wide range of parameters. The width and
the through-the-thickness position of delamination greatly affect the bifurcation load.

doi:10.1016/0263-8223(88)90028-1
ABSTRACT: The paper deals with buckling of complete and annular circular plates, made of symmetric
laminates with general orientation of the lamina fibers. The plate is subjected to an in-plane, symmetric,
destabilizing load. The load is applied at the outer edge for the complete plate and at the outer and inner edges
for the annular one. The plate is supported in various ways along its boundaries. The paper includes the
derivation of the governing equations and discusses the various methods of solution. Numerical results are
presented for a clamped plate.

of axially-loaded, moderately-thick, cylindrical laminated shells”, Composites Engineering, Vol. 1, No. 6, 1991,
pp. 375-391, doi:10.1016/0961-9526(91)90042-Q
ABSTRACT: A higher-order theory is developed (kinematic relations, constitutive relations, equilibrium
equations and boundary conditions), which includes initial geometric imperfections and transverse shear effects,
for a laminated cylindrical configuration, under the actions of lateral pressure, axial compression and torsion.
Through the perturbation technique, buckling equations and boundary conditions are derived for a symmetric
laminated configuration, for a higher-(third) order shear-deformation theory as well as for the cases of first-
order shear-deformation theory and classical theory. Critical axially-compressive loads are computed for finite
length cylinders for several stacking sequences, several radius-to-total-thickness ratios and length-to-radius
ratios and for all the above three theories. The material that was employed in generating results was
boron/epoxy.

ABSTRACT: Models for predicting delamination buckling of laminated complete thin cylindrical shells and cylindrical panels are presented. The load cases are uniform axial compression and uniform pressure, applied individually. The models are different for the two load cases and by design they are kept as simple as possible, to keep the mathematical representation of the model and the associated solution simple enough to permit extensive parametric studies. Through these studies one can identify important structural parameters and fully assess their effect on the critical load. Among the general conclusions are the following: (a) the most influential parameters for a given laminated geometry are the size of the delamination and its through-the-thickness position for both load cases; and (b) the effect of boundary conditions (along the straight edges) is important for the case of pressure, whereas for axial compression the effect of boundary conditions (ends) is small for large delaminations.

ABSTRACT: A general one-dimensional model of a delaminated composite structural element under axial loading is used for predicting the classical buckling load, with the bending-stretching coupling effect. Two cases are examined. In the first case the delamination is such that it does not cause any resistance in the motion of the two detached laminae, due to the applied axial loads. In the second case, the delamination is such that both laminae feel the existence of a spring distribution along the length of the delamination.

ABSTRACT: A higher order theory is developed (kinematic relations, constitutive relations, equilibrium equations, and boundary conditions), which includes initial geometric imperfections and transverse shear effects for a laminated cylindrical configuration under the actions of lateral pressure, axial compression, and eccentrically applied torsion. Equilibrium equations and boundary conditions are presented for the higher order shear deformation theory. The perturbation technique is employed and buckling equations are derived for symmetric laminates under the action of uniform axial compression and lateral pressure. Buckling loads are computed for axially compressed cylindrical laminates of finite length and pressure-loaded very long configurations.

ABSTRACT: The problem of instability of laminated circular cylindrical shells under the action of lateral pressure is investigated. The analysis is based on higher-order shear-deformation theory where the effect of transverse shear is taken into account. The buckling is elastic for moderately thick composite shells and the geometry is assumed to be free of initial imperfections. The equilibrium equations and the related boundary conditions are derived by variational methods. The buckling equations are derived through the perturbation
technique. Critical lateral pressures are computed for finite- and infinite-length cylinders for several stacking sequences and several radius-to-thickness ratios. The numerical results are presented in tabular and in graphical form.

ABSTRACT: A higher-order shell theory was developed (kinematic relations, constitutive relations, equilibrium equations and boundary conditions), which includes initial geometric imperfections and transverse shear effects for a laminated cylindrical shell under the action of pressure, axial compression and in-plane shear. Through the perturbation technique, buckling equations are derived for the corresponding 'perfect geometry' symmetric laminated configuration. Critical pressures are computed for very long cylinders for several stacking sequences, several radius-to-total-thickness ratios, three lamina materials (boron/epoxy, graphite/epoxy, and Kevlar/epoxy), and three shell theories: classical, first-order shear deformable and higher- (third-) order shear deformable. The results provide valuable information concerning the applicability (accurate prediction of buckling pressures) of the various shell theories.

ABSTRACT: The constant demand for lighter and more efficient structural configurations has led the structural engineer to the use of new man-made materials. At the same time, this demand has forced upon him very sophisticated methods of testing, analysis and design, as well as of fabrication and manufacturing. The recent explosive progress in the production and use of composite materials has pointed toward the clear possibility of man creating specific materials for specific applications. At the same time, it has been realized that there arise demands for: a complete understanding of the behaviour of composite materials and the influences on this behaviour; establishment of design criteria upon which proper use of composites can rest; and the training of engineers in the design and use of composite structures. For all three items, it is important to recognize that, with the advent of composite media, certain new material imperfections can be found in composite structures in addition to the better-known imperfections that one finds in metallic structures. Thus, broken fibres, delaminated regions, cracks in the matrix material, as well as holes, foreign inclusions and small voids constitute material and structural imperfections that can exist in composite structures. Imperfections have always existed and their effect on the structural response of a system has been very significant in many cases. References listed at the end of the paper:

ABSTRACT: The present paper is a review article on the problem of buckling of moderately thick, laminated, composite shells subjected to destabilizing loads. The loads consist of uniform axial compression, uniform lateral pressure and torsion applied individually or in combination. In all the works reported in the literature, the analysis is based on higher-order shear deformation (HOSD) shell theory and/or first-order shear deformation (FOSD) shell theory with or without a shear correction factor. Results obtained by these two shell theories and by employing classical thin shell theory are compared to determine the range of applicability of each in predicting critical conditions. The effect of stacking sequence, radius-to-thickness ratio and length-to-radius ratio is assessed. Typical numerical results are presented in tabular form. Moreover, some limited results, which are based on limit point analysis are also presented (imperfection sensitivity studies).

ABSTRACT: This study investigates problems associated with the design of scaled down models. Such study is important since it provides the necessary scaling laws, and the factors which affect the accuracy of the scale models. For better understanding the applicability of scaled down models in designing laminated composite structures, an analytical investigation was undertaken to assess the feasibility of their use. Employment of similitude theory to establish similarity among structural systems can save considerable expense and time, provided that the proper scaling laws are found and validated. In this study the limitation and acceptable interval of all parameters and corresponding scale factors are investigated. Particular emphasis is placed on the case of buckling of cross-ply cylindrical shells under uniaxial compressive loads. Both complete and partial similarity are discussed. This analytical study indicates that distorted models with a different number of layers and geometries than those of the prototype can predict the behavior of the prototype with good accuracy. However, it is shown that a scaled down model with different material properties than those of the prototype is incapable of predicting the response of the prototype.

ABSTRACT: This work deals primarily with the question of buckling of delaminated curved structural elements subjected to external pressure, and how the presence of the delamination affects the global load carrying capacity of the structure. A review of the effect of the presence of imperfections and defects on buckling in laminated configurations is presented. The emphasis is then placed on delaminations, and the simple mathematical models that have been used for the buckling analysis of delaminated shells. Through these models the parameters that have the largest effect on the buckling load are identified. It is concluded that the two most influencing parameters are the size of delamination and the through-the-thickness position of the delamination. Areas of future research are identified, through the critical review of the reported studies.

ABSTRACT: In order to understand the applicability of scaled down models in designing laminated composite structures, an analytical investigation was undertaken to assess the feasibility of their use. Employment of similitude theory to establish similarity among structural systems can save considerable expense and time, provided the proper scaling laws are found and validated. The developed methodology is demonstrated through application of similitude theory to laminated cylindrical shells. Particular emphasis is placed on the case of free vibration of cross-ply laminated cylindrical shells with double curvature. The results presented herein indicate that, for free vibration responses of laminated cylindrical shells of double curvature, based on structural similitude, a set of scaling laws can be found which are used to develop design rules for designing small scale models. This analytical study indicates that distorted models with a different number of layers, geometries and material properties than those of the prototype can predict the behavior of the prototype with good accuracy. However, it is shown that a scaled down model with distorted curvature is incapable of predicting the response of the prototype.

ABSTRACT: This paper deals with the development and use of scaled-down models in order to predict the structural behavior of large prototypes. The concept is fully described and examples are presented which demonstrate its applicability to beam-plates, plates and cylindrical shells of laminated construction. The concept is based on the use of field equations, which govern the response behavior of both the small model as well as the large prototype. The conditions under which the experimental data of a small model can be used to predict the behavior of a large prototype are called scaling laws or similarity conditions and the term that best describes the process is structural similitude. Moreover, since the term scaling is used to describe the effect of size on strength characteristics of materials, a discussion is included which should clarify the difference between “scaling law” and “size effect”. Finally, a historical review of all published work in the broad area of structural similitude is presented for completeness.

the static and dynamic critical loads decrease with increasing load duration and converge to those for the load case of infinite duration. The convergence rate is related to the fundamental frequency of the cylinder. In addition, both the static and dynamic critical loads decrease with increasing imperfection amplitude.

ABSTRACT: The dynamic stability of circular metallic and laminated cylindrical shells is investigated. The cylinders are geometrically imperfect and subjected to axial compression or pure bending moment. These loads are suddenly applied with constant magnitude and finite or infinite duration. The finite element method is employed to generate dynamic responses and the equations of motion approach to determine dynamic critical loads. The effects of load duration and imperfection amplitude on critical loads are discussed. It is found that the dynamic critical loads decrease with increasing load duration and converge to those for the load case of infinite duration. The convergence rate is related to the fundamental frequency of the cylinder. In addition, both the static and dynamic critical loads decrease with increasing imperfection amplitude.
ABSTRACT: The problem of instability of imperfect, moderately thick, circular cylindrical shells under the action of uniform lateral pressure is investigated. Two approaches are followed: First, an analysis is done based on nonlinear kinematic relations, where the effect of transverse shear is taken into account and an imperfection function is assumed. The Galerkin procedure is employed to solve the resulting partial differential equations. The second method is based on applying Koiter's general postbuckling theory. To this extent, the objective is the calculation of imperfection sensitivity by relating to the initial post-buckling behavior of the perfect structure. Again, a shear deformation theory which accounts for transverse shear strains and rotations about the normal to the shell mid-surface is employed to formulate the shell equations. The initial postbuckling analysis indicates that the range of imperfection sensitivity depends strongly on the material anisotropy, and also on the shell thickness and whether the end pressure loading is included or not.

PARTIAL INTRODUCTION: Consider a composite boxe

d beam filled with a soft elastic medium such as foam or a sandwich beam consisting of two fiber-reinforced sheets separated by a low-stiffness core. A bending load on these structures is equivalent to a compressive force on one face and a tensile force on the other. Furthermore, a delamination may be present on the compressively loaded composite face. In those cases the composite face rests on an elastic “foundation” which imposes reaction forces on the beam that are proportional to the deflection of the “foundation”. . .

G. A. Kardomateas (School of Aerospace Engineering, Georgia Institute of Technology, Atlanta, Georgia, USA), “Asymptotic analysis considerations on the initial postbuckling behavior of delaminated composites”, Acta Mechanica, Vol. 83, No. 3, pp 165-175, September 1990

SUMMARY: An asymptotic analysis for the initial postbuckling behavior of delaminated beam/plates is performed. Under the assumptions of inextensional deformation, the exact expressions that govern the plane elastic deformation of the different parts of the system are expanded in a Taylor series in terms of the distortion variable. Order of magnitude arguments are used to relate the distortion variables and these are subsequently used in an asymptotic solution for the deflections and the load. Finally, a comparison with experiments is performed.

