ABSTRACT: The aim of this investigation is to study the effect of different imperfection shapes on the inelastic stability of liquid-filled conical tanks and to determine the critical imperfection shape that would lead to the minimum inelastic limit load. The study is carried out numerically using a self-developed shell element used to simulate a number of conical tanks having an imperfection shape in the form of Fourier series of equal coefficients. The Fourier analysis of the buckling modes indicates that the existence of axisymmetric imperfection will lead to the critical inelastic limit load for conical tanks.

ABSTRACT: In the current study an optimum design technique of stiffened liquid-filled steel conical tanks subjected to global and local buckling constraints is developed using a numerical tool that couples a non-linear finite element model developed in-house and a genetic algorithm optimization technique. This numerical tool is an extended version of an earlier one, adapted for the optimum design of unstiffened conical tanks. The design variables considered in the current study are the shell thicknesses, the geometry of the steel vessel as well as the dimensions and number of stiffeners. The developed numerical tool is capable of selecting the set of design variables that leads to optimum safe design. The analysis is conducted twice; first, case of stiffeners free at their bottom edge, which represents the case of retrofitting an existing tank. In the second case the stiffeners are assumed to be anchored to the bottom slab of the tank, which represents the situation of a newly designed tank. Finally, the optimum design of the stiffened tanks is compared to the optimum design of unstiffened tanks computed in a previous study.

ABSTRACT: Empty and water filled cylindrical Tin (Sn) coated steel cans were loaded under axial compression at varying loading rates to study their resistance to withstand accidental loads. Compared to empty cans the water filled cans exhibit greater resistance to axially applied compression loads before a complete collapse. The time and load or stroke and load plots showed three significant load peaks related to three stages during loading until the cylinder collapse. First peak corresponds to the initial structural buckling of can. Second peak occurs when cylindrical can walls gradually come into full contact with water. The third peak shows the maximum load carrying capability of the structure where pressurized water deforms the can walls into curved shape until can walls fail under peak pressure. The collapse process of water filled cylindrical shell was further studied using Smooth Particle Hydrodynamics (SPH) technique in LSDYNA. Load peaks observed in the experimental work were successfully simulated which substantiated the experimental work.

ABSTRACT: The aim of this paper is to design an optimum Y-stiffener plate combination using multi-objective optimization with real-coded genetic algorithms under the action of uniaxial compressive loads, because the most important loads applied on stiffened plates in ship hull is longitudinal in-plane axial compression arising for instance due to longitudinal bending because the cargo is not distributed equally in holds or due to grounding, stranding or collision. Five of the Y-stiffened panel dimensions were selected to be the independent design variables of the optimization problem. The objective functions are the ultimate buckling load and the volume per unit area of the Y-stiffener plate combination. Nonlinear finite element analysis was used to calculate the ultimate buckling load of 35 different sets of the design variables, with certain range for each of the design variables. The effects of independent design variables on the ultimate buckling load and the volume per unit area for Y-stiffener plate combination were studied and discussed. A new surrogate function to predict the ultimate buckling load of Y-stiffener plate combination is created and validated using the values of the ultimate buckling loads calculated using nonlinear finite element analysis. The proposed surrogate function is valid only in the specific ranges of the design variables. The Pareto optimal sets were calculated using multi-objective optimization with real-coded genetic algorithms and the optimum set of the independent design variables which is associated with the optimal geometric dimensions of the Y-stiffened panel was selected as the set which has the maximum ultimate buckling load to volume per unit area ratio. The optimum set was tested and validated using sensitivity analysis technique.

ABSTRACT: Wrinkling criteria are proposed for an elastic isotropic and plastic anisotropic shell with compound curvatures in the noncontact region of a sheet subjected to internal forming stresses. A quasi-shallow shell is modeled by Donnell-Mushtari-Vlasov (DMV) shell theory. A bifurcation functional from Hill's general theory of uniqueness and bifurcation in elastic-plastic solids is used to model the local wrinkling phenomenon. Both strain hardening and transverse anisotropy are taken into consideration. This wrinkling criterion is especially useful as a failure criterion in three dimensional finite element modeling (FEM) of sheet forming. Given the principal stresses or strains and the geometry provided at each incremental deformation step, the criterion can be used to predict wrinkles in the elements in the unsupported region.

Special Issue: Advanced Methods in Materials Processing Defects, doi:10.1016/S0922-5382(97)80032-3

ABSTRACT: A numerical method for predicting the onset of flange wrinkles of small wavelength during deep drawing process is presented. The method is based on the approach developed by Cao and Boyce (1997) for predicting the buckling behavior of sheet metal under lateral constraint using a combination of energy conservation and finite element method. Continuum elements are used in a simple Finite Element Analysis model to study wrinkles with a maximum wavelength of ten times the sheet thickness. The analysis provides the critical buckling stress and the resulting buckling wavelength as functions of normal pressure. Such relationships are then implemented in a Finite Element Method (FEM) package that uses membrane elements to simulate the workpiece deformation during a forming process. The use of membrane elements significantly reduces the amount of computation time required in comparison to using structural shell elements with multiple integration points through the thickness. The stress histories calculated from the FEM membrane analysis are used to predict the onset of buckling during the forming process. The application of the forming of a rectangular pan is examined. The comparison between numerical simulation and the experimental results is presented. Our approach predicts the onset of buckling in excellent agreement with the experimental observations.

ABSTRACT: An experimental investigation was conducted on the initiation and growth of wrinkling due to nonuniform tension using the Yoshida buckling test. The initiation of wrinkling was detected by strain gages mounted on both surfaces of the samples in the loading and transverse directions. The bifurcation of aluminum auto body sheets appeared to be smooth and much less abrupt than that observed in a steel sheet. A special fixture was designed to, perhaps for the first time, continuously measure the in situ growth of the buckle heights so that the rates of buckle growth were monitored as functions of strain and stress in the loading direction. In contrast to what is commonly believed, it was found that the buckle height is not predominantly determined by the material yield strength, and lower average r value does not increase the rate of buckle growth. Crystallographic texture components and pole figures of the test materials were also measured, and the relationship of plastic anisotropy with wrinkling behavior was investigated by experiments with specimens aligned in the rolling direction, the transverse direction and 45-deg to the rolling direction of the sheet materials.

ABSTRACT: This study presents a numerical investigation on the deformation of the circular blanket against a male die under impulsive loading to form a torispherical head shape. A finite element model was developed and verified with experimental tests for the explosive forming of torispherical heads made of AA5083 aluminum alloy in the framework of LS-DYNA crash simulator software. The nature of the deformation was turned from the stretching to the buckling and compression of the specimen by using a male die, which is a novel concept in the high speed forming processes. Johnson-Cook (JC) and Modified Zerilli-Armstrong (MZA) constitutive equations were used to describe the behavior of the specimen in a high strain rate forming process with different stress status. Most of the experimentally observed material behaviors simulated well in pure tension or compression tests, while the transient zone was not adequately described. The predicted width for the transient rim is considerably smaller than experimental measurements. The blast loading process including the underwater detonation and the interaction with the specimen simulated using Arbitrary Lagrangian-Eulerian
formulation as well as cavitations and reloading effect. The simulation results for blast loading verified base on Cole’s relation for the underwater detonation of small charges, show a good agreement of 95% accuracy.

ABSTRACT: The initiation and growth of wrinkles in sheet metal forming processes are influenced by many factors such as the stress state, the mechanical properties of the sheet material, the geometry of the body, and the contact conditions. It is difficult to analyze wrinkling initiation and growth considering these factors, because the effects of the factors are very complex and the wrinkling behavior may show a wide variation for small deviation of the factors. In this study, bifurcation theory is introduced for the finite element analysis of wrinkling initiation and growth. All the above mentioned factors are conveniently considered by the finite element method. The wrinkling initiation is determined by checking the determinant of the stiffness matrix at each iteration and the wrinkling behavior is analyzed by successive iteration with the perturbed guess along the eigenvector. The finite element formulation is based on the incremental deformation theory and elastic–plastic material modeling. The finite element analysis is carried out using continuum-based resultant shell elements. The initiation and growth of wrinkling in the elliptical cup deep drawing process are analyzed by the proposed algorithm. The effect of the aspect ratio of a punch on the wrinkling behavior in the elliptical cup deep drawing process is investigated.

ABSTRACT: This paper deals with two-dimensional plane stress wrinkling model of elastic/plastic annular plate. Based on energy method and nonlinearity of strain-displacement law, a bifurcation functional in polar coordinate is derived analytically. This technique leads to the critical conditions for the onset of the elastic/plastic wrinkling of the flange during the deep-drawing process. Tresca yield criterion along with deformation theory of plasticity are utilized and the material of the plate is assumed to behave perfectly plastic. Moreover, the influence of the blankholder upon wrinkling and on the number of the generated waves is quantitatively predicted by the suggested scheme. The main advantage of the proposed solution is its better agreement with the experimental and analytical results found by the other researchers.

ABSTRACT: Tube Hydroforming Process (THF) is heavily affected by the pressure-displacement diagram, and adjustment of the raw tube. Three common defects of the process are bursting, buckling and wrinkling. In this work, the leading conditions to wrinkling defect have bee

ABSTRACT: The general wrinkling theory based on the rate formulation of the principle of virtual work has been applied in a number of studies on wrinkling during sheet metal forming. No contact with the die was allowed. In this study it is shown that with the right choice of wrinkling modes, the theory can also be used for contact situations. Furthermore, loads normal to the sheet can be taken into account. Therefore, the wrinkling theory has a larger area of application then it was previously considered.

Marisa P. Henriques, Ricardo J. Alves de Sousa, Robertt A. F. Valente (Department of Mechanical Engineering, University of Aveiro Campus Universitário de Santiago, Aveiro, Portugal), “Numerical Simulation Of Wrinkling Deformation In Sheet Metal Forming”, 7th EUROMECH Solid Mechanics Conference J. Ambrosio et.al. (eds.) Lisbon, Portugal, 7–11 September 2009

ABSTRACT: The main goal of the present paper is to perform an initial analysis of distinct numerical simulation strategies, based on the Finite Element Method (FEM), in the description of wrinkling initiation and propagation during sheet metal forming operations. Wrinkling defects in plastically formed parts can be characterized as compression instabilities, and from this fundamental point of view can then be seen as localized buckling, within the general theory of plastic bifurcation and lost of uniqueness. Seeking for a higher generality in the analysis, numerical simulation procedures – such as the FEM – allow for a strong contribution on the study of wrinkling effects in realistic sheet metal forming problems. For these cases, complexities in contact, loading, geometry and process parameters can completely impair the use of analytical tools, being numerical simulation strategies the most appropriate ones. From the FEM standpoint, the authors will focus the present study in two particular aspects: a) the influence of a given finite element formulation choice and b) the influence of the chosen anisotropic constitutive model in the prediction of the onset and propagation of wrinkling deformation modes during forming. Starting from the latter, this work intends to analyze the influence of accounting (or not) for planar anisotropy behaviours within finite element numerical simulation procedures. Free-forming examples will be taken into consideration, being analyzed with isotropic and anisotropic material models included in the FEM commercial package Abaqus. Additionally, the influence on
wrinkling onset and propagation as coming from the chosen finite element formulation will also be taken into account. To do so, different shell and tridimensional continuum finite elements will be used along with implicit numerical solution procedures, the later option allowing for the attenuation of numerical instabilities in triggering wrinkling effects. Following these guidelines, the present work intends to provide some preliminary insights into how numerical simulation parameters and modelling decisions can influence the results coming from finite element procedures, regarding wrinkling defects in sheet metal formed parts.

ABSTRACT: Wrinkling is one of the major defects in sheet metal products and may be also attributable to the wear of the tool. The initiation and growth of wrinkles are influenced by many factors such as stress ratios, mechanical properties of the sheet material, geometry of the workpiece, contact condition, etc. In the study, the bifurcation theory is introduced for the finite element analysis of wrinkling initiation and growth. All the above mentioned factors are conveniently considered by the finite element method. The wrinkling initiation is found by checking the determinant of the stiffness matrix at each iteration and the wrinkling behavior is analyzed by successive iteration with the perturbed guess along the eigenvector. The effect of magnitude of perturbation on the wrinkling behavior can be avoided by the Newton-type iteration method. The finite element formulation is based on the incremental deformation theory and elastic-plastic material modeling. The finite element analysis is carried out using the continuum-based resultant shell elements considering the planar anisotropy of the sheet metal. In order to investigate the effects of geometry and stress state on the wrinkling initiation and growth, a modified Yoshida buckling test is proposed as an effective buckling test. The finite element analysis are carried out for the modified Yoshida buckling test. The buckling behavior of the sheet is analyzed for various modified dimensions.

INTRODUCTION: Surface distortions in the form of localised buckles and wrinkles are often observed in sheet metals during stamping and other forming operations. In fact, wrinkling is becoming one of the most troublesome modes of failure in sheet forming mainly because of the trend towards thinner, high-strength sheet metals. Therefore, the critical conditions which promote the initiation of wrinkling are of fundamental significance to the design of deep drawn components and may be incorporated in a predictive model for FE simulation. The methods used in the past to predict wrinkling failures in sheet metals have been mostly empirical (e.g. Yoshida Buckling Test which consists of subjecting a square flat specimen to diagonal tension. Buckling eventually develops in the central region of the specimen and attempts are made to correlate buckle heights and buckling loads with various material properties). The Yoshida buckling test and other similar
empirical methods have, unfortunately, proved to be inadequate for predicting observed trends. A more recent approach for the analysis of local wrinkling has been presented by Hutchinson and Neale (1985). It consists of formulating the problem within the context of plastic bifurcation theory for thin shell elements. In this work the analysis of Hutchinson and Neale (1985) and its extension by Neale (1989) to account for more general constitutive models (e.g. anisotropy) is used.

ABSTRACT: Hutchinson approach has been successfully used by a number of researchers in thin sheet metal forming processes for wrinkling prediction. However, Hutchinson approach is limited to regions of the sheet that are free of any contact. Therefore, a new wrinkling indicator that can be used in the contact areas is proposed. Discretisation error indicators are also used to present a comprehensive approach to wrinkling prediction analysis.

ABSTRACT: In this work, the analysis of Hutchinson and Neale is used for wrinkling prediction. Under a number of assumptions, limitations and simplifications a wrinkling criterion with some restrictive applicability, is obtained. Unfortunately, Hutchinson analysis is limited to regions of the sheet that are free of any contact. When contact is taken into account the problem is further complicated. Consequently, a local indicator based on the change of curvatures under compressive stresses is developed. Both wrinkling indicators are used to drive the adaptive mesh refinement in order to be able to accurately spot wrinkling. The numerical results will be compared to those obtained through experimental testing. A number of hemispherical product samples have been used with various blank holder forces and drawn to different depths to capture the onset of wrinkling, its mode and location.

ABSTRACT: An analysis for the prediction of wrinkling in curved sheets during metal forming is presented. Using a local approach, similar to that employed for conventional forming limit diagram representations, we construct “wrinkling limit curves” (WLCs) which represent the combinations of the critical principal stresses for wrinkling in curved sheet elements. Wrinkling limit curves are first determined using a bifurcation analysis for plastic buckling in short-wavelength shallow modes. A study of the effects of material properties and sheet...
geometry on the critical conditions for wrinkling is carried out. We then analyse the effects of geometric imperfections on wrinkling. This analysis is based on the implementation of a finite element scheme. The influence of nonproportional loading is also investigated. In our analysis the material is assumed to be isotropic, elastic-plastic with the plastic part modelled using both J2 deformation theory and J2 flow theory of plasticity.

ABSTRACT: Excessive wavy surfaces formed by a cold- or hot-rolling process in a thin plate degrades the value of the plate significantly, which is called the flatness problem in the industry. It is a result of post-buckling due to the residual stress caused by the rolling process. Because the buckling occurs in a very long, continuous plate, a unique difficulty of the problem as a buckling problem is that the buckling length is not given but has to be found. In many previous works, the length that gives the lowest critical load of the plate for the given load profile was taken as the buckling length. In this work, it is shown that this approach is flawed, and a new approach is developed to solve the flatness problem by extending a classic post-buckling analysis method based on the energy principle. The approach determines the buckling length and amplitude without using any unfounded assumptions or hypothesis. Using simple displacement functions, approximate solutions are obtained in closed forms for the plate subjected to a linearly distributed residual stress. The new solution approach can be used to determine the condition for the maximum rolling production that does not cause the flatness problem.

ABSTRACT: In this study, static and free vibration characteristics of anisotropic laminated cylindrical shell with various end conditions are considered by making the use of differential quadrature method (DQM). Equations of motion are derived based on three-dimensional theory of elasticity. Applying the state space in conjunction with DQM to the governing differential equations and to the edges boundary conditions in term of displacements, new state equations at discrete points are derived. By solving the obtained state equations, static and frequency behavior of laminated shell are evaluated. To ensure the accuracy of the present approach, comparisons are made with those for the shell with simply supported edges which can be solved analytically. Finally, the effect of edges condition on the static and vibration behaviour of shell is investigated.

ABSTRACT: The differential quadrature method (DQM) is used to analyze the one-dimensional buckling of a laminated composite beam plate having an across-the-width delamination located at an arbitrary depth and an arbitrary location along its span. A beam theory with shear deformation is used in formulating the problem.
Several case studies are conducted to examine the buckling response of laminates hosting such a delamination. Using DQM, the system of equilibrium equations and the boundary conditions are transformed into a system of linear algebraic eigenvalue equations that are solved by a standard eigensolver. The influences of several parameters that affect the buckling strength of such laminates are investigated. The investigated parameters are the shear deformation factor, the length of the delamination, and the through-the-thickness and longitudinal positions of the delamination. The results verify the accuracy and efficiency of DQM.

ABSTRACT: The application of differential quadrature method (DQM), as an effective and robust numerical method, for the analysis of buckling of delaminated composite plates is introduced. The analysis investigated the response of laminated composite plates hosting a circular or an elliptical delamination. The delaminations were assumed to be fairly thinner than the plate hosting them, and thus, they could be treated as plates with clamped edges. Several case studies were used to verify the integrity of DQM in predicting the buckling strain of the plates. The investigation included the examination of several parameters influencing the buckling strength. The results obtained from DQM were compared with those obtained by the Rayleigh–Ritz and finite element solutions of other workers.

ABSTRACT: Optimization of the buckling load of a filamentary laminated circular cylindrical shell subjected to axial compression and/or external pressure has been undertaken. The shell is made up of a group of N orthotropic plies whose principal axis coincides with the shell axis. The optimization procedure adopted involves a two-step approach; a random search is employed to determine an initial guess for a systematic search based on Powell's method. The efficiency of this procedure is demonstrated for four-ply laminated cylindrical shells of various length-to-radius ratios involving three typical material systems.

ABSTRACT: The paper proposes a procedure of optimization of reinforced structures of aerospace employment. Such procedure, denominated NAPAO, uses the sizing code PANDA2 for the shell structures while the global optimization is realized through MSC.Nastran. NAPAO has been applied to structural modules of the International Space Station Alpha, of which Alenia Spazio S.p.A. has responsibility. The applications have shown that the procedure of proposed optimization represents a versatile and efficient tool which allows a reduction of mass in relatively brief times if compared with those of a structural optimization developed completely in a FEM code.

doi:10.1016/0263-8231(95)00037-2
ABSTRACT: The development of a new four node degenerated shell element is presented for the analysis of the shell structures undergoing large deformations. In the formulation of the new element, the assumed covariant transverse shear strains are used to avoid the shear locking problem, and the assumed covariant membrane strains which are separated from the covariant inplane strains by mid-surface interpolation, are applied to eliminate the membrane locking problem and also to improve the membrane bending performance. This element is free of serious shear and membrane locking problems and undesired spurious kinematic deformation modes. An incremental total Lagrangian formulation is presented which allows the calculation of arbitrarily large displacements and rotations. The resulting nonlinear equilibrium equations are solved by the Newton-Raphson method combined with load or arc-length control. The versatility and accuracy of this new degenerated shell element is demonstrated by solving several numerical examples.

DOI: 10.1088/0964-1726/17/01/015030
ABSTRACT: Active piezoelectric thin-walled structures, especially those with a notably higher membrane than bending stiffness, are susceptible to large rotations and transverse deflections. Recent investigations conducted by a number of researchers have shown that the predicted behavior of piezoelectric structures can be significantly influenced by the assumption of large displacements and rotations of the structure, thus demanding a geometrically nonlinear formulation in order to investigate it. This paper offers a degenerated shell element
and a simplified formulation that relies on small incremental steps for the geometrically nonlinear analysis of piezoelectric composite structures. A set of purely mechanical static cases is followed by a set of piezoelectric coupled static cases, both demonstrating the applicability of the proposed formulation.

ABSTRACT: The progressive introduction of advanced fibre composite materials into aerospace structures has enabled significant performance improvements to be achieved. Structures using these materials are generally designed so that their behaviour is essentially linearly elastic through to failure. The realisation of further significant weight reductions in light-weight aerospace structures is highly dependent on design technologies which will enable postbuckling stiffened panels to be utilised in primary structures. The capabilities of the finite element code, MSC/NASTRAN, to predict the onset of buckling and subsequent postbuckling behaviour of a blade-stiffened fibre composite panel have been investigated. The panel consists of T300/914 carbon/epoxy unidirectional tape and is reinforced by integral stiffeners. Basic modelling techniques for the efficient analysis of such postbuckling assemblies are presented. It is concluded that the prediction of their performance requires specialist modelling skills and a sound understanding of the behaviour of the composite materials used in the structure.

ABSTRACT: In stiffened panels with defects, such as skin delaminations or stringer debonding, buckling may occur prior to the designed critical buckling load. Depending on the damage parameters, such defects may also affect the post-buckling behaviour and consequently the structural performance. An automated finite element (FE) modelling tool has been developed to predict the post-buckling behaviour of panels. It was coupled with a linear elastic fracture mechanics approach to determine damage criticality, based on the “no-growth” principle. The structural behaviour in the post-buckling range and its interaction with the damage parameters were analysed. Local buckling occurred as a result of localised stiffness reduction in the damage region. Global buckling occurred when sufficient in-plane strain was reached. The onset of local buckling was an important factor on stringer debonding criticality as the local buckling mode had an effect on the corresponding global buckling. In comparison, the onset of local buckling for the skin delamination was lower due to the thin sub-laminate separation. However, it was less influential on the damage criticality because the local buckling slowly dissipated in the far post-buckling range. It was found that the initiation of local buckling, and the interaction between the local and global buckling mode, would determine the damage criticality.

ABSTRACT: In order to promote the efficient use of composite materials in civil engineering infrastructure, effort is being directed at the development of design criteria for composite structures. Insofar as design with regard to buckling of composite shells is concerned, it is well known that a key step is to investigate the influence of initial geometric imperfection on the non-linear behaviour of the composite shells. One possible approach is to use the validated numerical model based on the non-linear finite element analysis. Thus, the objective of this article is to present the formulation used in developing a composite shell element and to validate the element from the composite panels. The finite element used in the current study is an eight-noded shell element with six degrees of freedom per node. The non-linear formulation of the shell element is based on the updated Lagrangian method. The shell element is capable of small strain and large displacement analysis with finite rotations. In order to remove the rigid body rotation, a co-rotational method is used. The transverse shear deformation effects using the Reissner–Mindlin theory are included in formulating the linear and geometric stiffness matrix. Thus, the present composite shell element allows modeling of relatively thick composite plates and shells for both the linear and non-linear analyses. The validation of the composite shell element shows that the present results have very good agreement with existing references. Subsequently the postbuckling analyses for the modeling of the curved panel with initial imperfections are performed in order to investigate the effect of the initial geometric imperfection shape and amplitude. The results are used to estimate imperfection sensitivity for such panels.

ABSTRACT: The presence of in-plane loading may cause buckling of stiffened panels. An accurate knowledge of critical buckling load and mode shapes are essential for reliable and lightweight structural design. This paper presents some parametric studies on simply supported laminated composite blade-stiffened panels subjected to in-plane shear loading. A total of 450 models were analyzed using ANSYS 7.1 and a database is prepared for different plate and stiffener combinations. Studies are carried out by changing the panel orthotropy ratio, stiffener depth, pitch length (number of stiffeners), smeared extensional stiffness ratio of stiffener to that of the plate and extensional stiffness to shear stiffness ratio of the plate. Based on the studies, few important parameters influencing the buckling behaviour are identified and guidelines for better stiffener proportioning are developed, which will be helpful for the designer.

ABSTRACT: This article presents parametric studies on simply supported laminated composite stiffened panels subjected to in-plane shear loading. A number of models were analyzed using ANSYS and a database is prepared for blade-, angle-, T-, and hat-stiffened laminated composite panels. Studies are carried out by changing the type of stiffeners, the panel orthotropy ratio, smeared extensional stiffness ratio of stiffener to that of the plate, and extensional stiffness to shear stiffness ratio of the plate. The difference in buckling behavior of
different types of stiffened panels is presented. Based on key parameters influencing the buckling behavior, guidelines for better stiffener proportioning are developed, which will be helpful to the designers.

ABSTRACT: A generalized stochastic buckling analysis of laminated composite plates, with and without centrally located circular cutouts having random material properties, is presented under uniaxial compressive loading. In this analysis, the layerwise plate model is used to solve both prebuckling and buckling problems. The stochastic analysis is done based on mean centered first-order perturbation technique. The mean buckling strength of composite plates is validated with results available in the literature. It has been observed that the present analysis can predict buckling load accurately even for plates with large cutouts. Micromechanics based approach is used to study the effect of variation in microlevel constituents on the effective macrolevel properties like elastic moduli. Consequently, the effect of uncertainty in these material properties on the buckling strength of the laminated plates is studied. Parametric studies are carried out to see the effect of hole size, layups, and boundary conditions on the mean and variance of plate buckling strength.

ABSTRACT: Optimal design of laminated composite stiffened panels of symmetric and balanced layup with different number of T-shape stiffeners is investigated and presented. The stiffened panels are simply supported and subjected to uniform biaxial compressive load. In the optimization for the maximum buckling load without weight penalty, the panel skin and the stiffened laminate stacking sequence, thickness and the height of the stiffeners are chosen as design variables. The optimization is carried out by applying an ant colony algorithm (ACA) with the ply contiguous constraint taken into account. The finite strip method is employed in the buckling analysis of the stiffened panels. The results shows that the buckling load increases dramatically with the number of stiffeners at first, and then has only a small improvement after the number of stiffeners reaches a certain value. An optimal layup of the skin and stiffener laminate has also been obtained by using the ACA. The methods presented in this paper should be applicable to the design of stiffened composite panels in similar loading conditions.

ABSTRACT: This article presents a methodology and process for a combined wing configuration partial topology and structure size optimization. It is aimed at achieving a minimum structural weight by optimizing
the structure layout and structural component size simultaneously. This design optimization process contains two types of design variables and hence was divided into two sub-problems. One is structure layout topology to obtain an optimal number and location of spars with discrete integer design variables. Another is component size optimization with continuous design variables in the structure FE model. A multi city-layer ant colony optimization (MCLACO) method is proposed and applied to the topology sub-problem. A gradient based optimization method (GBOM) built in the MSC.NASTRAN SOL-200 module was employed in the component size optimization sub-problem. For each selected layout of the wing structure, a size optimization process is performed to obtain the optimum result and feedback to the layout topology process. The numerical example shows that the proposed MCLACO method and a combination with the GBOM are effective for solving such a wing structure optimization problem. The results also indicate that significant structural weight saving can be achieved.

ABSTRACT: This paper presents a theoretical study on the elastic-plastic interaction buckling of imperfect longitudinally stiffened panels under axial loads. A material and geometric nonlinear spline finite strip method is developed to analyse such interaction problems. The initial geometric imperfections and residual stresses due to welding are involved in the analysis. An iterative numerical procedure combining a modified arc-length method and Newton-Raphson iteration is employed for the solution of the nonlinear incremental equilibrium equations and a full range load deflection path is obtained. Numerical results are presented which show that the authors' method is not only an efficient tool but is also accurate in the analysis of large deflection elastic-plastic behaviour of folded plate structures.

ABSTRACT: The theoretical background and details of a computer program for the optimum design of multi-layered fibre composite stiffened plates (STIPSY) subjected to in-plane compression and secondary out-of-plane loading, are presented. The blade, angle and hat section stiffeners are considered in the program. The widths of the elements, the thickness of the three layers having commonly used fibre orientations (0°, ±45° and 90°) in each of the number of layers in each element are the design variables. Any desired set of constraints from the various serviceability, material strength, stability and side constraints available in the program may be invoked by the user along with the corresponding factor of safety. The Gradient Projection Method (GPM) and Sequential Unconstrained Minimization Technique (SUMT) are the alternate procedures available in the program to solve the resulting non-linear optimization problem. A few sample results are presented at the end.

ABSTRACT: An investigation into the buckling of stringer- or ring-stiffened laminated-composite circular-cylindrical shells subjected to axial compression or hydrostatic pressure has been undertaken. The stiffeners were made up of unidirectional fibre-reinforced epoxy while the shell laminate contained N orthotropic plies with equal amounts of fibres in the + theta-i and –theta-i directions in ith ply. Based on Koiter’s general theory of elastic stability, the stiffener eccentricity effect and the initial postbuckling behaviour were examined. It was found that, in every case studied, external stiffening was more efficient than internal stiffening, the buckling and initial postbuckling behaviour of stiffened laminated cylinders were significantly influenced by the laminate configuration. Consequently, taking the fibre orientations of lamina as optimizing parameters, a two-step optimization procedure was employed to maximize the buckling load of stiffened composite cylinders. The lamina fibre orientations of optimal shells were found to be strongly dependent on the reduced Batdorf parameter, Z.

ABSTRACT: A large number of internal resonances, sensitivity to small imperfections and to a small external non-conservative action are characteristic for a number of elastic shells subjected to conservative forces. It is shown that, in combination, these three features result in dynamic instability of a system, that manifests itself in the existence of a solution of the explosive instability type when the deviation from the equilibrium state becomes infinitely large in a finite time. A simple method is proposed to calculate the ultimately allowable load by which one should be guided in designing structures containing thin shells. This load calculated by a linear model corresponds to the appearance of the first internal resonance in the system. The results are illustrated by well-known experimental facts.

ABSTRACT: Within the framework of finite element analysis, an asymptotic method is presented for the study of geometrically nonlinear static behavior of thin structures under one-parameter conservative loading. The method can be applied when the prebuckling behavior is moderately non-linear so that the bifurcation analysis is no longer accurate enough. An iterative process makes it possible to find suitable deformation modes which enable a good approximation of the structural behavior around the buckling point. As in the Rayleigh-Ritz approach, a reduced energy can be formulated with only a small number of generalized degrees of freedom. The influence of small initial imperfections on the buckling load can easily be analyzed as in Koiter's asymptotic method. A comprehensive treatment and several improvements of this asymptotic iterative method are given and selected examples illustrate the basic features of the method.

ABSTRACT: The paper presents theoretical and experimental investigations on three varying-thickness circular cylinders, which were tested to destruction under external hydrostatic pressure. The five buckling theories that were presented were based on inelastic shell instability. Three of these inelastic buckling theories adopted the FEM
and the other two theories were based on a modified version of the much simpler von Mises theory. Comparison between experiment and theory showed that one of the inelastic buckling theories that was based on the von Mises buckling pressure gave very good results while the two finite element solutions, obtained by dividing the theoretical elastic instability pressures by experimentally determined plastic knockdown factors, gave poor results. The third finite element solution, which was based on material and geometrical nonlinearity, gave excellent results. Electrical resistance strain gauges were used to monitor the collapse mechanisms, and these revealed that collapse occurred in the regions of the highest values of hoop stress, where considerable deformation took place.

ABSTRACT: Flexible shells, designed to sustain elastic displacements, have a “semimembrane” type of deformation, described by simplified equations. In what follows, flexible shell equations are derived and used to analyse bending of curved tubes and buckling of tubes and toroidal shells under external pressure, as interdependent problems. Design formulas and curves are presented.

References listed at the end of the paper:

ABSTRACT: Flexure of cylinders and slightly curved pressurized tubes is investigated for given conditions on the edges, in particular for end flanges. The large precritical deformation is determined with the help of the Flexible-Shell-Theory. The stability analysis of the deformed shell is carried out with the aid of the hypothesis of local buckling. The critical bending moments which determine the collapse load are presented for various tube lengths, initial curvatures and external-pressure values by graphs.
References listed at the end of the paper:

ABSTRACT: A class of problems is considered where the buckling initially starts only in a part of the shell—locally. The stability analysis is focused on the zone of initial buckling. This leads to radical simplification. First the basic hypothesis and stability equations are formulated. Closed-form stability criteria asymptotically exact for very thin shells are discussed. This gives sufficient conditions for the local character of buckling and for the
adequacy of the asymptotic approximation. The analysis taking into account the variation of stresses and shape inside the buckling zone results in a check of stability by hand calculations or by simple coding of a desk-top computer. The adequacy of the simplest representation of the stress and strain variation in the buckling zone is tested.

ABSTRACT: This paper is concerned with further development of tube-analysis methods which are as simple as necessary for design and as accurate as possible in the shell theory. The basic assumptions are stated in Section 2. For ‘long’ tubes their accuracy is estimated in the course of derivation and simplification of nonlinear equations of axisymmetric flexure (Section 3). These equations and the estimates of the assumptions are extended to two-dimensional problems in Section 4. Equations of the semi-momentless theory encompassing shear deformation and appropriate edge conditions are discussed in Sections 5 and 6. Their solution, including a simple approximation, is in Sections 7–9 preceded by known calculations and experiment.

ABSTRACT: Specialization of the general thin-shell theory for the class of large deformations realizable by small strain is considered. This leads in three different ways to the intrinsic nonlinear theory of flexible shells. As an illustration, large displacements and rotations culminating in collapse of finite-length tubes are investigated.

References listed at the end of the paper:

ABSTRACT: The thin-shell theory is specialized for those large deformations realizable by small strain. This provides three different ways leading from the general theory to the intrinsic non-linear theory of flexible shells. The theory is applied to large elastic displacements of finite-length tubes. Their collapse is described as starting by local instability.

ABSTRACT: For small-strain unrestricted deformation of thin elastic shells the field equations and variational principles are rederived in terms of variables immediately representing physical quantities. The relevant strain and stress tensors turn out to be identical to those commonly known as the ‘modified’ and the ‘best’. The nonlinear theory exhibits a static-geometric duality. For orthogonal coordinates the tensor-form theory leads to a modification of the Luré–Novozhilov formulation. The general theory is specialized to that of ‘quasi-shallow shells’, to the membrane theory and to flexible-shell theory, which are explored with respect to basic hypotheses and accuracy.

ABSTRACT: The theory of small-strain unrestricted deformation of thin elastic shells is specialized to the ‘Donnell-type’ theory of quasi-shallow shells, which owes its consequent - intrinsic and dual - formulation to
the idea first enunciated by Avinoam Libai. This theory is explored with respect to the accuracy, adequacy range and the physical meaning of its basic hypotheses.

ABSTRACT: This paper presents an analysis of the post-buckling behaviour of isotropic cylindrical and conical shells under axial compression. The starting point of the paper is Lagrange's variational principle, the application of which consists in assuming a kinematically admissible strain and displacement field. The field is determined considering the geometry of quasi-isometric deformations of the shell after buckling. That permits solving the problem with no limitation on the magnitude of the displacements.

ABSTRACT: The use of air-supported membranes has attracted considerable attention in recent years. There are, however, a number of problems in the behavior of these structures that have not been fully investigated. For example, the problem of lateral stability of such membranes has not been discussed heretofore. The present paper presents an analysis of the sidesway instability of a cylindrical air-supported membrane with vertical longitudinal axis, subjected to concentrated loads applied nonsymmetrically. A critical value of the load is established at which the configuration of these structures changes dramatically. During such change the lower portion of the membrane comes into contact with the support surface. For the problem treated, safe load limits, critical lengths, and critical weight densities for the membrane are derived. The Lagrangian variational method is used throughout the paper in obtaining solutions.