ABSTRACT: The initial post-buckling and growth behavior of delaminations in plates is studied by a perturbation procedure. In this work, no restrictive assumptions regarding the delamination thickness and plate length are made, i.e., the usual thin film assumptions are relaxed. The perturbation procedure is based on an asymptotic expansion of the load and deformation quantities in terms of the distortion parameter of the delaminated layer, the latter being considered a compressive elastica. Closed-form solutions for the load and midpoint delamination deflection versus applied compressive displacement during the initial post-buckling phase are derived. Moreover, closed-form expressions for the energy release rate and the mixity ratio (i.e. Mode II versus Mode I) at the delamination tip are produced. A higher Mode I component is found to be present during the initial post-buckling phase for delaminations of increasing ratio of delamination thickness over plate thickness, h/T (i.e. delaminations further away from the surface). Moreover, the energy release rate corresponding to the same applied strain is larger for a higher h/T ratio. The reduced growth resistance of these
configurations is verified by experimental results on unidirectional composite specimens with internal delaminations.

ABSTRACT: The growth of internal delaminations in composite plates subjected to cyclic compression is investigated. Due to the compressive loading, these structures undergo repeated buckling-unloading of the delaminated layer with a resulting reduction of the interlaver resistance. An important characteristic of the problem is that the state of stress near the delamination tip is of mixed mode, I and II. Equations describing the growth of the delaminations under cyclic loads are obtained on the basis of a combined delamination buckling-post-buckling and fracture mechanics model. The latter is based on a mode-dependent critical fracture energy concept and is expressed in terms of the spread in the energy release rate in the pre- and post-buckling state. It is shown that such a model allows for the accumulation of microdamage at the delamination front. The growth laws developed in this manner are integrated numerically, in order to produce the delamination growth vs number of cycles curves. Furthermore, the investigation includes the possibility of unstable delamination growth. The study does not impose any restrictive assumptions regarding the delamination thickness and plate length (as opposed to the usual thin film assumptions). The results show that for a given value of delamination thickness h the fatigue delamination growth is strongly affected by the relative location of the delamination through the plate thickness T. the fatigue growth being slower for a smaller value of h T (delaminations located closer to the surface). These theoretical predictions are confirmed by experimental results that are obtained for the growth of delaminations in graphite-epoxy unidirectional specimens under cyclic constant amplitude compressive loading. The test data, which were obtained for several different locations of the delamination through the thickness (hence different degrees of mode mixity), and different applied maximum compressive displacement, seem be well correlated with the theory.

ABSTRACT: The buckling of an axially compressed orthotropic column is investigated by using a three-dimensional elasticity formulation. In this manner, an assessment of the thickness and orthotropy effects can be accurately performed. The column is in the form of a hollow circular cylinder. The critical loads from this elasticity solution are compared with the ones from the Euler or Timoshenko transverse shear correction formulas based on the axial modulus. Furthermore, a comparison is made with a recently suggested new formula for column buckling that adds a second term to the Euler value critical load and is supposed to account for thickness effects. As an example, the cases of an orthotropic material with stiffness constants typical of glass/epoxy and the reinforcing direction along the periphery or along the cylinder axis are considered. It is found that the elasticity approach predicts in all cases a lower than the Euler value critical load. Moreover, the degree of non-conservatism of the Euler formula is strongly dependent on the reinforcing direction; the axially reinforced columns show the highest deviation from the elasticity value. The first Timoshenko shear correction formula is in all cases examined conservative. The second Timoshenko shear correction formula is in most cases (but not always) conservative. However, the second estimate is always closer to the elasticity solution than the first one. For the isotropic case both Timoshenko formulas are conservative estimates. The recent new formula for column buckling that adds a second term to the Euler load expression is a non-conservative estimate
but performs very well with very thick sections, being closest to the elasticity solution; for moderate thickness it is in general no better than the Timoshenko formulas.

ABSTRACT: The bifurcation of equilibrium of a compressed transversely isotropic bar is investigated by using a three-dimensional elasticity formulation. In this manner, an assessment of the thickness effects can be accurately performed. For isotropic rods of circular cross-section, the bifurcation value of the compressive force turns out to coincide with the Euler critical load for values of the length-over-radius ratio approximately greater than 5. The elasticity approach predicts always a lower (than the Euler value) critical load for isotropic bodies; the two examples of transversely isotropic bodies considered show also a lower critical load in comparison with the Euler value based on the axial modulus, and the reduction is larger than the one corresponding to isotropic rods with the same length-over-radius ratio. However, for the isotropic material, both Timoshenko’s formulas for transverse shear correction are conservative; i.e., they predict a lower critical load than the elasticity solutions. For a generally transversely isotropic material only the first Timoshenko shear correction formula proved to be a conservative estimate in all cases considered. However, in all cases considered, the second estimate is always closer to the elasticity solution than the first one and therefore, a more precise estimate of the transverse shear effects. Furthermore, by performing a series expansion of the terms of the resulting characteristic equation from the elasticity formulation for the isotropic case, the Euler load is proven to be the solution in the first approximation; consideration of the second approximation gives a direct expression for the correction to the Euler load, therefore defining a new, revised, yet simple formula for column buckling. Finally,
the examination of a rod with different end conditions, namely a pinned-pinned rod, shows that the thickness effects depend also on the end fixity.

G.A. Kardomateas and M.S. Philobos (Georgia Institute of Technology, Atlanta, Georgia, USA), “Buckling of thick orthotropic cylindrical shells under combined external pressure and axial compression”, AIAA Journal, Vol. 33, No. 10, October 1995

ABSTRACT: A formulation based on the three-dimensional theory of elasticity is employed to study the buckling of an orthotropic cylindrical shell under combined external pressure and axial compression. A properly defined load interaction parameter expresses the ratio of axial compression and external pressure loading, and critical loads are thus derived for a given load interaction. The results from this elasticity solution are compared with the critical loads predicted by the orthotropic Donnell and Timoshenko nonshallow classical shell formulations. Two cases of orthotropic material are considered with stiffness constants typical of glass/epoxy and graphite/epoxy. Furthermore, two cases of load interaction are considered, representing a relatively high and a relatively low axial load. For both load interaction cases considered and for both materials, the Donnell and the Timoshenko bifurcation points are higher than the elasticity solution, which means that both shell theories are nonconservative. However, the bifurcation points from the Timoshenko formulation are always found to be closer to the elasticity predictions than the ones from the Donnell formulation. An additional common observation is that, for a high value of the load interaction parameter (relatively high axial load), the Timoshenko shell theory is performing remarkably well, approaching closely the elasticity solution, especially for thick construction. Finally, a comparison with some available results from higher order shell theories for pure external pressure indicates that these improved shell theories seem to be adequate for the example cases that were studied.

ABSTRACT: A three-dimensional elasticity solution to the problem of buckling of orthotropic cylindrical shells under torsion is presented. A mixed form of the Galerkin method with a series of Legendre polynomials in the thickness coordinate has been applied to solve the governing differential equations. The accuracy of existing shell theory solutions has been assessed through a comparison study for both isotropic and orthotropic cylinders. For isotropic cylinders the solutions based on the Donnell shell theory were found to predict nonconservative values for the critical loads. As the circumferential wave numbers increase, shell theory solutions provide more accurate values. For orthotropic cylinders, the classical shell theory predicts much higher critical loads for a relatively short and thick cylinder, while the shear deformation theories provide results reasonably close to the elasticity solutions. Detailed data are also presented for the critical torsional loads over a wide range of length ratios and radius ratios for isotropic, glass/epoxy, and graphite/epoxy cylinders.

ABSTRACT: There exist many formulas for the critical compression of sandwich plates, each based on a specific set of assumptions and a specific plate or beam model. It is not easy to determine the accuracy and range of validity of these rather simple formulas unless an elasticity solution exists. In this paper, we present an elasticity solution to the problem of buckling of sandwich beams or wide sandwich panels subjected to axially compressive loading (along the short side). The emphasis on this study is on the wrinkling (multi-wave) mode. The sandwich section is symmetric and all constituent phases, i.e., the facings and the core, are assumed to be orthotropic. First, the pre-buckling elasticity solution for the compressed sandwich structure is derived. Subsequently, the buckling problem is formulated as an eigen-boundary-value problem for differential equations, with the axial load being the eigenvalue. For a given configuration, two cases, namely symmetric and anti-symmetric buckling, are considered separately, and the one that dominates is accordingly determined. The complication in the sandwich construction arises due to the existence of additional “internal” conditions at the face sheet/core interfaces. Results are produced first for isotropic phases (for which the simple formulas in the literature hold) and for different ratios of face-sheet vs core modulus and face-sheet vs core thickness. The results are compared with the different wrinkling formulas in the literature, as well as with the Euler buckling load and the Euler buckling load with transverse shear correction. Subsequently, results are produced for one or both phases being orthotropic, namely a typical sandwich made of glass/polyester or graphite/epoxy faces and polymeric foam or glass/phenolic honeycomb core. The solution presented herein provides a means of accurately assessing the limitations of simplifying analyses in predicting wrinkling and global buckling in wide sandwich panels/beams.

ABSTRACT: This article investigates the thermal response of an axially restrained composite column, which is exposed to a heat flux due to fire. The heat damage, the charred layer formation and nonuniform transient temperature distribution in the column exposed to fire from one side are calculated by the thermal model developed by Gibson et al. [1]. For the thermal response analysis, the mechanical properties of the fire-damaged (charred) region are considered negligible, while the degradation of the elastic properties with temperature in the undamaged layer (especially near the glass transition temperature of the matrix) is accounted for using experimental data for the elastic moduli. Due to the nonuniform stiffness distribution through the thickness and the effect of the ensuing thermal moment, the structure behaves like an imperfect column, and responds by bending rather than buckling in the classical Euler (bifurcation) sense. Another important effect of the non-uniform temperature is that the neutral axis moves away from the centroid of the cross-section, resulting in an additional moment due to eccentric mechanical loading, which tends to bend the structure. The compressive behavior of a column subjected to simultaneous high intensity surface heating and axial compressive loading was investigated experimentally to verify the anticipated theoretical response. All specimens exhibited bending and subsequent catastrophic failure, even at compressive stresses well below these corresponding to the Euler load.

ABSTRACT: The elastica behavior of an extensional sandwich panel with a “soft” core when subjected to in-plane compressive loads is presented and it is compared with the response of its extensional equivalent single layer (ESL) with shear deformations model. The field equations along with the appropriate boundary conditions for the sandwich and the ESL panels have been derived through a variational approach following the High-order SAndwich Panel Theory (HSAPT) approach that takes into account the vertical flexibility of the core. The governing equations include the effects of the extension of the mid-surfaces of the face sheets of the sandwich panel or the mid-plane of the ESL model which the classical elastica approach misses. The results of the elastica response of a clamped-simply-supported sandwich panel and its ESL counterpart are presented and compared. They include the response along the panel, deformed shapes and equilibrium curves of in-plane loads versus structural quantities such as displacements and internal stress resultants and stresses. These results reveal that the predicted buckling load of the ESL panel is larger than that of the sandwich panel and that deep in the non-linear range the upper face sheet wrinkles with increasing overall and edge displacements and a release of the load. Hence, the use of an equivalent single layer panel especially when a sandwich panel with a compliant core is considered may lead to unsafe and unreliable predictions when large displacements and large rotations are considered.