DOI: 10.1007/978-3-642-82776-1_27
SUMMARY: The paper is devoted to the description of the present state of knowledge in the theory of inelastic shells under concentrated and local loads. Problems of current interest, and in the broad sense, the analytical and numerical methods that can be brought to bear, are discussed. Other problems involving stress concentration in shells, such as crack propagation and concentration of stresses caused by irregularities of the shape, or holes and cutouts, are not the subject of the paper. The action of concentrated loads on shells has drawn the attention of many researchers for the last 20 years. The problems concerning stress and displacement distribution in linear, elastic thin shells under the static action of concentrated loads applied at one point of shell surface, or subjected to locally distributed loads, were examined at first and were the subjects of those early investigations. Many papers from the western countries as well as from the U.S.S.R. were published in those years. Mostly, the linear theory of shells was the starting point of these works. This area seems to be sufficiently explored at present. However, as far as we consider the similar problems in inelastic, non-linear shells, we recognize that many problems are not yet solved or are not solved in a satisfactory, general manner. The rapid expansion of numerical methods and techniques in recent years has enabled the solution of many difficult problems. However, these solutions usually concern particular situations and are often difficult to generalize. The state of knowledge concerning the following problems of inelastic shells is presented in the paper.
1) The geometrical non-linearities, large deformations of elastic shells under local loads and complex loads when the local, concentrated load is accompanied by a distributed general load.
2) Contact problems in shells involving the geometrical and physical non-linearities
3) Problems related to concentrated loads acting on shells made of inelastic materials
4) Elasto-plastic behaviour of shells under concentrated loads associated with large deformations of shells, collapse and limit local loads.
5) Simplified solutions of dynamical problems.
6) Optimum design of shells loaded by concentrated forces. The paper covers both the results of experimental investigations in each of the above-mentioned areas, as well as the description of the analytical and numerical methods used.

ABSTRACT: Using Donnell-type shell theory a simple and exact procedure is presented for linear buckling analysis of laminated conical shells, with orthotropic stretching-bending coupling, under axial compressive load and external pressure. The solution is in the form of a power series in terms of a particularly convenient coordinate system. By analysing the buckling of a series of conical shells, under various boundary conditions and different material coefficients, the validity of the presented procedure is confirmed.

ABSTRACT: Vibration and buckling of curved plates, made of hybrid laminated composite materials, are studied using first-order shear deformation theory and Reissner's shallow shell theory. For an initial study, only simply-supported boundary conditions are considered. The natural frequencies and critical buckling loads are calculated using the energy method (Lagrangian approach) by assuming a combination of sine and cosine functions in the form of double Fourier series. The effects of curvature, aspect ratio, stacking sequence and ply-orientation are studied. The non-dimensional frequencies and critical buckling load of a hybrid laminate lie in between the values for laminates made of all plies of higher strength and lower strength fibres. Curvature enhances natural frequencies and it is more predominant for a thin panel than a thick one.

ABSTRACT: The paper is devoted to assessing the optimal arrangements of hybrid laminated faces of sandwich panels in order to maximize local buckling loads corresponding to the wrinkling of compressed faces. The analysis is carried out by modelling compressed faces as thin unsymmetric laminates resting on elastic two-parameter foundations. The First-order Shear Deformation Theory, in conjunction with the Rayleigh-Ritz method, has been used to evaluate buckling loads of simply supported flat laminates subjected to in-plane biaxial compression and shear forces. A numerical investigation is intended to support evidence for the
influence of laminate parameters (fibre orientation, geometrical dimensions) and foundation parameters (modulus of subgrade reaction and shear modulus); obtained results are reported and discussed in the paper.

ABSTRACT: The structural performance of sandwich panels made with hybrid laminated faces and a transversely flexible core can be optimised by varying the mechanical and geometrical parameters characterising both the faces and the core, taking into account also the whole cost. In particular the hybridisation technique applied to the faces seems to be a very attractive solution, giving an improvement from both a mechanical and economical point of view. However, because of the out of plane flexibility of the core and the great slenderness of these structures, instability problems assume a relevant role from a static point of view, becoming a complex phenomenon as well. In this paper a modified first order shear deformation theory has been used, which treats the displacement field of the sandwich panels as a combination of different buckling modes. Buckling loads are finally obtained as a solution of an eigenvalue problem by means of an energetic algorithm solved by the Rayleigh-Ritz method. The influence of mechanical and geometrical parameters, characterising the composite laminated faces and the core, on buckling phenomena were investigated for different in plane load conditions. A numerical FEM approach was also employed; comparisons between FEM and analytical results, in which some key parameters were varied, show the effectiveness of the analytical model.

ABSTRACT: A free vibration response of arbitrarily laminated – crafted with advanced fiber reinforced composite materials – thin and shallow cylindrical panels on rectangular planform with simply supported boundary conditions is analytically investigated. The thin shallow shell formulation of Reissner that follows the classical Kirchhoff–Love hypothesis of small displacements is considered to include arbitrarily laminated behaviors. The simply supported boundary condition having normal, tangential, and transverse displacements restrained at the edges is implemented. The solution functions in a form of mixed boundary continuous and discontinuous double Fourier series are assumed into the analytical solution formulation. The efficiency and accuracy of the solution methodology are determined by studying numerically the convergence behavior of frequencies for various parametric effects. The analytically obtained numerical results and mode shapes are compared with available finite element solutions, and the analytical results can be capitalized as base-line solutions for future comparisons.

ABSTRACT: Large deflections of shallow and deep spherical shells under ring loads are studied. The axisymmetric problem is solved through a Newton-Raphson technique on discretized nonlinear shell equations. Comparison of computed load-deflection curves to experimental data from both thick and thin shells generally
shows good agreement in peak loads and the type of instability. For a point load, the load increases monotonically with deflection; as the ring radius increases, transition-type (snap-through) and then local buckling occurs. In addition, the pre- and post-buckled mechanical behaviors of the shell are examined.

ABSTRACT: This paper examines the accuracy of a modified Reissner-Simmonds theory for thickwalled, rubberlike shells. The theory, which is valid for large membrane and moderately large bending strains, includes the effects of transverse shear deformation and transverse normal stress and strain. To these features, the present work adds hydrostatic pressure through a modified strain-energy density function. Shell theory and finite elasticity theory solutions are compared for two problems: cylindrical bending of a plate and combined extension, inflation, and torsion of a circular cylinder. The results show that the modified theory gives highly accurate stress distributions for most of the loading cases studied. Accuracy is good in cylinders as thick as R/h = 5 and generally improves with increasing reference surface stretching.

ABSTRACT: The problem of a steadily spinning shallow elastic shell of revolution under a uniform pressure distribution is investigated by perturbation and asymptotic methods. Accurate numerical solutions are also obtained to confirm the adequacy of perturbation and asymptotic solutions. The limiting case of a flat plate is first solved for the entire range of values of the two load parameters. The results provide a different interpretation of the existing nonlinear membrane solution for the same problem. Except for a narrow range of parameter values, the boundary value problem for the shell case is reduced either to the solution of a sequence of linear problems or to the solution of a previously solved nonlinear problem modified by the solutions of a sequence of linear problems. The analysis for the shell problem under a combined centrifugal and pressure loading shows a complex interplay among the load and geometric parameters. It also enables us to consider a number of previously investigated problems as special cases of our problem and to offer a unified treatment of these problems.

ABSTRACT: The stretching of a square sheet along one of its diagonals, called “Yoshida Test”, has been developed to simulate the wrinkling behavior in press forming of steel sheets into autobody panels. The finite deformation, onset of wrinkling, and growth of wrinkles in such a specimen are investigated. Hill's yield criterion for sheet materials having the normal anisotropy and Hill's quasistatic bifurcation criterion are employed. The growth of wrinkles in the finite deformation process is incrementally and numerically determined by a thin shell finite element in a convected coordinate system. The Lagrangian formulation of the thin shell finite element is based on Hill's variational principle for elastic-plastic solids, a modification of Love-Kirchhoff postulates and a quasiconforming element technique. The shell element fulfills the interelement C1 continuity condition in a variational sense. Reasonable agreements between the present numerical results and available analytical and experimental results are shown.

ABSTRACT: A solving method is applied to conduct research on the non-linear thermal buckling behavior of local delamination near the surface of fiber-reinforced laminated cylindrical shell. The shape of delaminated region considered is elliptic, triangular and lemniscates. Young's modulus and the thermal expansion coefficient of material are treated as a function of temperature, which leads to the force in the middle plane of the sub-laminated shells a non-linear function of temperature. The critical temperatures of laminated cylindrical shells with various shaped local delamination, different stacking patterns and different radius of the laminated cylindrical shells are obtained by making use of the energy principle. It has been found that linear solution of the critical buckling temperature gives a higher value than that of non-linear consideration.

ABSTRACT: A theoretical method is developed to investigate the effects of thermal load and ring stiffeners on buckling and vibration characteristics of the functionally graded cylindrical shells, based on the first-order shear
deformation theory (FSDT) considering rotary inertia. Heat conduction equation across the shell thickness is used to determine the temperature distribution. Material properties are assumed to be graded across the shell wall thickness of according to a power-law, in terms of the volume fractions of the constituents. The Rayleigh-Ritz procedure is applied to obtain the frequency equation. The effects of stiffener's number and size on natural frequency of functionally graded cylindrical shells are investigated. Moreover, the influences of material composition, thermal loading and shell geometry parameters on buckling and vibration are studied. The obtained results have been compared with the analytical results of other researchers, which showed good agreement. The new features of thermal vibration and buckling of ring-stiffened functionally graded cylindrical shells and some meaningful and interesting results obtained in this article are helpful for the application and the design of functionally graded structures under thermal and mechanical loads.

ABSTRACT: This article is the result of an investigation on the effect of thermal load on vibration, buckling and dynamic stability of functionally graded cylindrical shells embedded in an elastic medium, based on the first-order shear deformation theory (FSDT) considering rotary inertia and the transverse shear strains. A heat conduction equation along the width of the shell is applied to determine the temperature distribution. Material properties are assumed to be graded with distribution along the width according to a power-law in terms of the volume fractions of the constituents. Calculations, effects of material composition, thermal loading, static axial loading, medium stiffness and shell geometry parameters on vibration, buckling and the parametric resonance are described. The new features of thermal vibration, buckling and dynamic stability of functionally graded cylindrical shells embedded in an elastic medium and some meaningful and interesting results in this paper are helpful for the application and design of functionally graded structures under thermal and mechanical loads.

ABSTRACT: This paper presents the report of an investigation into thermoelastic vibration and buckling characteristics of the functionally graded piezoelectric cylindrical, where the functionally graded piezoelectric cylindrical shell is made from a piezoelectric material having gradient change along the thickness, such as piezoelectricity and dielectric coefficient et al. Here, utilizing Hamilton’s principle and the Maxwell equation with a quadratic variation of the electric potential along the thickness direction of the cylindrical shells and the first-order shear deformation theory, and taking into account both the direct piezoelectric effect and the converse piezoelectric effect, the thermoelastic vibration and buckling characteristics of functionally graded piezoelectric cylindrical shells composed of BaTiO3/PZT - 4, BaTiO3/PZT - 5A and BaTiO3/PVDF are, respectively, calculated. The effects of material composition (volume fraction exponent), thermal loading, external voltage applied and shell geometry parameters on the free vibration characteristics are described, and
the axial critical load, critical temperature and critical control voltage are obtained.

ABSTRACT: (none given)

ABSTRACT: The results from studies into the vibrations and dynamic stability of thin elastic shells with initial geometric imperfections are analyzed. The corresponding dynamic problems are solved in both linear and nonlinear formulations. The influence of initial axisymmetric and nonaxisymmetric deflections on natural, forced, parametrically excited, and self-excited vibrations (flutter) is studied. The dynamic buckling of imperfect shells under short-term impulsive loading is examined. Some aspects of experimental investigation into the vibrations of shells with small geometric imperfections (deviations from the design shape) are considered.

ABSTRACT: Results of systematic study of the stability and nonlinear vibrations of thin cylindrical shells interacting with a fluid flow are presented. The main patterns of dynamical deformation of shells during divergence and flutter are considered. The effect of different structural features (initial geometrical imperfections, added concentrated masses, boundary conditions, longitudinal and transverse static loads) on the critical (divergence and flutter) velocities is analyzed. The amplitude–frequency response of shells to external periodic radial loads and internal periodic pressure caused by small pulsations of the fluid velocity is determined. A method is proposed to solve nonlinear problems describing nonstationary processes of passing resonance zones by shells interacting with the fluid flow.

ABSTRACT: The objective of this paper is to investigate numerically the influence of the winding-induced geometrical imperfection on the elastic buckling load of submersible composite hulls. A linear Sanders-type buckling model of laminated cross-ply cylinders is developed. The imperfection is modeled by an axisymmetric thickness default of each composite ply by analogy to the real laminate ply imperfections. The effects of these defaults are taken into account by correcting the laminated stiffness coefficients. Numerical examples have been performed analyzing three types of stacking sequences for thin carbon/epoxy cylinders. For each case, the geometrical imperfections induce significant buckling load reductions. The results of the proposed approach appear to be in good agreement with standard FEM code calculus.

ABSTRACT: This paper deals with the optimal design of deep submarine exploration housings and autonomous underwater vehicles. The structures under investigation are thin-walled laminated composite unstiffened vessels. Structural buckling failure due to the high external hydrostatic pressure is the dominant risk factor at exploitation conditions. The search of fiber orientations of the composite cylinders that maximize the stability limits is investigated. A genetic algorithm procedure coupled with an analytical model of shell buckling has been developed to determine numerically optimized stacking sequences. Characteristic lamination patterns have been obtained. FEM analyses have confirmed the corresponding significant increases of buckling pressures with respect to initial design solutions. Experiments on thin glass/epoxy and carbon/epoxy cylinders have been performed. The measured buckling pressures appear to be in good agreement with numerical results and demonstrate the gains due to the optimized laminations.

ABSTRACT: Based on the concept of an “intermediate” class of deformations, a theory suitable for the nonlinear static and dynamic analysis of transverse shear deformable circular and noncircular cylindrical shells, composed of an arbitrary number of linearly elastic monoclinic layers, is developed. The theory is capable of satisfying zero shear traction boundary conditions at the inner and outer shell surfaces. Upon assuming that the shell is subjected to a certain initial stress state and applying the highly nonlinear governing equations derived to the adjacent equilibrium criterion, a set of Love-type linearized equations is further derived. These latter equations are suitable for buckling and/or vibration analyses; in a companion paper, they are solved and used for the study of the influence of transverse shear deformation on the buckling loads of axially compressed cross-ply laminated circular and oval cylindrical shells.

ABSTRACT: This numerical study deals with the stiffened composite underwater vessel design. The structures under investigation are laminated cylinders with rigid end-closures and internal circumferential and longitudinal unidirectional composite stiffeners. Structural buckling induced by the high external hydrostatic pressure is considered as the major failure risk. An optimization design tool has been developed to obtain the reinforcement definition which maximizes the limit of stability: an analytical model of cylindrical composite shell buckling
has been coupled to a genetic algorithm procedure. The numerical optimization tests carried out corroborate design tendencies validated previously by experiments.

ABSTRACT: The present work deals with the numerical prediction of the post buckling progressive and final failure response of stiffened composite panels based on structural nonlinear finite element methods. For this purpose, a progressive failure model (PFM) is developed and applied to predict the behaviour of an experimentally tested blade-stiffened panel found in the literature. Failure initiation and propagation is calculated, owing to the accumulation of the intralaminar failure modes induced in fibre reinforced composite materials. Hashin failure criteria have been employed in order to address the fiber and matrix failure modes in compression and tension. On the other hand, the Tsai-Wu failure criterion has been utilized for addressing shear failure. Failure detection is followed with the introduction of corresponding material degradation rules depending on the individual failure mechanisms. Failure initiation and failure propagation as well as the post buckling ultimate attained load have been numerically evaluated. Final failure behaviour of the simulated stiffened panel is due to sudden global failure, as concluded from comparisons between numerical and experimental results being in good agreement.

ABSTRACT: An experimental study was conducted in order to verify a proposed equation for the minimum required stiffness for longitudinal stiffeners attached on compression plates. Nine test specimens of stiffened plates were fabricated and tested to their ultimate strengths. Test results are compared with the maximum strengths predicted for stiffened plates by finite element analysis and by the proposed SSRC type critical stress curve. Fairly good correlations were observed, thereby confirming experimentally the adequacy of the proposed
equation for the minimum required stiffness of the longitudinal stiffener attached to the compression panel and a modified SSRC type critical stress curve encompassing both the buckling ranges of plastic yield and the transition zones. A set of conclusions is drawn from the experimental studies as to the buckling behaviors of stiffened plates.

ABSTRACT: This paper presents an optimum design of longitudinal stiffeners for box-girder compression flanges. The buckling behavior of longitudinally stiffened compression flanges has drawn considerable interest from early pioneers of theoretical mechanics, as illustrated by Timoshenko and Gere and Bleich. The longitudinally stiffened compression plate structural members generally render an economical structure by efficiently proportioning the material to resist the induced compressive stresses. This study presents results that are based on 3D finite-element analysis of several hundred hypothetical compression flange models stiffened by varying numbers of longitudinal stiffeners with realistic dimensions. The thickness of the compression flange t was varied from 0.50 to 2.50 in. (from 12.7 to 63.5 mm), the number of longitudinal stiffeners n was varied from 1 to 4, and the aspect ratio of the plate panel α was varied from 1 to 5. Two different plate transverse slenderness ratios w/t were analyzed. Analytical data were reduced using nonlinear regression analysis to a simplified design equation suitable for practicing engineers. Several example problems are given to illustrate the use of the regression equation. Comparative analyses are also made to demonstrate the versatility and reliability of the analytical study conducted.

ABSTRACT: Optimization is a central concept in the design of composite structures because of the adaptability of composite materials to a given design situation. Design parameters such as layer thicknesses and ply angles can be employed to great effect to achieve an optimized structure with improved weight and stiffness characteristics. This chapter deals with the lay-up optimization of laminated plates subject to buckling loads. A survey of the subject is presented and the optimal configurations of rectangular laminates are discussed. Designs are studied with respect to layer thicknesses and ply angles for symmetrical and antisymmetrical laminates of hybrid and non-hybrid construction. The effect of bending-twisting coupling on optimal designs is discussed and the optimal configurations with and without this effect are compared. Several factors affecting optimal designs are highlighted. These factors include the use of discrete ply angles and layer thicknesses, restrained edges, shear deformation, cut-outs, thermal loading, strength and stiffness constraints, multiple design objectives and shape design.

ABSTRACT: Multiobjective design of a laminated cylindrical shell is obtained with the objectives defined as the maximization of axial load and external and internal pressures subject to a strength constraint. The failure under axial load and external pressure may occur by buckling. The ply angle is taken as the design variable. The weighted global criterion method is employed to solve the vector-optimization problem, which involves minimization of the distance to ideal solution vector in L2 metric. A symmetrically laminated and balanced shell is considered as an example. Pareto optimal solutions are given for two- and three-objective design problems, and numerical results are presented in the form of tradeoff curves and surfaces. The effects of problem parameters are investigated, and the results are given for various weighting factors and shape parameters.

ABSTRACT: The multiobjective design of a symmetrically laminated shell is obtained with the objectives defined as the maximization of the axial and torsional buckling loads. The ply angle is taken as the optimizing variable and the performance index is formulated as the weighted sum of individual objectives in order to obtain
Pareto optimal solutions of the design problem. Single objective design results are obtained and compared with the multiobjective design. The effect of weighting factors on the optimal design is investigated. Results are given illustrating the dependence of the optimal fibre angle and performance index on the cylinder length, radius and wall thickness.

ABSTRACT: The effects of large vibration amplitudes on the first and second coupled radial-circumferential mode shapes of isotropic circular cylindrical shells of infinite length are examined. A theoretical model based on Hamilton’s principle and spectral analysis developed previously for clamped–clamped beams and fully clamped rectangular plates is extended to shell type structures, reducing the large-amplitude free vibration problem to the solution of a set of non-linear algebraic equations. The transverse and circumferential displacements are assumed to be harmonic and expanded in the form of a finite series of functions. The Donnel–Mushtari shell theory, taking into account the coupling between extensional and flexural deformations is used. Then, the non-linear deformation energy is expressed by taking into account the non-linear term due to the considerable stretching of the middle surface of the shell induced by large deflections. Tables of numerical results are given for the first and second non-linear modes, for a wide range of the vibration amplitude, which may be used for engineering purposes. For each value of the vibration amplitude considered, the corresponding contributions of the basic functions defining the non-linear transverse and circumferential displacement shapes are given, with the corresponding non-linear frequencies. Selected plots of mode shapes and bending stress distributions are presented, with an extensive discussion of the effects of non-linearity on the dynamic behaviour of shells.

ABSTRACT: The non-linear dynamic behaviour of infinitely long circular cylindrical shells in the case of plane strains is examined and results are compared with previous studies. A theoretical model based on Hamilton's principle and spectral analysis previously developed for non-linear vibration of thin straight structures (beams
and plates) is extended here to shell-type structures, reducing the large-amplitude free vibration problem to the solution of a set of non-linear algebraic equations. In the present work, the transverse displacement is assumed to be harmonic and is expanded in the form of a finite series of functions corresponding to the constrained vibrations, which exclude the axisymmetric displacements. The non-linear strain energy is expressed by taking into account the non-linear terms due to the considerable stretching of the shell middle surface induced by large deflections. It has been shown that the model presented here gives new results for infinitely long circular cylindrical shells and can lead to a good approximation for determining the fundamental longitudinal mode shape and the associated higher circumferential mode shapes \((n>3)\) of simply supported circular cylindrical shells of finite length. The non-linear results at small vibration amplitudes are compared with linear experimental and theoretical results obtained by several authors for simply supported shells. Numerical results (non-linear frequencies, vibration amplitudes and basic function contributions) of infinite shells associated to the first four mode shapes of free vibrations, are obtained, using a multi-mode approach and are summarized in tables. Good agreement is found with results from previous studies for both small and large amplitudes of vibration. The non-linear mode shapes are plotted and discussed for different thickness to radius ratios. The distributions of the bending stresses associated with the mode shapes are given and compared with those obtained via the linear theory.

ABSTRACT: The mechanism of wind-induced ovalling vibrations of cylindrical shells is numerically investigated by using a vortex method. The subject of this paper is limited to a two-dimensional structure in the subcritical regime. The aerodynamic stability of the ovalling vibrations in the second to fourth circumferential modes is discussed, based on the results of a forced-vibration test. In the analysis, two modal configurations are considered; one is symmetric and the other is anti-symmetric with respect to a diameter parallel to the flow direction. The unsteady pressures acting on a vibrating cylinder are simulated and the work done by them for one cycle of a harmonic motion is computed. The effects of a splitter plate on the flow around the cylinder as well as on the aerodynamic stability of the ovalling vibrations are also discussed. The consideration on the mechanism of ovalling vibrations is verified by the results of a free-vibration test.

ABSTRACT: This paper presents the effect of cone vertex angle on the crushing behaviour, energy absorption, failure mechanism and failure mode of filament-wound laminated (FWL) cone–cone intersection composite shell. The static crushing behaviour of FWL cone–cone intersection composite shell under uniform axial load is investigated experimentally. Two types of composites were tested, namely, carbon fibre/epoxy and glass fibre/epoxy. The cones vertex angles tested are 10°, 15°, 20° and 25°. Failure modes were examined using the photographs taken during crushing the specimens. The results showed that the initial failure was dominated by interfacial and shear failure, while the delamination and eventually fibre fracture dominated the failure mechanism after the initial first failure. The results also showed that the structure with vertex angles 20° and
25° exhibited good energy absorption capability. The volume reduction is obtained and found to be significant for these sets of angles.

ABSTRACT: This paper examines the effect of residual fabrication stresses on the crushing behaviour, energy absorption, failure mechanism and failure mode of a filament wound laminated conical composite shell. The static crushing behaviour of the conical composite shell under uniform axial compressive load is investigated experimentally. The cone vertex angles were 0°, 6°, 12° and 18°. The numerical result shows that residual stresses developed have been concentrated at the small ends of cones. Experimental results obtained from this investigation show that the initial failure was dominated by interfacial and shear failure, while the delamination and eventually fibre fracture were dominated by the failure mechanism after the initial failure. It is also found that the static crushing behaviour of the conical shell is highly sensitive to the change in cone vertex angle, which strongly dominates the residual fabrication stress development. It can be deduced that as the axial residual stress increases, the initial failure load decreases.

ABSTRACT: For elastic-viscoplastic structures the classical elastic-plastic bifurcation approach to inelastic buckling is not valid. Only an elastic bifurcation point exists in the elastic-viscoplastic case, and the inelastic buckling behaviour is controlled by a strong sensitivity to small imperfections. However, in the last few years some papers have been published on an approximation that leads to a so-called viscoplastic bifurcation point. Results of accurate numerical analyses for elastic-viscoplastic columns are compared with predictions based on the approximate bifurcation approach. In some cases the bifurcation approach gives a poor approximation of the actual elastic-viscoplastic column behaviour, whereas in other cases the discrepancy is less pronounced. The simple column model gives a clear illustration of the effect, but similar results for plates are also mentioned briefly.

ABSTRACT: Free vibration of a thin spherical shell filled with a compressible fluid is investigated. The interactions at the interface between the elastic structure and the compressible fluid are taken into account. The objective of this study is to develop a hybrid numerical technique for the free vibration analysis of sound-structure interaction problems. The boundary element method is employed for modeling the acoustic disturbances in the cavity, while the finite element method is used for modeling the structural dynamics of the shell. The formulations are then combined into a coupled numerical scheme for the total pressure-displacement field. Natural frequencies and mode shapes are calculated by using the singular value decomposition algorithm.
Physical insights into the resonance phenomena associated with sound-structure interactions are derived from the comparison between the results of the thin spherical shell, with and without the fluid loading effect.

ABSTRACT: In offshore, aerospace and car industries, circular cylindrical shells are frequently used as structural components. In many applications, this is due to a requirement for a high axial compressive strength-to-weight ratio and an ability to absorb energy during complete structural collapse. On the other hand, the high imperfection sensitivity of circular cylindrical shells under axial compression requires a thorough knowledge of the occurrence of geometric imperfections and their influence on the collapse behaviour of the structure. In addition to the geometric imperfection sensitivity, a rate dependence of the material behaviour may have a significant influence on the collapse behaviour.

ABSTRACT: In this paper we develop a general theory of thin inelastic shells for finite deformations. In a first step we present a general three-dimensional theory of inelastic material behavior. Any inelastic constitutive model with internal state variables can be used which is formulated without the explicit notion of a yield surface. In a next step we investigate the simplifications of our constitutive theory resulting from the assumption of small elastic strains which is well established for metallic materials. Furthermore, we introduce the assumption of persistent isotropy. Finally, we present the weak form of the balance of equilibrium and
indicate its linearization. To formulate our shell theory we first present the geometrical description of thin shells in the reference and current configuration, respectively. Next we introduce strain measures for the shell where we include transverse shear strains and also thickness changes of the shell. The shell theory is formulated by application of the projection method, i.e. we integrate all relevant equations of the three-dimensional theory over the shell thickness. This projection leads to a strictly two-dimensional shell theory which is formulated entirely on the shell midsurface. Finally, we indicate the numerical implementation of our shell theory.

ABSTRACT: The viscoelastic buckling and postbuckling behaviors of fiber-reinforced plastic (FRP) circular cylindrical shells, operating in the hygrothermal environment, subjected to uniform external pressure are investigated in this study. The FRP is assumed to be a hygrothermoeologically simple material (HTSM). The analysis is conducted within the framework of the quasi-elastic approach. The finite element method is employed to examine both buckling and post-buckling behaviors for shells having arbitrary lay-ups. The arc-length algorithm is incorporated into the finite element formulations to trace the post-limit equilibrium path. The structural responses of Glass/Epoxy shells are reported.

Huang (Department of Mechanical and Marine Engineering, National Taiwan Ocean University, Keelung, Taiwan, R.O.C.), “Influence of shear correction factors in the higher order shear deformation laminated shell theory”, International Journal of Solids and Structures, Vol. 31, No. 9, May 1994, pp. 1263-1277, doi:10.1016/0020-7683(94)90120-1
ABSTRACT: A third-order shell theory based on Reddy's parabolic shear strain distribution is presented. Upon applying the Donnell shallow shell approximation, the present theory leads to Reddy's formulation in the case that the laminate has a Euclidean middle surface and constant principal radii of curvatures. To accommodate the effect of the continuity condition of interlaminar transverse shear stresses, the shear correction factors are introduced to modify the shear strains in the present higher order theory. The shear correction factors are calculated using an iterative formulation based on the “shear strain energy equivalence”. The shell solutions are compared with the elasticity solutions to assess the improvement of using the higher order theory, coupled with the shear correction factors, in predicting the structural responses of moderately thick laminates.

ABSTRACT: Composite materials exhibit a scatter in their properties. This is generally ignored in conventional structural analysis leading to results that may be non-conservative. The present study discusses the critical buckling analysis for circular cylindrical shells of laminated composites incorporating the effects of randomness in the material properties. A perturbation approach has been employed to develop expressions for the mean and variance of the critical buckling load in terms of material property statistics. Working of the approach has been illustrated with an example.

ABSTRACT: A generalized layer-wise stochastic finite element formulation is developed for the buckling analysis of both homogeneous and laminated plates with random material properties. The pre-buckled stresses are considered in the derivation of geometric stiffness matrix and the effect of variation in these stresses on the mean and coefficient of variation of buckling strength is studied. The mean buckling strength of plates under uniform stress assumption exactly matches with those reported in the literature. However, it is shown that the actual mean buckling strength of plates can be significantly different based on the pre-buckled stress analysis which depends on boundary constraints, principal material directions, aspect and thickness ratios of plates. The statistics of buckling strength is determined using a Taylor series expansion based mean centered first order perturbation technique. The stochastic finite element solutions obtained using layer-wise plate theory is also validated with analytical solutions presented in this paper. Parametric studies are conducted for different aspect ratios, ply orientations and boundary conditions.

ABSTRACT: When a laminated composite plate is subjected to a compressive edge force lying in the plane of the plate, failure can occur by buckling at a stress below the strength of the material. Critical buckling loads of orthotropic plates are usually calculated using the analytical solutions which are based on the assumption of uniform end loads, despite the fact that real structures are subjected to various non-uniform inplane loads. This paper examines the buckling behavior of the orthotropic plates under non-uniform inplane loads with different boundary conditions (all edges simply supported, two loaded edges clamped and others simply supported, and all edges clamped) using the finite element method (FEM). Numerical results show that the existing formulas for buckling load based on the uniform load assumption leads to overestimation of buckling loads.

ABSTRACT: Optimum design of honeycomb sandwich constructions with buckling constraints is treated in this paper. Four modes of instability for honeycomb sandwich structures are considered in buckling constraints, including overall buckling, core shear instability, face wrinkling, and monocell buckling. The face thicknesses, core depth, cell wall thickness, and diameter of an inscribed circle in a honeycomb cell are taken as design variables. Eight-nodal quadrilateral honeycomb sandwich isoparametric shell elements and hybrid approximation techniques in combination with the dual solution are used. Some comparisons are also made between the cases with and without buckling constraints. Numerical results are given for four examples.

ABSTRACT: The finite element method is applied to study the problem of moisture and temperature effects on the stability of a general orthotropic cylindrical composite shell panel subjected to axial or in-plane shear loading. The element employed is a nine-node isoparametric shell element. As the hygrothermal effects on the elastic properties of the matrices and the fibers are very different, the degradation of elastic moduli, the transverse shear effect and the induced initial stress are all considered. Numerical investigation shows that if the temperature increases from 300 to 422 K and the moisture concentration is saturated, the buckling load with both the degradation of elastic moduli and transverse shear deformation considered is ca. 12% lower than Snead and Papazotto’s result where only the degradation of elastic moduli was considered. In addition, it is shown that the influence of the initial stress, induced by the same environmental variations, on the buckling load is far less significant.

ABSTRACT: Based on the classical thin shell theory and the first-order shear deformation shell theory, two models are developed in this paper for predicting the torsional buckling loads of thin and thick shells of revolution. The material property of a shell of revolution is described as a general type of laminated composites and natural coordinates are used to define its geometry in which any kind of kinematic boundary condition can be applied precisely. To effectively use the axi-symmetric property of a shell of revolution in the analysis, a multi-level substructuring technique is employed in which only one substructure is involved in each substructuring level so the size of the problem in real computation is always kept very small. The torsional buckling behaviours of a circular cylinder, a conic shell, an elliptic hyperboloid shell and an ellipsoid shell are investigated using these models.

ABSTRACT: The large-amplitude oscillations and buckling of an anisotropic cylindrical shell subjected to the initial inplane biaxial normal stresses have been analysed. The concept of anisotropy used by Lekhnitsky has been introduced into the field equations for cylindrical shells of isotropic material deduced by Donnell. The method of Galerkin and the method of successive approximation have been used to obtain the desired approximate solution. The expression for the critical loads for the buckling of anisotropic cylindrical shells has been obtained during intermediate stages of analysis. Some relevant frequency response graphs of the obtained solution are also presented. The minimum critical loads for various classes of anisotropy have also been given at the end of the discussion, to exhibit the effects of large deflections and imperfections on elastic buckling.

ABSTRACT: The paper presents the differential equation system of buckling of shallow sandwich shells with thick faces in the case of general anisotropy. A closed form solution is derived for the determination of the buckling load which can be applied for a wide range of cases. It is also shown that, in the case of isotropic shells, the effect of shearing deformation can be taken into account in many cases analogously to Föppl's formula.

ABSTRACT: The aim of this paper is to determine the buckling shapes and loads of an isotropic cylinders subjected to temperature and/or mechanical loads. First, the governing differential equations for buckling are derived. Second, their solution is presented. The buckling shapes are found to be trigonometrical functions in a skew coordinate system. With the aid of these functions, closed form solutions are developed for calculating the buckling loads. The paper presents some examples which illustrate unexpected results, e.g., unconstrained cylinders subjected to a change in temperature may buckle at a critical temperature, and may buckle either with increasing or with decreasing temperature.

ABSTRACT: An analytical model describing the instability of specially orthotropic composite tubes with geometric imperfections subject to biaxial compressive loads and under clamped-clamped boundary conditions is developed. Furthermore, the range of validity of the present solution is clarified, and comparisons are made to some studies on isotropic cylindrical shells. Six E-glass woven fabric-epoxy composite tubes with the same internal radius and different thicknesses and longitudinal lengths were fabricated and subjected to various combinations of external hydrostatic pressure and axial compressive load simultaneously. The normalized buckling stresses were found to agree in general with the theoretical predictions at various biaxial loadings. The buckling envelopes in normalization form provide useful design data on the strength of specially orthotropic composite tubes under a realistic range of biaxial loading conditions.

Oscar Barton, Jr. (Mechanical Engineering Department, United States Naval Academy, Annapolis, MD 21402, USA), “Eigensensitivity analysis of moisture-related buckling of marine composite panels”, Ocean Engineering, Vol. 34, Nos. 11-12, August 2007, pp. 1543-1551, doi:10.1016/j.oceaneng.2006.12.007
ABSTRACT: In this paper, an approximate closed-form solution is presented to compute the moisture-related buckling of symmetric angle-ply laminates. The environment corresponds to a steady state condition, which provides a uniform moisture distribution for the laminate. The laminate consists of four layers [+theta/-theta] constructed of low, moderate and high stiffness ratio materials. Comparative results using the Rayleigh-Ritz method provides a means of assessing the accuracy of the expression. For certain laminate architectures, several modes must be computed to ascertain the lowest buckling mode, and once identified, provides an excellent approximation for the mode computed using the Rayleigh-Ritz method.

ABSTRACT: Due to the intrinsic heterogeneity of sandwich structures, phenomena at various scales can co-exist in these layered-like assembly of thick-soft and thin-stiff materials. Especially under in-plane compression loadings, geometrical instabilities can occur at both global (structure) and local (skins) scales. Therefore, the in-plane compressive response of sandwich structures is of major concern in designing structural applications. In the present paper, the first applications of a novel unified model for sandwiches are presented, with closed-form solutions for both global and local buckling. For the perfect structure, analytical critical loads are extracted for a simply supported beam, through the calculation of two eigenvalues leading to three buckling modes: it appears that the eigenvalue associated with the antisymmetrical mode can correspond to the occurrence of either global or local (wrinkling) buckling. These global and local loads from the present unified model are shown to compare very well with the predictions given by the most complete specific models from the literature. Moreover, it is shown that conversely to the classical models, our approach yields critical loads that depend only on rigorous well-founded mechanical hypotheses. The simple but general analytical expressions from the unified model permit to select quickly configurations against local and global buckling. In this simplified
framework, conclusions can be drawn from this unified model capable of properly predicting the phenomena at both scales. This simplified study is essential in getting an insight in the role played by each geometrical and material parameter, the combination of which is of importance for subsequent non-linear interactive post-buckling analyses.