ABSTRACT: This paper concerns the dynamic analysis of shell structures, with emphasis on application to
steel and steel-concrete composite blast resistant doors. In view of the short duration and impulsive nature of the blast loading, an explicit integration method is adopted. This approach avoids time-consuming computations of structural stiffness matrix and solving of simultaneous nonlinear equations. Single-point quadrature shell elements are used, with numerical control to suppress spurious hourglass modes. Composite shells are handled by an appropriate integration rule across the thickness. Both material and geometric nonlinearities are accounted for in the formulation. Contact and gap problems are considered using bilinear spring elements in the finite element analysis. Numerical examples are presented for some benchmark problems and application study to blast resistant doors. Good correlation is generally obtained between the numerical results based on the software developed and the results obtained by other means including field blast tests.

ABSTRACT: The present work is concerned with the development of finite element techniques for nonlinear transient dynamic analysis of reinforced concrete plates and shells. Computational models have been developed and coded, which are applied to various engineering problems under static and dynamic loading conditions. The first part of the thesis deals with some aspects of linear-elastic, geometric and material nonlinear finite element formulations of general thin and thick shell analysis under static or quasistatic loading. A generalized displacement method is proposed to overcome the 'shear locking' problem for the degenerated thick shell element when used in the context of thin shell structures. The basic concept and mathematical formulation of the generalized displacement method are detailed and its application is illustrated by numerical examples. The method is also extended to the geometrically nonlinear analysis of thin shells based on both Updated and Total Lagrangian formulation. An elasto-viscoplastic analysis of anisotropic plates and shells is developed by means of the finite element displacement method. A discrete layered approach is adopted to represent different material properties and gradual plastification through the thickness. Viscoplastic yielding is based on the Huber-Mises criterion extended by Hill for anisotropic material and special consideration is given to the evaluation of the viscoplastic strain increment for anisotropic situations. The second part of this thesis is concerned with nonlinear dynamic transient analysis of reinforced concrete shell structures. Direct integration methods are reviewed and discussed. In particular, the general single step explicit, implicit and implicit-explicit algorithms with predictor-corrector forms are presented and corresponding stability conditions are deduced by invoking the energy method. The modelling of reinforced concrete behaviour in shell structures under fast loading conditions is considered. Both a strain rate sensitive elasto-viscoplastic model and a strain rate sensitive elasto-plastic model are presented for describing concrete nonlinearities due to multiaxial compressive or tensile yielding under dynamic loads. The models are used in conjunction with a tensile crack monitoring algorithm to trace concrete crack opening and closing. Various reinforced concrete plates and shells are analyzed and reported in detail, with the results obtained being compared with those from other sources.

ABSTRACT: The aircraft fuselage is a complex structure with relatively low margins of safety, operating in a highly demanding dynamic environment. In the present work, the loading scenario of an on board explosion is investigated. The main scope is to assess the damage induced on an operating fuselage by an explosive charge. Finite element models of a typical commercial fuselage were generated for two material configurations, aluminium and GLARE. The simulation was performed in three stages; initialization phase, where the flight loads are applied on the structure, the blast phase and the final phase where the flight loads are applied on the damaged structure. Simulations were performed for different charge locations for both material configurations. The extent and location of damage allowed the generation of a vulnerability index.

ABSTRACT: A new one-dimensional high-order theory for orthotropic elastic sandwich beams is formulated. This new theory is an extension of the high-order sandwich panel theory (HSAPT) and includes the in-plane rigidity of the core. In this theory, in which the compressibility of the soft core in the transverse direction is also considered, the displacement field of the core has the same functional structure as in the high-order sandwich panel theory. Hence, the transverse displacement in the core is of second order in the transverse coordinate and the in-plane displacements are of third order in the transverse coordinate. The novelty of this theory is that it allows for three generalized coordinates in the core (the axial and transverse displacements at the centroid of the core and the rotation at the centroid of the core) instead of just one (midpoint transverse displacement) commonly adopted in other available theories. It is proven, by comparison to the elasticity solution, that this approach results in superior accuracy, especially for the cases of stiffer cores, for which cases the other available sandwich computational models cannot predict correctly the stress fields involved. Thus, this theory, referred to as the “extended high-order sandwich panel theory” (EHSAPT), can be used with any combinations of core and face sheets and not only the very “soft” cores that the other theories demand. The theory is derived so that all core/face sheet displacement continuity conditions are fulfilled. The governing equations as well as the boundary conditions are derived via a variational principle. The solution procedure is outlined and numerical results for the simply supported case of transverse distributed loading are produced for several typical sandwich configurations. These results are compared with the corresponding ones from the elasticity solution. Furthermore, the results using the classical sandwich model without shear, the first-order shear, and the earlier HSAPT are also presented for completeness. The comparison among these numerical results shows that the solution from the current theory is very close to that of the elasticity in terms of both the displacements and stress or strains, especially the shear stress distributions in the core for a wide range of cores. Finally, it should be noted that the theory is formulated for sandwich panels with a generally asymmetric geometric layout.

ABSTRACT: The focus of this paper is the application of the recently introduced extended high-order sandwich panel theory to the global buckling of a sandwich beam/wide panel. Three different solution approaches using the extended high-order sandwich panel theory are presented to investigate the effects of simplifying the loading case by applying loads just on the face sheets and by including or excluding nonlinear axial strains in the core. The results are also compared with results from a benchmark elasticity solution and, furthermore, from the simple sandwich buckling formula by the earlier extended high-order sandwich panel theory. It is found that all three theories are close to the elasticity solution for “soft” cores with E(core)/E(facesheet) < 0.001. However, for “moderate” cores, i.e., with E(core)/E(facesheet) > 0.001, the theories diverge and the extended high-order sandwich panel theory is the most accurate.

“Blast response of a sandwich beam/wide plate based on the extended high-order sandwich panel theory and comparison with elasticity”, J. Appl. Mech., Vol. 80, No. 6, August 2013

ABSTRACT: This paper presents a one-dimensional analysis for the blast response of a sandwich beam/wide plate with a compressible core. The dynamic version of the recently developed extended high-order sandwich panel theory (EHSAPT) is first formulated. Material, geometric, and loading parameters are taken from blast experiments reported in literature. The novelty of EHSAPT is that it includes axial rigidity of the core and allows for three generalized coordinates in the core (the axial and transverse displacements at the centroid of the core and the rotation at the centroid of the core) instead of just one (shear stress in the core) of the earlier high-order sandwich panel theory (HSAPT). The solution procedure to determine the dynamic response to a general load applied on the top face sheet of a general asymmetric simply supported configuration is outlined. Although the dynamic EHSAPT is formulated in its full nonlinear version, the solution is for the linear problem so the accuracy of EHSAPT, along with the other theories, can be assessed by comparison to an available dynamic elasticity solution. Results show that the EHSAPT is very accurate and can capture the complex dynamic phenomena observed during the initial, transient phase of blast loading.

ABSTRACT: The initiation of failure in composite sandwich beams is heavily dependent on properties of the core material. Several core materials, including PVC foams and balsa wood were characterized. The various failure modes occurring in composite sandwich beams are described and their relationship to the relevant core properties is explained and discussed. Under flexural loading of sandwich beams, plastic yielding or cracking of the core occurs when the critical yield stress or strength (usually shear) of the core is reached. Indentation under localized loading depends principally on the square root of the core yield stress. The critical stress for facesheet wrinkling is related to the core Young’s and shear moduli in the thickness direction. Experimental mechanics methods were used to illustrate the failure modes and verify analytical predictions.

“Wrinkling of sandwich wide panels/beams based on the extended high-order sandwich panel theory: formulation, comparison with elasticity and experiments”, Archive of Applied Mechanics, Vol. 82, No. 10, pp 1585-1599, October 2012
ABSTRACT: There exist several high-order sandwich panel theories, most notably, the first to be introduced high-order sandwich panel theory (HSAPT) assumes a constant shear stress in the core. Recently, the extended high-order sandwich panel theory (EHSAPT) was introduced, its novelty being that it allows for three generalized coordinates in the core (the axial and transverse displacements at the centroid of the core, and the rotation at the centroid of the core) instead of just one (shear stress in the core) of the earlier theory. In this paper, the EHSAPT formulation for predicting the critical wrinkling load is presented for a simply supported sandwich of general asymmetric construction. The cases of (i) applying the loading just on the face sheets with a linear core assumption and (ii) applying uniform strain loading throughout the thickness of the panel and a nonlinear core assumption are examined. The results are compared with a benchmark elasticity solution. In addition, edgewise compression experiments were conducted on glass face/Nomex honeycomb core and the ensuing wrinkling point is compared with the theoretical predictions. A comparison is also made with earlier edgewise compression experiments on aluminum face/granulated-cork core reported in literature. Other wrinkling formulas that are included in the comparison are: Hoff–Mautner and the HSAPT.

ABSTRACT: The face/core debond is justifiably considered to be a weak link in the use of sandwich structures. This is because such debonds tend to grow and eventually completely delaminate the face sheet. The most common cause of these defects is poor or missing bonding due to careless manufacturing or a mismatch in the geometry. Similar defects may also arise during service due to thermo-mechanical loads, impact events, or structural fatigue. Debonds or delaminations are susceptible to the phenomenon of “delamination buckling” which occurs when local compressive loading is introduced at the debond site.

ABSTRACT: The most important issue regarding buckling of sandwich structures is the effect of transverse shear which can significantly reduce the Euler critical load. Simply put, the effect of transverse shear absolutely cannot be neglected. Therefore, all formulas for sandwich buckling are essentially ways to include this effect into the Euler formulas. Two basic ways for including transverse shear in column buckling are the Engesser (1891) and the Haringx (1948, 1949) approaches. Both of these approaches are also outlined by Timoshenko (1936).

ABSTRACT: Compression loaded faces of sandwich members are sometimes subject to local instability phenomena, the most prominent being the wrinkling or rippling and the intracell buckling or dimpling. This chapter presents the mechanics associated with these phenomena and the classical formulas that predict the conditions for inducing these forms of local instability.

ABSTRACT: The small internal length scales of nanomaterials/nano-devices may call the direct application of classical continuum models into question. In this research, a nonlocal elastic shell model, which takes the small scale effects into account, is developed to study the thermal buckling behavior of multi-walled carbon nanotubes. The multi-walled carbon nanotubes are considered as concentric thin shells coupled with the van der Waals forces between adjacent nanotubes. Closed form solutions are formulated for two types of thermal buckling of a double-walled carbon nanotube: Radial thermal buckling (as in a shell under external pressure) and axial thermal buckling. The effects of small scale effects are demonstrated, and a significant influence of internal characteristic parameters such as the length of the C-C bond has been found on the thermal buckling critical temperature. The study interestingly shows that the axial buckling is not likely to happen, while the “radial” buckling may often take place when the carbon nanotubes are subjected to thermal loading. Furthermore, a convenient method to determine the material constant, “e0,” and the internal characteristic parameter, “a,” is suggested.

ABSTRACT: In this paper, the vibrational behavior of the multiwalled carbon nanotubes (MWCNTs) embedded in elastic media is investigated by a nonlocal shell model. The nonlocal shell model is formulated by considering the small length scales effects, the interaction of van der Waals forces between two adjacent tubes and the reaction from the surrounding media, and a set of governing equations of motion for the MWCNTs are accordingly derived. In contrast to the beam models in the literature, which would only predict the resonant
frequencies of bending vibrational modes by taking the MWCNT as a whole beam, the current shell model can find the resonant frequencies of three modes being classified as radial, axial, and circumferential for each nanotube of a MWCNT. Big influences from the small length scales and the van der Waal’s forces are observed. Among these, noteworthy is the reduction in the radial frequencies due to the van der Waals’ force interaction between two adjacent nanotubes. The numerical results also show that when the spring constant $k_0$ of the surrounding elastic medium reaches a certain value, the lowest resonant frequency of the double walled carbon nanotube drops dramatically.