ABSTRACT: This paper is dedicated to the study of global (at the sandwich scale) and local (at the component scale) buckling in sandwich structures. First, a unified analytical characterization is given for both global and local buckling. Then these analytical critical loads are translated into sandwich configuration selection diagrams. A 'light' FE model is then proposed to carry out low CPU-time non-linear post-buckling analyses. The post-buckling response computed for elastic materials are mostly super-critical, for small geometrical imperfections. But for some configurations, interactive buckling can develop yielding a highly sub-critical response due to the occurrence of some unsymmetrically distributed geometrical localizations. When an elastoplastic core is considered the response becomes systematically sub-critical, and limit loads reduce consequently. A strong imperfection sensitivity is also noticed.

ABSTRACT: It is well known that the presence of bending-extension coupling in unsymmetrically laminated plates gives rise to bending curvatures under the action of pure in-plane loading. In view of this behaviour, it is generally believed that bifurcation buckling could normally not take place. In this investigation, the possibility of bifurcation instability in unsymmetrically laminated plates subjected to in-plane loading is examined. Based on the variationally consistent governing equations and edge conditions, conditions are derived which, if satisfied, ensure that the plate remains flat during the pre-buckling regime and thus guarantee bifurcation buckling. It is shown that these conditions are not essential for the bifurcation instability phenomenon to occur. A few plate configurations for which bending curvatures do occur during the pre-buckling stage but nevertheless still exhibit bifurcation instability are reported. The prescribed in-plane edge conditions assumed in the literature for the study of buckling phenomena are also examined with regard to their applicability. The existence of this phenomenon in the case of rectangular composite plates is demonstrated by modelling the plate with a four-node finite element having 10 degrees of freedom per node. a number of representative problems are examined, which reveal a number of interesting features.

ABSTRACT: The objective of the present paper is to investigate the influence of partial edge compression on the critical loads of moderately thick laminated plates. Towards this, an eight node isoparametric plate element is developed. The element has five degrees of freedom per node. The computer code developed accepts two sets of boundary conditions, one for pre-buckling stress analysis and the second for stability analysis. This flexibility is proposed to exploit the mid-line symmetry conditions. Two types of partial edge compression, viz., (I) uniform partial edge compression near the corners and (II) uniform partial edge compression at the middle of edges are considered. The effect of percentage of loaded edge length on the critical load of thin and thick composite plates with simply supported and clamped edge conditions is studied in detail.

ABSTRACT: Post buckling behaviour of rectangular laminated plates subjected to thermal loads is investigated in this paper. For this purpose, a four-node, lock-free, rectangular composite plate finite element having six degrees of freedom per node viz three translations, two bending rotations about x- and y-axes and a twist is developed. The element is based on a bicubic representation of the transverse displacement field. The field descriptions for other variables are derived using equilibrium equations of strips along x- and y-axes of the plate. As a result field descriptions involve material properties apart from the usual geometric variables. 3◊3 Guass Quadrature formula is employed to compute the elemental matrices. Though an exact integration rule has been employed, the element is free of shear locking even in the extreme thin plate regimes. The effect of boundary conditions, aspect ratio, number of layers and lay-up sequence on the post-buckling behavior is studied in detail. The numerical examples solved herein reveal the possibility of secondary bifurcations from the primary post-buckling path.

ABSTRACT: Composites are known to display a considerable amount of scatter in their material properties due to a large number of parameters associated with their fabrication and manufacturing processes. In the present study, the material properties have been modeled as random variables for accurate prediction of the system behavior. Shear deformation effects have been incorporated in the governing equations. First-order perturbation technique has been employed to obtain the second-order buckling load statistics. The results have been presented for composite cylindrical panels with all edges simply supported. These results demonstrate the dependence of scatter in buckling loads on the basic random variables. The effects of side-to-thickness ratio, aspect ratio, curvature-to-side ratio and change in standard deviation of input random variables have been investigated for cross-ply symmetric and anti-symmetric laminates. The approach has been validated by a comparison of the results with those obtained with Monte Carlo simulation. The results for the mean buckling load with different shear deformation theories have also been compared with those available in the literature.
ABSTRACT: The initial buckling behavior of thick laminated composite curved panels with random material properties subjected to various in-plane edge loads has been investigated. For this purpose, an approach is presented to obtain the governing equation and the buckling load statistics with the help of an accurate C0 finite element in conjunction with first-order perturbation technique. A higher order shear deformation theory has been used for the laminate. The laminate material properties, subjected to inherent variations about the mean value, have been modeled as random variables. Results for second-order statistics of buckling load have been presented for laminated spherical panels and validated with available results in literature and Monte Carlo simulation. The influence of curvature-to-side ratio, side-to-thickness ratios and edge support conditions on buckling load statistics has been studied. The sensitivity of buckling load statistics for spherical panels to variations in material properties has been compared with that of cylindrical panels.

ABSTRACT: In this paper, the sensitivity of randomness in material parameters on the thermal buckling of conical shells embedded with and without piezoelectric layer is examined. A higher order shear deformation theory is used to model the system behaviour of the conical shell. The lamina material properties are modelled as basic random variables. A deterministic finite element method in conjunction with the first-order perturbation technique is employed to handle the randomness in the material properties. Typical numerical results for the second order statistics of the linear thermal buckling load of the composite conical shells/panels with and without piezoelectric layer are obtained. Mean value results are validated with those available in the literature and standard deviation results are also validated with an independent Monte Carlo simulation.

ABSTRACT: Post-buckling strength and the critical buckling load parameter of laminated composite cylindrical/hyperboloid shallow shell panel subjected to uniform temperature field is investigated in this paper. The mathematical model is developed taking into account the full nonlinearity effect in stiffness matrices in Green–Lagrange sense based on the higher order shear deformation theory. Governing equations are derived by minimizing the total potential energy of the system. The panel is represented with the nonlinear finite element model. The system equations are solved by a direct iterative approach to find out the thermal post-buckling equilibrium path. Influence of different parameters such as lamination scheme, modular ratio, amplitude ratio, thickness ratio, curvature ratio, aspect ratio and various support conditions have been examined in details. The results are compared with those available in literature.

ABSTRACT: Post-buckling analysis of a laminated composite spherical shell panel embedded with shape memory alloy fibres using non-linear finite element method”, Proceedings of the
In this article, the buckling and post-buckling behaviours of a laminated composite spherical shallow shell panel embedded with shape memory alloy (SMA) fibres are studied under a thermal environment. System equations for a laminated composite spherical shell panel embedded with SMA fibres are for the first time derived by modelling the geometric non-linearity in the Green–Lagrange sense and the material non-linearity in SMA fibres in the framework of the higher-order shear deformation theory. The shell panel model is discretized by using a non-linear finite-element approach. The governing algebraic equations are then derived by the variational approach and solved using a direct iterative technique. Influences of the thickness ratio, boundary condition, aspect ratio, curvature ratio, lamination scheme, SMA volume fraction, percentage of prestrain, and amplitude ratio on the buckling and post-buckling temperatures of a laminated composite shell panel with and without SMA have been examined in detail. The results are computed using the present model and compared with those available in the literature.

ABSTRACT: In this article, nonlinear free vibration behaviour of thermally post-buckled laminated composite spherical shallow shell panel is analyzed. The nonlinearity in geometry of the shell panel is considered in Green–Lagrange sense and the mathematical model is developed based on higher order shear deformation theory (HSDT). System of governing differential equations are derived using Hamilton’s principle. A direct iterative method in conjunction with nonlinear finite element approach is used to solve the system of equations. Effects of various geometries and material properties on the nonlinear free vibration frequencies are examined in detail and discussed. Results are obtained using the present model and are compared with those available in literature. The difference between the results speaks the necessity and the requirement of the present model for the prediction of actual nonlinear characteristics of the laminated structures having severe nonlinearity in thermal environment.

ABSTRACT: In the present paper, buckling loads of rectangular composite plates having nine sets of different boundary conditions and subjected to non-uniform inplane loading are presented considering higher order shear deformation theory (HSDT). As the applied inplane load is non-uniform, the buckling load is evaluated in two steps. In the first step the plane elasticity problem is solved to evaluate the stress distribution within the prebuckling range. Using the above stress distribution the plate buckling equations are derived from the principle of minimum total potential energy. Adopting Galerkin's approximation, the governing partial differential equations are converted into a set of homogeneous linear algebraic equations. The critical buckling load is obtained from the solution of the associated linear eigenvalue problem. The present buckling loads are compared with the published results wherever available. The buckling loads obtained from the present method for plate with various boundary conditions and subjected to non-uniform inplane loading are found to be in
excellent agreement with those obtained from commercial software ANSYS. Buckling mode shapes of plate for different boundary conditions with non-uniform inplane loadings are also presented.

ABSTRACT: Postbuckling equilibrium paths of simply supported cross-ply laminated cylindrical shell panels subjected to non-uniform (parabolic) inplane loads are traced in this paper. Love's shell theory with higher order shear deformation theory and von Kármán nonlinear strain–displacement relations are used in the mathematical formulation of the problem. In the first step, the plate membrane problem is solved to evaluate the stress distribution within the prebuckling range as the applied inplane edge load is non-uniform. The governing shell panel postbuckling equations are derived from the principle of minimum total potential energy using the above stress distributions. Adopting multi-term Galerkin's approximation, the governing equations are reduced into a set of non-linear algebraic equations. Newton–Raphson method in conjunction with Riks approach is employed to plot the postbuckling paths through limit points. Numerical results are presented for symmetric (0/90/0) crossply laminated cylindrical shell panels under parabolic inplane load, lateral distributed load and initial imperfections. Limit loads and snap-through behavior of shell panels are studied.

V.R.Kar and S.K.Panda (Dept. of Mechanical Engg., NIT, Rourkela, 769008, 5th International & 26th All India Manufacturing Technology, Design and Research Conference (AIMTDR 2014) December 12th–14th, 2014, IIT Guwahati, Assam, India

ABSTRACT: The buckling behaviour of functionally graded cylindrical panels under thermal loading is investigated in this article. In functionally graded material, material properties vary smoothly from metal phase to ceramic phase. In this study, the effective material properties of the functionally graded panels are considered as temperature dependent and the gradation is taken in the transverse direction according to the power-law distribution of volume fractions of each constituent. Thermal buckling behaviour of cylindrical panel has been obtained numerically through ANSYS based on the ANSYS parametric design language code. The model has been discretised using an eight-node serendipity element with six degrees of freedom per node (SHELL281) from the ANSYS library. The solutions are obtained by solving the eigenvalue type buckling using Block Lanczos method. The accuracy of the model has been checked through corresponding convergence and comparison study with those available literatures. Finally, the simulation model has been extended to study the effect of different parameters such as power-law index, thickness ratio, curvature ratio and aspect ratio on buckling strength for both temperature independent and dependent material properties of each constituent.

ABSTRACT: In this paper, the effect of random system properties on the post buckling load of geometrically nonlinear laminated composite cylindrical shell panel subjected to hygrothermomechanical loading is investigated. System parameters are assumed as independent random variables. The higher order shear deformation theory and von-Kármán nonlinear kinematics are used for basic formulation. The elastic and hygrothermal properties of the composite material are considered to be dependent on temperature and moisture concentration using micromechanical approach. A direct iterative based C0 nonlinear finite element method in conjunction with first-order perturbation technique proposed by present author for the plate is extended for shell panel subjected to hygrothermomechanical loading to compute the second-order statistics (mean and variances) of laminated composite cylindrical shell panel. The effect of random system properties, plate geometry, stacking sequences, support conditions, fiber volume fractions and temperature and moisture distributions on hygrothermomechanical post-buckling load of the laminated cylindrical shell panel are presented. The performance of outlined stochastic approach has been validated by comparing the present results with those available in the literature and independent Monte Carlo simulation.

ABSTRACT: An overview is presented of considerations involved and some of the more interesting results found in the buckling of laminated composite plates. In the case of plates which are symmetrically laminated, classical orthotropic or anisotropic plate theory applies, and numerous theoretical results are available. For unsymmetrical laminates coupling exists between bending of the plate and stretching of its midplane, and a considerably more complicated theory must be used. Additional complicating factors are considered, including: interior holes, shear deformation, sandwich construction involving other materials, local effects, nonlinear stress-strain relationships, and hygrothermal effects. Postbuckling behavior and the effects of initial geometric imperfections are also discussed. The results summarized are taken from a recent comprehensive study of the world’s literature on this subject, encompassing approximately 300 references.

ABSTRACT: Extensive and accurate numerical results are presented for the critical buckling loads of simply supported, rectangular, laminated composite plates subjected to five types of loading conditions: (1) uniaxial, (2) hydrostatic biaxial, (3) compression-tension biaxial, (4) positive shear and (5) negative shear. Considerably different results are found for the two types of shear loading for angle-ply composites. The Ritz method, along with displacements assumed in the form of a double sine series, is used to solve the problems. Convergence studies are presented to demonstrate the accuracy of the results. Contour plots of the buckled mode shapes are shown for some of the more interesting plate and loading configurations.

ABSTRACT: An optimal design is presented to determine the stacking condition that maximizes the lowest frequency of a laminated composite shallow shell with rectangular planform. The shallow shell considered has a symmetric laminate and is supported by shear diaphragms along the four edges. An analytical solution for natural frequencies is derived by discarding the cross-elasticity terms and then solving the governing equations of motion. In the optimization, fiber orientation angles in the layers are introduced as design variables, and a set of differential equations are presented which satisfy the Kuhn—Tucker optimality conditions. Formulas are then derived to give the possible optimal fiber orientation angles. Using numerical examples, the effects of various shell curvatures upon the optimal fiber orientation angles are discussed for a wide range of shallow shell configurations.

ABSTRACT: Based on the large deflection dynamic equations of axisymmetric shallow shells of revolution, the nonlinear forced vibration of a corrugated shallow shell under uniform load is investigated. The nonlinear partial differential equations of shallow shell are reduced to the nonlinear integral-differential equations by the method of Green’s function. To solve the integral-differential equations, expansion method is used to obtain Green’s function. Then the integral-differential equations are reduced to the form with degenerate core by expanding Green’s function as series of characteristic function. Therefore, the integral-differential equations become nonlinear ordinary differential equations with regard to time. The amplitude-frequency response under harmonic force is obtained by considering single mode vibration. As a numerical example, forced vibration phenomena of shallow spherical shells with sinusoidal corrugation are studied. The obtained solutions are available for reference to design of corrugated shells.

ABSTRACT: Based on the dynamic equations of nonlinear large deflection of axisymmetric shallow shells of revolution, the nonlinear free vibration and forced vibration of a corrugated shallow shell under concentrated load acting at the center have been investigated. The nonlinear partial differential equations of shallow shell were reduced to the nonlinear integral-differential equations by using the method of Green’s function. To solve the integral-differential equations, the expansion method was used to obtain Green’s function. Then the integral-differential equations were reduced to the form with a degenerate core by expanding Green’s function as a series of characteristic function. Therefore, the integral-differential equations became nonlinear ordinary differential equations with regard to time. The amplitude-frequency relation, with respect to the natural frequency of the lowest order and the amplitude-frequency response under harmonic force, were obtained by considering single mode vibration. As a numerical example, nonlinear free and forced vibration phenomena of shallow spherical shells with sinusoidal corrugation were studied. The obtained solutions are available for reference to the design of corrugated shells.

ABSTRACT: The nonlinear thermal buckling of symmetrically laminated cylindrically orthotropic shallow spherical shell under temperature field and uniform pressure including transverse shear is studied. Also the analytic formulas for determining the critical buckling loads under different temperature fields are obtained by using the modified iteration method. The effect of transverse shear deformation and different temperature fields on critical buckling load is discussed.

ABSTRACT:

ABSTRACT: Experiments have been carried out to determine the failure envelopes which describe the leakage and fracture strengths of thin walled ±55° filament wound E-glass fibre/epoxy tubes under a variety of biaxial stress states produced by applying combinations of internal pressure and axial tensile and compressive loads. The fracture strengths vary from 70 MPa to 900 MPa depending on the ratio of applied circumferential to axial stresses. For some combinations of loading leakage occurs at much lower stresses than final failure.

ABSTRACT: Experimental data are presented to show the effects of winding angle on the strength of 100 mm diameter, 1 mm thick, filament wound E-glass fibre reinforced epoxy resin tubes tested under various combinations of internal pressure and axial tension or compression. Leakage and fracture strength envelopes are presented for ±45°, ±55° and ±75° winding angle tubes subjected to a wide range of different biaxial membrane stress states. Strengths range from 30 to 1250 MPa. Axial compression test results for tubes with wall thicknesses ranging from 1 to 3.6 mm establish the influence of shell buckling. Stress/strain curves up to fracture under three different types of loading show the effects of the winding angle on elastic constants and on nonlinear stress strain behaviour.

ABSTRACT: Thin-walled filament wound glass fibre reinforced tubes supported on a rigid flat plate were loaded laterally by a rigid spherical indenter. The finite element technique was used for the prediction of deformation and strains in the tube up to failure which occurred at high levels of indentation. The analysis made allowance for the large displacements. The tube wall material was modelled as a monolithic, orthotropic continuum. The theoretical results are compared with experimental data from tube indentation tests. Final failure is shown to be due to local axial shell buckling.

ABSTRACT: The finite element method has been used to analyse the behaviour of thin-walled, 100 mm diameter filament-wound GRP tubes supported on a flat plate and indented with a 50 mm diameter spherical indenter. The tube wall was treated as an angle-ply laminate and a half-tube model was employed with appropriate rotational symmetry conditions. The strain results were compared with those from a quarter-tube monolithic material model (homogeneous throughout and orthotropic with principal axes coincident with the axial and circumferential directions). The theoretical predictions were compared with experimental results. Local resin cracks occurred under the indenter. Two-cover (four-layer), 1 mm thick, ±55° and ±75° winding angle tubes finally failed at large indenter displacements by local shell buckling caused by the development of local axial compressive forces some distance away from the indenter. Four-cover (eight-layer), 2 mm thick, ±55° tubes delaminated under the indenter and failed by shell fracture, again some distance away from the indenter.

ABSTRACT: (cannot cut and paste)

ABSTRACT: The buckling and vibration of thick, orthotropic laminated composite shells is modelled using a simple layerwise higher-order theory. The theory accounts for a cubic variation of both the in-plane displacements and the transverse shear stresses within each layer, the latter being zero at the free surfaces without the need for shear correction factors. By imposing the continuity of the in-plane displacements and the transverse shear stresses at the interfaces, the number of variables is shown to be the same as that given by the FSDT, irrespective of the number of layers considered. A non-dimensionalized parameter called the General
Performance Index is defined in order to assess the overall performance of the models based on their flexural frequencies and the largest component of stress within the laminate. Numerical results for moderately short, one-, two- and three-layer shell panels are obtained for a range of base layer-to-core modulus of elasticity ratios. The normalized natural frequencies and stresses of the present theory are compared with a simple layerwise first-order theory and two other global higher-order theories that despite their similarity, indicate some interesting differences. The critical buckling loads are also given for a range of modulus and thickness ratios. Results indicate the present theory generally performs better over a range of the parameters mentioned predicting conservatively lower natural frequencies, smaller buckling loads and larger stresses for symmetric shells.

ABSTRACT: Unstiffened composite cylindrical shells show a large scatter in the load levels that the structure can withstand before buckling occurs. Such scatter is greatly influenced by the unavoidable imperfections of the structure, introduced during the fabrication phase. It is thus of key importance to be able to accurately model such imperfections in a numerical computation, in order to recreate and predict the scatter shown in experimental buckling tests. The imperfections can be analyzed by means of random fields, inferring their statistical properties from available measurements. In this manuscript, evolutionary spectra are used to derive random fields of surface and material imperfections of cylindrical shells. A procedure based on a moving window averaging technique is proposed in order to accurately capture the variation of material properties due to imperfect thickness and laminate manufacturing. Finally, Monte Carlo simulations of compression and torsional buckling of cylinders are carried out to show the combined effect of surface and thickness imperfections in the scatter of the buckling limit load.

ABSTRACT: An axisymmetric finite element is developed which includes such features as orthotropic material properties, doubly curved geometry, and both the first and second order nonlinear stiffness terms. This element can be used to predict the equilibrium state of an axisymmetric shell structure with geometrically nonlinear large displacements. Small amplitude vibration analysis can then be performed based on this equilibrium state. The nonlinear path is predicted by using the self-correcting incremental procedure and any point on the path can be checked by using the Newton-Raphson iterative scheme. The present formulation and solution procedure are evaluated by analyzing a series of examples with results compared with alternative known solutions. Examples include: free vibration of an isotropic cylindrical shell, a conical frustum, and an orthotropic cylindrical shell; buckling of a cylindrical shell; large deflection of a clamped disk, a spherical cap, and a steel belted radial tire. The final example is a free vibration analysis of the inflated tire and the natural frequencies obtained compared well with published experimental data.

ABSTRACT: To develop geometrically nonlinear, doubly curved finite shell elements the basic equations of nonlinear shell theories have to be transferred into the finite element model. As these equations in general are written in tensor notation, their implementation into the finite element matrix formulation requires considerable effort. The present paper will demonstrate how to derive the nonlinear element matrices directly from the incrementally formulated nonlinear shell equations using a tensor-oriented procedure. This enables the numerical realization of all structural responses, e.g. the calculation of pre- and post-buckling branches in snap-through analysis and especially in bifurcation analysis, including the detection of critical points and the consideration of geometric imperfections. To avoid loss of accuracy care is taken for a realistic computation of the geometric properties as well as of the external loads. Finally, the developed family of shell elements will be presented and its efficiency will be demonstrated by some applications to linear and geometrically nonlinear structural phenomena.

ABSTRACT: A 48-degree-of-freedom (d.o.f.) skewed quadrilateral thin shell finite element, including the effect of geometrical non-linearity, is formulated and appropriate numerical procedures are adopted for the development of an efficient approach for the static and dynamic analysis of general thin shell structures. The element surface is described by a variable-order polynomial in curvilinear co-ordinates. The displacement functions are described by bicubic Hermitian polynomials in curvilinear co-ordinates. The directions of the curvilinear co-ordinates at each nodal point are uniquely defined to coincide with the directions of the boundaries of the element. In the present case of a skewed quadrilateral with non-orthogonal curvilinear coordinates, the coupling terms of the metric tensor and curvature tensor of the surface no longer vanish, such as in the case of orthogonal co-ordinates. The tensor form is used in the setup of the shape functions, geometric derivatives, stiffness matrix and computer code. This allows for the treatment of shells with irregular shapes and variable curvatures. To evaluate the efficiency and accuracy of this formulation, a systematic list of examples is chosen: (i) linear and non-linear static analysis of square and rhombic plates, cylindrical and spherical shells; (ii) linear vibrations of trapezoidal flat and curved plates; (iii) large amplitude vibrations of a rhombic plate. For the square plate and cylindrical and spherical shell, skewed element meshes with various distortion angles are used to study the effect of the distortion angles on the accuracy of the results and to demonstrate the versatility of the present element. All results are compared with alternative available solutions including those obtained using regular rectangular meshes. Pinched thin cylindrical and spherical shells are studied using different skewed meshes and various Gauss integration meshes, and no membrane locking phenomenon is observed.

ABSTRACT: The emphasis of this paper is to use a thin shell finite element to study the dynamic buckling behavior of a class of thin shell problems due to the effects of three parameters with design significance: (1) axisymmetric and asymmetric imperfections; (2) orthotropic and anisotropic material properties; and (3) Rayleigh viscous damping. Five types of thin shells were considered: (1) an orthotropic annular spherical cap; (2) an orthotropic, axisymmetrically imperfect, whole spherical shell; (3) an axially compressed, laminated,
asymmetrically imperfect, cylindrical shell; (4) an orthotropic, axisymmetrically imperfect, spherical cap; and
(5) an orthotropic, asymmetrically imperfect, spherical cap. While some basic results are compared with
available solutions, extensive new results are also presented. The results quantify the effect of amplitude of
imperfections, which can significantly reduce the dynamic buckling load. The results also quantify the effects
of orthotropic material parameter and viscous damping.

ABSTRACT: A 48 degree-of-freedom doubly-curved quadrilateral laminated thin shell element including the
effect of anisotropic plasticity is formulated to study the static, dynamic response and buckling of thin shell
structures. The effect of geometric nonlinearity is also included. The formulation is based on the Kirchhoff-
Love thin shell theory and classical lamination theory. In the plastic range, the Huber-Mises yield criterion
combined with the Prandtl-Reuss flow rule are used. The state of stresses and strains of each layer is calculated
individually, and then integrated through the whole thickness of the shell to obtain the stress and moment
resultants, and the stress-strain relation. The stress and strain components, the stress-strain relation, and the
yield function which is used to identify the plastic surface are obtained in principal material directions of each
layer and then transformed to those in local coordinate axes of the element. The formulation and solution
procedure are evaluated by comparing results of two examples with existing alternative solutions. The practical
applicability is demonstrated by performing a series of static and dynamic buckling analyses of laminated thin
spherical and cylindrical shells.

Tarbes Cedex, France), “A rectangular finite element for analysing composite multilayered shallow shells in
pp. 627–653. doi: 10.1002/nme.1620360406
ABSTRACT: This paper presents a new 32-degree-of-freedom finite element of multilayered composite,
moderately thick, shallow shells. The element is a four-node C1 rectangular element and is built from standard
interpolations but with a new kind of kinematics which allows us to exactly ensure the continuity conditions for
displacements and stresses at the interfaces between the layers of a laminated structure and the boundary
conditions at the upper and lower surfaces of the shell. The transverse shear deformation which is represented
by cosine functions is of a higher order and allows us to avoid shear correction factors. The element is evaluated
on standard problems and in comparison with exact three-dimensional and analytical solutions for multilayered
plates and shells in statics, vibrations and stability.

axisymmetric shells”, Computers & Structures, Vol. 54, No. 5, March 1995, pp. 897-920,
ABSTRACT: A two dimensional kinematics is proposed for moderately thick plates and curved shells without
any assumption other than neglecting the transverse normal strain. The transverse shear is taken into account by
using a function $f$ depending on the thickness coordinate and which is introduced in the assumed kinematics. The boundary value problem is derived from the principle of virtual power. With the function $f$ in the kinematics, all equations are directly applicable to Kirchhoff-Love, Reissner-Mindlin, Reddy theories and, obviously, our theory by using a certain sine function $f$. This latter is justified in plates from three-dimensional elasticity theory. The corresponding theory has been found efficient in statics (buckling) and in dynamics (free vibrations) for composite structures without needing shear correction factors. In addition, a new finite element is proposed to analyse axisymmetric semi-thick shells in elasticity and for small displacements. The element has three nodes and ten degrees of freedom, is of $C_1$ continuity for the transverse displacement and $C_0$ for the membrane displacement and the ‘membrane-shear’ rotation. Finally, an introduction to the edge effects for axisymmetric shells is presented. The study has shown some surprises concerning the hard clamped edge, in comparison with a two-dimensional eight node isoparametric solid finite element model used in reference.

ABSTRACT: The aim of this work is to analyze the geometrically nonlinear mechanical behaviour of multilayered structures by a high order plate/shell finite element in order to predict displacements and stresses of such composite structures for design applications. Based on a conforming finite element method, a $C_1$ triangular six node finite element is developed using trigonometric functions for the transverse shear stresses. The geometric nonlinearity is based on von-Kármán assumptions and only five generalized displacements are used to ensure:

1. a cosine distribution for the transverse shear stresses with respect to the thickness co-ordinate, avoiding shear correction factors;
2. the continuity conditions between layers of the laminate for both displacements and transverse shear stresses;
3. the satisfaction of the boundary conditions at the top and bottom surfaces of the shells.

ABSTRACT: This work deals with the performances of a refined shell model for modelizing cylindrical multilayered deep or shallow, thin or thick shells. To this end, new 3D analytical solutions are built from the well known Ren cylindrical shell panel and stand for reference solutions. Next, a parametric study varying the shell geometry (radius of curvature, thickness, curve side length of the panel) and the number of layers is carried out numerically using a $C_1$ finite element based on the present shell model. Numerical results are then compared to the new set of reference solutions established for laminates of 1, 2, 3 and 5 layers. Finally, use restrictions according to the shell geometry can be done. Moreover, indications about shell curvature can be obtained considering the ratio between radius and curve length.

ABSTRACT: The buckling behavior of circular cylindrical composite shells under axial compression, bending, and combined compression-bending is studied. Both Donnell-and refined Love-type equations of motion are solved using Galerkin's method. Numerical results reflecting a wide range of radius-to-thickness and length-to-thickness ratios are presented and discussed. The interaction between axial compression and bending in the combined loading case show significant deviation from the linear noninteracting beam-column type solutions.

ABSTRACT: A two-dimensional global higher-order deformation theory is presented for the evaluation of critical temperatures in cross-ply laminated composite shallow shells subjected to thermal loading. The effects of prebuckling deformations of the shells subjected to a temperature change that is independent of the in-plane coordinates are taken into account in the present analysis. By using the method of power series expansion of continuous displacement components, a set of fundamental governing equations which can take into account the effects of both transverse shear and normal stresses are derived through the principle of virtual work. Several sets of truncated $M$th order approximate theories are applied to solve the thermal buckling problems of a simply supported multilayered shell. Critical temperatures are shown for two cases of including the effects of prebuckling displacements and neglecting these effects. The modal stresses can be calculated by integrating the three-dimensional equations of equilibrium in the thickness direction, and satisfying the continuity conditions at the interface between layers and stress boundary conditions at the external surfaces. The present results are verified to be accurate enough for cross-ply laminated composite shallow shells through the convergence study and energy balance computations.

ABSTRACT: We analyze thermal buckling of both circular isotropic plates and square antisymmetric angle-ply laminates with a hole in the middle, and subject to a uniform temperature rise, by either closed form solution for the former or finite-element method for the latter. Thin-plate theory is used to analyze the isotropic plates. However, a high-order displacement theory including high-order terms along the transverse direction taking into account transverse normal strain is used in the case of laminates. Results for the isotropic plates indicate that in contrast to the reduction in mechanical buckling loads due to the hole, the thermal buckling temperature actually rises as the size of the hole increases, which indicates that the effect on stress reduction exceeds that on stiffness decrease. Results are more complicated for laminated plates, due to anisotropy.

Jeng-Shian Chang (Institute of Applied Mechanics, National Taiwan University, Taipei, Taiwan 10764, Republic of China), “FEM analysis of buckling and thermal buckling of antisymmetric angle-ply laminates according to transverse shear and normal deformable high order displacement theory”, Computers & Structures, Vol. 37, No. 6, 1990, pp. 925-946, doi:10.1016/0045-7949(90)90006-N
ABSTRACT: Buckling and thermal buckling of the antisymmetric angle-ply laminates clamped and subject to in-plane edge loads or a uniform temperature rise are analyzed by the finite element method. A higher order displacement theory including higher order terms along the transverse direction, taking into account transverse normal strain, is applied through the analysis. Effects of important parameters, such as ply angle, ratio of thickness to edge length, number of layers, ratio of in-plane to transverse modulus, etc. are studied. The numerical results are presented.

ABSTRACT: A higher-order deformation theory, which accounts for transverse shear and transverse normal strains, is derived for the thermal buckling analysis of antisymmetric angle-ply laminates that are simply supported and subject to a uniform temperature rise. The theory includes six dependent variables but can account for cubic distribution of in-plane displacements and parabolic distribution of transverse normal displacement. By using the present higher-order displacement field and the three-dimensional Hooke's law, exact-closed form solutions of the thermal buckling temperature are obtained. For purposes of comparison, numerical values of buckling temperature based on the first-order shear deformation theory and Reddy's higher-order shear deformation theory are also calculated, by reducing the present higher-order deformation theory. The results show that surprising discrepancies exist among the present theory and the other two theories, which indicates the importance of incorporating the effect of transverse normal strain in the thermal buckling analysis of antisymmetric angle-ply laminates.

ABSTRACT: The thermal buckling analysis of antisymmetric angle-ply laminated cylindrical shells that are simply supported and subjected to a uniform temperature rise is analyzed by a finite element method based on the higher order displacement functions. Comparisons to the first order displacement theory are made. Both theories allow transverse shear deformation, but only the higher order one takes into account the transverse normal strain. The numerical results show that first order theory overestimates the thermal buckling temperature of the shell panel, which suggests that the higher order displacement fields should be used in the analysis of thermal buckling for a laminated shell. Effects of important parameters are also studied.

ABSTRACT: The problem of overall buckling and postbuckling behavior of beam-like sandwich plates, which are composed of orthotropic face sheets and soft cores and are rigidly joined at one pair of opposite sides, are analyzed in this work. The other pair of edges is unsupported and widely separated so that the sandwich plates in fact act like wide beams and the complexity of analysis is reduced. The in-plane loads are assumed to apply at the middle of the rigid joints. A set of equilibrium equations and compatibility conditions are then formulated.
for the buckling and postbuckling behavior. Numerical examples based on finite difference methods and Newton-Raphson iterations for the nonlinear governing equations are presented. As the results indicate, the postbuckling behavior for such plates is found to be slightly unstable.

Jeng-Shian Chang and Chen-Hong Lin (Institute of Applied Mechanics, National Taiwan University, Taipei, Taiwan 10764), “Buckling and free vibration of cross-ply laminated circular cylindrical shells subjected to axial thrust and lateral pressure loading according to a higher order displacement field”, Thin-Walled Structures, Vol. 13, No. 3, 1992, pp.177-196, doi:10.1016/0263-8231(92)90040-4
ABSTRACT: An analytical solution is presented for the stability and free vibration of the cross-ply laminated thin circular cylindrical shells which are simply supported at both ends and subject to axial and lateral pressure. Based on the principles of virtual work and a nine-term higher order transverse shear and transverse normal deformable displacement field, a set of governing equations for thermal buckling of thin circular cylindrical shells together with the associated boundary conditions are derived. Navier double series method is then applied to find the closed-form solutions. Effects of important parameters such as degree of orthotropy, ratio of length to radius, ratio of radius to thickness, etc., are studied.

ABSTRACT: This work is concerned with a two-dimensional finite element study of the transient response of laminated thin circular cylindrical shell panels subjected to thermal impact under the framework of linear coupled thermoelasticity. A nine-node isoparametric element is applied to the FEM formulation. Numerous examples are given, in which the shell panels are assumed to be thermally isolated at four edges and the bottom surfaces and a heat flux is then imposed suddenly on their top surfaces. The effects of boundary conditions, ply-angles and radii of curvature are discussed. In addition, the differences between uncoupled and coupled problems are especially addressed.

ABSTRACT: The natural frequencies and critical velocities of laminated circular cylindrical shells with fixed-fixed ends conveying fluids are studied. Equations of motion are derived by the Hamilton principle under the scope of the Mindlin-type first-order transverse shear deformable cylindrical shell theory. Fluid pressure acting on the wall is obtained through the nonpenetration condition and the assumption of ideal flow. Dynamic characteristic equations are then obtained under the assumption of harmonic motion. Using linear superposition, the natural frequencies corresponding to each flow velocity are found by satisfying dynamic characteristic equation and boundary conditions. Critical velocities are those where the natural frequencies vanish, wherein the static divergence, i.e. buckling, occurs. Numerical examples are presented, in which the parameter studies include stacking angle, length-to-thickness and radius-to-thickness ratios.
ABSTRACT: A review of the analytical research of smart composite structures that have a relevance to buckling, vibrations, parametric vibrations, and dynamic stability of one and two-dimensional mechanical systems applied in mechanical and civil engineering is presented. Special attention is paid to the dynamic behavior of circular cylindrical shells due to nonuniform time-dependent temperature fields. The shell is heated, and it is assumed that a time- and space-dependent temperature field is known. To stabilize thermally induced transverse vibrations the host structure is integrated with a control system consisting of piezoelectric sensors and actuators. Distributed piezoelectric elements are implemented to suppress the motion caused by thermal disturbances. Two particular problems are analyzed in detail. The first is devoted to the stability analysis of a closed cylindrical shell subjected to a time-dependent temperature field. The stabilization is obtained by applying the velocity feedback and electroded piezoelectric sensors/actuators with a suitable polarization profile. In the second problem the technique of the dynamic stability analysis is extended to the thermally activated shape memory alloy hybrid rotating cylindrical shell.

ABSTRACT: Nonlinear vibrations of thin circular cylindrical shells are investigated in this paper. Based on Love thin shell theory, the governing partial differential equations of motion for the rotating circular cylindrical shell are formulated using Hamilton principle. Taking into account the clamped-free boundary conditions, the partial differential system is truncated by using the Galerkin method. Sequentially, the effects of temperature, geometric parameters, circumferential wave number, axial half wave number and rotating speed on the nature frequency of the rotating circular cylindrical shell are studied. The dynamic responses of the rotating circular cylindrical shell are also investigated in time domain and frequency domain. Then, the effects of nonlinearity, excitation and damping on frequency responses of steady solution are investigated.