ABSTRACT: Sandwich panels have been developed to either produce lighter structures capable of carrying prescribed loads or increase the load-carrying capacity subject to limitations on weight. In these panels, facings carry bending and in-plane loads while the core functions similarly to the web of a beam, mostly resisting transverse shear. Improvements in the load-carrying capacity of sandwich panels can be achieved through modifications in their geometry, boundary conditions, and material distribution. One of the methods recently considered by the authors is based on using facings with a step-wise variable thickness that increases at the critical region of the structure. It was illustrated that the strength of a sandwich panel can be considerably enhanced using such stepped facings, without a detrimental increase of the weight. The present paper expands the study of the feasibility of the stepped-facing sandwich panel concept concentrating on three structural problems, i.e. a possible improvement in stability, changes in the natural frequencies, and forced dynamic response to the explosive blast. It is illustrated that the stepped-facing design can improve stability of the panel and its response to blast loading. However, fundamental frequencies of stepped-facing panels decrease compared to those in their conventional equal-weight counterparts. Such decrease is detrimental in the majority of engineering applications representing a limitation of stepped-facing panels. Nevertheless, the usefulness of the stepped-facing design is proven in the problems of bending, stability, and blast loading. Numerous examples presented in the paper validate our suggestion that the combination of a relatively simple manufacturing process and an improved structural response of sandwich panels with stepped facings may present the designer with an attractive alternative to conventional sandwich structures.

ABSTRACT: Closed-form algebraic expressions for the energy-release rate and the mode mixity are obtained for a debonded sandwich (trimaterial). The most general case of an “asymmetric” sandwich is considered (i.e., the bottom face sheet not necessarily of the same material or thickness as the top face sheet). The energy-release rate is obtained by use of the J-integral, and the expression is derived in terms of the forces and moments at the debond section. Regarding the mode mixity, a closed-form expression is derived in terms of the geometry, material, and applied loading, and it is proven that, in the trimaterial case, just as in the bimaterial case, the
mode mixity can be obtained in terms of a single scalar quantity $\omega$, which is independent of loading; the $\omega$ value for a particular geometry and material can be extracted from a numerical solution for one loading combination. Thus, this analysis extends the existing formulas in the literature, which are for either a delamination in a homogeneous composite or an interface crack in a bimaterial. These new “trimaterial with a crack” formulas are also proven to yield the formulas for the limits of a bimaterial or for a homogeneous section with a crack.

ABSTRACT: The extended high-order sandwich panel theory was formulated in its one-dimensional version for orthotropic elastic sandwich beams. This theory includes the in-plane rigidity of the core, and the compressibility of the soft core in the transverse direction is also considered. The novelty of this theory is that it allows for three generalized coordinates in the core (the axial and transverse displacements at the centroid of the core, and the rotation at the centroid of the core) instead of just one (midpoint transverse displacement) commonly adopted in other available theories. The theory was derived so that all core/face displacement continuity conditions are fulfilled. It is proven, by comparison to the elasticity solution, that this approach results in superior accuracy, especially for the cases of stiffer cores, for which cases of the other available sandwich computational models cannot correctly predict the stress fields involved. In this paper, a linear finite element is formulated based on the extended high-order sandwich panel theory. The element equations are outlined, and numerical results for the simply supported case of transverse distributed loading are produced for several typical sandwich configurations. These results are compared with the corresponding ones from the elasticity solution. The comparison among these numerical results shows that, with a relatively small number of elements, the results are very close to the elasticity ones in terms of both the displacements and stress or strains. Thus, the finite element version of the extended high-order sandwich panel theory constitutes a very powerful analytical tool for sandwich panels.

ABSTRACT: The Sanders-type theory of elliptical sandwich shells with different facings is formulated. The governing equations account for transverse shear strains and for rotations about the normal to the middle surface of the shell. The constitutive equations correspond to a sandwich shell where each facing is formed of an even number of regular symmetrically laminated layers. Accordingly, the matrix of extensional, coupling and bending stiffnesses is fully populated, except for the elements A16 and A26 that are equal to zero. In addition, a geometrically nonlinear formulation is presented for an elliptical facing resting on an elastic foundation, based on the Sanders nonlinear shell theory. In this formulation, the rotations about the normal to the middle surface as well as transverse shear strains are disregarded. Both the governing equations for the sandwich shell and the nonlinear solution for a facing are reduced to the corresponding results for a circular cylindrical shell if the radius of curvature of the shell is constant. Numerical examples are presented for the problem of buckling of a
long cylindrical shell subjected to a lateral pressure. This solution, developed by using the energy method, illustrates the penalty involved in using different facings, which may nevertheless be necessary to improve the design by reinforcing the facing exposed to low-velocity impact and other loads.

ABSTRACT: The paper presents a theoretical formulation for spherical shells reinforced by meridional and circumferential stiffeners. Active damping of the shell is introduced through control action of piezoelectric coupled pairs bonded to the meridional stiffeners. The induced loads can include radial pressure and a thermal field that are independent of the circumferential coordinate. Neglecting local deformations between adjacent meridional stiffeners, the response of the shell will be axisymmetric. The analysis employs the Donnell-Mushtari-Vlasov version of Love's theory of shells together with a smeared stiffeners technique. The paper also considers a particular case of shell mounted piezoelectric coupled pairs without conventional stiffeners. A closed form solution is derived for spherical panels without conventional stiffeners within the range of the meridional coordinate between 75° and 90° using a version of the Geckeler approximation.

ABSTRACT: This paper outlines several issues related to the design of sandwich structures with a truss-reinforced polymeric or hollow core. The first part of the paper employs a simple analytical model that illustrates the contribution of such a core to the structure’s facing stability. While the enhancement of the facing-stability due to truss reinforcement is shown to be considerable, the problems of local strength and truss-element (pin) stability have to be analyzed prior to the acceptance of the design concept discussed in the paper. Accordingly, the second part of the paper presents the results of finite-element analysis used to pinpoint potentially weak elements in the considered design. The paper results in a number of practical conclusions and recommendations that may be useful for the development and implementation of sandwich structures with truss-reinforced cores.

ABSTRACT: A non-linear shallow thin shell element is described. The element is a curved quadrilateral one with corner nodes only. At each node, six degrees of freedom (i.e. three translations and three rotations) make the element easy to connect to space beams, stiffeners or intersecting shells. The curvature is dealt with by Marguerre's theory. Membrane bending coupling is present at the element level and improves the element behaviour, especially in non-linear analysis. The element converges to the deep shell solution. The sixth degree of freedom is a true one, which can be assimilated to the in-plane rotation. The present paper describes how overstiffness due to membrane locking on the one hand and to the sixth degree of freedom on the other hand can be corrected without making use of numerical adjusted factors. The behaviour of this new element is analysed in linear and non-linear static and dynamic tests.

ABSTRACT: The problem of local buckling, debonding initiation and growth process of the debonding of a bonded two-layer plate is treated. In the weaker layer of the plate, compression appears due to the external compressive axial force and bending moment. The conditions for local buckling of the weaker layer have been studied where the possibility that the stress state in the layers could be in elasto-plastic domain has been considered. A mathematical model is developed to determine the bending displacements of laminate layers after the weaker layer buckles locally, and in the state after the plate has been unloaded. The third-order theory introduced by Chwalla has been implemented. Mechanical properties of the layers and adhesive used in the numerical model were measured with experiments. Experimental work comprised the determination of mechanical properties of the chosen materials and experimental verification of the presented mathematical model. Numerically obtained results are compared with those obtained by an experimental approach, and are found to be in good agreement.

ABSTRACT: The conventional approach to analysis the buckling of rectangular laminates containing an embedded delamination subjected to the in-plane loading is to simplify the laminate as a beam-plate from which
the predicted buckling load decreases as the length of the laminate increases. Two-dimensional analyses are employed in this paper by extending the one-dimensional model to take into consideration of the influence of the delamination width on the buckling performance of the laminates. The laminate is simply supported containing a through width delamination. A new parameter \( \beta \) defined as the ratio of delamination length to delamination width is introduced with an emphasis on the influence of the delamination size. It is found that (i) when the ratio \( \beta \) is greater than one snap-through buckling prevails, the buckling load is determined by the delamination size and depth only; (ii) as the ratio \( \beta \) continues to increase, the buckling load will approach to a constant value. Solutions are verified with the well established results and are found in good agreement with the latter.

ABSTRACT: Delaminated composites under pure bending can undergo snap buckling under certain conditions of applied bending load and geometrical configuration. The phenomenon is demonstrated experimentally and is investigated theoretically by an energy procedure. The geometric non-linearities are included in the formulation. First, a theoretical analysis is performed to model the behavior of the system and define the conditions for snap buckling. The predicted buckling loads are then compared with experimentally obtained data from pure bending loading of Kevlar epoxy specimens with internal delaminations. Good agreement is obtained between the experimental and theoretical results.

Jea-Hyeong Han, George A. Kardomateas, George J. Simites, “Elasticity, shell theory and finite element results for the buckling of long sandwich cylindrical shells under external pressure”, Composites: Part B 35
ABSTRACT: The buckling of a sandwich cylindrical shell under uniform external hydrostatic pressure is studied in three ways. The simplifying assumption of a long shell is made (or, equivalently, ‘ring’ assumption), in which the buckling modes are assumed to be two-dimensional, i.e. no axial component of the displacement field, and no axial dependence of the radial and hoop displacement components. All constituent phases of the sandwich structure, i.e. the facings and the core, are assumed to be orthotropic. First, the structure is considered a three-dimensional (3D) elastic body, the corresponding problem is formulated and the solution is derived by solving a set of two linear homogeneous ordinary differential equations of the second-order in \( r \) (the radial coordinate), i.e. an eigenvalue problem for differential equations, with the external pressure, \( p \) the parameter/eigenvalue. A complication in the sandwich construction is due to the fact that the displacement field is continuous but has a slope discontinuity at the face-sheet/core interfaces, which necessitates imposing ‘internal’ boundary conditions at the face-sheet/core interfaces, as opposed to the traditional two-end-point boundary value problems. Second, the structure is considered a shell and shell theory results are generated with and without accounting for the transverse shear effect. Two transverse shear correction approaches are employed, one based only on the core, and the other based on an effective shear modulus that includes the face-sheets. Third, finite element results are generated by use of the ABAQUS finite element code. In this part, two types of elements are used: a shear deformable shell element and a solid 3D (brick) element. The results from all these three different approaches are compared.

and kevlar/epoxy laminates with 0° deg orientation with respect to the hoop direction, and for alloy-foam core. Shell theory results are generated with and without accounting for the transverse shear effect. Two transverse shear correction approaches are compared, one based only on the core, and the other based on an effective shear modulus that includes the face sheets. The results show that the shell theory predictions without transverse shear can produce highly non-conservative results on the critical pressure, but the shell theory formulas with transverse shear correction produce reasonable results with the shear correction based on the core only being in general conservative (i.e., critical load below the elasticity value). The results are presented for four mean radius over shell thickness ratios, namely 15, 30, 60, and 120 in order to assess the effect of shell thickness (and hence that of transverse shear). For the same thickness, the differences between elasticity and shell theory predictions become larger as the mean radius over thickness ratio is decreased. A comparison is also provided for the same shell with homogeneous composite construction. It is shown that the sandwich construction shows much larger differences between elasticity and shell theory predictions than the homogeneous composite construction. The solution presented herein provides a means of a benchmark for accurately assessing the limitations of shell theories in predicting stability loss in sandwich shells.

ABSTRACT: Delamination is one of the basic defects inherent to laminated shell structures. Under uniform external pressure such delaminations may buckle and subsequently propagate. This phenomenon is modeled here as a first approximation by considering a two-dimensional geometry (ring approximation) and a thin delaminated layer. Growth is studied by a fracture mechanics-based energy release rate criterion. Closed-form expressions for the critical pressure and growth conditions are derived, as well as for the cutoff level of the
delamination range below which local delamination buckling cannot take place. A formulation that accounts for the effects of transverse shearing forces is also presented.

G.A. Kardomateas and C.B. Chung (School of Aerospace Engineering, Georgia Institute of Technology, Atlanta, Georgia), “Buckling of a thick orthotropic cylindrical shell under external pressure including hygroscopic effects”, AMD Vol. 162, Mechanics of Thick Composites, ASME 1993

ABSTRACT: The stability of equilibrium of an orthotropic thick cylindrical shell subjected to external pressure in a hygroscopic environment is investigated. In this approach, the structure is considered a three-dimensional elastic body rather than a shell. First, a fundamental analysis that formulates the basic buckling equations with the appropriate boundary conditions in the elasticity context is performed. Subsequently, the critical loads for pure mechanical loading (external pressure) are derived. Following this benchmark analysis, the particular emphasis is placed on examining the effect of the boundary-layer transient hygroscopic stress field on the critical load. Constant moisture concentrations on the inner and outer surfaces are imposed in addition to the external pressure. Since the moisture diffusion process is relatively slow, the hygroscopic stresses are confined for practical time values to a boundary-layer region near the surfaces. The analysis first uses the series expansion for the Bessel functions for small arguments and then the Hankel asymptotic expansions since an increasing number of terms is found to be needed. Compared to the classical shell theory approach, the results of this research show that the shell theory predictions on the critical load can be highly non-conservative when moderately thick construction is involved. However, the hygroscopic boundary-layer has a negligible influence on the critical load.

ABSTRACT: The stability of equilibrium of a transversely isotropic thick cylindrical shell under axial compression is investigated. The problem is treated by making appropriate use of the three-dimensional theory of elasticity. The results are compared with the critical loads furnished by classical shell theories. For the isotropic material cases considered, the elasticity approach predicts a lower critical load than the shell theories, the percentage reduction being larger with increasing thickness. However, both the Flugge and Danielson and Simmonds theories predict critical loads much closer to the elasticity value than the Donnell theory. Moreover, the values of $n$, $m$ (number of circumferential waves and number of axial half-waves, respectively, at the critical point) for both the elasticity, and the Flugge and the Danielson and Simmonds theories, show perfect agreement, unlike the Donnell shell theory.

PARTIAL ABSTRACT: The bifurcation of equilibrium of an orthotropic thick cylindrical shell under axial compression is studied by an appropriate formulation based on the three dimensional theory of elasticity. The results from this elasticity solution are compared with the critical loads predicted by the orthotropic Donnell and Timoshenko non-shallow shell formulations...

ABSTRACT: An elasticity solution to the problem of buckling of orthotropic cylindrical shells subjected to external pressure is presented. In this context, the structure is considered a three-dimensional body. The results show that the shell theory predictions can produce nonconservative results on the critical load of composite shells with moderately thick construction. The solution provides a means of accurately assessing the limitations of shell theories in predicting stability loss.

ABSTRACT: A formulation based on the three dimensional theory of elasticity is employed to study the buckling of an orthotropic cylindrical shell under external pressure. In this paper, a non-zero axial displacement and a full dependence of the buckling modes on the three coordinates is assumed, as opposed to the ring approximation employed in the earlier studies. The results from this elasticity solution are compared with the critical loads predicted by the orthotropic Donnell and Timoshenko non-shallow shell formulations. Two cases
of end conditions are considered; one with both ends of the shell fixed, and the other with both ends capped and under the action of the external pressure. Moreover, two cases of orthotropic material are considered with stiffness constants typical of glass/epoxy and graphite/epoxy. For the isotropic material case, the predictions of the simplified (single expression) Donnell and the Flügge and the Danielson and Simmonds theories are also compared. In all cases, the elasticity approach predicts a lower critical load than the shell theories, the percentage reduction being larger with increasing thickness. The degree of non-conservatism depends strongly on the material properties, being smaller for the isotropic case. Furthermore, although it is a commonly accepted notion that the critical point in loading under external pressure occurs for $n = 2$ and $m = 1$ (number of circumferential waves and number of axial half-waves, respectively), it was found that this is not the case for the strongly orthotropic graphite/epoxy material and the moderately thick construction; for this case, the value of $m$ at the critical point is greater than 1 (yet, in all cases $n = 2$).

ABSTRACT: Benchmark solutions to the problem of buckling of orthotropic cylindrical shells, which are based on the three-dimensional theory of elasticity, are presented in this review article. It is assumed that the shell is under external pressure or axial compression or a combination of these loadings. These solutions provide a means of accurately assessing the limitations of the various shell theories in predicting critical loads. A comparison with some classical shell theories shows that the classical shell theories may produce, in general, highly non-conservative results on the critical load of composite shells with thick construction. One noteworthy exception: the Timoshenko shell buckling equations produce conservative results under pure axial compression.

ABSTRACT: The objective of this paper is to answer the question of how accurately the simple Euler or transverse shear correction Engesser/Haringx/Timoshenko column buckling formulae are, when orthotropic composite material and moderate thickness are involved. The column is in the form of a hollow circular cylinder and the Euler or Timoshenko loads are based on the axial modulus. For this purpose, a three-dimensional elasticity solution is presented. As an example, the cases of an orthotropic material with stiffness constants typical of glass/epoxy or graphite/epoxy and the reinforcing direction along the periphery or along the cylinder axis are considered. First, it is found that the elasticity approach predicts in all cases a lower than the Enter value critical load. Moreover, the degree of non-conservatism of the Euler formula is strongly dependent on the reinforcing direction; the axially reinforced columns show the highest deviation from the elasticity value. The degree of non-conservatism of the Euler load for the circumferentially reinforced columns is much smaller and is comparable to that of isotropic columns. Second, the Engesser or first Timoshenko shear correction formula is in all cases examined conservative, i.e., it predicts a lower critical load than the elasticity solution. The Haringx or second Timoshenko shear correction formula is in most cases (but not always) conservative. However, in all cases considered, the second estimate is always closer to the elasticity solution than the first one. For the isotropic case both Timoshenko formulas are conservative estimates. Examination of a new formula for column buckling that adds a second term to the Euler load expression and is supposed to account
for thickness effects, shows that this estimate is a non-conservative estimate but performs very well with very thick sections, being closest to the elasticity solution, but in general no better than the Timoshenko formulas for moderate thickness.

ABSTRACT: Two important issues associated with structural integrity of composite shells are the prediction of the conditions for the loss of stability and the question of accurately assessing the behavior of the structure in the presence of defects. Since the structures under consideration are subjected to high values of external pressure, which in turn results in both an axial and circumferential local compressive field, buckling/postbuckling of delaminated and pure (without delaminations) shells is an important part of the structural integrity concept. Two other issues that are included in this project are a study of the growth of internal delaminations, and an investigation of the effect of the hygroscopic environment in the context of predicting the combined effects of moisture sorption and external compression with respect to the stress and deformation fields in thick composite shells, and the possibility of local spalling (initiation of internal debonds and interlaminar separation).

References:

ABSTRACT: An improved elasticity solution to the problem of buckling of orthotropic cylindrical shells subjected to external pressure is presented. The 2D axisymmetric cylindrical shell is studied (ring approximation). Specifically, in the development of the governing equations and boundary conditions for the buckling state, the solution includes the terms with the prebuckling normal strains and stresses as coefficients (i.e., the terms $e_{a0}$ and $a_{e0}$ which were neglected in the earlier work as being too small compared to the terms $a_{e0}$ and $a_{k0}$, respectively). The formulation results in a two-point boundary eigenvalue problem for ordinary differential equations in $r$, with the external pressure $p$ as the parameter. The results show that the effect of including the
nonnal strains and stresses is to further decrease the critical load. This decrease (versus the earlier elasticity solution without these terms) depends on the shell thickness and is generally moderate, and in no event comparable with the (quite large) decrease of the elasticity versus the shell theory prediction. This decrease depends also on the degree of orthotropy, and it is smaller for the isotropic case. Finally, a formula is derived for the critical pressure based on a first-order shear deformation formulation, and the comparison shows an improvement versus the classical shell for thick shells, but still the elasticity solution is noticeably lower than the first-order shear deformation prediction.

ABSTRACT: The elasticity solution is constructed for a cylindrical sandwich shell under external and/or internal pressure and for the same shell under axial load. The solution is an extension of the one for a
homogeneous, monolithic shell and is provided in closed form. All three phases, that is, the two face sheets and the core, are assumed to be orthotropic. Moreover, there are no restrictions as far as the individual thicknesses of the face sheets and the sandwich construction may be asymmetric. These solutions can be used as benchmarks for assessing the performance of various sandwich shell theories. Illustrative results are provided in comparison to the sandwich shell theory.

ABSTRACT: The response of composite columns under axial compressive loading, and in which a non-uniform temperature distribution through the thickness exists, is investigated. This non-uniform temperature distribution can develop when one side of the structures is exposed to heat flux. In this paper, we assume that this distribution is linear, which corresponds to a steady state temperature profile due to heat conduction. The degradation of the elastic properties with temperature (especially near the glass transition temperature of the matrix) is accounted for, by using experimental data for the elastic moduli. Furthermore, the formulation includes transverse shear and it is done first for the general non-linear case and subsequently linearized. Due to the non-uniform stiffness and the effect of the ensuing thermal moment, the structure behaves like an imperfect column, and responds by bending rather than buckling in the classical Euler (bifurcation) sense. Another important effect of the non-uniform temperature is that the neutral axis moves away from the centroid of the cross-section, resulting in another moment due to eccentric loading, which would tend to bend the structure away from the heat source. Simple equations for the response of the column are derived and results are presented for the variation of the deflection with the heat flux, as well as for the combined effects of the applied
load and heat flux. It is found that the thermal moment would tend to bend the structure away from the heat source for small temperatures (small heat fluxes) but towards the heat source for large temperatures. On the contrary, the moment induced due to the eccentric loading would always tend to bend the structure away from the heat source. Results indicate the combined influences of these moments and that of axial constraint.

ABSTRACT: Thick composite and sandwich shells are used in many naval submersible structures and in other applications such as space vehicles. Stability under the prevailing high external pressure in deep ocean environments is of primary concern. In many other applications the loading involves a combination of external pressure and axial compression. It is well known that for these structures the simple classical formulas are in much error, due to both the large thickness and the large extensional over shear modulus ratios of modern composite and sandwich materials. Although there exist several advanced theories, such as first order shear and higher order shear theories, each based on a specific set of assumptions, it is not easy to determine the accuracy and range of validity of these advanced models unless an elasticity solution exists. This paper presents the research performed over the last 15 years on benchmark elasticity solutions to the problem of buckling of (i) orthotropic homogeneous cylindrical shells and (ii) sandwich shells with all constituent phases i.e., facings and core assumed to be orthotropic. The paper focuses on uniform external pressure loading. In this context, the structure is considered a three-dimensional body. The results show that the shell theory predictions can produce in many cases highly non-conservative results on the critical loads. A comparison with the corresponding formulas from shell theory with shear included, is also performed. The present solutions provide a means of accurately assessing the limitations of the various shell theories in predicting stability loss.