ABSTRACT: Vibration characteristics of micro-scale simply supported cylindrical shells conveying fluid and embedded in an elastic medium are analysed using the new equations of motion developed based on the modified couple stress theory. It is found that the natural frequencies predicted by the established model are size-dependent, and change with the fluid flow velocity and elastic medium parameter. The size dependence is shown when the characteristic radius size is comparable with the material length-scale parameter, but decreases with the increase in characteristic size. The fluid inside the shell is also found to help in decreasing natural frequency sharply.

ABSTRACT: In this paper, a simple process is suggested to estimate the interfacial toughness of the material system 'aluminum film/soft PDMS substrate'. The specimen, i.e. the aluminum film deposited on the soft polydimethylsiloxane (PDMS) substrate, is subject to a tensile load, and delaminating and buckling of aluminum film are observed in the perpendicular direction to the tensile strain. With the aid of the buckling blisters, the interfacial toughness of the material system is estimated. Large deformation is considered during the buckling of the thin film, and the interfacial toughness is deduced from a fracture theory. Besides, the evolution from one single blister to three blisters and then four blisters is observed in situ under microscope. This simplified method has potential applications to flexible electronics in which interfacial toughness of the metal film/soft substrate must be well controlled.

ABSTRACT: An investigation is carried out to understand the thermal buckling behavior of local delamination near the surface of fiber-reinforced laminated cylindrical shells and the delaminated growth. The shape of the delaminated region considered is elliptic and triangular. The direction of the fiber material's axis is arbitrary. The relationships between the critical thermal load and the geometrical and physical parameters of base laminated shells and sublaminated shells are described and some valuable conclusions are obtained. Finally, the possible expanding direction of the elliptic and triangular delaminated shape under thermal load is discussed.

ABSTRACT: In this article, a novel numerical approach for the delamination growth simulation in composite panels under compressive load is proposed. This approach, suitable for preliminary design and optimization purposes, is able to simulate the delamination propagation by means of a limited number of linear analyses. It is based on the determination of the delamination buckling and on the evaluation of the energy released during the delamination propagation by means of eigenvalue and linear static analyses. The proposed approach has been implemented into the finite element code ANSYS and applied to composite panels with circular embedded and rectangular through-the-width delaminations under compressive load. A first validation has been carried out by comparing the results in terms of delamination growth load and energy release rate distributions along the delamination front to two-dimensional and three-dimensional nonlinear results taken from literature.

ABSTRACT: In this paper, the postbuckling governing equations and the analytical expression of the energy release rates associated with delamination growth in a compression-loaded cylindrical shell are derived by using the variational principle of moving boundary and the Griffith fracture criterion. The finite difference method is used to generate the postbuckling solutions of the delaminated cylindrical shells, and with these solutions, the values of the energy release rates are determined. In simulational examples, the effects of a wide range of parameters, such as delamination sizes and depths, boundary conditions, geometrical parameters, material properties and laminate stacking sequences on the energy release rates of axisymmetrical laminated cylindrical shells are intensively discussed.

ABSTRACT: The growth of delamination in cylindrical shells under external pressure may lead to structural failure. Based on the variational principle of moving boundary (Qian WC. Variational calculus and finite element. Beijing: Science Press; 1980 [in Chinese].) and considering the contact effect between delamination regions, in this paper, the nonlinear governing equations for the delaminated cylindrical shells are derived, and the corresponding boundary and matching conditions are given. Moreover, according to the Griffith criterion, the formulas of energy release rate along the delamination front are obtained. As the numerical example, the delamination growth of axisymmetrical laminated cylindrical shells is analyzed, and the effects of delamination sizes and depths, geometrical parameters, material properties and laminate stacking sequences on delamination growth are discussed.

ABSTRACT: The dynamic stability is studied for isotropic viscoelastic cylindrical shell and symmetrically cross-ply laminated viscoelastic cylindrical shell under constant axial loading. The basic equations are established based on Timoshenko-Mindlin theory, the characteristics equation are derived by Laplace transformation for those two kinds of cylindrical shells with two simply supported ends. The stability condition applied in the calculation of critical loads is determined through Routh-Hurwitz theorem. In the numerical examples, critical loads are reduced due to the relaxation feature of the materials and greater effects of transverse shearable deformation on the critical loads are observed in symmetrically cross-ply laminated viscoelastic cylindrical shell than in isotropic viscoelastic cylindrical shell. The influence of rotary inertia is rather small and can be ignored.

ABSTRACT: The delamination growth may occur in delaminated cylindrical shells under external pressure. This will lead to failure of structure. By using the variational principle of moving boundary and considering the contact effect between delamination regions, in this work, the delamination growth was investigated for cylindrical shells under the action of external pressure. At the same time, according to the Griffith criterion, the formulas of energy release rate along the delamination front were obtained. In the numerical calculation, the
delamination growth of axisymmetrical laminated cylindrical shells was analyzed, and the effects of delamination sizes and depths, the geometrical parameters, the material properties, and the laminate stacking sequences on delamination growth were discussed.

ABSTRACT: The delamination growth may occur in delaminated cylindrical shells subjected to external dynamic load and it will further cause structural failure. Based on the variational principle of moving boundary and considering the contact effect between delamination regions, in this paper, the nonlinear governing equations for the delaminated cylindrical shells under the action of circumferential concentrated dynamic load are derived, and the corresponding boundary and matching conditions are given. At the same time, according to the Griffith criterion, the formulas of energy release rate along the delamination front are obtained and the delamination growth is studied. In the numerical calculation, the delamination growth of axisymmetrical
laminated cylindrical shells is analyzed, and the effects of the delamination sizes and depths, the geometrical parameters, the material properties and the laminate stacking sequences on delamination growth are discussed.

Hong Xiang, Yi-ming Fu and Yong-hong Lu, “Post-buckling analysis of orthotropic plate considering damage”, Journal of Hunan University (Natural Sciences), 2007-09
ABSTRACT: On the basis of algebra invariant theory, the expression of Helmholtz's free energy for orthotropic material considering damage effect was derived. Then, the corresponding constitutive relationship and damage evolution equations were obtained, based on irreversible thermodynamics theory. From Von Karman's plate theory, the nonlinear buckling equations for orthotropic material considering damage effect were founded. Numerical results have indicated that the deflection of the plate under constant load cannot remain unchanged but increases with time due to the damage evolution, and the influences of damage on the deflection of the plate are more and more obvious with the load and initial deflection increase and the length-width ratio decrease.

ABSTRACT: A set of nonlinear motion equations for laminated shallow spherical thick shell subjected to impact loading is established. According to the Hertzian law and the effect of contact between the striking object and the shallow spherical shell, the contact force acted on the shell is determined. By using the finite difference method and the time increment procedure, the nonlinear equations are resolved. In the numerical examples, the effects of initial impact velocity, the radius of the middle surface and the point of contact on the impact forces and displacements of the shells are discussed.

ABSTRACT: The good performance of the mixed degenerate shell finite element with drilling degrees of freedom (DDSE) in linear and nonlinear static analysis problems is in the basis of the present work concerned with its extension to nonlinear dynamic regime. The 9-noded element (DDSE9) has exhibit in a previous work the best performance among the other elements of the DDSE family. It is, consequently, chosen to experience the nonlinear dynamic behaviour in this paper. Both geometrical and material nonlinearities are taken into account and the different integration schemes are considered in the present investigation. The results of the benchmarks treated by the DDSE proved its accuracy and efficiency when compared to those available in the literature. This conclusion will enhance the main advantage of this kind of elements which remains their suitability to model many engineering problems without any numerical "tricks" or adjustments.

Dynamic stability of piezoelectric laminated cylindrical shells with delamination

ABSTRACT: The dynamic stability of a composite laminated cylindrical shell containing a throughout delamination along circumferential direction integrated with piezoelectric layers at both inner and outer surfaces is investigated in this article. The Heaviside step function is used to describe the displacement components in the regions with and without delamination. Based on the classical shell theory, linear piezoelectric constitutive...
relationship, and variational principle, the governing equations of motion are derived and then solved by employing Rayleigh–Ritz method and Bolotin method to obtain the principal unstable region. Numerical results are presented in both tabular and graphical forms to show the effects of the piezoelectric layer; the length, depth, and location of the delamination; and the static axial force on the resonance frequency and the principal unstable region of the delaminated piezoelectric laminated shell.

Abstract: Based on the first order shear deformation theory and classic buckling theory, the paper investigates the creep buckling behavior of viscoelastic laminated plates and laminated circular cylindrical shells. The analysis and elaboration of both instantaneous elastic critical load and durable critical load are emphasized. The buckling load in phase domain is obtained from governing equations by applying Laplace transform, and the instantaneous elastic critical load and durable critical load are determined according to the extreme value theorem for inverse Laplace transform. It is shown that viscoelastic approach and quasi-elastic approach yield identical solutions for these two types of critical load respectively. A transverse disturbance model is developed to give the same mechanics significance of durable critical load as that of elastic critical load. Two types of critical loads of boron/epoxy composite laminated plates and circular cylindrical shells are discussed in detail individually, and the influencing factors to induce creep buckling are revealed by examining the viscoelasticity incorporated in transverse shear deformation and in-plane flexibility.

Abstract: The present study employs the method of atomistic simulation to estimate the thermal stress experienced by Si/Ge and Ge/Si, ultrathin, core/shell nanowires with fixed ends. The underlying technique involves the computation of Young’s modulus and the linear coefficient of thermal expansion through separate simulations. These two material parameters are combined to obtain the thermal stress on the nanowires. In addition, the thermally induced stress is perceived in the context of buckling instability. The analysis provides a trade-off between the geometrical and operational parameters of the nanostructures. The proposed methodology can be extended to other materials and structures and helps with the prediction of the conditions under which a nanowire-based device might possibly fail due to elastic instability.

Abstract: The aim of this paper is to establish a continuum elastic model for core–shell nanowires with weak interfacial bonding. In order to achieve it, a new beam model is proposed, which vanishes the surface shear stress and satisfies the interfacial cohesive law automatically. Critical buckling loads and resonant frequencies of simply supported nanowires are obtained by using the Ritz method. Numerical examples indicate that the weak interface's effect reduces the overall structural stiffness, which is most significant when the inner–
outer radius ratio of the shell is near 0.65. It is also found that the shear deformation and weak interface's effects only need consideration when the nanowire is not quite long, and they affect buckling behaviors more significantly than vibration characteristics.

ABSTRACT: The lithiation and de-lithiation during the electrochemical cycling of lithium–ion batteries (LIBs) can introduce local deformation in the active materials of electrodes, resulting in the evolution of local stress and strain in the active materials. Understanding the structural degradation associated with lithiation-induced deformation in the active materials is one of the important steps towards structural optimization of the active materials used in LIBs. There are various degradation modes, including swelling, cracking, and buckling especially for the nanowires and nanorods used in LIBs. In this work, a shear-lag model and the theory of diffusion-induced stress are used to investigate diffusion-induced buckling of core–shell nanowires during lithiation. The critical load for the onset of the buckling of a nanowire decreases with the increase of the nanowire length. The larger the surface current density, the less the time is to reach the critical load for the onset of the buckling of the nanowire.

ABSTRACT: Yeast cells can be regarded as micron-sized and liquid-filled cylindrical shells. Owing to the rigid cell walls, yeast cells can bear compressive forces produced during the biotechnological process chain. However, when the compressive forces applied on the yeast go beyond a critical value, mechanical buckling will occur. Since the buckling of the yeast can change the networks in its cellular control, the experimental research of the buckling of the yeast has received considerable attention recently. In this paper, we apply a viscoelastic shell model to study the buckling of the yeast. Meanwhile, the turgor pressure in the yeast due to the internal liquid is taken into account as well. The governing equations are based on the first-order shear deformation theory. The critical axial compressive force in the phase space is obtained by the Laplace transformation, and the Bellman numerical inversion method is then applied to the analytical result to obtain the corresponding numerical results in the physical phase. The concepts of instantaneous critical buckling force, durable critical buckling force, and delay buckling are set up in this paper. And the effects of the transverse shear deformation and the turgor pressure on the buckling phenomena are also given. The numerical results show that the transverse shearing effect will decrease the instantaneous critical buckling force and the durable critical buckling force, while the turgor pressure will increase both of them.

ABSTRACT: An asymptotic theory is developed for dynamic response of anisotropic inhomogeneous and laminated cylindrical shells. The formulation is based on three-dimensional elasticity without a priori
assumption. By means of asymptotic expansion with multiple time scales, the basic equations are decomposed into differential equations of various orders which can be integrated successively. It is shown that the three-dimensional asymptotic solution to the problem can be determined hierarchically by solving the two-dimensional equations in the classical laminated shell theory. Modifications to the solution are obtained in a systematic way by treating the higher-order equations and eliminating the secular terms. Various thickness effects, such as transverse shear and rotary inertia, can be accounted for in a natural and consistent manner. It is demonstrated along the way that a uniform expansion that yields asymptotic solution valid regardless of the time span is obtained with the use of multiple time scales, whereas a straightforward expansion fails to produce valid results for long times. The theory is illustrated by determining the vibration characteristics of a multilayered cross-ply cylindrical shell.

ABSTRACT: An asymptotic theory for dynamic analysis of doubly curved laminated shells is formulated within the framework of three-dimensional elasticity. Multiple time scales are introduced in the formulation so that the secular terms can be eliminated in obtaining a uniform expansion leading to valid asymptotic solutions. By means of reformulation and asymptotic expansions the basic three-dimensional equations are decomposed into recursive sets of equations that can be integrated in succession. The classical laminated shell theory (CST) is derived as a leading-order approximation to the three-dimensional theory. Modifications to the leading-order approximation are obtained systematically by considering the solvability conditions of the higher-order equations. The essential feature of the theory is that an accurate elasticity solution can be determined hierarchically by solving the CST equations in a consistent way without treating the layers individually. Illustrative examples are given to demonstrate the performance of the theory.

ABSTRACT: The asymptotic theory developed recently for dynamic analysis of doubly curved laminated shells is refined by including the transverse rotations as auxiliary variables. The theory embraces the first-order shear deformation theory (FSDT) and the higher-order shear deformation theory (HSDT) as the first-order approximation. Higher-order corrections to the approximation are determined by solving the FSDT or HSDT equations in a hierarchic way. The secular terms in the asymptotic solution are eliminated systematically by means of multiple scales and solvability conditions for the higher-order equations. The performance of the refined theory is illustrated by applying it to benchmark problems. Numerical comparisons are made to examine the convergence of the solutions.

ABSTRACT: On the basis of 3D elasticity, asymptotic solutions for buckling analysis of multilayered anisotropic conical shells under axial compression are presented. By means of proper nondimensionalization, asymptotic expansion, and successive integration, the classical shell theory is derived as a first-order approximation to the 3D theory. Because the governing equations for various orders consist of partial differential equations with variable coefficients, the use of analytical techniques is restricted. The method of differential quadrature is adopted in the present study. The modifications of the buckling loads and associated buckling modes can be determined in a consistent and hierarchic manner by considering the solvability and normalization conditions for various orders. The critical loads of cross-ply conical shells with simply supported-simply supported boundary conditions are studied to demonstrate the performance of the present asymptotic theory.

ABSTRACT: Laminated composite plates are fabricated of laminae (also called layers or plies), where each lamina consists of high-strength fibres (e.g. glass, boron, graphite) embedded in a surrounding matrix material
(e.g. epoxy resin). The present work is limited to laminae wherein the fibres are assumed to be all parallel and continuous (i.e. long fibres). Thus each layer may be treated in a macroscopic sense as being a homogeneous, orthotropic material, for which the deformation behaviour is linearly elastic.

**ABSTRACT:** Within the framework of three-dimensional (3D) elasticity, an asymptotic theory is presented for the thermoelastic buckling analysis of laminated composite conical shells subjected to a uniform temperature change. A dimensionless parameter of thermal load related to the temperature change is defined. The method of perturbation is applied in the present formulation where the critical thermal loads and the primary field variables are expanded as a series of even powers of a small perturbation parameter. Through a straightforward derivation, the asymptotic formulation leads to recursive sets of governing equations for various orders. The
classical shell theory is derived as a first-order approximation to the 3D theory. The method of differential quadrature is used to solve for the asymptotic solutions at each order level. The solvability conditions and normalization conditions for higher-order problems are derived. By considering these conditions, we can obtain the higher-order modifications. The critical thermal loads of simply supported, cross-ply conical shells are studied to demonstrate the performance of the present asymptotic theory.

ABSTRACT: A refined asymptotic theory for the static analysis of laminated circular conical shells is presented. The formulation begins with the basic equations of three-dimensional (3D) elasticity in curvilinear circular conical coordinates. By means of proper nondimensionalization and asymptotic expansion, the 3D equations can be decomposed into recursive sets of differential equations at various levels. After bringing the effect of transverse shear deformations to the picture earlier and then applying successive integration, we obtain the recursive sets of governing equations leading to the ones of first-order shear deformation theory (FSDT). The FSDT becomes a first-order approximation to the 3D theory. The method of differential quadrature (DQ) is used for determining the present asymptotic solutions for various orders. The illustrative examples are given to demonstrate the performance of the present asymptotic theory.

ABSTRACT: Thermally induced dynamic instability of laminated composite conical shells is investigated by means of a perturbation method. The laminated composite conical shells are subjected to static and periodic thermal loads. The linear instability approach is adopted in the present study. A set of initial membrane stresses due to the elevated temperature field is assumed to exist just before the instability occurs. The formulation begins with three-dimensional equations of motion in terms of incremental stresses perturbed from the state of neutral equilibrium. After proper nondimensionalization, asymptotic expansion and successive integration, we obtain recursive sets of differential equations at various levels. The method of multiple scales is used to eliminate the secular terms and make an asymptotic expansion feasible. Using the method of differential quadrature and Bolotin's method, and imposing the orthonormality and solvability conditions on the present asymptotic formulation, we determine the boundary frequencies of dynamic instability regions for various orders in a consistent and hierarchical manner. The principal instability regions of cross-ply conical shells with simply supported–simply supported boundary conditions are studied to demonstrate the performance of the present asymptotic theory.

ABSTRACT: A methodology to select the best material combination and optimally design composite sandwich cylinders having fibre reinforced skins and low density cores for minimum mass is described. Sandwich constructions generally provide improved stiffness/mass ratios and more tailoring opportunities than monolithics, and thus greater chance of satisfying design constraints. The objective of the optimisation is to minimise the laminate mass by selecting the skin and core material combination, layer thicknesses and skin fibre angles optimally, subject to load and cost constraints. As the optimisation problem contains a number of continuous (ply angles and thicknesses) and discrete (material combinations) design variables, a sequential solution procedure is devised in which the optimal variables are computed in different stages. The procedure and its benefits are demonstrated using Graphite, Glass or Kevlar/Epoxy facings, and Balsa or PVC cores.

ABSTRACT: This paper presents an efficient numerical integration scheme for evaluating the matrices (stiffness, mass, stress-stiffness and thermal load) for a doubly curved, multilayered, composite, quadrilateral shell finite element. The element formulation is based on three-dimensional continuum mechanics theory and it is applicable to the analysis of thin and moderately thick composite shells. The conventional formulation requires a 2 x 2 x 2 or 2 x 2 x 1 Gauss integration per layer for the calculation of element matrices. This method becomes uneconomical when a large number of layers is used owing to an excessive amount of computations. The present formulation is based on explicit separation of the thickness variable from the shell surface parallel variables. With the through-thickness variables separated, they are combined with the thickness dependent material properties and integrated separately. The element matrices are computed using the integrated material matrices and only a 2 x 2 spatial Gauss integration scheme. The response results using the present formulation are identical to those obtained using the conventional formulation. For a small number of layers, the present method requires slightly more CPU time. However, for a larger number of layers, numerical data are presented to demonstrate that the present formulation is an order-of-magnitude economical compared to the conventional scheme.

ABSTRACT: This study presents the dynamic equations of a stiffened composite laminated conical thin shell under the influence of initial stresses. The governing equations of a truncated conical shell are based on the Donnell-Mushtari theory of thin shells including the transverse shear deformation and rotary inertia. The extension-bending coupling is considered in the derivation. The composite laminated conical shell is also reinforced at uniform intervals by elastic rings and/or stringers. The stiffening elements are relatively closely spaced, and therefore the stiffeners are smeared out along the conical shell. The inhomogeneity of material properties because of temperature, moisture, or manufacturing processes is taken into account in the constitutive equations. A generalized variational theorem is derived so as to describe the complete set of the fundamental equations of the conical shell. Next, the uniqueness is examined in solutions of the dynamic equations of the conical shell, and the boundary and initial conditions are shown to be sufficient for the uniqueness in solutions. The equations of the laminated composite conical shell are solved by the use of the finite difference method as an illustrative example. The accuracy of results is tested by certain earlier results, and a good agreement is found.

ABSTRACT: The buckling behavior of laminated composite plates subjected to a uniform temperature field is studied. Transverse shear flexibility is accounted for in the analysis using the thermo-elastic version of the first-order shear deformation theory. The prebuckling behavior of the plate under a uniform temperature field is studied prior to predicting the initial thermal buckling load. Numerical results are presented for thermal buckling problems using a nine-noded isoparametric quadrilateral finite element. The influence of boundary conditions, ply orientation, and plate geometries on the critical buckling temperature is examined.

ABSTRACT: The thermal stress analysis of laminated doubly curved shallow shells is presented using a shear flexible finite element model. The basic equations of the laminated shell theory are the extensions of Sanders' shell theory to include shear deformation and the thermal strains. The present finite element solution for isotropic and composite plates is compared with the closed form solutions available in the literature. A wide variety of laminated shell problems subjected to different temperature fields are studied. The influence of temperature dependent material properties, panel sizes, and boundary conditions on the thermal deformations are demonstrated.

K. Chandrashekhara and D. V. T. G. Pavan Kumar (Department of Civil Engineering, Indian Institute of
ABSTRACT: This paper examines the accuracy of classical shell theories (CST) according to Flugge, Sanders, Love and Donnell, with respect to the recently available three-dimensional elasticity solution, for cross-ply laminated circular cylindrical shells under static loads. Further, a study has also been made to examine to what extent incorporation of first order shear deformation (FSDT), in aforementioned shell theories, improves the results. In general, all the basic equations (for both CST and FSDT), of aforementioned shell theories, have been presented in a unified form using tracer coefficients. A Navier type solution has been used to analyse both a simply supported circular cylindrical shell of revolution and an all round simply supported circular cylindrical shell panel. A parametric study has been carried out keeping in view the lamination schemes and geometrical parameters of the shell. From the detailed comparisons of the results it has been shown that (i) Donnell's theory (CST and FSDT) could be in error for certain lamination schemes and geometrical parameters and (ii) improved results for stresses and displacements could be obtained by incorporating shear deformation on more accurate theory like Flügge’s.

ABSTRACT: A detailed study, on the static response of cross-ply laminated composite circular cylindrical shell of revolution and shell panel with various support conditions, has been made using Levy type of solution and the classical shell theories of Fl Sanders, Love and Donnell in an unified form. It has been shown that while developing a Levy type of solution using aforementioned theories, certain difficulty is encountered for determining the particular integral in respect of Fl Sanders and Love theories. This difficulty has been overcome by making use of the membrane solution as a particular integral. A comparative study has been carried out using the above shell theories for different geometrical parameters, lamination schemes and support conditions. It has been shown that Donnell theory predicts inaccurate results for certain lamination schemes, support conditions and geometrical parameters of the shell. It is suggested that, for developing shear deformation shell theories, it would be better to use a more accurate shell theory like Flügge.

ABSTRACT: The buckling analysis of cross-ply laminated square plates subjected to three types of in-plane forces and various edge boundary conditions is presented on the basis of a unified five-degree-of-freedom shear deformable plate theory. The employment of the appropriate “shear deformation shape functions” in the theory leads to certain shear deformable plate theories developed previously, also, fulfills the requirement of the continuity conditions among the layers. The governing equations of buckling behaviour of completely simply supported cross-ply laminated plates are solved analytically. For the plates with different combinations of free, clamped and simply supported boundary conditions at their edges, the Ritz method is applied by assuming the displacement components as the double series of simple algebraic polynomials. The numerical results obtained on the basis of various plate theories for uniaxial, biaxial compression and compression–tension types of loading and different length-to-thickness ratios are presented and compared with the ones available in the literature.

ABSTRACT: In the present study, unified shear deformation theory which was proposed by Soldatos, K.P. and Timarci, T. (1993). A Unified Formulation of Laminated Composite, Shear Deformable Five-degrees-of-freedom Cylindrical Shells on the Basis of a Unified Shear Deformable Shell Theory, Compos. Struct., 25(1–4): 165–171 is used to analyze simply supported symmetric cross-ply rectangular plates for deflections, stresses, natural frequencies, and buckling loads. This theory enables the selection of different in-plane displacement components to represent shear deformation. Exponential shear deformation theory, which is proposed by Karama et al., 40(6) (2003). Mechanical Behavior of Laminated Composite Beam by New Multi-layered Laminated Composite Structures Model with Transverse Shear Stress Continuity, Int J Solids Struct., 40: 1525–1546, is used for the first time to analyze the problem considered. ABSTRACT: A new hyperbolic shear deformation theory taking into account transverse shear deformation effects is presented for the buckling and free vibration analysis of thick functionally graded sandwich plates. Unlike any other theory, the theory presented gives rise to only four governing equations. Number of unknown functions involved is only four, as against five in case of simple shear deformation theories of Mindlin and Reissner (first shear deformation theory). The plate properties are assumed to be varied through the thickness following a simple power law distribution in terms of volume fraction of material constituents. The theory presented is variationally consistent, does not require shear correction factor, and gives rise to transverse shear stress variation such that the transverse shear stresses vary parabolically across the thickness satisfying shear stress free surface conditions. Equations of motion are derived from Hamilton's principle. The closed-form solutions of functionally graded sandwich plates are obtained using the Navier solution. The results obtained for plate with various thickness ratios using the theory are not only substantially more accurate than those obtained using the classical plate theory, but are almost comparable to those obtained using higher order theories with more number of unknown functions.

ABSTRACT: The present study is concerned with the buckling analysis of cross-ply laminated beams subjected to different sets of boundary conditions. The analysis is based on a three-degree-of-freedom shear deformable beam theory. The requirement of the continuity conditions between layers for symmetric cross-ply laminated beams are satisfied by the use of the shape function incorporated into the theory which also unifies the one-dimensional shear deformable beam theories developed previously. The governing equations are obtained by means of Minimum Energy Principle. Three different combinations of free, clamped and simply supported edge boundary conditions are considered. The critical buckling loads are obtained by applying the Ritz method where the three displacement components are expressed in a series of simple algebraic polynomials. The numerical results were obtained for different length-to-thickness ratios and lay-ups are presented and compared with the
ones available in the literature.

ABSTRACT: The present study is concerned with the thermal buckling analysis of cross-ply laminated beams subjected to different sets of boundary conditions. The analysis is based on a three-degree-of-freedom shear deformable beam theory. The requirement of the continuity conditions between layers for symmetric cross-ply laminated beams is satisfied by the use of the shape function incorporated into the theory which also unifies the one dimensional shear deformable beam theories developed previously. The governing equations are obtained by means of minimum energy principle. Three different combinations of clamped and hinged edge boundary conditions are considered. The critical thermal buckling temperatures are obtained by applying the Ritz method where the three displacement components are expressed in a series of simple algebraic polynomials. The numerical results obtained for different length-to-thickness ratios and lay-ups are presented and compared with the ones available in the literature. It is interesting to note that some cross-ply beams buckle upon cooling instead of heating and some of them do not buckle irrespective of whether they are heated or cooled.

Metin Aydogdu (Department of Mechanical Engineering, Trakya University, 22180 Edirne, Turkey), “A general nonlocal beam theory: Its application to nanobeam bending, buckling and vibration”, Physica E: Low-dimensional Systems and Nanostructures, Vol. 41, No. 9, September 2009, pp. 1651-1655, doi:10.1016/j.physe.2009.05.014

ABSTRACT: In the present study, a generalized nonlocal beam theory is proposed to study bending, buckling and free vibration of nanobeams. Nonlocal constitutive equations of Eringen are used in the formulations. After deriving governing equations, different beam theories including those of Euler–Bernoulli, Timoshenko, Reddy, Levinson and Aydogdu [Compos. Struct., 89 (2009) 94] are used as a special case in the present compact formulation without repeating derivation of governing equations each time. Effect of nonlocality and length of beams are investigated in detail for each considered problem. Present solutions can be used for the static and dynamic analyses of single-walled carbon nanotubes.

ABSTRACT: The hybrid nonlocal Euler-Bernoulli beam model is applied for the bending, buckling, and vibration analyzes of micro/nanobeams. In the hybrid nonlocal model, the strain energy functional combines the local and nonlocal curvatures so as to ensure the presence of small length-scale parameters in the deflection expressions. Unlike Eringen’s nonlocal beam model that has only one small length-scale parameter, the hybrid nonlocal model has two independent small length-scale parameters, thereby allowing for a more flexible and
accurate modeling of micro/nanobeamlike structures. The equations of motion of the hybrid nonlocal beam and
the boundary conditions are derived using the principle of virtual work. These beam equations are solved
analytically for the bending, buckling, and vibration responses. It will be shown herein that the hybrid nonlocal
beam theory could overcome the paradoxes produced by Eringen’s nonlocal beam theory such as vanishing of
the small length-scale effect in the deflection expression or the surprisingly stiffening effect against deflection
for some classes of beam bending problems.

“On nonconservativeness of Eringen’s nonlocal elasticity in beam mechanics: correction from a discrete-based
approach”, Archive of Applied Mechanics, Vol. 84, No. 9, pp 1275-1292, October 2014
ABSTRACT: In this paper, the self-adjointness of Eringen’s nonlocal elasticity is investigated based on simple
one-dimensional beam models. It is shown that Eringen’s model may be nonself-adjoint and that it can result in
an unexpected stiffening effect for a cantilever’s fundamental vibration frequency with respect to increasing
Eringen’s small length scale coefficient. This is clearly inconsistent with the softening results of all other
boundary conditions as well as the higher vibration modes of a cantilever beam. By using a (discrete)
microstructured beam model, we demonstrate that the vibration frequencies obtained decrease with respect to an
increase in the small length scale parameter. Furthermore, the microstructured beam model is consistently
approximated by Eringen’s nonlocal model for an equivalent set of beam equations in conjunction with
variationally based boundary conditions (conservative elastic model). An equivalence principle is shown
between the Hamiltonian of the microstructured system and the one of the nonlocal continuous beam system.
We then offer a remedy for the special case of the cantilever beam by tweaking the boundary condition for the
bending moment of a free end based on the microstructured model.

ABSTRACT: The axisymmetric dynamic behaviour of clamped isotropic and orthotropic spherical cap with central circular hole under a uniform step pressure of infinite duration is investigated. The critical loads are determined by using the rapidly converging Chebyshev series in a space domain and a Houbolt numerical integration scheme in time domain. Three different cases of openings are investigated and detailed numerical results have been obtained for the isotropic case and two different cases of orthotrophy, which may be useful for design engineers.

ABSTRACT: The problem of axisymmetric non-linear behaviour of laminated orthotropic spherical shells is formulated using the principle of virtual work. The efficacy and applicability of the method of global interior collocation for the solution of the title problem are investigated. The zeroes of a Chebyshev polynomial are used as the collocation points. Parametric studies are conducted to bring out the effects of factors like orthotropic ratio, R/h ratio, shear deformation and opening angle on the non-linear static response of two-layered annular cross-ply shells. The results using the analytical solution presented herein should serve as bench-mark numerical results to test the accuracy of non-linear composite shell elements employed in finite element analysis.

ABSTRACT: Dynamic response of laminated orthotropic spherical shells under axisymmetric dynamic load is investigated. The shell is assumed to be composed of layers of orthotropic materials whose principal material directions coincide with the shell curvature directions. The motion of the shell is described by a displacement field so as to include the effects of transverse shear deformation. Three coupled differential equations in terms of three generalized displacements at a point of the shell reference surface are written neglecting the rotatory inertia effects. These equations are then discretized in the time domain using the unconditionally stable Newmark–β integration scheme. The time discretized equations at any time step are solved by the method of global interior collocation at zeros of a Chebyshev polynomial of suitable order. Numerical results are presented to show the efficacy of the method. Results of parametric studies are presented to bring out the effects of the opening angle, material orthotropy, and shear deformation on the transient response.

ABSTRACT: The governing differential equations for the problem of laminated axisymmetric spherical shells undergoing large deformations are formulated using the principle of virtual work. An analytical solution of the governing equations based on the Chebyshev-Galerkin spectral method is investigated. The efficacy and applicability of the solution procedure is discovered using numerical results. Parametric studies are conducted to bring out the effect of factors like orthotropy ratio, R/h ratio, shear deformation and opening angle on the large deflection behaviour of laminated orthotropic spherical shells and interesting observations are made. The numerical results should prove helpful in testing the nonlinear composite shell finite elements.

ABSTRACT: The effect of low density polyurethane foam on the axial crushing of thin-walled (D/t>600) circular metal tubes is studied under quasi-static and dynamic loading conditions. The mode of deformation of the tube is found to change from irregular diamond crumpling to axisymmetric bellows folding due to the filler. Assuming the axisymmetric mode of crushing and using the model of foam recently developed (M.F. Ashby, Metals Trans.14A, 1755–1769, 1983), the behaviour is analysed. Theoretical predictions agree well with experiments. Numerical results show that there is an optimum foam density which produces a maximum specific energy absorption of the filled cylinders.

“Bending crush behavior of foam-filled sections”, 1999, (publisher not given in the pdf file)

ABSTRACT: Bending crush behavior of thin--walled columns filled with closed-cell aluminum foam is studied experimentally and numerically. Non linear dynamic finite element code was used to simulate quasi-static three point bending experiments. Two strengthening mechanisms are observed. First, the aluminum foam filler retards inward fold formation in the compressive flange, therefore preventing the drop in load carrying capacity due to sectional crush. Then, the inward fold retardation changes the crushing mode from single stationary fold, a typical bending crush behavior of an empty beam, to multiple propagating folds. The progressive fold formations spread plastic deformations, thus dissipating more energy. These phenomena are captured from both experiments and numerical simulations. High bending resistance is also maintained when the foam is placed only locally in the zone of high bending moment. The concept of the effective foam length is then developed, and potential applications of foam-filled sections for crashworthy structures are suggested.

ABSTRACT: This paper deals with the post-buckling deformation characteristics of aluminum alloy extruded polygonal section tubes subjected to dynamic axial impacts. The explicit finite element code LS-DYNA is the primary analytical tool used in this investigation. The study focuses on investigating a post-buckling deformation phenomenon that is primarily manifested by an axial crumpling action that generates material folds as the impact energy is dissipated. The research is conducted in two phases. The first phase consists of validating the LS-DYNA model parameters and numerical results pertaining to thin-walled aluminum extruded square tubes with actual published experimental data. The post-buckling deformation characteristics of the specimens such as the overall final configuration and the various folding deformation modes (extensional, symmetric and asymmetric) resulting from the axial collapse of the member is also investigated in a subsequent phase. Based on the numerical simulation results, it is apparent that the increase in the number of walls (flanges) has a direct impact on the mean axial crushing force and permanent displacement parameters. In particular, the adoption of a hexagonal tube section as an axially loaded energy absorbing column yields an average increase of 11% in the mean axial crushing force and an average decrease of 10% in the permanent displacement. The greatest benefits are obtained in the specimens with the thinnest nominal wall thickness, where the upper bound results show an average increase of 27% in the mean axial crushing force and average decrease of 20% in the permanent displacement.

ABSTRACT: The three-dimensional theory of elasticity in curvilinear coordinates is employed to investigate the dynamic buckling of an imperfect orthotropic circular cylindrical shell under mechanical and thermal loads. Accurate form of the strain expressions of imperfect cylindrical shells is established through employing the general Green’s strain tensor for large deformations and the equations of motion are derived in terms of the second Piola-Kirchhoff stress tensor. Then, the governing equations are properly formulated and solved by means of an efficient and relatively accurate solution procedure proposed to solve the highly nonlinear equations resulting from the above analysis. The proposed formulation is very general as it can include the
influence of the initial imperfections, temperature distribution, and temperature dependency of the mechanical properties of materials, effect of various end conditions, possibility of large-deformation occurrence and application of any combination of mechanical and thermal loadings. No simplifications are done when solving the resulting equations. Furthermore, in contrast to the displacement-based layer-wise theories and the three-dimensional approaches proposed so far, the stress, force and moment boundary conditions as well as the displacement type ones, can be incorporated accurately in these formulations. Finally, a few examples of mechanical and thermal buckling of some orthotropic cylindrical shells are considered and results of the present three-dimensional elasticity approach are compared with the buckling loads predicated by the Donnell’s equations, some single-layer theories, some available results of the layer-wise theory and the recently published three-dimensional approaches and the accuracy of the later methods are discussed based on the exact method presented in this paper.