ABSTRACT: Ocular rigidity is the change in intraocular pressure produced by an incremental change in intraocular volume. Ocular rigidity was determined in 14 donor eyes by injecting small increments of a balanced salt solution through the limbus, while continually monitoring the intraocular pressure with a transducer. A buckling procedure was then performed in these eyes with the use of various solid silicone or stainless steel encircling elements, and the experiments were repeated. Buckled eyes were significantly less rigid than unbuckled eyes, and eyes with higher buckles were significantly less rigid than those with shallower buckles. The observed changes in rigidity are likely secondary to changes in the shape and stress distribution of the scleral shell and are only to a small degree related to the elasticity of the encircling element. Greater volumes of vitreous substitutes, gases, or antibiotics may be injected into buckled eyes compared with unbuckled eyes before excessive intraocular pressures are reached.

ABSTRACT: Thin-walled shells have wide applications as primary structural elements in simple and complex lightweight structures. In these applications, cylindrical shells contain several imperfections and material discontinuity, namely variously shaped cutout. The understanding of the effects of initial geometric imperfection and cutout on the buckling behavior of such shells is very important. A finite element analysis, using commercial finite element software, is used to study the buckling behavior of cylindrical shells with imperfection or circular cutouts. Particular emphasis is placed on circular cylindrical shells subjected to an axial compression load. Both perfect shells with cutouts and shells with initial geometric imperfection are considered. The main objective of this study is to investigate the buckling behavior of laminated composite shells with circular cutouts and initial geometric imperfection. The effect of cutout geometry and size, material properties, fiber angle, stacking sequences, and initial geometric imperfection are discussed. The results presented herein indicated that, buckling response of laminated composite shells is significantly changed by cutout size, fiber orientation, stacking sequences, and amplitude of initial geometric imperfections.

PARTIAL ABSTRACT: The experimental results from implosion tests of various graphite/epoxy and glass/epoxy cylinders are correlated with predictions from a performance model for thick composite cylinders subjected to external hydrostatic pressure. That performance model consists of a stress module, a stability module, and a material failure module….

ABSTRACT: A parametric study is presented on the accuracy of stability data for axial compression and
torsion by classical and first-order shear deformation theories for laminated composite cylinders. Comparisons
of the data in the forms of curves of critical stress versus L/a (dimensionless wave-length/radius ratio) are made
with those by Biot's theory, which is predicated on three-dimensional elasticity. Two thickness/radius ratios
were considered: H/a = 0.01 and 0.1, typical of thin and thick shell geometries, respectively. First, a comparison
of the data for a homogeneous, isotropic cylinder was given to have a baseline for understanding the role of
material anisotropy. Then, a number of regular symmetric and antisymmetric laminates were considered, all
laminate profiles based on one material system only, that of EL/ET = 25. The data for thin geometries (H/a
greater-or-equal, slanted 0.01) showed that classical theory for laminated composite shells can be trusted to give
accurate results over a reasonably wide range of L/a. For the thick shell geometry, there were regions of
relatively good agreement and regions where classical and first-order shear deformation theories were not
appropriate.

ABSTRACT: The dynamic stability of an imperfect fiber reinforced composite cylindrical shells under axial
or/torsional impulsive load in the form of a step function is investigated. Donnell-von Kármán type
nonlinear equations are derived for the initially imperfect laminated composite cylinder. Two buckling criteria
are used for comparison. Critical loads are computed for different imperfection parameters. The sensitivity is
established through plots of critical loads versus imperfection amplitude. The larger the drop in critical load
value with increasing amplitude, the greater the sensitivity. Compared with the static case, there is a significant
reduction of the dynamic buckling load subject in axial direction. For the torsional load, no significant reduction
has been found. Comparing dynamic buckling loads obtained by using the Simitses criteria and by using the
Budiansky and Roth criteria, with the Simitse criteria one can get conservative results.

N.S. Rallis and A.N. Kounadis (Civil Engineering Department, National Technical University of Athens,
Greece), “Nonlinear sway-buckling of geometrically imperfect rectangular frames”, Ingenieur-Archiv, Vol. 55,
No. 2, pp 90-97, March 1985
ABSTRACT: By using as model an unbraced rectangular frame, the effect of geometric imperfections due to
right angle deviations is thoroughly discussed. It is found that the value of the angle between the center lines of
the two members is of decisive importance for the response of the frame. There is a critical angle for which the
response of the frame changes from buckling to unbuckled states exhibiting a monotonically rising equilibrium
path. It is shown that this critical angle depends on the column slenderness ratio as well as on the length and
moment of inertia ratio of the two members. Moreover, formulas for direct evaluation of the critical angle as
well as of the load-carrying capacity of the frame are established.

ABSTRACT: A nonlinear stability analysis based on an analytical approach of elastic type is performed for the first time on a simple two-bar frame. In order to obtain an exact determination of its buckling and postbuckling behavior the effect of compressibility of the bar centroidal axis is taken into account. This effect implies very slight increase in the buckling load which can be safely ignored. Moreover, it is found that even in the most extreme cases of geometry and stiffness, the critical buckling displacements are of negligibly small magnitude contrary to existing results obtained by the nonlinear kinematic stability analysis. The two foregoing findings enable us to replace the limit point by a bifurcation point. Such a simplification, being correct in an asymptotic sense, allows the application of a stability analysis of frames by considering their bars as incompressible. A variety of numerical results shows the degree of accuracy and the range of applicability of the aforementioned nonlinear kinematic stability analysis by comparing it with the exact method of stability analysis proposed herein.

SUMMARY: A thorough study of the critical and post-critical large displacement response of simple discrete and continuous systems made from a nonlinear elastic material, is presented. Simple material-dependent stability conditions are established, whose application does not require the solution of the intractable nonlinear differential equations of equilibrium. The predominant role of the nonlinear component of the curvature on the buckling mechanism of the foregoing systems, is revealed. Moreover, it is found that elastic systems which were considered as exhibiting post-buckling strength might be imperfection sensitive, if the effect of material nonlinearity is taken into account. An approximate but very efficient analytical approach leading to very reliable results is derived for establishing the large displacement behavior of a nonlinear elastic cantilever bar. The degree of accuracy of this approach is checked by comparing it with the “exact” numerical solution of Runge Kutta. The numerical results presented herein contribute to our understanding of this problem and at the same time show the efficiency, reliability and range of applicability of the proposed approach.

ABSTRACT: In this investigation the effect of two loadings interaction and right angle deviation on the response of a rectangular two-bar frame is thoroughly discussed. It is found that there is a critical value of the two loadings ratio as well as of the right angle deviation for which the physical equilibrium path and the physically unacceptable complementary path meet each other at an asymmetric bifurcation point. This state constitutes the boundary between stability and instability, since the response of the frame changes from snapthrough buckling to a stable equilibrium path. Moreover, a very efficient and simple to use stability analysis, employed for the first time at a non-rectangular frame, gives reliable results compared to those of the nonlinear kinematic stability analysis.

ABSTRACT: The nonlinear dynamic buckling response of discrete systems under step loading of infinite duration is thoroughly discussed by using one-degree-of-freedom models. The analysis is based on the exact nonlinear differential equations of motions and refers to those systems which when subjected to the same loading applied statically exhibit a limit-point instability. It is found that an unbounded motion may start for the smallest step load which forces the system to pass through an unstable equilibrium state of the postbuckling path with zero total potential energy. This leads to dynamic buckling criteria which allow the determination of exact dynamic buckling loads without solving the corresponding nonlinear differential equations of motion. A comparison of dynamic buckling estimates of previous works with those obtained herein shows that the latter are exact regardless of the magnitude of the initial imperfection. Moreover, some additional results provide a better insight into the actual mechanism of nonlinear dynamic buckling associated with the foregoing type of loading.

ABSTRACT: The large postbuckling response of a uniform cantilever beam subjected to a partial follower
compressive load of constant magnitude is presented. The range of values of the nonconservativeness loading parameter for which a divergence instability occurs is theoretically established. The boundary between divergence and flutter instability corresponds to a double critical point where the first and second buckling loads (eigenvalues) coincide. It was also theoretically established that the critical points corresponding to these loads are stable symmetric. Except of the double critical point, the buckling loads of the first and second eigenmodes are distinct for the entire region of the nonconservativeness loading parameter. However, this is not true for the corresponding postbuckling paths. Indeed using an elastica analysis suitable for rotations up to 360°, it was found that at a certain critical tip rotation depending on the value of the nonconservativeness parameter the first and second postbuckling modes meet each other asymptotically. Numerical results have been obtained using various approximate analytic techniques which are checked by the method of elliptic integrals as well as the numerical schemes of Adams and Runge-Kutta.

Lignos (Civil Engineering Department, National Technical University of Athens, Athens, Greece), “Buckling of tube-like shells filled with other material under uniform axial compression”, Engineering Structures, Vol. 22, No. 8, June 2000, pp. 961-967, doi:10.1016/S0141-0296(99)00047-4

ABSTRACT: Symmetrical buckling of steel tube-like shell structures fully filled with a softer material is considered. Such a compound cross-section, after assuming complete condensation of the contained material, is subjected to uniform axial compression by means of two rigid end plates. We further assume simple boundary conditions on both ends with zero radial displacements. The proposed solution allows establishment of the effect of hoop stresses on the load-carrying capacity of the filled tube.

ABSTRACT: This work deals with dynamic buckling universal solutions of discrete nondissipative systems under step loading of infinite duration. Attention is focused on total potential energy functions associated with universal unfoldings of cuspoid type catastrophes with one active coordinate. The fold, dual cusp and tilted cusp catastrophes under statically applied loading occurring via limit points, asymmetric/symmetric bifurcations and nondegenerate hysteresis points are extended to the case of dynamic loading. Catastrophe manifolds of these types showing imperfection sensitivity under both types of loading are fully assessed. Important findings regarding dynamic buckling of imperfect systems generated by perfect systems associated with ‘imperfect’ bifurcations are explored. The analysis is supplemented by a numerical application of a system exhibiting imperfect bifurcation when it is perfect as well as a hysteresis point associated with a tilted cusp catastrophe, when it becomes imperfect.

ABSTRACT: The postbuckling response of perfect and geometrically imperfect elastic columns resting on an
elastic Winkler type foundation is thoroughly discussed. This is established by employing an approximate analytic technique leading to very reliable results in the vicinity of the critical state. It was found that the critical state of perfect columns is a stable symmetric bifurcation point and consequently there is no sensitivity to initial geometrical imperfections. Moreover, a simple but readily analyzed mechanical model is proposed to simulate the salient features of buckling mechanism of the column on elastic foundation with those of the model. The simplicity, reliability and efficiency of the proposed analysis as well as the successful modeling of the buckling mechanism of the column by that of a single mode mechanical model are illustrated with the aid of numerical examples.

ABSTRACT: The lateral postbuckling response of thin-walled structures such as bars and frames with members having steel rolled shapes as well as circular cylindrical shells under axial compression is thoroughly reconsidered. More specifically via a simple and very efficient technique it is found that beams with rolled shapes (symmetric or non symmetric) under uniform bending and axial compression exhibit a stable lateral–torsional secondary path with limited margins of postbuckling strength. New findings for the static and dynamic stability of frames with crooked steel members—due to the presence of residual stresses—are also reported. It is comprehensively established that the coupling effect due to initial crookedness and loading eccentricity may have a beneficial effect on the load-carrying capacity of the frames. Moreover, simple mechanical models are proposed for simulating the buckling mechanism of axially compressed circular cylindrical shells. Very recently Bodner and Rubin proposed an 1-DOF mechanical model whose buckling parameters correlated to those of the
shells by using an empirical formula based on experimentally observed shell buckling loads. In the present analysis a new 2-DOF model for the static and dynamic buckling of axially compressed circular cylindrical shells, which can include mode coupling, is presented.

Ronalds, B.F. and Dowling, P.J., “Buckling of intact and damaged offshore shell structures”, Advances in Marine Structures Conference, Dunfermline, Scotland, May 1986

ABSTRACT: Compression tests are described on longitudinally stiffened cylindrical shells with denting damage. The behavior is compared with that of similar intact shells to ascertain the stiffness and strength reduction in the presence of local damage. Modes of buckling are also discussed. The results suggest a simple analytical procedure which may be used in estimating the consequences of ship collision damage to buoyant offshore platforms.

ABSTRACT: This article presents results from static and dynamic tests on thick filament wound glass/epoxy tubes. The first part involves the identification of damage initiation and its development. Ultrasonic inspection was employed first to determine projected damage areas. A large number of samples were then sectioned and polished and the true damage area was revealed by a dye penetrant technique. This has made possible detailed descriptions of damage development. The true damage area is roughly 10 times the projected area. The second part of the article is concerned with the evaluation of the influence of this damage on residual strength under hydrostatic pressure loading. The improved understanding of these phenomena and the development of predictive tools is part of an ongoing effort to improve the long-term integrity of composite structures for underwater applications.

ABSTRACT: The effect of the number and size of rings on the buckling strength of ring-stiffened cylinders is studied experimentally. The results of ten machined ring-stiffened cylinders subjected to lateral pressure are presented. Five of the cylinders failed by the general instability mode and the rest failed by the shell instability mode. A sample of the experimental results which shows longitudinal and circumferential strains as well as the development of the circularity contours till collapse is presented. Buckling pressures obtained from the experiments are shown to be within ±30% of the corresponding value obtained from the theoretical analysis available in the literature.

ABSTRACT: The effect of initial imperfections on the elastic-buckling behaviour of ring-stiffened cylinders
under external pressure is examined using the potential energy approach. Experimental results in the open literature of four ring-stiffened cylinders tested under external pressure were used to compare and verify the theoretical analysis. Both the theoretical and experimental results indicate no apparent influence of initial imperfections on the buckling behaviour within the elastic range. This was so in spite of the presence of an appreciable amount of initial imperfections. The results from this work indicate that less stringent requirements in the manufacturing of ring-stiffened cylinders may be tolerated, leading to possible economy.

ABSTRACT: A numerical study using the finite element method has been carried out to investigate the response of composite shells with cutouts subjected to internal pressure and axial compression. The CAE package ABAQUS, has been employed for the analysis. The buckling and post-buckling responses in a series of shells with different size cutouts are presented. The numerical results show that the buckling load decreases as the size of the cutout is increased and the buckling load increases as the internal pressure is increased. Results also show that for the equivalent cutout areas the cutout with higher width (measurement in the circumferential direction) creates a lower buckling load. The results indicate that the response of a compression loaded cylinder with a cutout is influenced by the internal pressure, cutout area and orientation.

ABSTRACT: Finite element models were developed to study global, local and mixed mode buckling behaviour of composite plates with embedded delaminations under compression. The global modelling results were compared with corresponding experimental results. It is shown that the numerical results for embedded delaminations agree very well with the experimental results, whereas the difference between the results was high for delaminations located at the edge of the plates. It is also shown that at lower loading levels the interaction of global and local buckling is negligible. At higher loading levels the strain energy release rate distribution and the delamination growth potential at the delamination front strongly depend on the shape of the debonded region and the local buckling mode. It was observed that the local buckling mode was highly influenced by the laminate stacking sequence. In the course of global buckling, a parametric study was carried out to investigate the influence of the delamination size, shape and alignment of a series of composite plates.

ABSTRACT: Composite cylindrical shells and panels are widely used in aerospace structures. These are often
subjected to defects and damage from both in-service and manufacturing events. Delamination is the most important of these defects. This paper deals with the computational modelling of delamination in isotropic and laminated composite cylindrical shells. The use of three-dimensional finite elements for predicting the delamination buckling of these structures is computationally expensive. Here combined double-layer and single-layer of shell elements are employed to study the effect of delamination on the global load-carrying capacity of such systems under axial compressive load. It is shown that through-the-thickness delamination can be modelled and analysed effectively without requiring a great deal of computing time and memory. A parametric study is carried out to study the influence of the delamination size, orientation and through-the-width position of a series of laminated cylinders. The effect of material properties is also investigated. Some of the results are compared with the corresponding analytical results. It is shown that ignoring the contact between the delaminated layers can result in wrong estimations of the critical buckling loads in cylindrical shells under compressive load.

ABSTRACT: A series of finite element analyses on the delaminated composite cylindrical shells subject to combined axial compression and pressure are carried out varying the delamination thickness and length, material properties and stacking sequence. Based on the FE results, the characteristics of the buckling and postbuckling behaviour of delaminated composite cylindrical shells are investigated. The combined double-layer and single-layer of shell elements are employed which in comparison with the three-dimensional finite elements requires less computing time and space for the same level of accuracy. The effect of contact in the buckling mode has been considered, by employing contact elements between the delaminated layers. The interactive buckling curves and postbuckling response of delaminated cylindrical shells have been obtained. In the analysis of post-buckled delaminations, a study using the virtual crack closure technique has been performed to find the distribution of the local strain energy release rate along the delamination front. The results are compared with the previous results obtained by the author on the buckling and postbuckling of delaminated composite cylindrical shells under the axial compression and external pressure, applied individually.

ABSTRACT: A numerical study using the non-linear finite element analysis has been carried out to investigate the response of composite cylindrical shells subject to combined loading. The interaction buckling curves of perfect composite cylinders subject to different combinations of axial compression, torsion, bending and lateral pressure are obtained. The postbuckling analysis of composite cylinders with geometric imperfections of eigenmode-shape is carried out to study the effect of imperfection amplitude on the critical buckling load. The initial buckling load of composite shells is substantially reduced by the existence of imperfections. Here it is shown that the effects of imperfections are more apparent when the composite cylindrical shells are subject to combined loadings. The results show that the buckling and non-linear response of geometrically imperfect shell structures subjected to complex loading conditions may not be characterized correctly by an elastic linear bifurcation buckling analysis.

ABSTRACT: Composite cylindrical shells and panels are widely used in aerospace structures. These are often subjected to defects and damage from both in-service and manufacturing events. Delamination is the most important of these defects. This paper deals with the instability analysis of delaminated composite cylindrical shells subject to pure bending and also combined bending and axial compression, using the finite element method. The combined double-layer and single-layer of shell elements are employed, which in comparison with the three-dimensional finite elements requires less computing time and space for the same level of accuracy. The effect of contact in the buckling mode has been considered, by employing contact elements between the delaminated layers. The interactive buckling curves and postbuckling response of delaminated cylindrical shells
have been obtained. In the analysis of post-buckled delaminations, a study using the virtual crack closure technique has been performed to find the distribution of the strain energy release rate along the delamination front. The results show that under pure bending, laminated cylindrical shells are more sensitive to the presence of delamination, than they are under pure axial compression. It was also observed that the effects of delamination are more apparent when the composite cylindrical shells are subjected to combined axial compression and bending. In this case, with a slight increase of the applied bending moment, the strain energy release rate distribution on the compressive side of the cylinder changes drastically.

ABSTRACT: Improved numerical models have been developed for predicting the compressive strength of impact-damaged sandwich composites comprised of woven-fabric graphite-epoxy facesheets and Nomex honeycomb cores. The proposed methodology contains three key elements: (1) the use of nondestructive inspection estimates of damage, (2) the incorporation of nonlinear through-the-thickness core-crush constitutive response to account for core failure, and importantly (3) the simulation of progressive loss of facesheet structural integrity based upon userspecified ply failure criteria. The finite element predictions of residual strength for panels impacted with relatively blunt objects correlate well with the experimental observations; this is in contrast to a number of estimates from literature that tend to overestimate the strength. The proposed approach may potentially facilitate sandwich design by providing insight into the relationships between material configuration and damage that lead to improved damage tolerance characteristics.

ABSTRACT: Nonlinear vibration and postbuckling behavior of a single layer graphene sheet (SLGS) embedded in a polymer matrix aroused by the nonlinear van der Waals (vdW) forces are investigated using the Kirchhoff plate theory. The interfacial vdW forces are described by a nonlinear function in terms of the graphene deflection. Through harmonic balance method, the nonlinear relation between deflection amplitudes and resonant frequencies of free vibrations of the SLGS and its postbuckling equilibrium path are derived. It is found that variation of resonant frequencies of an embedded SLGS is less dependent on the graphene aspect ratio and mode numbers as compared with a free-standing one. In-plane load effects upon the vibrational behavior of the SLGS and its postbuckling are also discussed. Simulation results have demonstrated the significance of considering the surrounding medium effect and its nonlinearity in the study of the vibration and buckling of the embedded graphene with applications in nanocomposites.

ABSTRACT: Recent research studies on the application of the nonlocal continuum theory in modeling of carbon nanotubes and graphene sheets are reviewed, and substantial nonlocal continuum models proposed for static and dynamic analyses of the nano-materials are introduced. The superiority of the nonlocal continuum theory to its local counterpart, and the necessity of calibration of the small-scale parameter as the key parameter revealing small-scale effects are discussed. The nonlocal beam, plate, and shell models are briefly presented and potential areas for future research are recommended. It is intended to provide an introduction to the development of the nonlocal continuum theory in modeling the nano-materials, survey the different nonlocal continuum models, and motivate further applications of the nonlocal continuum theory to nano-material modeling.

ABSTRACT: A systematic parametric study was carried out to investigate the elastic and elastic-plastic buckling behaviors of imperfect steel shell subject to axial compression and internal pressure. Studied parameters include the magnitude of internal pressure, steel strength, and ratio of cylinder radius to shell thickness. Design equations were proposed for calculating the elastic and elastic-plastic buckling strength of imperfect steel shells under combination of axial compression and internal pressure. The buckling strength predicted by proposed equations agrees well with that from the numerical simulation.

ABSTRACT: A hybrid continuum mechanics and molecular mechanics model is developed in this paper to predict the critical strain, stress, and buckling load of the inelastic buckling of carbon nanotubes. With the proposed model, the beamlike and shell-like buckling behavior of carbon nanotubes can be analyzed in a unified approach. The buckling solutions from the hybrid model are verified from molecular dynamics simulations via the MATERIALS STUDIO software package and from available research findings. The existence of the optimum diameter, at which the buckling load reaches its maximum, and the correlation of the diameter with the length of carbon nanotubes, as predicted by Liew (2004, “Nanomechanics of Single and Multiwalled Carbon Nanotubes,” Phys. Rev. B, 69(11), pp. 115429), are uncovered by the hybrid model. The simplicity and effectiveness of the proposed model are not only able to reveal the chiral and size-dependent buckling solutions for carbon nanotubes, but also enable a thorough understanding of the stability behavior of carbon nanotubes in potential applications.

ABSTRACT: Elastic buckling of layered/fibre reinforced composites is investigated. Assuming the existence of both shear and transverse modes of failure, the fibre is analysed as a layer embedded in a matrix. Interacting stresses, acting at the interfaces are determined from an exact derived stress field in the matrix. It is shown that buckling can occur only in the shear buckling mode and that the transverse buckling mode is spurious. As opposed to the well known Rosen shear buckling mode solution (predicated on an infinite buckling wavelength), shear buckling is shown to exist under two regimes: buckling of dilute composites with finite wavelengths and buckling of non-dilute composites with infinite wavelengths. Based on the analysis, a model is constructed which defines the fibre concentration at which the transition between the two regimes occurs. The buckling strains are shown to be (approximately) constant for dilute composites and, in the case of very stiff fibres, to have realistic values compatible with elastic behaviour. For the case of non-dilute composites, the strains are found to be in agreement with those given by the Rosen shear buckling solution. Numerical results for the buckling strains and stresses are presented and compared with the Rosen solution. These reveal that the Rosen solution is valid only for the case of non-dilute composites. The investigation demonstrates that elastic buckling may be a dominant failure mechanism of composites consisting of very stiff fibres fabricated in the framework of nano-technology.