ABSTRACT: Only static buckling of the hybrid functionally graded material (FGM) cylindrical shells has been investigated so far. In the present paper, dynamic buckling of imperfect FGM cylindrical shells with integrated surface-bonded sensor and actuator layers subjected to some complex combinations of thermo-electro-mechanical loads is investigated. The general form of Green's strain tensor in curvilinear coordinates and a high-order shell theory proposed earlier by the author are used. The complicated nonlinear governing equations are solved using the finite-element method. Buckling load is detected by a modified Budiansky's criterion proposed earlier by the author. Effects of temperature dependency of material properties, volume fraction index, load combination, and initial geometric imperfections on thermo-electro-mechanical post-buckling behavior are evaluated. Results reveal that the volume fraction index, temperature gradient, layer sequence, and the adaptive feedback control somewhat may affect the buckling load.

ABSTRACT: FGM components are constructed to sustain high temperature gradients. There are many applications where the FGM components are vulnerable to transient thermal shocks. If a component is already under compressive external loads (e.g. under a combination of axial compression and external pressure), the mentioned thermal shocks will cause the component to exhibit dynamic behavior and in some cases may lead to buckling. On the other hand, a preheated FGM component may undergo dynamic mechanical loads. Only static thermal buckling investigations were developed so far for the FGM shells. In the present paper, dynamic buckling of a pre-stressed, suddenly heated imperfect FGM cylindrical shell and dynamic buckling of a mechanically loaded imperfect FGM cylindrical shell in thermal environment, with temperature-dependent properties are presented. The general form of Green’s strain tensor in curvilinear coordinates and a high order shell theory proposed already by the author are used. Instead of using semi-analytical solutions that rely on the validity of the separation of variables concept, the complicated nonlinear governing equations are solved using the finite element method. Buckling load is detected by a modified Budiansky criterion proposed by the author.
The effects of temperature-dependency of the material properties, volume fraction index, load combination, and initial geometric imperfections on the thermo-mechanical post-buckling behavior of a shell with two constituent materials are evaluated. The results reveal that the volume fraction index and especially, the differences between the thermal stresses created in the outer and the inner surfaces may change the buckling behavior. Furthermore, temperature gradient and initial imperfections have less effect on buckling of a shell subjected to a pure external pressure.

M. Shariyat (Faculty of Mechanical Engineering, KNT University of technology, Pardis Street, Molla-Sadra Street, Vanak Square, Tehran, Iran), “Dynamic buckling of imperfect laminated plates with piezoelectric sensors and actuators subjected to thermo-electro-mechanical loadings, considering the temperature-dependency of the material properties”, Composite Structures, Vol. 88, No. 2, April 2009, pp. 228-239, doi:10.1016/j.compstruct.2008.03.044

ABSTRACT: Dynamic buckling of piezolaminated plates under thermo-electro-mechanical loads has not been investigated so far. In the present paper, effects of the thermo-piezoelectricity on the dynamic buckling under suddenly applied thermal and mechanical loads are investigated for imperfect rectangular composite plates with surface-bonded or embedded piezoelectric sensors and actuators. A finite element formulation based on a higher-order shear deformation theory is developed. Both the initial geometric imperfections of the plate and the temperature-dependency of the material properties are taken into account. Complex dynamic loading combinations include in-plane mechanical loads, heating, and electrical actuations are considered. A nine-node second order Lagrangian element, an efficient numerical algorithm for solving the resulted highly nonlinear governing equations, and an instability criterion already proposed by the author are employed. A simple negative proportional feedback control is used to actively control the transient response of the plate. Results show that buckling mitigation due to utilizing integrated piezoelectric sensors and actuators is mainly achieved in extremely high gain values. It is also noticed that in many cases, effects of the control voltage on the results may be ignored compared to the temperature-dependency of the material properties and initial geometric imperfections effects.

ABSTRACT: The available accurate shell theories satisfy the interlaminar transverse stress continuity conditions based on linear strain–displacement relations. Furthermore, in majority of these theories, either influence of the transverse normal stress and strain or the transverse flexibility of the shell has been ignored. These effects remarkably influence the non-linear behavior of the shells especially in the postbuckling region. Furthermore, majority of the buckling analyses performed so far for the laminated composite and sandwich shells have been restricted to linear, static analysis of the perfect shells. Moreover, almost all the available shell theories have employed the Love–Timoshenko assumption, which may lead to remarkable errors for thick and relatively thick shells. In the present paper, a novel three-dimensional high-order global-local theory that satisfies all the kinematic and the interlaminar stress continuity conditions at the layer interfaces is developed for imperfect cylindrical shells subjected to thermo-mechanical loads. In comparison with the layerwise, mixed, and available global-local theories, the present theory has the advantages of: (1) suitability for non-linear analyses, (2) higher accuracy due to satisfying the complete interlaminar kinematic and transverse stress
continuity conditions, considering the transverse flexibility, and releasing the Love–Timoshenko assumption, (3) less required computational time due to using the global-local technique and matrix formulations, and (4) capability of investigating the local phenomena. To enhance the accuracy of the results, compatible Hermitian quadrilateral elements are employed. The buckling loads are determined based on a criterion previously published by the author.

Struct 92 (1) (2010), pp. 130–143, DOI: 10.1016/j.compstruct.2009.07.007

ABSTRACT: The available plate theories have been generally calibrated using linear strain–displacement expressions. Furthermore, many of them do not consider the transverse normal stress continuity and the transverse flexibility of the sandwich plates. Majority of the investigations performed so far in the buckling analysis of the sandwich plates, have been restricted to linear buckling analysis of the perfect sandwich plates based on theories that either violate the continuity condition of the transverse stresses at the layer interfaces or do not satisfy the mentioned condition when nonlinear strain–displacement expressions are used. Therefore, their results may be unreliable for nonlinear stress and buckling (especially in the postbuckling region) analyses. In the present paper, nonlinear strain–displacement expressions are employed for imperfect sandwich plates subjected to thermo-mechanical loads to propose an accurate global–local theory that satisfies the continuity of all of the transverse stress components. The theory is presented in a compact matrix form. Compatible Hermitian elements with C1 continuity are employed to enhance the results. Buckling and wrinkling loads are detected employing a criterion previously published by the author. Comparisons made in the paper with results reported by well-known references, confirm the accuracy and the efficiency of the proposed theory and the relevant solution algorithm.

ABSTRACT: The accurate shell theories proposed so far have been calibrated based on linear kinematic relations. Many of them have ignored either the interlaminar stress continuity conditions at the interfaces or the transverse flexibility of the layers. Therefore the available shell theories may encounter accuracy problems when analyzing the nonlinear behaviors, especially for sandwich shells with soft cores. Moreover, almost all of the available shell theories have been proposed employing the Love-Timoshenko assumption. Ideas of the previous global-local plate theory of the author are extended to develop the present nonlinear high-order global-local shell theory. The present theory has the advantages of: (1) suitability for nonlinear analyses, (2) higher accuracy due to satisfying the complete interlaminar kinematic and transverse stress continuity conditions at the layer interfaces under thermo-mechanical loads, employing the exact Green’s strain tensor of the curvilinear coordinates, considering the transverse flexibility, and releasing the Love-Timoshenko assumption, (3) less required computational time due to using the global-local technique and matrix formulations, and (4) capability of investigating the local phenomena. To enhance the accuracy of the results, compatible Hermitian elements
are employed. Various comparative examples are included in the present paper to validate the theory and to examine its accuracy and efficiency.

ABSTRACT: The objective of this research is determining the buckling load of composite truncated conical shells under external loading by theoretical and numerical methods. The boundary conditions are assumed to be clamped. At first, basic equations and stability relations of conical shells were derived. The analysis is carried out using Donnell-type stability equations for thin cross-ply conical shells. By applying Galerkin’s method, these equations are converted to a system of ordinary time dependent differential equations. Ritz method is employed for finding the dynamic stability load. Finally, the critical static and dynamic buckling loads and the corresponding wave numbers have been found analytically. Then comparison of results is considered. Results of analytical calculations are compared with numerical results and with other researchers’ analytical results. The effects of geometric parameters, the cone semi-vertex angle, number of layers and material of fibers on buckling loads are discussed.

ABSTRACT: Dynamic buckling of an orthotropic cylindrical shell which is subjected to rapidly applied compression is considered. A nonlinear differential equation of Donnell–Kármán type is derived with the initial imperfection taken into account. An energy method is used to obtain the equation of motion which is then solved numerically by means of a Runge-Kutta method. These numerical results show that the critical load is increased over the corresponding static case. An analytical solution is also obtained for the problem of hydrostatic pressure.

ABSTRACT: The Nonlinear dynamic buckling and stability of nonlinearly elastic autonomous discrete systems under conservative step loading (of infinite or finite duration), impact and impulsive loading is examined in detail. Discrete structural systems which under the same loading applied statically exhibit snap-through buckling are mainly considered. Emphasis is focused on the coupling effect of nonlinearities (geometric and/or material) and structural damping. A qualitative discussion of the dynamic buckling mechanism is comprehensively presented on the basis of energy and topological concepts in the light of recent progress of
nonlinear dynamics and chaos. This leads to useful criteria for establishing exact, approximate and lower-upper bound dynamic buckling estimates without integrating the highly nonlinear equations of motion. It is shown that dynamic buckling can be defined as an escaped motion through a saddle of the (static) unstable postbuckling equilibrium path which leads either to an “unbounded” motion or to a point attractor associated with a remote stable equilibrium point. As byproducts of this analysis various phenomena such as restabilization (metastability), loading discontinuity, sensitivity to initial-conditions and to damping as well as chaoticlike Phenomena, are revealed. The theory is illustrated with analyses of single, two and three degrees of freedom models.

ABSTRACT: In this paper the effect of the interaction of two loadings, and of the deviation from right angle on the buckling mechanism of a rectangular two-bar frame is discussed. Using a nonlinear stability analysis it is found that there is a critical value of the ratio of the two loadings, as well as of the deviation from right angle, for which the physical equilibrium path and the physically unacceptable complementary path meet each other at an asymmetric bifurcation point. At this point, the response of the frame changes from an elastic limit point
instability to a stable equilibrium path associated with inelastic buckling. The analysis is supplemented by a variety of numerical results obtained by an efficient and reliable simplified nonlinear stability analysis applied for the first time to a non-rectangular frame.

ABSTRACT: The nonlinear lateral buckling response of perfect stocky beams in the vicinity of the critical bifurcational state is discussed. Attention is focused on the initial post-buckling response. This depends on the nature of the critical branching point which is explored by using a nonlinear (lateral) bending-curvature relationship. It is found that the plane of loading (associated with the major moment of inertia) looses its stability through a stable symmetric bifurcation point. Hence, the above beams are not sensitive to imperfections, exhibiting post-buckling strength. However, the post-buckling equilibrium path is quite shallow, so that the load-carrying capacity of such beams above the critical state is rather limited. The analysis is supplemented by illustrative examples for I-beams for which the effect of various parameters on the initial postbuckling path is also discussed.

References listed at the end of the paper:

ABSTRACT: The pre-critical, critical, and post-critical nonlinear response of an imperfect due to loading eccentricity two-bar frame is thoroughly discussed. In seeking the maximum load-carrying capacity of this non-sway frame, it was qualitatively established that its loss of stability occurs through a limit point and hence, the case of an asymmetric bifurcation can be considered only in an asymptotic sense. After deriving the nonlinear equilibrium equations with unknowns for the two bar axial forces, we can consider such a continuous system as a two-degree-of-freedom model with generalized coordinates the above axial forces. Then, the equilibrium equations and the stability determinant of the frame can be determined in terms of the first and second derivatives of its total potential energy (TPE) with respect to the axial forces. The vanishing of the second variation of the TPE together with the equilibrium equations allows a simple and direct evaluation of the buckling load. Numerical examples demonstrate the efficiency and the reliability of the proposed method.

ABSTRACT: The design optimization of axially loaded, simply supported stiffened cylindrical shells for minimum mass is considered. The design variables are thickness of shell wall, thicknesses and depths of rings and stringers, number-spacing of rings and stringers. Natural frequency, local and overall buckling strengths and direct stress constraints are considered in the design problems. Three different combinations of stiffeners are considered. In each case, the independent effects of behaviour constraints are also studied. The optimum designs are achieved with one of the standard nonlinear constrained optimization techniques (Davidon-Fletcher-Powell method with interior penalty function formulation) and few optimal solutions are checked for the satisfaction of Kuhn-Tucker conditions.

ABSTRACT: The design optimization of axially loaded, simply supported stiffened conical shells for minimum weight is considered. The design variables are thickness of shell wall, thicknesses and depths of rings and stringers, number-spacing of rings and stringers. Natural frequency, overall buckling strength and direct stress constraints are considered in the design problems. Optimization results are obtained by placing the stiffeners inside as well as outside the conical shell. In both these cases, the independent effects of behavior constraints are also studied. The optimum designs are achieved with one of the standard nonlinear constrained optimization techniques (Davidon-Fletcher-Powell method with interior penalty function formulation) and few optimal solutions are checked for the satisfaction of Kuhn-Tucker conditions.

ABSTRACT: The effect of nonlinear material behavior on the buckling of an infinitely long cylindrical shell under pure bending is studied. The maximum moment and associated curvature is determined as a function of material and geometric parameters. The curvature at which short wave-length bifurcations occur is also determined. The results are compared with behavior in the elastic range.

S. Gellin (Dept. of Civil Engineering, State University of New York at Buffalo, New York, USA), “Effect of an

ABSTRACT: The effect of a sinusoidal axisymmetric shape imperfection on the plastic buckling of a long cylindrical shell under axial compression is studied. The load at which nonaxisymmetric bifurcation from the axisymmetric state occurs is determined as a function of the imperfection amplitude for relatively thin shells. Imperfection-sensitivity in the plastic range is contrasted with that in the elastic range.

ABSTRACT: The buckling of a short, elastic cylindrical shell in pure bending is explored. A set of solutions is found which appears to give slightly more conservative bifurcation load estimates than those obtained by previous investigators. Some explanations are put forth to explain the difference in results.

ABSTRACT: Composite cylindrical shells are being used more extensively for structural applications in both rotary- and fixed-wing aircraft where low weight and high strength are important design issues. This paper addresses the energy absorption capability of such shells, under axial compressive loading. A design optimization procedure is developed to improve the energy absorption by maximizing the buckling and postbuckling characteristics of the shells. The sensitivity of both geometric and material properties is investigated by studying thin-walled shells of several thicknesses, made of different types of orthotropic laminates. Constraints are imposed on the longitudinal, normal, and in-plane shear stresses of each ply by utilizing a failure criteria. Design variables include shell diameter and ply orientations. The optimization is performed using the nonlinear programming method of feasible directions. A two-point exponential approximation is also used to reduce computational effort. Results are presented for Graphite/Epoxy, Glass/Epoxy, and Kevlar/Epoxy composite cylindrical shells with symmetric ply arrangements.

ABSTRACT: A higher-order shear deformation theory has been employed for evaluating accurately the transverse shear effects in delamination buckling of cylindrical shells under axial compression. The governing differential equations of the present theory are obtained by applying the principle of the stationary value of the total potential. The Rayleigh-Ritz method is used to solve the equations by assuming a double Fourier expansion of the displacements with trigonometric coordinate functions. Numerical results for linear delamination buckling of axially compressed cylindrical shells with clamped ends are presented to validate the theory. Comparisons are made with the classical laminate theory and first-order theory results.

Haozhong Gu and Aditi Chattopadhyay (Arizona State University, Tempe, Arizona), "Delamination buckling

ABSTRACT: A higher-order deformation theory is developed for accurately evaluating the transverse shear effects in delamination buckling and postbuckling of cylindrical shells under axial compression. The theory assures a more accurate description of displacement field and the satisfaction of stress-free boundary conditions for the delamination problem. The governing differential equations of the present theory are obtained by applying the principle of virtual displacement. The Rayleigh-Ritz method is used to solve both linear and nonlinear equations by assuming a double trigonometric series for the displacements. Both linearized buckling analysis and nonlinear postbuckling analysis are performed for axially compressed cylindrical shells with clamped ends. Comparisons made with the classical laminate theory and a first-order theory show significant deviations.

ABSTRACT: Variational finite-difference methods of solving linear and nonlinear problems for thin and non-thin shells (plates) made of homogeneous isotropic (metallic) and orthotropic (composite) materials are analyzed and their classification principles and structure are discussed. Scalar and vector variational finite-difference methods that implement the Kirchhoff–Love hypotheses analytically or algorithmically using Lagrange multipliers are outlined. The Timoshenko hypotheses are implemented in a traditional way, i.e., analytically. The stress–strain state of metallic and composite shells of complex geometry is analyzed numerically. The numerical results are presented in the form of graphs and tables and used to assess the efficiency of using the variational finite-difference methods to solve linear and nonlinear problems of the statics of shells (plates)

ABSTRACT: The buckling of the piezoelectric laminated cylindrical shell with throughout circumference delamination is analyzed in this paper. By introducing the Heaviside step function into assumed displacement components and using elastic piezoelectric theory, the constitutive relations of the piezoelectric laminated shell with delamination are established. Then the buckling governing equations of the structure are derived through variational principle. In numerical examples, the effects of delamination length, depth, material property and thickness of piezoelectric layer on the buckling load of piezoelectric laminated shell with delamination are investigated.

ABSTRACT: High precision finite elements for both thin plate and stiffener are developed in this paper to analyse the stability of thin plates subjected to arbitrary membrane loading with arbitrarily oriented stiffeners. Application of these elements to some complex stability problems show high accuracy even with a relatively coarse finite element mesh. For all the problems considered the predicted critical loads are accurate upper bounds.

ABSTRACT: The behaviour of thin tubes made of sheet metal and not so thin extruded tubes filled with wood and subjected to axial crushing is studied. Experiments show that the mode of elastic buckling is changed by the presence of the wood filler. The plastic crushing of thin tubes resulted in Euler-type buckling, while a considerable enhancement in the load carrying capacity and energy absorption was seen in the case of thicker walled tubes which were examined both under quasi-static and dynamic loading conditions. A new idealized deformation mechanism for the progressive crushing of the wood-filled tube is suggested and analysed. The results obtained for the mean loads agree reasonably with experimental observations. An alternative method employed to predict the mean crushing load of empty tubes and using a thickness that provides an equivalent stiffness to that of a filled tube is also seen to produce reasonable agreement with the experiment.
ABSTRACT: The response to pure bending of tubes with rectangular cut-outs is considered. Experiments on 1000-mm long, 100-mm diameter, and 2.55-mm wall thickness DIN 2391 ST NBK supported steel tubes are described. Such a thickness-to-diameter ratio is typical of structural columns, rather than shell structures. Tubes containing cut-outs with an axial dimension of up to 30 mm and a circumferential size of up to 180° were tested. It was found that plastic hinge mechanisms dominated the response when the cut-out was on the compressive side, whereas fracture behaviour dominated the response when the cut-out was on the tensile side. Finite element and semi-empirical analyses were carried out to predict the global load-deformation behaviour of the tubes. All analyses gave reasonable predictions of the experimental results for the majority of the cut-out parameters investigated. The aim of this study is to investigate the feasibility of using cut-outs to initiate and control the toppling of offshore jacket structures.

T.Y. Yang, Rakesh K. Kapania and Sunil Saigal (School of Aeronautics and Astronautics, Purdue University, West Lafayette, Indiana, USA), “Linear and nonlinear dynamic response analysis of complex shell structures”, (no publisher or date given in the pdf file; most recent reference is 1983)
ABSTRACT: The elastic-inelastic and geometrically nonlinear formulations and solution procedures have been developed for two types of finite elements, a six d.o.f beam element and a 48 d.o.f. quadrilateral curved shell element, for the static or dynamic response analysis of beam and shell structures with one or both types of nonlinearities. Three example structures are studied: an R.C. beam, a spherical cap, and a full spherical shell. The elastic formulations are used to analyze a cooling tower shell due to earthquake and wind loads. For earthquake loads, response spectrum analysis is performed. For wind loads, frequency domain analysis is performed.

ABSTRACT: Formulations and computational procedures are presented for the finite element analysis of laminated anisotropic composite thin shells including imperfections. The derivations of the nonlinear geometric element stiffness matrices were based on the total Lagrangian description. A 48 degree-of-freedom (d.o.f.) general curved shell element with arbitrary distribution of curvatures was used to model the shell middle-surface. Numerical results include the large deflection behavior of a variety of perfect plate and shell examples; buckling of a spherical shell with an axially symmetric imperfection; and buckling of a cylindrical panel using measured initial transverse imperfections. A good comparison with existing results is obtained.

ABSTRACT: Structural failure under dynamic loads may occur at load levels that are less than the
corresponding static load. Presence of local geometric imperfections may induce an early failure for both static and dynamic loadings. The phenomenon of ‘dynamic weakening’ is studied for a general class of shell structures under a general class of time dependent loadings. A doubly curved quadrilateral Love-Kirchhoff shell finite element is used. Geometric deviations of the shell middle surface are included within the element formulation by suitably modifying the strain-displacement relations. This is accomplished by retaining additional terms that are quadratic in spatial derivatives of imperfections and displacement components. The nonlinear equations of motion are written in the Lagrangian system and are solved by using an incremental algorithm based on Newmark's generalized operator. The dynamic buckling responses of a spherical cap with and without local imperfections are presented. The formulation is general and can be applied to obtain the dynamic buckling response of a wide variety of shell structures.

ABSTRACT: Natural frequencies and forced responses of thin laminated composite shells of general form are investigated using a high-order curved shell finite element. The effect of geometric nonlinearity is included in the determination of the forced responses which are obtained using Newmark’s numerical integration scheme. A class of shell problems which are general with respect to geometry; boundary conditions; number, stacking sequence, and angle of orientation of the lamina; and load function can be solved using the present formulations. Numerical results and their comparisons with existing solutions are presented for cylindrical shells, shells of positive and negative Gaussian curvature, spherical caps, and shells of translation with different boundary conditions.

ABSTRACT: Linear and nonlinear analysis of shell structures are performed using finite elements. Shell elements are formulated to capture the linear and nonlinear behavior of shell structures. Although general, the elements are specially suited for tubular joints. An automatic geometric modeling and mesh generation procedure for T, K and DT-joints is first developed. A set of shell elements are then developed and implemented in a general purpose, research oriented finite element analysis program (FEAP) to carry out linear, materially-nonlinear only, geometrically-nonlinear-only and geometric and material nonlinear analyses of thin shell structures with special emphasis on tubular joints which represent essential components of offshore platforms. A six-degree-of-freedom per node (including a true drilling degree of freedom) assembly allows easy modeling of complicated shell structures such as tubular joints or stiffened shells. The displacement interpolation is carefully chosen in order to avoid shear and membrane locking in linear and nonlinear problems. The curvature effects (initial curvature and changes in curvature due to large displacements and rotations) are incorporated by a simple modification of the flat linear shell element. This computationally very inexpensive modification increases the performance of the element by several folds. The total corotational formulation, a Lagrangian formulation, is used to treat geometric nonlinearity. Each point in the thickness of the shell is considered to be under plane stress conditions. Von Mises yield criterion with linear isotropic and kinematic hardening and the associated Prandtl-Reuss flow rule is used to model the plastic flow behavior of the
shell material. The flow rule and hardening law are integrated using the return map algorithm. The robustness of the analysis tool developed is demonstrated by solving a range of linear and nonlinear problems of shell analysis. It is demonstrated through examples and comparison with known analytical or reliable numerical solutions that the elements developed are accurate in predicting both displacements and stresses. The ultimate test of the predictive ability of the analysis tool developed is performed by considering three well documented tubular joint examples (T-, K-, and DT-joints) for which experimental results in terms of load deflection curve are available. The prediction of the collapse load and load-deflection curve for the T-joint is in excellent agreement with the experimental results. This agreement between numerical and experimental results for both the K- and DT-joints is also very good considering the complexity of the actual joint structure. Finally, a parametric study of tubular T-joints is conducted to study the effects of the various geometric parameters on the collapse load.

ABSTRACT: Stability analysis of perfect and imperfect cylindrical shells under wind pressures is performed using the finite element method. A 48 degree-of-freedom (d.o.f.) thin shell element previously developed by the present authors is used. The element is free from both shear and membrane locking and is capable of modelling shells with arbitrary imperfections. Nonlinear effects due to prebuckling rotations are taken into account. The nonlinear response is obtained using Riks-Wempner algorithm. Effects of the imperfection amplitude and that of the material orthotropy on the limit load points are studied. Wherever possible, the present results are compared with existing results. A favorable agreement is observed.

ABSTRACT: The spectral method is a powerful numerical technique for solving engineering differential equations. The method is a specialization of the method of weighted residuals. Trial functions that are easily and exactly differentiable are used. Often the functions used also satisfy an orthogonality equation, which can improve the efficiency of the approximation. Generally, the entire domain is modeled, but multiple sub-domains may be used. A Chebyshev-Collocation Spectral method is used to solve a two-dimensional, highly nonlinear, two parameter Bratu's equation. This equation previously assumed to have only symmetric solutions are shown to have regions where solutions that are non-symmetric in x and y are valid. Away from these regions an accurate and efficient technique for tracking the equation's multi-valued solutions was developed. It is found that the accuracy of the present method is very good, with a significant improvement in computer time.

ABSTRACT: The objective of this paper is to analyze the effect of complex, arbitrary in-plane and out-of-plane loads on the transverse vibrations of thin arbitrarily laminated panels with or without geometric imperfections. The finite-element method is used. A 48 degree-of-freedom thin shell element previously formulated by the senior author is employed. The formulation is general with respect to the boundary conditions, types of imperfections, and number, orientation, and stacking sequence of the lamina. A large radius to thickness ratio is assumed so as to ignore the shear and rotary inertia effects. The results are presented for angle-ply rectangular plates and cross-ply cylindrical panels, with both of these having simply supported edge conditions along all the four edges, and isotropic square plates involving free edges under non-uniform combined loads. The panels are subjected to both axial and shear in-plane stresses. The effects of geometric parameters (aspect ratio, panel curvature, and geometric imperfections) and material properties (varying the number of layers but the same thickness) are examined. The results are presented in the form of frequency-load interaction curves for various geometric parameters. Whenever possible, the present results are compared with those available in the existing literature. A good agreement is observed.

ABSTRACT: The nonlinear transient response of thin imperfect laminated plates subjected to impact loads is studied using a 48 DOF finite element based on the classical laminated plate theory. Comparison between the first-order shear deformation theory and the classical laminated plate theory is also made to study the effect of shear deformation. The modified Hertzian law by Tan and Sun is incorporated to evaluate the impact loads due to a projectile. The transient response of an example problem is obtained using both full and reduced equations of motion. A reduction method using Ritz vectors as the basis vectors is employed to reduce the size of the nonlinear problem and thus save computational effort. The resulting reduced (but still coupled) set of equations is integrated in a step-by-step fashion using the Newmark constant-average acceleration time integration scheme along with an iterative scheme for dynamic equilibrium. It is observed that geometric imperfections cause significant changes in the impact response of thin laminated plates. The reduction method used in this study was not found to be very efficient for obtaining the nonlinear impact responses. Further research is needed to develop reduction methods that are more suitable for studying nonlinear impact responses.

ABSTRACT: The paper analyzes the effect of geometric imperfections on the free-vibration, and static and dynamic responses of hyperbolic shells. The effect of geometric nonlinearity is included. A 48 degree-of-freedom thin shell element, capable of modeling arbitrary geometric imperfections, is employed. A reduced basis method using the normal modes as the basis vectors is employed to reduce the size of the nonlinear problem and thus save computational effort. The resulting reduced (but still coupled) set of equations is integrated in a step-by-step fashion using the Wilson-theta method along with an iterative scheme. The integration scheme, first evaluated on a series of examples (both linear and nonlinear) is employed to obtain the dynamic response of hyperbolic shells with geometric imperfections. The shell is subjected to wind loads with
an assumed time history. The results are presented for the nonlinear static response of a cooling tower under wind loads; for the fundamental frequencies of a hyperbolic shell under increasing axisymmetric pressure loads; and finally for the dynamic response (normal displacements and the in-plane stress resultants) of an example hyperbolic shell under dynamic wind loads. Whenever possible, the present results are compared with those available in the existing literature. A good agreement is observed.

ABSTRACT: Reduction methods using eigenvectors and Ritz vectors as basis vectors are employed to reduce the finite element nonlinear system of equations using a 48 D.O.F. doubly curved thin plate/shell element. With and without basis updating, the solutions obtained by reduction methods are compared with the direct solutions. It is observed that basis updating is essential to obtain accurate solutions. The present reduction methods need a large number of basis vectors (eigenvectors and Ritz vectors) to account for the impact load which has high frequency characteristics. Furthermore, for nonlinear analysis, the reduction achieved in the CPU time are only marginal since most of the CPU time was spent in the calculation of the internal nodal force vector. These considerations indicate that reduction methods may not be efficient for the impact response analysis.

ABSTRACT: We conducted a fundamental study to investigate the dynamic behavior of laminated structures. Both finite element and analytical solutions were developed. Using a 48 degree-of-freedom shell finite element (FE) developed by Kapania and coworkers, the effect of arbitrary inplane and out-of-plane loads on the transverse vibrations of thin arbitrarily laminated panels with or without geometric imperfections was analyzed. The element was used to investigate the effect of geometric imperfections on geometrically nonlinear impact response of thin laminated plates and cylindrical panels using reduced basis methods. A FE model was also developed to study the linear and geometrically nonlinear transient behavior of laminated beams. A postprocessor was developed that can use the transverse displacements from a classical laminated plate theory (CLPT) or a first order shear deformation theory (FSDT) to determine the transverse normal and shear stresses. The nonlinear dynamic equations of the first-order shear deformation theory and the third-order shear deformation plate theory of Reddy was reformulated to describe the interior and edge zone problems of rectangular plates. A three-dimensional elasticity solution for the free vibration analysis of general cross-ply laminated plates has been carried out by combining Fourier series solution with a state space representation and the transfer matrix approach. A close theoretical examination have clarified the accuracy of the various single layer theories and a layerwise theory with the exact elasticity solution. Composite materials, Impact response, Imperfect plates, Plates, Reduced basis methods, Response due to short duration loads, Shells, Transverse effects.

ABSTRACT: Although a large number of studies dealing with the impact response of flat laminated panels has been conducted in the past, relatively little work seems to be available on impact of laminated cylindrical panels. In this paper an analytical study is conducted to predict the nonlinear transient response of thin imperfect laminated cylindrical panels subjected to impact loads. A review is also given regarding the state of the art on the impact response of laminated plates and shells. The imperfect panels are modeled using a 48 degree-of-freedom (DOF) finite element based on the classical laminated plate theory. Linear and nonlinear transient responses are obtained using the modal superposition method (MSM) and a reduction method based on Ritz vectors (R-R), both in conjunction with direct integration schemes (Wilson-theta or Newmark methods). The effect of the number of modes used is also discussed. A modified contact law is incorporated to evaluate the impact loads due to a projectile. Different nondimensional shell radii $[r/h]$ are used in order to study the effect of nondimensional shell radii $[r/h]$ on the impact response of laminated cylindrical panels. The effect of geometric imperfections on linear and nonlinear transient response under sudden impact loads is also analyzed. Both the MSM and R-R methods used in the analysis are found to have acceptable accuracy and the accuracy increased with the number of modes used. It is observed that the reduction of the nondimensional shell radius $[r/h]$ causes significant changes in the impact response of the cylindrical panel: a significant decrease in the central deflection and contact force histories. The introduction of geometric imperfections led to similar conclusions.

ABSTRACT: The layerwise theory of Reddy is used to study the low velocity impact response of laminated plates. Forced-vibration analysis is developed by the modal superposition technique. Six different models are introduced for representation of the impact pressure distribution. The first five models, in which the contact area is assumed to be known, result in a nonlinear integral equation similar to the one obtained by Timoshenko in 1913. The resulting nonlinear integral equation is discretised using a time-element scheme. Two different interpolation functions, namely: (i) Lagrangian and (ii) Hermite, are used to express the impact force. The Hermitian polynomial-based representation, obviously more sophisticated, is introduced to verify the Lagrangian-based representation. Due to its modular nature the present numerical technique is preferable to the existing numerical methods in the literature. The final loading model, in which the time dependence of the contact area is taken into account according to the Hertzian contact law, resulted in a relatively more complicated but more realistic, nonlinear integral equation. The analytical developments concerning this model are all new and are reported for the first time in this paper. Also a simple, but accurate, numerical technique is developed for solving our new nonlinear integral equation which results in the time-history of the impact force. Our numerical results are first tested with a series of existing example problems. Then a detailed study concerning all the response quantities, including the in-plane and interlaminar stresses, is carried out for symmetric and antisymmetric cross-ply laminates and important conclusions are reached concerning the usefulness and accuracy of the various plate theories.

ABSTRACT: A layer-wise theory is used to study the low velocity impact response of laminated plates. The forced-vibration analysis is developed by the modal superposition technique. Six different models are introduced for representation of the impact pressure distribution. The first five models, in which the contact area is assumed to be known, result in a nonlinear integral equation similar to the one obtained by Timoshenko in 1913. The resulting nonlinear integral equation is discretised using a time-finite-element scheme. Two different interpolation functions, namely: (i) Lagrangian and (ii) Hermite are used to express the impact force. The Hermitian-polynomials based representation, obviously, more sophisticated, is introduced to verify the Lagrangian based representation. Due to its modular nature the present numerical technique is preferable to the existing numerical methods in the literature. Our numerical results are first tested with a series of existing example problems. Then a detailed study concerning all the response quantities, including the in-plane and interlaminar stresses, is carried out for cross-ply laminates and important conclusions are reached concerning the usefulness and accuracy of the various plate theories.

ABSTRACT: Finite element static, free vibration and thermal analysis of thin laminated plates and shells using a three noded triangular flat shell element is presented. The flat shell element is a combination of the Discrete Kirchhoff Theory (DKT) plate bending element and a membrane element derived from the Linear Strain Triangular (LST) element with a total of 18 degrees of freedom (3 translations and 3 rotations per node). Explicit formulations are used for the membrane, bending and membrane-bending coupling stiffness matrices and the thermal load vector. Due to a strong analogy between the induced strain caused by the thermal field and the strain induced in a structure due to an electric field the present formulation is readily applicable for the analysis of structures excited by surface bonded or embedded piezoelectric actuators. The results are presented for (i) static analysis of (a) simply supported square plates under doubly sinusoidal load and uniformly distributed load (b) simply supported spherical shells under a uniformly distributed load, (ii) free vibration analysis of (a) square cantilever plates, (b) skew cantilever plates and (c) simply supported spherical shells; (iii) Thermal deformation analysis of (a) simply supported square plates, (b) simply supported-clamped square plate and (c) simply supported spherical shells. A numerical example is also presented demonstrating the application of the present formulation to analyse a symmetrically laminated graphite/epoxy laminate excited by a layer of piezoelectric polyvinylidene fluoride (PVDF). The results presented are in good agreement with those available in the literature.

ABSTRACT: The study focuses on the development of a simple and accurate global/local method for calculating the static response of stepped, simply-supported, isotropic and composite plates with circular and elliptical cutouts. The approach primarily involves two steps. In the first step a global approach, the Ritz method, is used to calculate the response of the structure. Displacement based Ritz functions for the plate without the cutout are augmented with a perturbation function, which is accurate for uniform thickness plates only, to account for the cutout. The Ritz solution does not accurately satisfy the natural boundary conditions at the cut-out boundary, nor does it accurately model the discontinuities caused by abrupt thickness changes. Therefore, a second step, local in nature is taken in which a small area in the vicinity of the hole and encompassing other points of singularities is discretized using a fine finite element mesh. The displacement boundary conditions for the local region are obtained from the global Ritz analysis. The chosen perturbation function is reliable for circular cutout in uniform plates, therefore elliptical cutouts were suitably transformed to circular shapes using conformal mapping. The methodology is then applied to the analysis of composite plates, and its usefulness successfully proved in such cases. The proposed approach resulted in accurate prediction of stresses, with considerable savings in CPU time and data storage for composite flat panels.