ABSTRACT: Based on nonlocal theory of thermal elasticity mechanics, an elastic multiple column model is developed for column buckling of MWNTs with large aspect ratios under axial compression coupling with temperature change. The present model treats each of the nested tubes as an individual column interacting with adjacent nanotubes through the intertube van der Waals forces. The thermal effect is incorporated in the formulation. In particular, an explicit expression is derived for the critical axial strain of a double-walled carbon nanotube which clearly demonstrates that small scale effects contribute significantly to the thermo-mechanical behavior of multiwalled carbon nanotubes and cannot be ignored.

ABSTRACT: In this paper, static bending and buckling of a functionally graded (FG) nanobeam are examined based on the nonlocal Timoshenko and Euler-Bernoulli beam theory. This non-classical (nonlocal) nanobeam model incorporates the length scale parameter (nonlocal parameter) which can capture the small scale effect. The material properties of the FG nanobeam are assumed to vary in the thickness direction. The governing equations and the related boundary conditions are derived using the principal of the minimum total potential energy. The Navier-type solution is developed for simply-supported boundary conditions, and exact formulas...
are proposed for the deflections and the buckling load. The effects of nonlocal parameter, aspect ratio, various material compositions on the static and stability responses of the FG nanobeam are discussed. Some illustrative examples are also presented to verify the present formulation and solutions. Good agreement is observed. The results show that the new nonlocal beam model produces larger deflection and smaller buckling load than the classical (local) beam model.

ABSTRACT: Nonlocal elasticity theory is a popular growing technique for the mechanical analyses of MEMS and NEMS structures. The nonlocal parameter accounts for the small-size effects when dealing with nano-size structures such as single-walled carbon nanotubes (SWCNTs). In this article, nonlocal elasticity and Timoshenko beam theory are implemented to investigate the stability response of SWCNT embedded in an elastic medium. For the first time, both Winkler-type and Pasternak-type foundation models are employed to simulate the interaction of the (SWCNT) with the surrounding elastic medium. A differential quadrature approach is utilized and numerical solutions for the critical buckling loads are obtained. Influences of nonlocal effects, Winkler modulus parameter, Pasternak shear modulus parameter and aspect ratio of the SWCNT on the critical buckling loads are analyzed and discussed. The present study illustrates that the critical buckling loads of SWCNT are strongly dependent on the nonlocal small-scale coefficients and on the stiffness of the surrounding medium.

ABSTRACT: In this paper, the thermal buckling behavior of single-walled carbon nanotubes (SWCNTs) embedded in an elastic medium is studied. To this end, the SWCNTs are modeled based on the nonlocal Timoshenko beam theory into which the effect of the elastic medium is incorporated. The generalized differential quadrature (GDQ) method is employed to discretize the governing differential equations and to consider different commonly used boundary conditions (BCs). For simply supported BCs, the results obtained from the present analysis are compared with the ones from the exact solution and an excellent agreement has been achieved. The effects of the aspect ratio, nonlocal parameter and the Winkler parameter on the dimensionless critical buckling temperature are carefully investigated.

ABSTRACT: In this article, a semi-analytical finite element approach based on the nonlocal elastic shell model is proposed to study the thermal buckling of multiwalled carbon nanotubes (MWCNTs). By taking nonlocality into consideration, the small scale effect is incorporated into the model presented herein. Based upon the Eringen nonlocal elasticity, the displacement field equations coupled by the van der Waals interaction force are derived. Comprehensive results for the thermal buckling of multiwalled carbon nanotubes are given. The influences of the small scale parameter and boundary conditions on the thermal instability of MWCNTs are examined. It is indicated that the possibility of the radial buckling mode of deformation due to radially elevated temperature is significantly higher than that of axial buckling mode of deformation due to uniformly reduced temperature when carbon nanotubes experience thermal loads.

R. Ansari and M. Hemmatnezhad (Department of Mechanical Engineering, University of Guilan, P.O. Box 3756, Rasht, Iran), “Nonlinear finite element analysis for vibrations of double-walled carbon nanotubes”,

ABSTRACT: The large-amplitude free vibration analysis of double-walled carbon nanotubes embedded in an elastic medium is investigated by means of a finite element formulation. A double-beam model is utilized in which the governing equations of layers are coupled with each other via the van der Waals interlayer forces. Von-Karman type nonlinear strain-displacement relationships are employed where the ends of the nanotube are constrained to move axially. The amplitude-frequency response curves for large-amplitude free vibrations of single-walled and double-walled carbon nanotubes with arbitrary boundary conditions are graphically illustrated. The effects of material constant of the surrounding elastic medium and the geometric parameters on the vibration characteristics are investigated. For a double-walled carbon nanotube with different boundary conditions between inner and outer tubes, the nonlinear frequencies are obtained apparently for the first time. Comparison of the results with those from the open literature is made for the amplitude free vibration analysis of double walled carbon nanotube ropes. The large amplitude free vibration analysis of double walled carbon nanotube ropes.

ABSTRACT: Silicon carbide nanotubes possess outstanding properties which enable them to have many applications. The buckling behaviour of silicon carbide nanotubes have been studied here. To do this, a 3D finite element method, known as space frame model has been proposed. Molecular mechanics are linked to density functional theory to derive the properties of this finite element method. It has been shown that the critical buckling force will diminish with increasing aspect ratio. Also, it is represented that increasing the aspect ratio will result in reducing the effect of boundary conditions.

ABSTRACT: A size-dependent finite element (FE) formulation including surface free energy effect is developed in this article to study the post-buckling behavior of nanofilms under the action of thermal loads. The Gurtin-Murdoch surface elasticity theory is utilized to consider the surface effects. Moreover, the principle of virtual work is used so as to derive the equilibrium equations. The proposed FE formulation is based on the first-order shear deformation theory (FSDT). The von Kármán nonlinear relations are also employed to take the geometric nonlinearity into account. After deriving the FE equations, the resulting set of parameterized non-
linear equations is solved using the pseudo arc-length continuation algorithm, and bifurcation diagrams of nanofilms are obtained. Selected numerical results are presented for the influences of surface stress on the thermal post-buckling characteristics of nanofilms subject to different types of boundary conditions.

ABSTRACT: The main goal in this investigation is optimization of two, four, eight and twelve layer shells in order to identify optimized fiber angle in different layers aiming maximizing critical load. In order to identify critical load parameter, a hybrid approach including Finite Element Method (FEM) and Neural Networks (NN) is employed. To achieve the above results, required data for NN is supplied by FEM and the appropriate network is trained. For optimization of obtained function, Genetic Algorithm (GA) is utilized. In this case, GA is also employed over and over in order to obtain the effect of different parameters. Furthermore, existence of several close optimized points and interactions among layers, critical load and fiber angle are discussed.

ABSTRACT: This paper describes an analytical tool for the design of thin-wall tubes for passage through minimal radius of curvature trajectory. The design is based on a model of thin-wall tube buckling under pure bending. An extended analytical solution for general initial cross section is found based on Brazier method by energy theory of elastic stability. The model predicts the critical moment, curvature, flattening, and stress and allows choosing the most suitable cross section shape for a specific purpose. For example, tubes with ocular and rounded-ocular cross sections were found suitable for semiflexible applications such as endoscopy, where they elastically cross a sharp corner.

ABSTRACT: Composite materials thin-walled structures are widely used as skin panel in flight vehicles in recent years. These structures will encounter severe complex loading conditions, which may be a combination of mechanical, aerodynamic, thermal and acoustic loads. Thin-walled structures subjected to this kind of loadings will exhibit nonlinear response; as a result, fatigue failure will occur. High temperature may cause large thermal deflection and stress, for some special conditions, may cause thermal buckling. Once the thermal buckling appears, the stiffness will change correspondingly, it will cause significant influence on the dynamic response and fatigue failure. Accordingly, it is important to research the nonlinear response of this kind of structures under elevated thermal environment. Nonlinear response and thermal pre-buckling/post-buckling behavior of a Graphite-Epoxy composite plate subjected to server thermal loading is numerically investigated in this paper. A composite laminated plate with clamped-clamped boundary conditions is chosen as simulated body, nonlinear finite element model is developed using the first-order shear deformable plate theory, Von Karman strain-displacement relations, and the principle of virtual work. The thermal load is assumed to be a steady-state with different predefined temperature distribution. The thermal strain is stated as an integral quantity of the thermal expansion coefficient with respect to temperature. Then the modes of the plate are analyzed, the nature frequencies and modal shapes are obtained. The critical temperature of buckling is calculated. The static nonlinear equations of motions are solved by the Newton-Raphson iteration technique to
obtain the thermal post-buckling deflection. The Riks method is used to analyze static post-buckling behavior. In the numerical examples, four types of situations are studied, which include i) the buckling behaviors for different initial imperfections, ii) the buckling behaviors for different thickness to width ratios, and iii) The buckling behaviors for different width to length ratios; The critical temperature, the static thermal post-buckling deflection and the load to displacement relation are presented respectively. The influences of different boundary conditions on the buckling behaviors of the plate are achieved as well. The simulation method and results presented in this paper can be valuable references for further analysis of the nonlinear responses of thin-walled structures under complex loading conditions.

ABSTRACT: In this study, a new technique based on Ritz method is developed for damage detection of the circular cylindrical shell structures. Sander's thin shell theory in association with the Ritz method is used to analyze the dynamic behaviour of circular cylindrical shells. By equating the strain and kinetic energy mathematically, the eigenvalue problem is solved which will give the natural frequencies of the circular cylindrical shell. The crack damage on the shell surface is modelled by a line spring along the circumference of the shell. Different damage scenarios are simulated by the changes of the crack locations and spring stiffness. The location and extent of the damage are predicted by the changes of modal parameters. Numerical simulations show that the method is effective and accurate to determine the crack damage in the cylindrical shell structures.

ABSTRACT: The feasibility of replacing substructure and component testing by analytical "virtual testing" is addressed here for composite structures. The special difficulties in estimating the failure loads of composite structures are described, especially when initiation starts from a local stress concentration. Damage may initiate and then propagate, but final failure can occur at loads significantly higher than that for initiation. The separate modes of in-plane (fibre-dominated) and delamination (matrix dominated) are shown to need different strength and fracture strategies. Several examples are chosen of realistic structures, ranging from notches through to stiffened compression panels, starting with the easiest (in-plane dominated) and finishing with the most difficult mixed in-plane and debonding case.

PARTIAL INTRODUCTION: The problem of impact damage in laminated composite structures, and the
consequent reduction in residual strength, has been a topic of continual research for over two decades. The number of journal papers on the subject now runs into four figures and most have been conscientiously reviewed by Abrate (1991, 1994, 1998). This review is not intended to be in the academic tradition, with emphasis on acknowledging the authorship of all the various research initiatives. Instead we present our opinions so that the reader can appreciate our current understanding of the problem, our capability of predicting by analysis, and the scope of the design tools for avoiding structural damage, or at least designing damage tolerant aerospace structures. There are two types of impact, namely that when a foreign body strikes a structure, or in contrast that when a complete aircraft or helicopter suffers a crash landing of some sort. This latter case is usually discussed as ‘crashworthiness’ and has become a routine feature of automobile design where the energy-absorbing properties of ductile metals are exploited to the full. The objective here is to design a structure which can deform and absorb energy but leave the passenger compartment more or less intact.