ABSTRACT: This paper presents a simple and accurate global-local method to calculate the static response of simply-supported, composite plates with small cracks. The approach primarily involves two steps. In the first step a global approach, the Ritz method, is used to calculate the response of the structure. Displacement based Ritz functions for the plate without the crack are augmented with a perturbation function, which is accurate for isotropic plates only, to account for the crack. The Ritz solution does not accurately satisfy the natural boundary conditions at the crack boundary. Therefore, a second step, local in nature, is taken in which a small area in the vicinity of the crack and encompassing other points of singularities, is discretized using a fine finite element mesh. The displacement boundary conditions for the local region are obtained from the global Ritz analysis. The methodology is applied for the local model including the crack. The proposed approach resulted in accurate prediction of stresses, with 85% savings in computational time and 92% in data storage for the analysis of composite flat panels.

ABSTRACT: (none given).
PARTIAL ABSTRACT: GMRES(k) is widely used for solving nonsymmetric linear systems. However, it is inadequate either when it converges only for k close to the problem size or when numerical error in the modified Gram-Schmidt process used in the GMRES orthogonalization phase dramatically affects the algorithm performance. An adaptive version of GMRES(k) which tunes the restart value k based on criteria estimating the GMRES convergence rate for the given problem is proposed here. This adaptive GMRES(k) procedure outperforms standard GMRES(k), several other GMRES-like methods, and QMR on actual large scale sparse structural mechanics postbuckling and analog circuit simulation problems…

ABSTRACT: A triangular flat shell element for large deformation analysis of linear viscoelastic laminated composites is presented. Hygrothermomechanically simple materials are considered for which a change in the hygrothermal environment results in a horizontal shifting of the relaxation moduli curves on a log timescale, in addition to the usual hygrothermal loads. Recurrence relations are developed and implemented for the evaluation of the viscoelastic memory loads. The nonlinear deformation process is computed using an incremental/iterative approach with the Newton-Raphson method used to find the incremental displacements in each time step. The presented numerical examples consider the large deformation and stability of linear viscoelastic structures under deformation-independent mechanical loads, deformation-dependent pressure loads, and thermal loads. Unlike elastic structures that have a single critical load value associated with a given snapping or buckling instability phenomenon, viscoelastic structures will usually exhibit a particular instability for a range of applied loads over a range of critical times. Both creep buckling and snap through examples are presented here. In some cases, viscoelastic results are also obtained using the quasi-elastic method in which load-history effects are ignored, and time-varying viscoelastic properties are simply used in a series of elastic problems. The presented numerical examples demonstrate the capability and accuracy of the formulation.

ABSTRACT: Because of the inherent complexity of fiber-reinforced laminated composites, it can be challenging to manufacture composite structures according to their exact design specifications, resulting in unwanted material and geometric uncertainties. Thus the understanding of the effect of uncertainties in laminated structures on their static and dynamic responses is highly important for a reliable design of such structures. In this research, we focus on the probabilistic stability analysis of laminated structures subject to subtangential loading, a combination of conservative and nonconservative tangential loads, using the dynamic
criterion. In order to study the dynamic behavior by including uncertainties into the problem, three models were developed: exact Monte Carlo simulation, sensitivity-based Monte Carlo simulation, and probabilistic FEA. These methods were integrated into the existing finite element analysis. Also, perturbation and sensitivity analysis have been used to study nonconservative problems to study the stability analysis using the dynamic criterion.

Post-buckling analysis of nonfrictional contact problems using linear complementarity formulation”, Computers & Structures, Vol. 57, No. 5d, pp 783-794, December 1995, DOI: 10.1016/0045-7949(95)00077-T

ABSTRACT: A linear complementary problem formulation is proposed for post-buckling analysis of geometrically nonlinear structures with nonfrictional contact constraints. The arc-length method with updated normal plane constraint used to trace the equilibrium paths of the structures is combined to generate a path-following algorithm as a predictor-corrector procedure. The initial load increment is determined in the predictor phase, considering the change of contact status. For the corrector phase, the unknown load scale parameter is eliminated using the arc-length constraint. The unknown contact variables such as contact status and contact forces can be directly solved by the linear complementarity problem without any ad-hoc technique. Several newly defined buckling and post-buckling with contact constraints are solved to illustrate the algorithm and the detail complex behaviors. It is demonstrated that the algorithm is very stable and efficient in dealing with the rather difficult class of buckling problems with obstacles.

ABSTRACT: A stability analysis of laminated beam structures subject to subtangential loading, a combination of conservative and nonconservative tangential follower loads, using the dynamic criterion is performed. These loads are characterized using a nonconservativeness loading parameter. This parameter allows us to study the effect of the level of load conservativeness on the stability of laminated beams. The element tangent stiffness and mass matrices are obtained using analytical integration through the dynamic version of the principle of virtual work for laminated composites. Results for the conservative loading, for both isotropic and laminated beams, are in very good agreement with those available in the literature. For the case of partially conservative loads, results show that for both isotropic and laminated composite beams, and in the absence of damping, all values of the nonconservativeness loading parameter less than or equal to 0.5 will be governed by the divergence instability, and by flutter instability otherwise.

ABSTRACT: Innovative manufacturing techniques like Electron Beam Free Form Fabrication (EBF3), Friction Stir Welding (FSW), and Selective Laser Sintering (SLS) are additive in nature as opposed to subtractive, meaning that the material is deposited wherever necessary on the contrary to removal of unnecessary material from the structures. These techniques have created new opportunities and much bigger design space to optimize structures of complex shapes especially the aerospace vehicles without much material wastage and energy (Green Technologies). Earlier research has shown that panels with curvilinear stiffeners may have a reduced weight than panels with straight stiffeners having the same strength performance (buckling and stress
constraints). Fuselage, supersonic and subsonic wing panels which are curved can be stiffened using curvilinear (alignment) stiffeners. Our research in supersonic wing optimization using curvilinear spars and ribs has realized that the panels bounded by these spars and ribs may have 3 to 6 curved edges that created a new opportunity and complexity in design of curved panels with curvilinear stiffeners. To design and optimize such panels, a framework is developed which consists of MD-PATRAN, MDNASTRAN, VisualDoc and MATLAB. To create the geometry of stiffened curved panels in the parametric fashion using MD PATRAN, three approaches are proposed, namely, 1) Bounding Box Method, 2) Interpolation of the Shell and Manifold Method, and 3) Interpolation of the Shell and Curve Projection Method. Advantages and disadvantages of these approaches are discussed, including remedies for some of the limitations. Amongst these approaches, the last one, Interpolation of the Shell and Curve Projection Method is the best to create and analyze the arbitrary geometry panel with curvilinear blade-stiffeners. These approaches efficiency and accuracy are compared for flat rectangular panel with curved edges and cylindrical shell with curved edges during optimization.

ABSTRACT: The objective of the current paper is to present a Ritz type analytical model for the buckling analysis of cracked stiffened structures. Complex structures typically used in aerospace and marine engineering such as a cracked stiffened panel is considered. In the Ritz-type model, we use the local trigonometric trial functions to define the displacement function of the crack-stiffened panel, which is discretized into several elements based on the crack location and stiffener location. The interface continuity conditions for cracked thinwalled structures are derived and investigated in detail; the interface conditions are used to condense the global eigenvalue problem by eliminating redundant Ritz coefficients. Examples are presented to illustrate the effectiveness of the current model for the buckling analysis. Buckling results from the current model are found to agree well with those obtained using a shell finite element method.

ABSTRACT: The objective of the current paper is to present a Ritz-type analytical model for predicting the behavior of discontinuous beams such as thin-walled beams with cracks and multiply-stepped beams. The beam is discretized in the cracked as well as the un-cracked domains for a cracked thin-walled beam and in uniform beams for a multiple-stepped beam. A set of local trigonometric trial functions is used to define the twist angle for the cracked domain and the un-cracked domains, as well as to define the displacement field for uniform domains. A global equation system of unknown Ritz coefficients is derived by minimizing the Lagrangian functional or the total potential energy. In the present Ritz model, the interface continuity conditions between sub-domains are investigated and enforced into the global equation system using the condensation procedure or the Lagrange multipliers. Examples are presented to illustrate the effectiveness of the current model for free vibration and torsional analysis. Results obtained from the current model are found to agree well with those obtained using a detailed finite element method or with existing results in literature. The proposed model offers an efficient approach to reduce the modeling efforts and computational time required to analyze complex beams with cracks or multiple steps.

ABSTRACT: Thin-walled circular cylinders, and frusta (truncated circular cones) of aluminium alloy were subjected to axial static loading. Their initial axial length and the outside diameter of the cylinders and frusta (the larger top end) were kept constant whilst their wall thickness was varied. The load-deformation or compression behaviour of the cylinder and frusta of various thicknesses and semi-apical angles were recorded and the modes of collapse were observed and studied. The main purpose of results for circular cylinders is to give a basis of comparison for the frusta. Relatively thick tubes fail by collapsing into circumferential axisymmetric rings and thin ones by folding progressively into diamond-shaped lobes after assuming an initially axisymmetric ring mode of deformation. In the latter case the initial axisymmetric rings developed into nonsymmetric diamond patterns (elliptic, triangular and square, etc.) as loading progressed. Also, initially non-symmetric diamond buckle patterns were observed to be characteristic modes of frustum collapse. Initial peak failure loads and mean post-buckling loads for the various modes of deformation were obtained experimentally. It is shown that buckling loads for both cylinders and frusta increase with increasing slenderness ratio (t/D for cylinders and t/Dbar for frusta) following, broadly, a parabolic law. Empirical expressions for the post-buckling load required to effect crumpling have been obtained.

ABSTRACT: The crumpling of thin-walled frusta, under axial compression, in the ‘concertina’ mode is studied. The energy expended in bending at the plastic hinges and in stretching the metal between the hinges is minimized for the total decrease in height due to collapse. The thinning of the cross-section due to stretching is neglected. A theoretical model has been developed and numerical results are obtained that show the effect of slenderness, t/D, and the semi-apical angle of the frusta. Good qualitative agreement in trends is exhibited when comparison with available experimental results is made.

ABSTRACT: Experimental investigations were conducted into the quasi-static collapse and energy absorption characteristics of thin-walled steel tubes containing a number of geometrical discontinuities in the form of grooves of constant depth and axial length. The failure modes and load-deflection characteristics are discussed and compared with the corresponding theoretical values. An inextensional collapse mechanism is used to describe a non-symmetrical diamond mode shell folding which takes into account the concept of stationary circumferential and inclined travelling hinges.

ABSTRACT: A theoretical model describing the progressive extensible plastic collapse of thin-wall conical and cylindrical shells is presented. The proposed theory enables the load-deflection curves during axial compression following the deformation history of the shell to be evaluated. The comparison of theoretical curves with experimental ones shows a fair degree of accuracy.

ABSTRACT: A theoretical analysis of the observed stable collapse mechanism of thin-walled circular frusta and tubes, crushed under axial static and/or dynamic loading, for calculating crushing loads and the energy absorbed during collapse, is reported. The analysis is based on experimental observations regarding the energy-absorbing collapse mechanisms developed during the crushing process. The proposed theoretical model was experimentally verified and proved to be very efficient for theoretically predicting the energy-absorbing capability of the conical shells.

ABSTRACT: The present paper deals with the implementation of the explicit FE Code LS-DYNA to simulate the crash behaviour and energy absorption characteristics of steel thin-walled tubes of octagonal cross-section subjected to axial loading. The collapse procedure is successfully simulated and the obtained numerical results are compared with actual experimental data from small-scale models and useful concluding remarks pertaining to the design requirements of the crushing process are drawn.

ABSTRACT: In this paper the results of experimental works pertaining to the crash behaviour, collapse modes and crashworthiness characteristics of carbon fibre reinforced plastic (CFRP) tubes that were subjected to static axial compressive loading are presented in detail. The tested specimens were featured by a material combination of carbon fibres in the form of reinforcing woven fabric in thermosetting epoxy resin, and they were cut out at various lengths from three CFRP tubes of the same square cross-section but different thickness, laminate stacking sequence and fibre volume content. CFRP tubes were compressed in a hydraulic press of 1000 kN loading capacity at very low-strain rate typical for static testing. The influence of the most important specimen geometric features such as the tube axial length, aspect ratio and wall thickness on the compressive response and collapse modes of the tested tubes is thoroughly analysed. In addition, the effect of the laminate material properties such as the fibre volume content and stacking sequence on the energy absorbing capability of the thin-wall tubes is also examined. Particular attention is paid on the analysis of the mechanics of the tube axial collapse modes from macroscopic and microscopic point of view, emphasizing on the mechanisms related to the crash energy absorption during the compression of the composite tubes.

ABSTRACT: In the simulation works described in this paper the LS-DYNA3D explicit finite element code is used to investigate the compressive properties and crushing response of square carbon FRP (fibre reinforced plastic) tubes subjected to static axial compression and impact testing. A series of models was created to simulate some of the static and dynamic tests performed in the National Technical University of Athens using CFRP tubes featured by the same material combination (woven fabric in thermosetting epoxy resin) and external cross-section dimensions, but different length, wall thickness, laminate stacking sequence and fibre volume content. Simulation works focused on modelling the three modes of collapse (i.e. progressive end-crushing with tube wall laminate splaying, local tube-wall buckling and mid-length collapse) observed in the series of static and dynamic compression tests. Satisfactory level of agreement between calculations and test results was obtained regarding the main crushing characteristics of the tested CFRP tubes—such as peak compressive load and crash energy absorption and the overall crushing response—as the finite element models were refined several times in order to obtain optimum results.

ABSTRACT: In the present paper Artificial Neural Networks (ANN) are applied in order to predict the buckling modes of thin-walled PVC tubes under compressive axial forces. For the development of the models the neural network toolbox of Matlab was applied. The results show that these models can satisfactorily face these problems and they constitute not only a fast method, compared to time consuming experiments, but also a
A reliable tool that can be used for the studying of such parts which are usually employed as structural elements for the absorption of the energy of an impact, in automotive and aerospace applications.

ABSTRACT: The behaviour of orthogonal layers of aluminium and mild steel tubes under lateral compression is considered. The results for each material are presented separately in Parts I and II of the paper. In all the tests the initial separation of tubes in the same layer is sufficiently large to preclude contact being established between adjacent tubes as they deform.

Part I: Aluminium systems are examined and two principal categories of behaviour are identified. As well as providing basic load-deflection data in a suitably non-dimensionalised form, certain particular features of the modes of deformation of individual tubes in the systems are examined in detail.

Part II: This presents data and observations concerning mild steel systems. Of especial interest is the difference between the behaviour of as-received tubes, which develop cracks in the regions of greatest deformation, and that of annealed mild steel tubes which show similar characteristics to those of the aluminium systems.

ABSTRACT: Experimental results are provided for the quasi-static and dynamic axial crushing of thin-walled square and rectangular tubes manufactured from sheet metal. The tubes were tested both empty and filled with polyurethane foam of various densities. Both the stability and the energy absorbing characteristics of the tubes
are described and discussed. Simple theoretical models are proposed to explain and quantify the interaction between the foam and the sheet metal tubes.

ABSTRACT: Following earlier work on the axial crushing of foam-filled sheet metal tubes of square and rectangular cross-section and empty tapered tubes the behaviour of foam-filled tapered tubes is considered. Theoretical estimates of the variation in the mean crushing loads for both quasi-static and dynamic loading conditions are provided and compared with experimental data.

ABSTRACT: The linear and geometric nonlinear buckling load including transverse shear deformation are calculated by Timoshenko first-order shear deformation theory and Reddy higher-order shear deformation theory respectively. The effects of lamination angle, number of layers and radius-to-thickness ratio on the buckling pressure are analyzed. The combination of a Random-Search approach and the flexible-tolerance method is employed to search for the optimization lamination angles. The Mixed-discrete-optimization program is used to solve the optimization problem in which the lamination angles are assumed to have discrete values. The experiments of the carbon-epoxy cylindrical shell models show that the results presented in this paper are reliable.

ABSTRACT: The bending, buckling and free vibration problems of non-homogeneous composite laminated cylindrical shells are considered. Hamilton–Reissner's mixed variational principle is used to deduce a consistent first-order theory of composite laminated cylindrical shells with non-homogeneous elastic properties. The governing equations with their required boundary conditions are derived without introducing any shear correction factors. Numerical results for the transverse deflections, stresses, natural frequencies and critical buckling loads are presented to show the advantages of this theory. The influences of the non-homogeneity and thickness ratio on the shell structural response are investigated. The study concludes that the inclusion of the non-homogeneity effect is required, even if it is weak, for predicting the actual structural response of the shells.

ABSTRACT: A two-dimensional solution is presented for bending analysis of simply supported functionally graded ceramic–metal sandwich plates. The sandwich plate faces are assumed to have isotropic, two-constituent material distribution through the thickness, and the modulus of elasticity and Poisson’s ratio of the faces are assumed to vary according to a power-law distribution in terms of the volume fractions of the constituents. The core layer is still homogeneous and made of an isotropic ceramic material. Several kinds of sandwich plates are used taking into account the symmetry of the plate and the thickness of each layer. We derive field equations for functionally graded sandwich plates whose deformations are governed by either the shear deformation theories or the classical theory. Displacement functions that identically satisfy boundary conditions are used to reduce the governing equations to a set of coupled ordinary differential equations with variable coefficients. Numerical results of the sinusoidal, third-order, first-order and classical theories are presented to show the effect of material distribution on the deflections and stresses.

ABSTRACT: The sinusoidal shear deformation plate theory, presented in the first part of this paper, is used to study the buckling and free vibration of the simply supported functionally graded sandwich plate. Effects of rotatory inertia are considered. The critical buckling load and the vibration natural frequency are investigated. Some available results for sandwich plates non-symmetric about the mid-plane can be retrieved from the present analysis. The influences of the transverse shear deformation, plate aspect ratio, side-to-thickness ratio and volume fraction distributions are studied. In addition, the effect of the core thickness, relative to the total thickness of the plate, on the critical buckling load and the eigenfrequencies is investigated.

ABSTRACT: Thermal buckling response of functionally graded plates is presented in this paper using sinusoidal shear deformation plate theory (SPT). The material properties of the plate are assumed to vary according to a power law form in the thickness direction. Equilibrium and stability equations are derived based on the SPT. The non-linear governing equations are solved for plates subjected to simply supported boundary conditions. The buckling analysis of a functionally graded plate under various types of thermal loads is carried out. The influences of many plate parameters on buckling temperature difference will be investigated. Numerical results are presented for the SPT, demonstrating its importance and accuracy in comparison to other theories.

DOI: 10.1007/s004190050122

ABSTRACT: A phenomenological constitutive model for characterization of creep and damage processes in metals is applied to the simulation of mechanical behaviour of thin-walled shells and plates. Basic equations of the shell theory are formulated with geometrical nonlinearities at finite time-dependent deflections of shells and plates in moderate bending. Numerical solutions of initial/boundary-value problems have been obtained for rectangular thin plates (two-dimensional case) and axisymmetrically loaded shells of revolution (one-dimensional case). Based on the numerical examples for the two problems, the influence of geometrical nonlinearities on the creep deformation and damage evolution in shells and plates is discussed.

ABSTRACT: Modern design rules for thin-walled structures which operate at elevated temperatures are based on the demand that the creep and may be the damage behaviour should be taken into account. In the last four decades various models including the scalar or tensor valued hardening and damage variables are established. These models reflect the influence of the deformation or the damage induced anisotropy on the creep response. One problem in creep analysis of thin-walled structures is the selection of the structural mechanics model which has to be adequate to the choice of the constitutive equations. Considering complex loading conditions the structural mechanics model has to reflect for instance the different constitutive behaviour in tension and compression. Below the applicability of classical engineering models for beams, plates and shells to the creep-damage analysis is discussed. It will be shown that a first improvement of the classical approach can be given within the assumptions of the first order shear deformation theory. Based on the beam equations we demonstrate that the shear correction factors have to be modified within the time-step analysis.

PARTIAL INTRODUCTION: At present the shell theory finds out new branches of applications. Biological membranes, thin polymeric films and thin structures made from shape memory materials may be pointed out as examples. In addition, the manufacturing technology of shells leads to significant changes of the material properties. As a result the conventional variants of the shell theory, based on the derivation of the basic equations from the 3D-theory of elasticity, cannot be used….

ABSTRACT: From the practice of power and petrochemical plants it is well known that pipe bends are the most
critical structural components with respect to possible creep failures. In this paper we review recent approaches to analyze non-linear behavior of plate and shell structures under creep-damage conditions. Furthermore, we perform a numerical analysis of the long-term behavior for a real spatial pipeline. We take into account the non-uniformity of the wall thickness in the pipe bends as a result of processing by induction bending. The material behavior is described by a Kachanov-Rabotnov-Hayhurst type constitutive model with a scalar valued damage parameter. The results are compared with data from in-service observation of the pipeline.

ABSTRACT: One of the research direction of Horst Lippmann during his whole scientific career was devoted to the possibilities to explain complex material behavior by generalized continua models. A representative of such models is the Cosserat continuum. The basic idea of this model is the independence of translations and rotations (and by analogy, the independence of forces and moments). With the help of this model some additional effects in solid and fluid mechanics can be explained in a more satisfying manner. They are established in experiments, but not presented by the classical equations. In this paper the Cosserat-type theories of plates and shells are debated as a special application of the Cosserat theory.

ABSTRACT: A finite element based on the efficient higher-order zig-zag theory with multiple delaminations is developed. The bending part of the formulation is constructed from the concept of DKQ element. Unlike conventional elements, a developed element has its reference in the bottom surface which simplifies zig-zag terms on formulation. Exact patch solutions are developed on elements which have the bottom reference system. The present element passes proper bending patch tests in the arbitrary mesh configurations in isotropic materials. Zig-zag formulation is adopted to model laminated plates with multiple delaminations. To assess the accuracy and efficiency of the present element based on higher-order zig-zag theory with multiple delaminations, the linear buckling problem of laminated plates with multiple delaminations has been analysed. The results have been compared with three-dimensional elasticity solutions. The present element works as an efficient tool for analysing the behaviour of the laminated composites with multiple delaminations.

“Buckling analysis of a composite shell with multiple delaminations based on a higher order zig-zag theory”,

ABSTRACT: A new three-node triangular shell element based on a higher order zig-zag theory is developed for laminated composite shells with multiple delaminations. The baseline higher order zig-zag composite shell theory for multiple delaminations has been developed in a general curvilinear coordinate system and in general tensor notation. All the complicated curvatures of the surface including twisting curvatures can be described in an exact manner since the developed shell finite element is based on the geometrically exact surface representation. It is therefore possible to apply the present finite element formulation to the composite structures with arbitrary shaped multiple delaminations, general layup configurations and arbitrary boundary conditions. The slopes of deflections are included as independent degrees of freedom, which require the normal slope continuities between element interfaces. The nonconforming shape functions of Specht's three-node triangular plate bending element are employed to interpolate out-of-plane displacements. The developed element passes the bending and twisting patch tests for flat surface configurations. The element is then used to analyze the linear buckling problem of composite cylindrical shells with multiple delaminations. Throughout the numerical examples, it is demonstrated that the developed shell finite element is numerically efficient because it has minimal nodal degrees of freedom to describe the composite shells having multiple delaminations. The finite element realization of a higher order zig-zag shell theory with multiple delaminations can be served as a powerful numerical tool to analyze the complicated shell structures for the critical buckling loads as well as the corresponding mode shapes.

ABSTRACT: A new two-dimensional theory for the analysis of deep, doubly curved, multilayered shells is proposed. The theory is based on a kinematical approach in which the continuity conditions for displacements and shear stresses at layer interfaces and on the bounding surfaces of the shell are exactly satisfied, while, at the same time, refinements of the shear and membrane terms are taken into account, by means of trigonometric functions. The accuracy of the model is assessed in statics and dynamics through investigation of significant problems, for which an exact three-dimensional elasticity solution is known. In statics, the cylindrical bending of a cylindrical panel, of thickness h, and inner radius R, is examined. The results obtained are in good agreement with the analytical solution of Ren [Comput. Sci Technol. 29 (1987) 169–187], and prove that no shear-correction factors are requested. In dynamics, wave propagation in a three-layered elastic cylinder is explored. The accuracy of the theory is assessed by comparison with the exact three-dimensional elasticity solution of Armenakas [J. Acoust. Soc. Am. 49 (5, Part 2) (1971) 1511–1520]. The model is then applied to the exploration of the dispersive behavior of a viscoelastic cylinder.

A V Krishna Murthy and T S R Reddy, “A higher order theory of laminated composite cylindrical shells”, 1986 (publisher not given, mendeley.com)

ABSTRACT: A new higher order theory has been proposed for the analysis of composite cylindrical shells. The formulation allows for arbitrary variation of inplane displacements. Governing equations are presented in the form of a hierarchy of sets of partial differential equations. Each set describes the shell behavior to a certain degree of approximation. The natural frequencies of simply-supported isotropic and laminated shells and stresses in a ring loaded composite shell have been determined to various orders of approximation and compared with three dimensional solutions. These numerical studies indicate the improvements achievable in
estimating the natural frequencies and the interlaminar shear stresses in laminated composite cylinders.

ABSTRACT: Vibration analysis of a rotating composite blade is the main purpose of this study. A general formulation is derived for an initially twisted rotating shell structures including the effect of centrifugal force and Coriolis acceleration. In this work, the blade is assumed to be a moderately thick open cylindrical shell that includes the transverse shear deformation and rotary inertia, and is oriented arbitrarily with respect to the axis of rotation to consider the effects of disc radius and setting angle. For a thick shell, we must consider the transverse shear deformation as well as rotary inertia. Thus, based on the concept of the degenerated shell element with the Reissner–Mindlin’s assumptions, the finite element method is used for solving the governing equations. In the numerical study, effects of various parameters are investigated: initial twisting angles, thickness to radius ratios, layer lamination and fiber orientation of composite blades. Also, they are compared with the previous works and experimental data.

ABSTRACT: Three-dimensional thermal buckling analysis is performed for functionally graded materials. Material properties are assumed to be temperature dependent, and varied continuously in the thickness direction according to a simple power law distribution in terms of the volume fraction of a ceramic and metal. The finite element model is adopted by using an 18-node solid element to analyze more accurately the variation of material properties and temperature field in the thickness direction. Furthermore, the assumed strain mixed formulation is used to prevent locking as well as maintaining kinematic stability of the finite element model for thin plates and shells. The thermal buckling behavior under uniform or nonuniform temperature rise across the thickness is analyzed. Numerical results are compared with those of the previous works. In addition, the changes of critical buckling temperature due to the effects of temperature field, volume fraction distributions, and system geometric parameters are studied.

ABSTRACT: Three-dimensional thermomechanical buckling analysis is investigated for functionally graded composite structures that composed of ceramic, functionally graded material (FGM), and metal layers. Material properties are assumed to be temperature dependent, and in FGM layer, they are varied continuously in the thickness direction according to a simple power law distribution in terms of the ceramic and metal volume fractions. The finite element model is adopted by using an 18-node solid element to analyze more accurately the
variation of material properties and temperature field in the thickness direction. Temperature at each node is obtained by solving the thermomechanical equations. For a time discretization, Crank–Nicolson method is used. In numerical results, the thermal buckling behavior of FGM composite structures due to FGM thickness ratios, volume fraction distributions, and system geometric parameters are analyzed.

ABSTRACT: In this article, the elastic buckling behavior of orthotropic small scale plates under biaxial compression is studied. Analysis is carried out with the consideration of small scale effects. Employing nonlocal elasticity theory (Eringen, 1983) governing equations for the aforementioned problems are derived. Explicit expressions for modified buckling loads are obtained for micro/nanoplates with isotropic and orthotropic properties; and under uniaxial and biaxial compressions. The effects of the small scale on the buckling loads of plates considering various material and geometrical parameters are examined.

ABSTRACT: Classical plate theory (CLPT) and first-order shear deformation plate theory (FSDT) of plates are reformulated using the nonlocal elasticity theory. Developed nonlocal plate theories have been applied to study buckling behavior of nanoplates. Nonlocal elasticity theory, unlike traditional elasticity theory introduces a length scale parameter into the formulation to take into account the discrete structure of the material to some extent. Both single-layered and multilayered nanoplates have been included in the analysis. Navier's approach has been used to obtain exact solutions for buckling loads for simply supported boundary conditions. Dependence of the small scale effect on various geometrical and material parameters has been investigated. Present study reveals the presence of significant small scale effect on the buckling response of nanoplates. The theoretical development and the numerical results presented in the present work are expected to promote the use of nonlocal theories for more accurate prediction of stability behavior of nanoplates and nanoshells.

ABSTRACT: Thermo-mechanical buckling behaviour of Single Walled Carbon Nanotube (SWCNT) on Winkler foundation is reported. Non-local elasticity theory and differential transformation method are applied. Effects of (i) size of SWCNT, (ii) non-local parameter, (iii) Winkler modulus, (iv) boundary conditions and (v) temperature on buckling load are investigated.

ABSTRACT: This paper studies the thermal effect on axially compressed buckling of a multi-walled carbon nanotube. The effects of temperature change, surrounding elastic medium and van der Waals forces between the inner and outer nanotubes are taken into account. Using continuum mechanics, an elastic multi-shell model with thermal effect is presented for axially compressed buckling of a multi-walled carbon nanotube embedded in an elastic matrix under thermal environment. Based on the model, numerical results for the general case are obtained for the thermal effect on axially compressed buckling of a multi-walled carbon nanotube. It is shown that the axial buckling load of multi-walled carbon nanotube under thermal loads is dependent on the wave number of axially buckling modes. And a conclusion is drawn that at low and room temperature the critical load for infinitesimal buckling of a multi-walled carbon nanotube increase as the value of temperature change increases, while at high temperature the critical load for infinitesimal buckling of a multi-walled carbon nanotube decrease as the value of temperature change increases.
ABSTRACT: Bending manipulation and direct force measurements of ultrathin boron nitride nanotubes (BNNTs) were performed inside a transmission electron microscope. Our results demonstrate an obvious transition in mechanics of BNNTs when the external diameters of nanotubes are in the range of 10 nm or less. During in situ transmission electron microscopy bending tests, characteristic “hollow” ripple-like structures formed in the bent ultrathin BNNTs with diameters of sub-10 nm. This peculiar buckling/bending mode makes the ultrathin BNNTs hold very high post-buckling loads which significantly exceed their initial buckling forces. Exceptional compressive/bending strength as high as ∼1210 MPa was observed. Moreover, the analysis of reversible bending force curves of such ultrathin nanotubes indicates that they may store/adsorb strain energy at a density of ∼400 × 10⁶ J m⁻³. Such nanotubes are thus very promising for strengthening and toughening of structural ceramics and may find potential applications as effective energy-absorbing materials like armor.

ABSTRACT: One of the best approaches for modeling large deformation of shells is the Cosserat surface. However, the finite-element implementation of this model suffers from membrane and shear locking, especially for very thin shells. The basic assumption of this theory is that the mid-surface of the shell is regarded as a Cosserat surface with one inextensible director. In this paper, it is shown that by constraining the director vector normal to the mid-surface, besides very good and accurate results, shear locking is also eliminated. This constraint is in fact a limiting analysis of the Cosserat theory in which Kirchhoff’s hypothesis is enforced. Numerical solution is performed using nine-node isoparametric element. The principal of virtual work is used to obtain the weak form of the governing differential equations and the material and geometric stiffness matrices are derived through a linearization process. The validity and the accuracy of the method are illustrated by numerical examples.

ABSTRACT: In this paper a new element is developed that is based on Cosserat theory. In the finite element implementation of Cosserat theory shear locking can occur, especially for very thin shells. In the present investigation the director vector is constrained to remain perpendicular to the mid surface during deformation. It will be shown that this constraint yields accurate results in very large deformation of thin shells also the rate of convergency is very good. For plastic formulation, the model introduced by Simo is used and it has been reduced for constrained director vector and the consistent elasto-plastic tangent moduli is extracted for finite element solution. This model includes both kinematic and isotropic hardening. For numerical investigations an isoparametric nine node element is employed then by linearization of the principle of virtual work, material and
geometric stiffness matrices are extracted. The validity and the accuracy of the proposed element is illustrated by the numerical examples and the results are compared with those available in the literature.

ABSTRACT: The elastic buckling behavior of quadrilateral single-layered graphene sheets (SLGS) under bi-axial compression is studied employing nonlocal continuum mechanics. Small-scale effects are taken into consideration. The principle of virtual work is employed to derive the governing equations. The Galerkin method in conjunction with the natural coordinates of the nanoplate is used as a basis for the analysis. The buckling load of skew, rhombic, trapezoidal, and rectangular nanoplates considering various geometrical parameters are obtained. It is shown that nonlocal effects are very important in arbitrary quadrilateral graphene sheets and their inclusion results in smaller buckling loads. Also the effects of geometrical parameters such as aspect ratio, angle, and mode number on the buckling load decrease when scale coefficient increases, for all arbitrary quadrilateral SLGS.

ABSTRACT: Minute concentrations of suspended particles can dramatically alter the behavior of a drying droplet. After a period of isotropic shrinkage, similar to droplets of a pure liquid, these droplets suddenly buckle like an elastic shell. While linear elasticity is able to describe the morphology of the buckled droplets, it fails to predict the onset of buckling. Instead, we find that buckling is coincident with a stress-induced fluid to solid transition in a shell of particles at a droplet's surface, occurring when attractive capillary forces overcome stabilizing electrostatic forces between particles. When replacing water by a mixture of ethanol and water, the buckling threshold changes. For a fixed colloid solid fraction, the buckling threshold evolves as a function of ethanol content, due to changes of the solvent mixture physical properties, such as viscosity and evaporation rate. A simplified model predicting the qualitative behaviour of the buckling threshold as a function of the initial ethanol mass fraction has been developed that fits well experimental results.

ABSTRACT: Morphological transformation during evaporation-induced self-assembly of a mixed colloidal suspension in micrometric droplets has been investigated. It has been demonstrated that a buckling-driven shape transition of drying droplets of mixed colloidal suspension takes place during evaporation-induced self-assembly. Further, it is also shown that the distortion modulations get significantly amplified with enhancement
in volume fraction of anisotropic soft colloidal component of the mixed colloids. It has been argued that the reduction in elastic modulus of formed shell, at the boundary of a drying droplet, and the anisotropic nature of one of the colloidal components facilitate the deformation process. Hierarchical structures of these assembled colloidal grains have been probed using electron microscopy and scattering techniques.

ABSTRACT: In this paper, buckling phenomenon of single walled carbon nanotubes under torsional and axial combined loading by finite element method is investigated. Models are constructed via an individual structural model in Ansys software. CNTs hexagon geometrical structure is simulated by means of porous shell. Single walled carbon nanotubes of zigzag (12,0) and (21,0) with various aspect ratios (length to diameter ratio) are selected and they are subjected to torsional and axial combined loads. In this study, the effects of radius, length and aspect ratio on the critical buckling loads are investigated. Numerical results indicate that with increment of length and aspect ratio, the critical buckling loads will decrease generally. Also diagrams show that in lengths greater than 5 nm, nanotubes (21,0) will endure more critical buckling loads relative to nanotube (12,0). This result is followed by the increase in surface area by increasing the diameter of the nanotube. In this study the changes trend of critical buckling loads in terms of the different variables is good agreement with previous studies.

ABSTRACT: In the present work differential transformation method (DTM) is used to predict the buckling behaviour of single walled carbon nanotube (SWCNT) on Winkler foundation under various boundary conditions. Four different boundary conditions namely clamped–clamped, simply supported, clamped hinged and clamped free are used to study the critical buckling loads. Effects of (i) size of SWCNT (ii) nonlocal parameter and (iii) Winkler elastic modulus on nonlocal critical buckling loads are being investigated and discussed. The DTM is implemented for the nonlocal SWCNT analyses and this yields results with high degree of accuracy. Further, present method can be applied to linear and nonlinear problems.

J. Patrick Wilber (Dept. of Theoretical and Applied Mathematics, University of Akron, Akron, Ohio, USA), “Buckling of graphene layers supported by rigid substrates”, arXiv:1002.0724v1 [cond-mat.mes-hall] 3 Feb 2010

ABSTRACT: We formulate a nonlinear continuum model of a graphene sheet supported by a flat rigid substrate. The sheet is parallel to the substrate and loaded on a pair of opposite edges. A typical cross-section of the sheet is modeled as an elastica. We use elementary techniques from bifurcation theory to investigate how the buckling of the sheet depends on the boundary conditions, the composition of the substrate, and the length of the sheet. We also present numerical results that illustrate snap-buckling of the sheet.

ABSTRACT: Atomistic simulations are used to study the bending of rectangular graphene nano ribbons subjected to axial stress both for free boundary and supported boundary conditions. The shape of the deformations of the buckled graphene nano ribbons, for small values of the stress, are sine waves where the number of nodal lines depend on the longitudinal size of the system and the applied boundary condition. The buckling strain for the supported boundary condition is found to be independent of the longitudinal size and estimated to be 0.86%. From a calculation of the free energy at finite temperature we find that the equilibrium projected two-dimensional area of the graphene nano ribbon is less than the area of a flat sheet. At the optimum length the boundary strain for the supported boundary condition is 0.48%.

ABSTRACT: In this paper, buckling analysis of biaxially compressed graphene sheets with non-local elasticity theory is reported. The equations of motion for graphene sheet are derived using non-local local elasticity theory. Levy’s approach has been used to solve the governing equations for various boundary conditions of the
graphene sheet. Present results from Levy’s solution agree with the results for all edges simply supported available in the literature. Further, the effect of the (i) non-local parameter, (ii) size of the graphene sheet and (iii) various boundary conditions on the critical buckling loads of the graphene sheets are investigated. It is observed that non-local parameter and boundary conditions significantly influence the critical buckling loads of the small size graphene sheets.

Jin-Xing Shi, Toshiaki Natsuki, Xiao-Wen Lei and Qing-Qing Ni (Shinshu University, Tokida, Japan), “Buckling instability of carbon nanotube atomic force microscope probe clamped in an elastic medium”, Journal of Nanotechnology in Engineering and Medicine, Vol. 3, No. 2, September 2012
ABSTRACT: Carbon nanotubes (CNTs) can be used as atomic force microscope (AFM) probes due to their robust mechanical properties, high aspect ratio and small diameter. In this study, a model of CNTs clamped in an elastic medium is proposed as CNT AFM probes. The buckling instability of the CNT probe clamped in elastic medium is analyzed based on the nonlocal Euler–Bernoulli beam model and the Whitney–Riley model. The clamped length of CNTs, and the stiffness of elastic medium affect largely on the stability of CNT AFM probe, especially at high buckling mode. The result shows that the buckling stability of the CNT AFM probe can be largely enhanced by increasing the stiffness of elastic medium. Moreover, the nonlocal effects of buckling instability are investigated and found to be larger for high buckling mode. The theoretical investigation on the buckling stability would give a useful reference for designing CNT as AFM probes.

ABSTRACT: In this paper, we study the buckling properties of circular double-layered graphene sheets (DLGSs), using plate theory. The two graphene layers are modeled as two individual sheets whose interactions are determined by the Lennard-Jones potential of the carbon–carbon bond. An analytical solution of coupled governing equations is proposed for predicting the buckling properties of circular DLGSs. Using the present theoretical approach, the influences of boundary conditions, plate sizes, and buckling-mode shapes on the buckling behaviors are investigated in detail. The buckling stability is significantly affected by the buckling-mode shapes. As a result of van der Waals interactions, the buckling stress of circular DLGSs is much larger for the anti-phase mode than for the in-phase mode.

ABSTRACT: In this paper, a theory for non-linear bending of symmetrically laminated, cylindrically orthotropic, shallow, conical shells subjected to an axisymmetrically distributed load including transverse shear effects is established. By means of this theory and the modified iteration method, the analytical solution of the critical buckling pressure for a symmetrically laminated, cylindrically orthotropic, shallow, conical shell with a rigidly clamped edge under the action of uniform lateral pressure is obtained.
ABSTRACT: In this paper, a non-linear buckling problem of a symmetrically laminated, cylindrically orthotropic, truncated, shallow, spherical shell with a rigidly clamped outer edge and a non-deformable rigid body at the center under the action of uniform pressure, taking into account the effect of the transverse shear deformation, has been solved by the modified iteration method. Finally, this paper discusses the effects of transverse shear on the buckling of the shell.

ABSTRACT: In this paper, a model of cusped catastrophe at nonlinear dynamic buckling of a symmetrically laminated cylindrically orthotropic shallow spherical shell is presented. The shell is subjected to an axisymmetrical load. Effects of transverse shear are taken into account. Effects of the shear modulus, geometry and parameters of the material on the nonlinear dynamic buckling are discussed.

ABSTRACT: In this paper, a nonlinear bending theory for a corrugated shallow spherical shell is constructed. By means of this theory and the modified iteration method, the analytical solution of the critical buckling pressure for a corrugated shallow spherical shell with a rigidly clamped edge under the action of uniform pressure is obtained.

ABSTRACT: This paper is presented to solve the nonlinear dynamic buckling problem of a new type of composite cylindrical shells, made of ceram/metal functionally graded materials. The material properties vary smoothly through the shell thickness according to a power law distribution of the volume fraction of the constituent materials. The dynamic axial load is set in a linear increase form with regard to time. By taking the temperature-dependent material properties into account, the effect of environmental temperature rise is included. The nonlinear dynamic equilibrium equation of the shell was obtained by applying an energy method, and was then solved using the four-order Runge–Kutta method. The critical condition was eventually determined using B-R dynamic buckling criterion. Numerical results show the dynamic buckling load is higher than its static counterpart. Meanwhile, various effects of the inhomogeneous parameter, loading speed, dimension parameter, environmental temperature rise and initial geometrical imperfection on nonlinear dynamic buckling are discussed.

ABSTRACT: By using the Ritz energy method and finite element method, buckling behaviors of combined-loaded functionally graded cylindrical shells are investigated. The combined loads are composed of axial, lateral, and torsional loads. Results show that the contribution of lateral pressure to buckling is more significant than that of axial compression or torsion and the contributions of axial compression and torsion are almost the same. Also, a practical method is proposed in this article to determine the load-dominant bound between the single buckling mode due to one dominant load and the mixed buckling mode due to interaction of the two loads.

ABSTRACT: The linear and geometric nonlinear buckling load including transverse shear deformation is calculated by Timoshenko first-order shear deformation theory and Reddy higherorder shear deformation theory respectively. The effects of lamination angle, number of layers and radius-to-thickness ratio on the buckling pressure are analyzed. The combination of a Random-Search approach and the Flexible-Tolerance method is employed to search for the optimum lamination angles that have the highest buckling loads. The Mixed-Discrete-Optimization program is used to solve the optimization problem in which the lamination angles are assumed to have discrete values. The experiments of the carbonepoxy cylindrical shell models show that the results presented in this paper are reliable.

ABSTRACT: Focusing upon finding an optimum shape of crash box, which is one of the most important part of an automobile body to absorb impact energy at the time of a collision, for ensuring large energy absorption, the effect of introducing notch into a crash box on controlling plastic buckling behaviour was examined by three-dimensional finite element analyses. The influences of notch shape and arrangement on the deformation mode of a polygonal crash box was numerically examined and an optimum range of the dimensions of notch was quantitatively determined for ensuring stable buckling deformation. As a result, a fundamental scheme to optimise the shape and arrangement of the notches to ensure large energy absorption was proposed, which is applicable to a crash box with optional cross-sectional shape.

ABSTRACT: The present study proposes a simple procedure to evaluate the seismic risk of the spatial structures by using grid computing system. As an example for calculating the seismic risk by using the system, numerical studies for single layer lattice domes supported by substructure implemented with buckling restricted braces are presented considering a simple rule for judging the damages of the structural and non-structural elements. The effectiveness of the system is discussed through the numerical example for dome structures.
ABSTRACT: The nonlinear mathematical theory for initial and post local buckling analysis of plates of abruptly varying stiffness based on the principle of virtual work is established. The method is programmed, and several numerical examples are presented to demonstrate the scope and efficacy of the procedure. Local buckling coefficients of perforated and stepped plates are obtained and the results are compared with known solutions. Post-buckling behaviour of perforated and stepped plates is studied for different geometries. The non-dimensional applied loads (P/Pcr), dimensionless lateral displacements and stress distribution of plates with varying stiffness in the post buckling region are given in several tables and graphs.

ABSTRACT: This paper addresses the finite strip formulations for the stability analysis of viscoelastic composite plates with variable thickness in the transverse direction, which are subjected to in-plane forces. While the finite strip method is fairly well-known in the buckling analysis, hitherto its direct application to the buckling of viscoelastic composite plates with variable thickness has not been investigated. The equations governing the stiffness and the geometry matrices of the composite plate are solved in the time domain using both the higher-order shear deformation theory and the method of effective moduli. These matrices are then assembled so that the global stiffness and geometry matrices of a moderately thick rectangular plate are formed which lead to an eigenvalue problem that is solved to determine the magnitude of critical buckling load for the viscoelastic plate. The accuracy of the proposed model is verified against the results which have been reported elsewhere whilst a comprehensive parametric study is presented to show the effects of viscoelasticity parameters, boundary conditions as well as combined bending and compression loads on the critical buckling load of thin and moderately thick viscoelastic composite plates.

ABSTRACT: This paper addresses the inelastic local buckling of the curved plates using finite strip method in which buckling modes and displacements of the curved plate are calculated using sinusoidal shape functions in the longitudinal direction and polynomial functions in the transverse direction. A virtual work formulation is employed to establish the stiffness and stability matrices of the curved plate whilst the governing equations are then solved using a matrix eigenvalue problem. The accuracy and efficiency of the proposed finite strip model is verified with finite element model using ABAQUS as well as the results reported elsewhere while a good agreement is achieved. In order to illustrate the proposed model, a comprehensive parametric study is
performed on the steel and aluminum curved plates in which the effects of curvature, the length of the curved plate as well as circumferential boundary conditions on the critical buckling stress are investigated. The developed finite strip method is also used to determine the buckling loads of the curved plates with thickness-tapered sections as well as critical stresses of the aluminum cylindrical sectors that are subjected to uniform longitudinal stresses.

ABSTRACT: This paper is concerned with the determination of exact buckling loads and vibration frequencies of multi-stepped rectangular plates based on the classical thin (Kirchhoff) plate theory. The plate is assumed to have two opposite edges simply supported while the other two edges can take any combination of free, simply supported and clamped conditions. The proposed analytical method for solution involves the Levy method and the state-space technique. By using this analytical method, exact buckling and vibration solutions are obtained for rectangular plates having one- and two-step thickness variations. These exact solutions are extremely useful as benchmark values for researchers developing numerical techniques and software for analyzing non-uniform thickness plates.

ABSTRACT: This paper presents new exact solutions for vibration of thin circular cylindrical shells with intermediate ring supports, based on the Goldenveizer–Novozhilov shell theory (Theory of thin shells; The theory of thin elastic shells). An analytical method is proposed to study the vibration behaviour of the ring supported cylindrical shells. In the proposed method, the state-space technique is employed to derive the homogenous differential equation system for a shell segment and a domain decomposition approach is developed to cater for the continuity requirements between shell segments. Exact frequency parameters are presented in tables and design charts for circular cylindrical shells having multiple intermediate ring supports and various combinations of end support conditions. These exact vibration frequencies may serve as important benchmark values for researchers to validate their numerical methods for such circular cylindrical shell problems.

ABSTRACT: This paper presents an analytical procedure for determining the free vibration frequencies of open
circular cylindrical shells with intermediate ring supports based on the Flügge thin shell theory. The shell can be divided into several segments at the locations of the ring supports. The state-space technique is adopted to derive the homogenous differential equations for a shell segment, and the domain decomposition method is employed to impose the equilibrium and compatibility requirements along the interface of the shell segments. Shells with any number of intermediate ring supports and various combinations of edge support conditions are studied. Furthermore, the effects of the intermediate ring support and their locations, boundary conditions, number of ring supports as well as the variation of the included angle on the natural frequencies are examined.

ABSTRACT: This paper presents the Ritz method for the elastic buckling analysis of shells with ring-stiffeners under general pressure loading. The stiffeners may be of any cross-sectional shape and arbitrarily distributed along the shell length. Using polynomial functions multiplied by boundary equations raised to appropriate powers as the Ritz functions, the method can accommodate any combination of end conditions. As far as it is known, the Ritz method has not been automated in this way for the buckling of ring-stiffened shells. By formulating in a nondimensional form, generic buckling solutions for shells with various end conditions, stiffener distributions and under various pressure distributions, were presented. These new buckling solutions should serve as useful reference sources for checking the validity and accuracy of other numerical methods and software for buckling of cylindrical shells. This paper also shows that the appropriate distribution of ring stiffeners can lead to a significant increase in the buckling capacity over that of a stiffened shell with evenly spaced and identical ring stiffeners.

ABSTRACT: This paper is concerned with the elastic buckling of axially compressed, circular cylindrical shells with intermediate ring supports. The simple Timoshenko thin shell theory and the more sophisticated Flügge thin shell theory have been adopted in the modeling of the cylindrical shells. We used these two representative theories to examine the sensitivity of the buckling solutions to the different degree of approximations made in shell theories. By dividing the shell into segments at the locations of the ring supports, the state-space technique is employed to derive the solutions for each shell segment, and the domain decomposition method is utilized to impose the equilibrium and compatibility conditions at the interfaces of the shell segments. First-known exact buckling factors are obtained for cylindrical shells of one and multiple intermediate ring supports and various combinations of boundary conditions. Comparison studies are carried out against benchmark solutions and independent numerical results from ANSYS and p-Ritz analyses. The influence of the locations of the ring supports on the buckling behaviour of the shells is examined.

ABSTRACT: A solid shell element model is proposed for the elastic bifurcation buckling analysis of double-walled carbon nanotubes (DWCNTs) under axial compression. The solid shell element allows for the effect of transverse shear deformation which becomes significant in a stocky DWCNT with relatively small radius-to-thickness ratio. The van der Waals (vdW) interaction between the adjacent walls is simulated by linear springs. Using this solid shell element model, the critical buckling strains of DWCNTs with various boundary conditions are obtained and compared with molecular dynamics results and those obtained by other existing shell and beam models. The results obtained show that the solid shell element is able to model DWCNTs rather well, with the appropriate choice of Young’s modulus, tube thickness, and spring constant for modeling the vdW forces.

ABSTRACT: Molecular dynamics simulations are performed on single- (SWCNTs) and double-walled carbon nanotubes (DWCNTs) to investigate the effects of strain rate on their buckling behavior. The Brenner’s second-generation reactive empirical bond order and Lennard-Jones 12-6 potentials are used to describe the short range bonding and long range van der Waals atomic (vdW) interaction within the carbon nanotubes, respectively. The sensitivity of the buckling behavior with respect to the strain rate is investigated by prescribing different axial velocities to the ends of the SWCNTs and DWCNTs in the compression simulations. In addition, the effects of vdW interaction between the walls of the DWCNTs on their buckling behavior are also examined. The simulation results show that higher strain rates lead to higher buckling loads and buckling strains for both SWCNTs and DWCNTs. A distinguishing characteristic between SWCNTs and DWCNTs is that the former experiences an abrupt drop in axial load whereas the axial load in latter decreases over a finite, albeit small, range of strain after buckling initiates. The buckling capability of DWCNT is enhanced in the presence of vdW interaction. DWCNTs can sustain a higher strain before buckling than SWCNTs of similar diameter under otherwise identical conditions.

ABSTRACT: Buckling of multiwalled carbon nanotubes (MWCNTs) subjected to bending deformation is studied using molecular dynamics simulations. We show that the initial buckling mode of a thick MWCNT is quite different from that of a thin MWCNT. Only several outer layers buckle first while the rest inner layers
remain stable in a very thick MWCNT, while in a relatively thin MWCNT, all individual tubes buckle simultaneously. Such a difference in the initial buckling modes results in quite different size effects on the bending behavior of MWCNTs. In particular, the critical buckling curvature of a thick MWCNT is insensitive to the tube thickness, which is in contrast with linear elasticity. It is found also that the initial buckling wavelength is weakly dependent on the thickness of the MWCNT. We demonstrate that rippling deformation does decrease the effective modulus of a bent MWCNT, as observed in experiments. Finally, we show that the interlayer van der Waals interactions have little effect on the bending behavior of a MWCNT in the linear elastic regime.

ABSTRACT: This paper presents an assessment of continuum mechanics (beam and cylindrical shell) models in the prediction of critical buckling strains of axially loaded single-walled carbon nanotubes (SWCNTs). Molecular dynamics (MD) simulation results for SWCNTs with various aspect (length-to-diameter) ratios and diameters will be used as the reference solutions for this assessment exercise. From MD simulations, two distinct buckling modes are observed, i.e. the shell-type buckling mode, when the aspect ratios are small, and the beam-type mode, when the aspect ratios are large. For moderate aspect ratios, the SWCNTs buckle in a mixed beam–shell mode. Therefore one chooses either the beam or the shell model depending on the aspect ratio of the carbon nanotubes (CNTs). It will be shown herein that for SWCNTs with long aspect ratios, the local Euler beam results are comparable to MD simulation results carried out at room temperature. However, when the SWCNTs have moderate aspect ratios, it is necessary to use the more refined nonlocal beam theory or the Timoshenko beam model for a better prediction of the critical strain. For short SWCNTs with large diameters, the nonlocal shell model with the appropriate small length scale parameter can provide critical strains that are in good agreement with MD results. However, for short SWCNTs with small diameters, more work has to be done to refine the nonlocal cylindrical shell model for better prediction of critical strains.

ABSTRACT: Seismic response of cylindrical storage tanks anchored to rigid base slabs is considered. Finite elements are used for the liquid and tank wall, idealized as a thin shell. For steel tanks of practical dimensions, design charts are presented for natural frequencies, maximum shear and overturning moment on the foundation, and maximum stress resultants in the tank wall. Furthermore, an analytical expression for the superelevation of the free surface is presented.

ABSTRACT: This paper is concerned with the elastic buckling of super ellipsoidal shells under external uniform pressure. The middle surface of a super ellipsoidal shell is defined by the following equation:
\[(x/a)^n + (y/b)^n + (z/c)^n = 1,\]
where \(n\) is an integer varying from unity to infinity. It is clear from the equation that the range of shell shapes covered sphere (\(n=1, a=b=c\)) to cube (View the MathML source) and ellipsoid (\(n=1\)) to cuboid (\(n=∞\)). By adopting a recently proposed solid shell element for the buckling analysis, the critical buckling pressures of thin to thick super ellipsoidal shells are obtained and tabulated for engineers. The shell element allows for the effect of transverse shear deformation which becomes significant in thick shells. Their buckling shapes are also examined. In addition, a simple approximate formula for predicting the critical buckling pressure of thick spherical shells is proposed.

ABSTRACT: Based on the classical nonlinear von Kármán plate theory, axisymmetric large deflection bending of a functionally graded circular plate is investigated under mechanical, thermal and combined thermal–mechanical loadings, respectively, and axisymmetric thermal post-buckling behavior of a functionally graded circular plate is also investigated. The mechanical and thermal properties of functionally graded material (FGM) are assumed to vary continuously through the thickness of the plate, and obey a simple power law of the volume fraction of the constituents. Governing equations for the problem are derived, and then a shooting method is employed to numerically solve the equations. Effects of material constant \(n\) and boundary conditions on the temperature distribution, nonlinear bending, critical buckling temperature and thermal post-buckling behavior of the FGM plate are discussed in details.

ABSTRACT: Based on the first-order shear deformation theory of plate, governing equations for the axisymmetric buckling of functionally graded circular/annular plates are derived. The coupled deflections and rotations in the pre-buckling state of the plates are neglected in analysis. The material properties vary continuously through the thickness of the plate, and obey a power law distribution of the volume fraction of the
constituents. The resulting differential equations are numerically solved by using a shooting method. The critical buckling loads of circular and annular plates are obtained, which are compared with those obtained from the classical plate theory. Effects of material properties, ratio of inter to outer radius, ratio of plate thickness to outer radius, and boundary conditions on the buckling behavior of FGM plates are discussed.

ABSTRACT: This work presents the analysis of critical thermo electromechanical buckling (TEMB) of a micro elastic and isotropic annular plate that is simultaneously subjected to a thermal load and symmetric electrostatic force. The annular plate is assumed to be rigidly clamped at its outer radius edge and free at the inner radius edge. TEMB is the bifurcation response which results from the coupling of electromechanical bifurcation and thermo-mechanical buckling. It will be shown that the TEMB state depend on the value of two different loading parameters. The capability to determine the value of the critical buckling temperature or the critical buckling voltage enable us to instigate buckling even when the in-plane thermal stresses are in tension. The most interesting result that will be shown is that TEMB allow us to determine the number of buckled elastic flexures along the circumference of the annular plate. On other words, TEMB of annular plate permit manipulating of the critical buckling values and the shape mode of the buckling response. Finally, it will be shown for the first time that symmetric electrostatic forces can be modeled as an active “virtual” elastic foundation with a stiffness that can be manipulated to achieve the desired thermo-electro-mechanical response.

ABSTRACT: High load-bearing efficiency is one of the advantages of biological structures after the evolution of billions of years. Biomimicking from nature may offer the potential for lightweight design. In the viewpoint of mechanics properties, the culm of bamboo comprises of two types of cells and the number of the vascular bundles takes a gradient of distribution. A three-point bending test was carried out to measure the elastic modulus. Results show that the elastic modulus of bamboo decreases gradually from the periphery towards the centre. Based on the structural characteristics of bamboo, a bionic cylindrical structure was designed to mimic the gradient distribution of vascular bundles and parenchyma cells. The buckling resistance of the bionic structure was compared with that of a traditional shell of equal mass under axial pressure by finite element simulations. Results show that the load-bearing capacity of bionic shell is increased by 124.8%. The buckling mode of bionic structure is global buckling while that of the conventional shell is local buckling.

ABSTRACT: Based on von Kármán-Donnell kinematic assumptions for laminated shells, the non-linear vibration and postbuckling behaviour of unsymmetrically laminated cross-ply circular cylindrical shells with
clamped and simply-supported ends are studied by a multi-mode approach. A solution is formulated and satisfies the associated compatibility equation and all boundary conditions. The transverse equation of motion is fulfilled by the Galerkin procedure. In the case of non-linear vibration problems, the solution is obtained by the method of harmonic balance. The effect of initial imperfection is also included. Results in non-linear vibration and postbuckling are presented for different amplitudes of initial imperfection and four sets of boundary conditions. Present results are compared with available data.

ABSTRACT: Based on the Timoshenko-Mindlin kinematic hypothesis, the Donnell-type shell theory is extended to include transverse shear and rotary inertia for the nonlinear analysis of an anti-symmetrically laminated cross-ply circular cylindrical shell. The resulting governing equations are expressed in terms of a stress function, two rotations and transverse displacement. The shell is assumed to be all-simply-supported and all-clamped. A solution is formulated by a multi-mode approach and the method of harmonic balance for non-linear vibrations. The corresponding postbuckling problem is treated as a special case. The results are compared with available data.

ABSTRACT: A multi-mode solution to the dynamic Marguerre-type nonlinear equations is presented for the nonlinear free vibration of doubly curved, symmetrically laminated, imperfect shallow shells of rectangular planform on a Winkler-Pasternak elastic foundation. The shell edges are assumed to be transversely supported and the variation of rotational stiffness is identical along opposite edges. Generalized double Fourier series with time-dependent coefficients and the method of harmonic balance are used in the solution. The boundary condition for the varying rotational stiffness is fulfilled by replacement of bending moments along the four edges by an equivalent lateral pressure. Based on a single-mode approximation numerical results for the amplitude-frequency response of doubly curved isotropic, orthotropic, cross-ply and angle-ply shallow shells with square planform are presented for various boundary conditions, material properties, curvature ratios, initial imperfections, edge tensions, and moduli of the elastic foundation. Graphical results for postbuckling behavior of an imperfect angle-ply cylindrical panel are also presented as a special case.

ABSTRACT: A dynamic non-linear theory for generally laminated shallow cylindrical panels is developed with the aid of Hamilton's principle. The effects of transverse shear deformation, rotatory inertia and geometrically initial imperfection are included in the analysis. A multi-mode solution is formulated for non-linear free vibration of an anti-symmetric angle-ply cylindrical laminate with its edges elastically restrained against rotation. The resulting equations for time functions are solved by the method of harmonic balance. The postbuckling behavior of the panel is treated as a special case. Numerical results in non-linear vibration and
postbuckling are presented for different values of the amplitude of initial imperfection, side-to-thickness ratio, rotational edge stiffness, aspect ratio, orientation angle, number of layers and material properties. Present results are compared with available data.

ABSTRACT: Non-linear vibrations of generally laminated circular cylindrical shells are examined using the Timoshenko-Mindlin kinematic hypothesis and an extension of the Donnell-type shell theory. The effects of transverse shear deformation, rotatory inertia and geometrically initial imperfection are included in the analysis. A solution for non-linear free vibrations of these cylindrical shells is formulated using a multimode approach. The boundary condition for the varying rotational end stiffness in the circumferential direction is satisfied by replacement of the end bending moments by an equivalent lateral pressure near the shell ends. The Galerkin procedure furnishes an infinite system of equations for time functions which are solved by the method of harmonic balance. The postbuckling behavior of the shell is treated as a special case. Numerical results in non-linear vibration and postbuckling of cylindrical laminates are presented graphically for different parameters and compared with available data.

M.M. Banerjee and S. Chanda (A.C. College, Jalpaiguri, W.B., India), “Nonlinear vibration of doubly-curved orthotropic shallow shells under a thermal gradient”, Transactions of the Thirteenth International Conference on Structural Mechanics in Reactor Technology (SMiRT 13), Porto Alegre, Brazil, August, 1995

ABSTRACT: The present investigation aims at the finding of the effect of a thermal gradient on a doubly-curved orthotropic shallow shell. The basic governing differential equations have been derived under the effect of a temperature distribution varying linearly and uniaxially.

ABSTRACT: The static and dynamic non-linear axisymmetric response of a shallow spherical shell with a circular opening at the apex has been investigated. The shell consists of a number of radially orthotropic layers perfectly bonded together but symmetrically laminated. The governing equations are expressed in terms of the transverse displacement, rotation and stress function. The effects of transverse shear and rotatory inertia are included in the analysis. The shell edge is elastically restrained against rotation and in-plane displacement. The vanishing of the rotation and in-plane displacement at the opening are assumed. A Fourier-Bessel series solution is formulated for the postbuckling and large amplitude free vibration of the shell. The Galerkin procedure furnishes a set of non-linear ordinary differential equations for time functions which are solved by the method of harmonic balance. Numerical results in postbuckling response and non-linear free vibration are presented for various boundary conditions, ratios of base radius to thickness, and shell rise to thickness, and numbers of layers. The results are also compared with available data.

ABSTRACT: This research investigates the free vibration and buckling of a two-layered cylindrical shell made of inner functionally graded (FG) and outer isotropic elastic layer, subjected to combined static and periodic axial forces. Material properties of functionally graded cylindrical shell are considered as temperature dependent and graded in the thickness direction according to a power-law distribution in terms of the volume fractions of the constituents. Theoretical formulations are presented based on two different methods of first-order shear deformation theory (FSDT) considering the transverse shear strains and the rotary inertias and the classical shell theory (CST). The results obtained show that the transverse shear and rotary inertias have considerable effect on the fundamental frequency of the FG cylindrical shell. The results for nondimensional natural frequency are in close agreement with those in literature. It is inferred from the results that the geometry parameters and material composition of the shell have significant effect on the critical axial force, so that the minimum critical load is obtained for fully metal shell. Good agreement between theoretical and finite element results validates the approach. It is concluded that the presence of an additional elastic layer significantly increases the nondimensional natural frequency, the buckling resistance and hence the elastic stability in axial compression with respect to a FG hollow cylinder.

DOI: 10.1016/j.apm.2013.03.020

ABSTRACT: This paper investigates the nonlinear vibration and instability of the embedded double-walled boron nitride nanotubes (DWBNNTs) conveying viscous fluid based on nonlocal piezoelectricity cylindrical shell theory. The elastic medium is simulated as Winkler–Pasternak foundation, and adjacent layers interactions are assumed to have been coupled by van der Walls (vdW) force evaluated based on the Lennard–Jones model. The nonlinear strain terms based on Donnell’s theory are taken into account. The Hamilton’s principle is employed to obtain coupled differential equations, containing displacement and electric potential terms. Differential quadrature method (DQM) is applied to estimate the nonlinear frequency and critical fluid velocity for clamped supported mechanical and free electric potential boundary conditions at both ends of the DWBNNTs. Results indicated that some parameters including nonlocal parameter, elastic medium’s modulus, aspect ratio and vDW force have significant influence on the vibration and instability of the DWBNNT while the fluid viscosity effect is negligible. In addition, the low aspect ratio should be taken into account for DWBNNT in optimum design of nano/micro devices.

ABSTRACT: In this paper, free vibration and buckling analysis of functionally graded cylindrical shells subjected to combined static and periodic axial forces is presented considering the effect of transverse shear and rotary inertia. Material properties of functionally graded cylindrical shells are considered as temperature dependent and graded in the thickness direction according to a power-law distribution in terms of the volume fractions of the constituents. Numerical results for silicon nitride-nickel cylindrical shells are presented based on two different methods of first-order shear deformation theory (FSDT) considering the transverse shear strains and the rotary inertias and the classical shell theory (CST). The results obtained show that the effect of transverse shear and rotary inertias on free vibration and buckling of functionally graded cylindrical shells subjected to combined static and periodic axial forces is dependent on the material composition, the temperature environment, the amplitude of static load, the deformation mode, and the shell geometry parameters.

Farzad Ebrahimi and Erfan Saleri (Department of Mechanical Engineering, Faculty of Engineering, Imam Khomeini International University, Qazvin, Iran), “Size-dependent thermo-electrical buckling analysis of functionally graded piezoelectric nanobeams”, Smart Materials and Structures, Vol. 24, No. 12, October 2015, https://doi.org/10.1088/0964-1726/24/12/125007

ABSTRACT: In the present study, thermo-electrical buckling characteristics of functionally graded piezoelectric (FGP) Timoshenko nanobeams subjected to in-plane thermal loads and applied electric voltage are carried out by presenting a Navier type solution for the first time. Three kinds of thermal loading, namely, uniform, linear and nonlinear temperature rises through the thickness direction are considered. Thermo-electro-mechanical properties of FGP nanobeam are supposed to vary smoothly and continuously throughout the thickness based on power-law model. Eringen's nonlocal elasticity theory is exploited to describe the size dependency of nanobeam. Using Hamilton's principle, the nonlocal governing equations together with corresponding boundary conditions based on Timoshenko beam theory are obtained for the thermal buckling analysis of graded piezoelectric nanobeams including size effect and they are solved applying analytical solution. According to the numerical results, it is revealed that the proposed modeling can provide accurate critical buckling temperature results of the FG nanobeams as compared some cases in the literature. In following a parametric study is accompanied to examine the effects of the several parameters such as various temperature distributions, external electric voltage, power-law index, nonlocal parameter and aspect ratio on the critical buckling temperature difference of the size-dependent FGP nanobeams in detail. It is found that the small scale effect and electrical loading have a significant effect on buckling temperatures of FGP nanobeams.

PARTIAL INTRODUCTION: Behavior of buckling for shell structure has been wide attention for absorption of impact energy [1]. Both high strength and the ability to absorb energy during structural collapse are important factors for structural design in crush problems. The collapse analyses have been carried out analytically and experimentally [2-4]. Recently, numerical techniques have become available and computer simulation for collapse analysis has become very attractive [5,6]. …

ABSTRACT: A dynamic nonlinear theory for layered shallow shells is derived by means of the von Karman-Tsien theory, modified by the generalized Berger-approximation. Moderately thick shells with polygonal planform composed of multiple perfectly bonded layers are considered. The shell edges are assumed to be prevented from in-plane motions and are simply supported. A distributed lateral force loading is applied to the structure, and additionally, the influence of a static thermal prestress, corresponding to a spatial distribution of cross-sectional mean temperature, is taken into account. In the special case of laminated shells made of transversely isotropic layers with physical properties symmetrically distributed about the middle surface, a correspondence to moderately thick homogeneous shells is found. Application of a multi-mode expansion in the Galerkin procedure to the governing differential equation, where the eigenfunctions of the corresponding linear plate problem are used as space variables, renders a coupled set of ordinary time differential equations for the generalized coordinates with cubic as well as quadratic nonlinearities. The nonlinear steady-state response of shallow shells subjected to a time-harmonic lateral excitation is investigated and the phenomenon of primary resonance is studied by means of the “perturbation method of multiple scales”. A unifying non-dimensional representation of the nonlinear frequency response function is presented that is independent of the special shell planform.

ABSTRACT: Deterministic and random vibrations are considered for the case of shear deformable shallow shells composed of multiple perfectly bonded layers. The nontrivial generalization of the flat plate vibrations is expressed by the fact of “small amplitude” vibrations existing about the curved equilibrium position together with the snap-through and snap-buckling type large amplitude vibrations about the flat position. The geometrically nonlinear vibrations are treated by applying Berger’s approximation to the generalized von Karman-type plate equations considering hard hinged supports of the straight boundary segments of skew or
even more generally shaped polygonal shells. Shear deformation is considered by means of Mindlin’s kinematic hypothesis and a distributed lateral force loading is applied. Application of a multi-mode expansion in the Galerkin procedure to the governing differential equation, where the eigenfunctions of the corresponding linear plate problem are used as space variables, renders a coupled set of ordinary time differential equations for the generalized coordinates with cubic and quadratic non-linearities. For reasons of convergence, a light viscous modal damping is added. The nonlinear steady-state response of shallow shells subjected to a time-harmonic lateral excitation is investigated and the phenomenon of primary resonance is studied by means of the “perturbation method of multiple scales”. The use of a nondimensional formulation and introduction of the eigen-time of the basic mode of the associated linearized problem provides a unifying result with respect to the planform of the shell. Within the scope of random vibrations, it is assumed that the effective forces can be modelled by uncorrelated, zero-mean wide-band noise processes. Considering the set of modal equations to be finite, the Fokker-Planck-Kolmogorov (FPK) equation for the transition probability density of the generalized coordinates and velocities is derived. Its stationary solution gives the probability of eventual snapping after a long time has elapsed. However, the probability of first occurrence follows from the (approximate) integration of the nonstationary FPK equation. The probability of first dynamic snap-through is derived for a single mode approximation with the influence of higher modes taken into account. Using the two-mode expansion, the probability distribution of the asymmetric snap-buckling is also evaluated.

PARTIAL ABSTRACT: In the course of transient random vibrations of shallow structures the phenomenon of dynamic snap-buckling is observed. The nontrivial generalization of the flat plate vibrations is expressed by the fact of “small amplitude” vibrations to exist about the curved equilibrium position together with the snap-through and the snap-buckling type large amplitude vibrations about the flat position….
space variables, renders a coupled set of ordinary time differential equations for the generalized coordinates with (mixed) cubic and quadratic non-linearities. The nonlinear steady-state response of panels subjected to a time-harmonic lateral excitation is investigated and the phenomena of primary, superharmonic, and subharmonic resonances are studied by means of the perturbation method of multiple scales. Numerical results are cast in the form of graphs with a structural parameter varying in a wide range.

“Non-linear random response of laminated composite shallow shells using finite element modal method.
doi: 10.1002/nme.1672
ABSTRACT: This paper investigates the large-amplitude multi-mode random response of thin shallow shells with rectangular planform at elevated temperatures using a finite element non-linear modal formulation. A thin laminated composite shallow shell element and the system equations of motion are developed. The system equations in structural node degrees-of-freedom (DOF) are transformed into modal co-ordinates, and the non-linear stiffness matrices are transformed into non-linear modal stiffness matrices. The number of modal equations is much smaller than the number of equations in structural node DOF. A numerical integration is employed to determine the random response. Thermal buckling deflections are obtained to explain the intermittent snap-through phenomenon. The natural frequencies of the infinitesimal vibration about the thermally buckled equilibrium positions (BEPs) are studied, and it is found that there is great difference between the frequencies about the primary (positive) and the secondary (negative) BEPs. All three types of motion: (i) linear random vibration about the primary BEP, (ii) intermittent snap-through between the two BEPs, and (iii) non-linear large-amplitude random vibration over the two BEPs, can be predicted.

ABSTRACT: This paper reports numerical analyses of free vibration of laminated composite plate/shell structures of various shapes, span-to-thickness ratios, boundary conditions and lay-up sequences. The method is based on a novel four-node quadrilateral element, namely MISQ20, within the framework of the first-order shear deformation theory (FSDT). The element is built by incorporating a strain smoothing method into the bilinear four-node quadrilateral finite element where the strain smoothing operation is based on mesh-free conforming nodal integration. The bending and membrane stiffness matrices are based on the boundaries of smoothing cells while the shear term is evaluated by 2 x 2 Gauss quadrature. Through several numerical examples, the capability, efficiency and simplicity of the element are demonstrated. Convergence studies and comparison with other existing solutions in the literature suggest that the present element is robust, computationally inexpensive and free of locking.

ABSTRACT: This paper presents buckling and free vibration analysis of composite plate/shell structures of various shapes, modulus ratios, span-to-thickness ratios, boundary conditions and lay-up sequences via a novel smoothed quadrilateral flat element. The element is developed by incorporating a strain smoothing technique into a flat shell approach. As a result, the evaluation of membrane, bending and geometric stiffness matrices are based on integration along the boundary of smoothing elements, which leads to accurate numerical solutions even with badly-shaped elements. Numerical examples and comparison with other existing solutions show that the present element is efficient, accurate and free of locking.

ABSTRACT: This paper further extends a cell-based smoothed finite element method for free vibration and buckling analysis of shells. A four-node quadrilateral Mindlin-Reissner shell element with a gradient smoothing operator is adopted. The membrane-bending and geometrical stiffness matrices are computed along the boundaries of the smoothing cells while the shear stiffness matrix is calculated by an independent interpolation in the natural coordinates as in the MITC4 (the Mixed Interpolation of Tensorial Components) element. Various numerical results are compared with existing exact and numerical solutions and they are in good agreement. The advantage of the present formulation is that it retains higher accurate than the MITC4 element even for heavily distorted meshes without increasing the computational cost.

ABSTRACT: This study focuses on the buckling of cylindrical shells with small thickness variations under external pressure. Asymptotic formulas in terms of the thickness non-uniformity parameter are derived by the combined perturbation and Bubnov–Galerkin methods. In addition to the analytic investigation based on the thin shell theory, a numerical analysis is also performed. Results from these formulas are discussed and compared with those obtained by other authors.

References listed at the end of the paper:

as for a ring, the present model obtains a slightly lower buckling pressure which depends on the length.

ABSTRACT: The governing Flügge stability equations in coupled form are used for cylinders subjected to external pressure that varies circumferentially. Three cases are considered: fluid (hydrostatic) pressure, wind pressure and partial (patch) circumferential pressure. The wind load follows the Australian Standard AS 1170.2 (1989). Longitudinal variation of the load is not considered. The numerical process gives the stagnation buckling pressure for different shell geometry and simple support conditions at each end. The Galerkin method is employed to orthogonalize the error made with the introduction of the finite series into the governing equations. The solutions are compared with a few published solutions in the literature.

ABSTRACT: In this paper, the problems of thermal buckling in axial direction of cylindrical shells made of functionally graded materials are discussed. Based on the Donnell’s shell theory, the equilibrium and stability equations of the cylindrical shell subjected to thermal loads are derived firstly. Then the closed form solutions are presented for the shell with simply supported boundary conditions subjected to three types of thermal loading. The material properties are assumed varying as a power form of thickness coordinate variable. The influences of the aspect ratio, the relative thickness and the functionally graded index on the buckling temperature difference are carefully discussed.

ABSTRACT: A thermal buckling analysis of imperfect circular cylindrical shells of functionally graded material is considered. The material properties are assumed varying as a power form of thickness coordinate variable. The Donnell equilibrium and stability equations are considered and the Wan-Donnell model for initial geometrical imperfection is adopted. The thermal loads include the uniform temperature rise and nonlinear temperature change across the thickness of shell. A closed form solution for the thermal buckling of simply supported cylindrical FG shell under the described thermal loads is obtained. The influences of the relative thickness, the imperfection size and the power law index on buckling thermal loads are all discussed.

ABSTRACT: This paper presents an analytical approach to investigate nonlinear response of functionally graded cylindrical panels under uniform lateral pressure with temperature effects are incorporated. Material properties are assumed to be temperature-independent, and graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of constituents. Equilibrium and compatibility equations for cylindrical panels are derived by using the classical shell theory with both geometrical nonlinearity in von Karman–Donnell sense and initial geometrical imperfection are taken into consideration. The resulting equations are solved by Galerkin method to determine explicit expressions of nonlinear load-deflection curves. Stability analysis for a simply supported panel shows the effects of material and geometric parameters, in-plane restraint and temperature conditions, and imperfection on the nonlinear response of the panel.

ABSTRACT: A titanium-matrix orthotropic cylindrical shell with the principal direction of orthotropy following a parallel constant angle helix, has been studied when it is subjected to uniform loading conditions of internal pressure, axial load and pure twisting moment. Nondimensional parameters pertaining to loading and deformations have been calculated and results plotted. The results obtained can be usefully applied in robotic actuators where lightweight considerations with high strength are of prime importance. The study is further extended to investigate the effect of temperature on the deformations. Through parametric studies, deformation patterns are calculated and plotted that are unique to orthotropy. In most of the cases, it is observed that deformation patterns are same, but deformation is increasing with temperatures.

“Buckling Of A Shallow Rectangular Bimetallic Shell Subjected To Outer Loads And Temperature”, SDSS’Rio 2010 Stability And Ductility Of Steel Structures E. Batista, P. Vellasco, L. de Lima (Eds.) Rio de Janeiro, Brazil, September 8 - 10, 2010

ABSTRACT: In the article, we have formulated a geometric non-linear mathematical-physical model of the snap-through of the system of a thin-walled shallow bimetallic translation shell in a homogenous temperature field according to the theory of large displacements, moderate rotations, and small strains of the shell element. The model enables the calculation of the geometric conditions, of shallow translation shells, due to the influences of temperature and mechanical loads. The results are based on the numeric solution of a non-linear system of partial differential equations with boundary conditions according to the finite difference method.

Marko Jakomin, "Shallow Axi-symmetric Bimetallic Shell as a Switching Element in a Non-Homogenous

ABSTRACT: In this contribution we discuss the stability of thin, axi-symmetric, shallow bimetallic shells in a non-homogeneous temperature field. The presented model with a mathematical description of the geometry of the system, displacements, stresses and thermoelastic deformations on the shell, is based on the theory of the third order, which takes into account not only the equilibrium of forces on a deformed body but also the nonlinear terms of the strain tensor. The equations are based on the large displacements theory. As an example, we present the results for a bimetallic shell of parabolic shape, which has a temperature point load at the apex. We translated the boundary-value problem with the shooting method into saving the initial-value problem. We calculate the snap-through of the system numerically by the Runge-Kutta fourth order method.

ABSTRACT: In this contribution, we discuss the stress, deformation, and snap-through conditions of thin, axisymmetric, shallow bimetallic shells of so-called parabolic-conic and plate-parabolic type shells loaded by thermal loading. According to the theory of the third order that takes into account the balance of forces on a deformed body, we present a model with a mathematical description of the system geometry, displacements, stress, and thermoelastic deformations. The equations are based on the large displacements theory. We numerically calculate the deformation curve and the snap-through temperature using the fourth-order Runge-Kutta method and a nonlinear shooting method. We show how the temperature of both snap-through depends on the point where one type of the rotational curve transforms into another.

ABSTRACT: Bimetallic shallow shells are thermal sensors. The paper presents relevant technical information on bimetallic shallow shells and describes some interesting physical experiments. It is shown how, through simple measurements and calculations, it is possible to determine the initial speed (~3.5 m/s), the acceleration (~30000 m/s²) and the lower and upper snap temperature (~22 °C; ~32 °C) of the bimetal. The results from simple measurements and calculations are comparable to those obtained by a high speed camera. The videos give an even deeper insight into the phenomenon of the snap-through.

ABSTRACT: Conceptual hardware architecture of skin-like circuits is described. An elastomeric skin carries rigid islands on which active subcircuits are made. The subcircuit islands are interconnected by stretchable metallization. We concentrate on recent advances in stretchable thin-film conductors, by covering their construction, evaluation, and laboratory and theoretical analysis. Reversibly stretchable conductors with electrically-critical strains ranging from 10% to 100% have been made.

Martin Hall, College Park, MD 20742, USA), “A mechanics model of microtubule buckling in living cells”, Journal of Biomechanics, Vol. 41, No. 8, 2008, pp. 1722-1729, doi:10.1016/j.jbiomech.2008.03.003
ABSTRACT: As the most rigid cytoskeletal filaments, microtubules bear compressive forces in living cells, balancing the tensile forces within the cytoskeleton to maintain the cell shape. It is often observed that, in living cells, microtubules under compression severely buckle into short wavelengths. By contrast, when compressed, isolated microtubules in vitro buckle into single long-wavelength arcs. The critical buckling force of the microtubules in vitro is two orders of magnitude lower than that of the microtubules in living cells. To explain this discrepancy, we describe a mechanics model of microtubule buckling in living cells. The model investigates the effect of the surrounding filament network and the cytosol on the microtubule buckling. The results show that, while the buckling wavelength is set by the interplay between the microtubules and the elastic surrounding filament network, the buckling growth rate is set by the viscous cytosol. By considering the nonlinear deformation of the buckled microtubule, the buckling amplitude can be determined at the kinetically
constrained equilibrium. The model quantitatively correlates the microtubule bending rigidity, the surrounding filament network elasticity, and the cytosol viscosity with the buckling wavelength, the buckling growth rate, and the buckling amplitude of the microtubules. Such results shed light on designing a unified experimental protocol to measure various critical mechanical properties of subcellular structures in living cells.

ABSTRACT: The buckling behaviors of microtubules (MTs) in a living cell have been studied based on the nonlocal anisotropic shell theory and Stokes flow theory. The analytical expressions for the buckling load and the growth rate of the buckling are obtained and discussed. In addition, the pressure on MTs, resulting from cytosol motion, is derived on the basis of the Stokes flow theory. The influences of filament network elasticity and the shear modulus of MTs, especially the cytosol viscosity and MT small scale effects on MT buckling behaviors, are investigated. The analytical results show that the MT buckling growth rate increases with the MT small scale parameter, while decreases as the filament network elastic modulus, the MT shear modulus and cytoplasm viscosity increase. Although the cytosol viscosity has a significant influence on the value of the growth rate, it shows little effects on the range of the axial wave number of buckling as well as the critical axial wave number that corresponds to the maximal growth rate. Finally, the MT buckling growth rates have been calculated using the beam model, the isotropic shell model, and the anisotropic shell model. The results indicate that using the anisotropy shell theory to model the buckling behavior of MTs is necessary.

ABSTRACT: The analytical solutions of the first-order shear deformation theory are developed to study the buckling behaviour of functionally graded (FG) cylindrical shells under three types of mechanical loads. The Poisson's ratios of the FG cylindrical shells are assumed to be constant, while the Young's moduli vary continuously throughout the thickness direction according to the volume fraction of constituents given by power-law or exponential function. The stability equations are employed to obtain the closed-form solutions for critical buckling loads of each loading case. The dependence of the critical buckling loads on the variations of the material properties with a power-law or exponential function is studied. It is observed that these effects change appreciably the critical buckling loads. Results for critical loads are tabulated for thin and moderately thick shells. Although the critical buckling load of FG cylindrical shells decreases as the circumferential wave numbers increase, it rises for axially compressed long shells as the longitudinal wave numbers increase.

ABSTRACT: This paper presents the buckling analysis of short and long functionally graded cylindrical shells under thermal and mechanical loads. The shell properties are assumed to vary continuously from the inner
surface to the outer surface of the shell. The equilibrium and stability equations are derived using the total potential energy equations, Euler equations and first order shear deformation theory assumptions. The resulting equations are solved for simply supported boundary conditions. The critical temperature and pressure loads are calculated for both short and long cylindrical shells. Comparison studies show the effects of functionally graded index, loading type and shell geometry on critical buckling loads of short and long functionally graded cylindrical shells.

ABSTRACT: Layerwise finite element analyses of geodesically stiffened cylindrical shells are presented in this work. The Layerwise Laminate Theory of Reddy (LWTR) is developed and adapted to circular cylindrical shells. The Ritz variational method is used to develop an analytical approach for studying the buckling of simply supported geodesically stiffened shells with discrete stiffeners. This method utilizes a Lagrange multiplier technique to attach the stiffeners to the shell. The development of the layerwise shells couples a one-dimensional finite element through the thickness with a Navier solution that satisfies the boundary conditions. The buckling results from the Ritz discrete analytical method are compared with smeared buckling results and with NASA testbed finite element results. The development of layerwise shell and beam finite elements is presented and these elements are used to perform the displacement field, stress, and first-ply failure analyses. The layerwise shell elements are used to model the shell skin and the layerwise beam elements are used to model the stiffeners. This arrangement allows the beam stiffeners to be assembled directly into the global stiffness matrix. A series of analytical studies are made to compare the response of geodesically stiffened shells as a function of loading, shell geometry, shell radii, shell laminate thickness, stiffener height, and geometric nonlinearity. Comparisons of the structural response of geodesically stiffened shells, axial and ring stiffened shells, and unstiffened shells are provided. In addition, Interlaminar stress results near the stiffener intersection are presented. First-ply failure analyses for geodesically stiffened shells utilizing the Tsai-Wu failure criterion are presented for a few selected cases.
ABSTRACT: The nonlinear dynamic response of doubly curved shallow shells resting on Winkler–Pasternak elastic foundation has been studied for step and sinusoidal loadings. Dynamic analogues of Von Karman–Donnel type shell equations are used. Clamped immovable and simply supported immovable boundary conditions are considered. The governing nonlinear partial differential equations of the shell are discretized in space and time domains using the harmonic differential quadrature (HDQ) and finite differences (FD) methods, respectively. The accuracy of the proposed HDQ-FD coupled methodology is demonstrated by numerical examples. The shear parameter $G$ of the Pasternak foundation and the stiffness parameter $K$ of the Winkler foundation have been found to have a significant influence on the dynamic response of the shell. It is concluded from the present study that the HDQ-FD methodology is a simple, efficient, and accurate method for the nonlinear analysis of doubly curved shallow shells resting on two-parameter elastic foundation.

ABSTRACT: In this paper, size effect of microtubules (MTs) is studied via modified strain gradient elasticity theory for buckling. MTs are modeled by Bernoulli–Euler beam theory. By using the variational principle, the governing equations for buckling and related boundary conditions are obtained in conjunctions with the strain gradient elasticity. The size effect for buckling analysis of MTs is investigated and results are presented in graph form. The results obtained by strain gradient elasticity theory are discussed through the numerical simulations. The results based on the modified couple stress theory, nonlocal elasticity theory and classical elasticity theories have been also presented for comparison purposes.

Ömer Civalek (Akdeniz University, Civil Engineering Department, Division of Mechanics, Antalya, Turkey), “Geometrically nonlinear dynamic and static analysis of shallow spherical shell resting on two-parameters elastic foundations”, International Journal of Pressure Vessels and Piping, Vol. 113, pp 1-9, 2014 DOI: 10.1016/j.ijpvp.2013.10.014

ABSTRACT: In the present study nonlinear static and dynamic responses of shallow spherical shells resting on Winkler–Pasternak elastic foundations are carried out. The formulation of the shells is based on the Donnell theory. The nonlinear governing equations of motion of shallow shells are discretized in space and time domains using the discrete singular convolution and the differential quadrature methods, respectively. The validity of the present method is demonstrated by comparing the present results with those available in the open literature. The effects of the Winkler and Pasternak foundation parameters on nonlinear static and dynamic response of shells are investigated. Some results are also presented for circular plate as special case. Damping effect on nonlinear dynamic response of shells is studied. It is important to state that the increase in damping parameter causes decrease in the dynamic response of the shells. It is shown that the shear parameter of the foundation has a significant influence on the dynamic and static response of the shells. Also, the response of the shell is decreased with the increasing value of the shear parameter of the foundation. Parametric studies considering different geometric variables have also been investigated.

Lentzen, S. and Schmidt, R. (Institute of General Mechanics, Technical University Aachen, Germany),

ABSTRACT: In order to show the significance of considering nonlinear deformations in piezoelectrical structures, a geometrical nonlinear shell element with integrated piezoelectric layers is introduced. The strain-displacement relations are implemented using first-order shear deformation theory with small strains but moderate rotations. The element has been tested on several benchmark problems and it can be concluded that the effect of geometrical nonlinearity is significant when the sensor properties of the piezoelectrical layers are predicted.

ABSTRACT: In this paper a geometrically nonlinear composite shell element with integrated magnetostrictive layers is presented. Three translational and two rotational nodal degrees of freedom are used for the first-order transverse shear approximation. The finite element is used in order to investigate shape and stability control problems of structures with magnetostrictive actuator layers in the range of large deformations. The numerical approximations to this static problem are obtained using the total Lagrangian formulation for the moderate rotation shell theory. The aforementioned finite element is used to numerically investigate the actuation behaviour of the integrated magnetostrictive layers. Since the magnetic field is prescribed, the coupled magnetoelastic problem turns into a decoupled problem.

“Geometrically nonlinear finite element simulation of smart piezolaminated plates and shells”, Smart Materials and Structures, Vol. 16, No. 6, October 2007, DOI: 10.1088/0964-1726/16/6/029

ABSTRACT: In this work a geometrically nonlinear finite shell element is presented, incorporating piezoelectric layers. The finite element is implemented in a total Lagrangian approach, which requires special attention to be given to the proper definition of the mechanical and electrical quantities. The strain–displacement relations are based on the assumption of small strains and moderate rotations. The transverse displacement field and the transverse electric potential are assumed to vary linearly through the thickness. With the presented finite element, static as well as dynamic examples are calculated. The differences between the results obtained with linear and nonlinear theory are emphasized.

ABSTRACT: By using the mixed Lagrangian–Eulerian description and adopting the von Kármán's strain approximation, the non-linear magnetoelastic interactions of a circular cylindrical thin shell experiencing
moderately large deflections are fully explored. The shell is assumed to be perfectly electroconductive and immersed in an applied magnetic field and carrying electric current. The magnetoelastic loads acting on the shell associated with the Lorentz forces and Maxwell's stress jumps are explicitly represented and the approximated governing systems for the induced magnetic fields outside the shell in total Lagrangian description are obtained. Case study on a shell's cross section model is conducted and pertinent conclusions are drawn.

ABSTRACT: The generalized Donnell-type equations governing large deflection of antisymmetrically laminated cross-ply cylindrical shells counting for transverse shear deformations are derived and presented. An asymptotic series solution is constructed by regular perturbation technique for postbuckling behaviors of the cylindrical shells with simply supported edges subjected to axial compression. Boundary layer influence at both ends of the shells on overall buckling and postbuckling are considered, and for consistency of the boundary valued problem, the boundary layer solutions are also designed to match the out-of-plane edge conditions by singular perturbation approach. Effects of transverse shear deformation, Batdorf’s parameter, elastic moduli ratio, and initial geometric imperfection on buckling and postbuckling performance of the shells are examined. Some numerical examples are taken for comparison of the present results of buckling loads and load–deflection curves of the shells with corresponding theoretical predictions to show effectiveness and accuracy of the present asymptotic perturbation solution.

ABSTRACT: A theoretical development is presented for the parametric resonance of layered anisotropic circular cylindrical shells. The shell's ends are clamped and subjected to axial loading consisting of a static part and a harmonic part. The shell is modelled by using linear shell theory; classical lamination theory is used to determine the stiffness of the overall composite shell structure. The shell's response is divided into a pre-instability (unperturbed) part and an incremental perturbation--which can be dynamically unstable. Rather than assuming the unperturbed state to be a static membrane state of stress, here unperturbed response inertia and spatial variations are retained. A successful solution strategy is developed by employing several Fourier expansions. By means of it, the equations of motion of the perturbed response are reduced to a system of Mathieu equations. The stability of such a system can be determined by known methods. Numerical results are presented in part II.
(Cannot cut and paste references from the pdf file)

ABSTRACT: Numerical results for the parametric resonance response of layered anisotropic circular
cylindrical shells are presented based on a theoretical development given in part I [1]. The principal regions of parametric resonance are determined numerically from the system of Mathieu equations derived in part I. Results are given for two particular graphite-epoxy shells. The effects of pre-instability inertia in the composite shell is shown to be similar to that discussed previously [2] in connection with isotropic shells. Specifically, it is found that inclusion of pre-instability inertia may result in increased widths of the instability regions of modes having instability forcing frequency very close to a natural frequency of the pre-instability motion of the shell. Also, the effect of pre-instability spatial variation on the principal regions of parametric resonance is separately studied. It is found that the widths of the instability regions may be greatly increased by inclusion of these spatial variations.

ABSTRACT: The dynamic stability of thin, clamped, composite circular cylindrical shells is studied for combined axial and torsional loading. Each load is taken to be harmonically varying; the frequencies of the two loads differ, in general. For the case in which the frequencies are commensurate, the applied load function is periodic. The equations of motion for the shell are reduced to a system of Hill equations by means of Fourier series expansions. Instability regions of principal and combination parametric resonance are determined by use of the monodromy matrix. Numerical results are generated for boron-epoxy layered shells for various cases of pure axial, pure torsional, and combined loading. The width of the principal instability region is presented as a function of fiber orientation for a laminate case. Stability diagrams are presented covering about 6 times the lowest natural frequency for various ratios of the applied axial and torsional frequencies.

ABSTRACT: The purpose of this work is to analyse the problem: what is the effect of the assumed types and intensities of random initial geometrical imperfections on the equilibrium paths and the limit loads? To this end a new method of simulation of nonhomogeneous two-dimensional random fields on regular nets has been developed. The method is based on two concepts: an envelope of the random field and local covariance matrices classified according to the symmetry groups. The numerical examples deal with post-buckling responses of FEM models of shallow shells with different types of imperfections (whitenoise, Wiener and degenerated fields) using a Monte Carlo approach.

“Consistent mixed model for stability of stiffened panels with cut-outs”, Computers & Structures, Vol. 54,
ABSTRACT: In contrast to the familiar Kirchoff approach, a simple, consistent, shear flexible model for the stability analysis of stiffened panels has been developed in the context of hybrid mixed technique. This model is composed of a quadrilateral plate element, as well as its complementary skeletal grid element. The formulation is based on the Hellinger/Reissner mixed variational principle with independently assumed displacement and strain fields. The proposed model has been utilized to develop a general finite element code for determination of critical buckling stresses of stiffened panels for any case of in-plane loadings and boundary conditions. The effectiveness and practical usefulness of this model have been demonstrated by a variety of numerical results for practical applications. In particular, design curves for buckling stresses of simply supported rectangular panels with central cut-outs and lateral stiffeners have been developed under in-plane load-type. These curves provide a valuable insight into the behavior of stiffened panels and could be useful for design codes.

ABSTRACT: Modern theory for applications of laminated plates and shells calls for detailed study of the effect of large spatial rotations on the geometric stiffness for stability analysis as well as inertia operators for vibrations. These two issues are carefully examined here in conjunction with the recently developed mixed finite element formulation for plates and shells with low-order displacement/strain interpolations. An extensive set of stability and vibration problems has been solved to demonstrate the effectiveness and general utilities of the formulation described for laminated plate and shells with arbitrary geometry.

ABSTRACT: From a more recent and comprehensive perspective, work on the nonlinear dynamic response of plates and shells calls for detailed studies of several important factors. These include the effect of large spatial rotations on the geometric stiffness and inertia operators, the accurate updating procedures for nodal rotations and associated angular velocities and accelerations, as well as material inelasticity (especially for finite strains). Several of these issues are examined here in conjunction with a recently developed mixed finite element formulation for plates and shells with low-order displacement/strain interpolations. To this end, and restricting the scope to the case of large overall motions but small strains, low-order displacement/strain interpolations are utilized, together with a radial return algorithm (backward-Euler-integration scheme) for plasticity effects. The Newmark implicit scheme has been employed to integrate the semi-discrete equations of motion. A selective set of elastic as well as elasto-plastic problems has been solved to demonstrate the effectiveness and practical utility of the formulation described for plate and shells with arbitrary geometry.

ABSTRACT: The finite element method based on the total Lagrangian description of the motion and the Hellinger–Reissner principle with independent strain is applied to investigate the non-linear static and dynamic responses of spherical laminated shells under external pressure. The non-linear dynamic problem is solved by employing the implicit time integration method. The critical load of thin spherical laminated panels is investigated by examining the static and dynamic responses. The critical dynamic load is determined by the phase-plane and the Budiansky–Roth criteria. The effect of the artificial coefficient of Rayleigh damping on the dynamic response is considered. The dynamic response with damping included converges to the static response. The damping coefficient greatly affects a highly non-linear dynamic response. For a thin spherical panel with the snapping phenomena, the critical dynamic load is lower than the static one.

ABSTRACT: This paper investigates the effect of intertube van der Waals interaction on the stability of pristine and covalently functionalized carbon nanotubes under axial compression, using molecular mechanics simulations. After regulating the number of inner layers of the armchair four-walled (5, 5)-(10, 10)-(15, 15)-(20, 20) and zigzag four-walled (6, 0)-(15, 0)-(24, 0)-(33, 0) carbon nanotubes, the critical buckling strains of the corresponding tubes are calculated. The results show that each of the three inner layers in the functionalized armchair nanotube noticeably contributes to the stability of the outermost tube, and together increase the critical strain amplitude by 155%. However, the three inner layers in the corresponding pristine nanotube, taken together, increase the critical strain of the outermost tube by only 23%. In addition, for both the pristine and functionalized zigzag nanotubes, only the (24, 0) layer, among the three inner layers, contributes to the critical strain of the corresponding outermost tube, by 11% and 29%, respectively. The underlying mechanism of the enhanced stability related to nanotube chirality and functionalization is analyzed in detail.

ABSTRACT: The buckling of multiwalled carbon nanotubes under torsional load coupling with temperature change is researched. The effects of torsional load, temperature change, surrounding elastic medium, and van der Waals forces between the inner and outer nanotubes are taken into account at the same time. Using continuum mechanics, an elastic multishell model with thermal effect is presented for buckling of a multiwalled carbon nanotube embedded in an elastic matrix under thermal environment and torsional load. Based on the model, numerical results for the general case are obtained for the thermal effect on buckling of a multiwalled carbon nanotube under torsional load. It is shown that the buckling torque of a multiwalled carbon nanotube under a certain value of temperature change is dependent on the wave number of torsional buckling modes, and a conclusion is drawn that at room or lower temperature the critical torsional load for infinitesimal buckling of a multiwalled carbon nanotube increases as the value of temperature change increases, while at temperature
higher than room temperature the critical torsional load for infinitesimal buckling of a multiwalled carbon nanotube decreases as the value of temperature change increases.

ABSTRACT: An elastic double-shell model is presented for the buckling and postbuckling of a double-walled carbon nanotube subjected to axial compression. The analysis is based on a continuum mechanics model in which each tube of a double-walled carbon nanotube is described as an individual elastic shell and the interlayer friction is negligible between the inner and outer tubes. The governing equations are based on the Kármán–Donnell-type nonlinear differential equations. The van der Waals interaction between the inner and outer nanotubes and the nonlinear prebuckling deformations of the shell are both taken into account. A boundary layer theory of shell buckling is extended to the case of double-walled carbon nanotubes under axial compression. A singular perturbation technique is employed to determine the buckling loads and postbuckling equilibrium paths. Numerical results reveal that the single-walled carbon nanotube and the double-walled carbon nanotube both have an unstable postbuckling behavior.

ABSTRACT: The curvature effects of interlayer van der Waals (vdW) forces on pressure-induced buckling of empty or filled double-walled carbon nanotubes (DWNTs) are studied for various radii, length-to-radius ratios, end conditions and internal-to-external pressure ratios. The analysis is based on a double-elastic shell model and assumes that the interlayer vdW pressure at a point between the inner and outer tubes depends not only on the change of the interlayer spacing, but also on the change of the curvatures of the inner and outer tubes at that point. Here the role of filling substances inside DWNTs is modeled by a uniformly distributed internal pressure. The present work aims to study the curvature effects on critical radial pressure. An explicit formula is obtained for the external buckling pressure of empty or filled DWNTs. The critical value of external pressure is estimated with various internal-to-external pressure ratios. It is shown that the curvature effects play a more significant role in buckling problems under radial pressure for small radii DWNTs than under pure axial stress. Our results show that loading transfer through vdW forces prior to buckling is important for the pressure-induced buckling of DWNTs rather than axially compressed buckling.

ABSTRACT: Based on a curvature model for van der Waals (vdW) pressure between the interlayer of a double-walled carbon nanotube (DWNT), explicit expressions are derived for the critical buckling load of a DWNT which is modeled as a double-elastic shell under combined axial compression and lateral pressure. The critical load is calculated for various radii, length-to-radius ratios and load combinations. New results show that the curvature effects play a significant role in buckling problems for DWNTs of small radii. Neglecting the curvature effect usually leads to an under-estimate of the critical load for DWNTs when lateral pressure dominates. In addition, unlike Wang et al (2003b Int. J. Solids Struct. 40 3893) and Qian et al (2005 Int. J. Solids Struct. 42 5426), the buckling mode corresponding to the minimum axial buckling strain is unique, even when the lateral pressure is very small. For the DWNTs under combined axial compression and lateral pressure, the critical axial strain is reduced due to the external pressure.

ABSTRACT: In this paper, a theoretical analysis of the torsional buckling instability of double-walled carbon nanotubes (DWCNTs) and the DWCNTs embedded in an elastic medium is presented based on the continuum elastic shell model and Winkler spring model. Using the proposed theoretical approach, the influences of the aspect ratio, the buckling modes and the surrounding medium on the torsional stability are examined in detail. The simulation results show that the torsional instability of DWCNTs can occur in different buckling modes according to the aspect ratio. The van der Waals (vdW) interaction force between nanotubes reinforces the stiffness of nanoshells. Thus, the DWCNTs possess higher buckling stability than the SWCNTs without considering vdW interaction force.

ABSTRACT: Carbon nanotubes (CNTs) can be used as atomic force microscope (AFM) probes due to their robust mechanical properties, high aspect ratio and small diameter. In this study, a model of CNTs clamped in an elastic medium is proposed as CNT AFM probes. The buckling instability of the CNT probe clamped in elastic medium is analyzed based on the nonlocal Euler–Bernoulli beam model and the Whitney–Riley model. The clamped length of CNTs, and the stiffness of elastic medium affect largely on the stability of CNT AFM probe, especially at high buckling mode. The result shows that the buckling stability of the CNT AFM probe can be largely enhanced by increasing the stiffness of elastic medium. Moreover, the nonlocal effects of buckling instability are investigated and found to be larger for high buckling mode. The theoretical investigation on the buckling stability would give a useful reference for designing CNT as AFM probes.
**ABSTRACT:** A layerwise (zigzag) finite element formulation is developed for the buckling analysis of stiffened laminated plates. The laminated plate is discretized into layers along the thickness direction. Each layer of the laminated plate is modeled by the degenerated shell elements, and the stiffener is modeled by the general 3-D beam elements. Layers are stacked together according to the interlayer continuity. In-plane displacements are considered in the derivation of geometric stiffness matrix. The advantage of the proposed model is its applicability to both thin and thick laminated plates. The significance of this study lies in the disclosure of the interaction between the lateral buckling of the stiffener and the buckling of the laminate. The inverse iteration method is adopted to extract the lowest eigenvalue corresponding to buckling. Parametric and comparative studies are conducted for different plate aspect ratios, plate thickness to length ratios, degrees of layer orthotropy, ply orientations, and stiffener depth to plate thickness ratios.

**ABSTRACT:** The free vibration analysis of stiffened laminated composite plates has been performed using the layered (zigzag) finite element method based on the first order shear deformation theory. The layers of the laminated plate is modeled using nine-node isoparametric degenerated flat shell element. The stiffeners are modeled as three-node isoparametric beam elements based on Timoshenko beam theory. Bilinear in-plane displacement constraints are used to maintain the inter-layer continuity. A special lumping technique is used in deriving the lumped mass matrices. The natural frequencies are extracted using the subspace iteration method. Numerical results are presented for unstiffened laminated plates, stiffened isotropic plates, stiffened symmetric angle-ply laminates, stiffened skew-symmetric angle-ply laminates and stiffened skew-symmetric cross-ply laminates. The effects of fiber orientations (ply angles), number of layers, stiffener depths and degrees of orthotropy are examined.

**ABSTRACT:** An 18-node solid element has been developed to model the behavior of laminated composite shells undergoing large deflection. The element formulation utilizes independently assumed strain in addition to assumed displacement. The strain and the determinant of the Jacobian matrix are assumed to be linear in the thickness direction. This allows analytical integration through the thickness regardless of ply layups. Numerical results demonstrate the validity of the present formulation.

ABSTRACT: The aim of this article is to compare Donnell's, Love's, Sanders' and Flügge's thin shell theories in the evaluation of natural frequencies of cylinders stiffened with rings and stringers, whose effect is smeared over the entire surface of the cylinder. It is demonstrated that due to the large increase in bending stiffness related to rings, Donnell's theory provides highly inaccurate results with respect to the other three theories. Numerical results related to aluminum and composite stiffened cylinders and a comparison with results obtained with a finite element model of a stiffened cylinder complete the work.

ABSTRACT: In this paper a set of stability equations for thick cylindrical shells is derived and solved analytically. The set is obtained by integration of the differential stability equations across the thickness of the shell. The effects of transverse shear and the non-linear variation of the stresses and displacements are accounted for with the aid of the higher order shell theory proposed by [Voyiadjis, G.Z. and Shi, G., 1991, A refined two-dimensional theory for thick cylindrical shells, International Journal of Solids and Structures, 27(3), 261–282.]. For a thick shell under external hydrostatic pressure, the stability equations are solved analytically and yield an improved expression for the buckling load. Reference solutions are also obtained by solving numerically the differential stability equations. Both the full set that contains strains and rotations as well as the simplified set that contains rotations only were solved numerically. The relative magnitude of shear strain and rotation was examined and the effect of thickness was quantified. Differences between the benchmark solutions and the analytic expressions based on the refined theory and the classical shell theory are analysed and discussed. It is shown that the new analytic expression provides significantly improved predictions compared to the formula based on thin shell theory.

ABSTRACT: The purpose of this paper is to examine computationally the stability of shells consisting of two layers when subjected to external circumferential strain. This loading appears often in biomechanics when the smooth muscle surrounding various organs such as esophagus, lung airways, or gastrointestinal tract contracts. The differential stability equations are discretized using the finite volume method and the resulting generalized eigenvalue problem is solved using the QZ decomposition technique. The predicted number of folds agrees well with available experimental measurements. The present results show that the buckling behavior under circumferential strain loading is entirely different compared with external hydrostatic pressure loading. More specifically, in the latter case, the number of folds with the smallest critical load is always equal to 2. In the former case, however, it depends on the thickness and modulus of elasticity of each layer. The thickness of the inner layer significantly affects the number of folds and the critical buckling load. The influence of the thickness of the outer layer and the ratio of the two moduli of elasticity was also examined, but their effect was not as strong as that of the thickness of the inner layer.

Asokendu Samanta and Madhujit Mukhopadhyay (Department of Ocean Engineering and Naval Architecture, Indian Institute of Technology, Kharagpur 721 302, India), “Finite element large deflection static analysis of

ABSTRACT: Geometric nonlinear static analysis of shallow and deep stiffened shells has been conducted on the basis of a combination of Allman's plane stress triangle and Discrete Kirchhoff triangle (DKT) plate bending element. The compatibility condition at the shell beam junction is ensured as the same displacement function used for both the shell and the stiffener element. The formulation of the stiffener is done in such a manner that it can be placed anywhere within the shell element. The large deflection equations are based on von Kármán's theory. An iterative solution procedure, either Newton–Raphson method or modified Riks method, is employed to trace the nonlinear equilibrium path. The nonlinear static analysis of deep stiffened shell has been done for the first time. A variety of numerical examples are presented to demonstrate the versatility and efficiency of the present stiffened shell element.

ABSTRACT: An essential problem in dealing with composite laminates is an accurate prediction of interlaminar stresses playing an important role in the design, particularly in the failure analysis of these structures. The objective of the present paper is to develop a multi-layer shell-element family capable to deal with this aspect in the presence of strong nonlinearities. First a multi-director shell theory is presented on the basis of a quadratic approximation of the displacement field. A particular attention is given to the parametrization of the inextensible shell director in order to make the formulation accessible to finite rotations. This is accomplished by using Euler-angles as well as an updated rotation formulation. The single layer theory is then coupled with a multi-layer concept, which has been shown to be very predictive in dealing with complex through-thickness stress distributions. The constitutive relations are formulated so as to consider the particularities of composite materials. After standard linearization, shell equations are transformed into multi-layer finite shell elements using assumed strain concept and enhanced strain formulation as stabilization algorithms. The performance of the finite elements concerning various aspects is discussed on adequate examples.

ABSTRACT: Free vibration analysis of composite cylindrical shells with different boundary conditions is presented in this paper using differential quadrature method (DQM). Equations of motion are derived based on first order shear deformation theory taking the effects of shear deformation and rotary inertia terms into account. By applying the differential quadrature formulation and the required modified relationships for implementing the different boundary conditions, equations of motion of a circular cylindrical shell are transformed into a set of algebraic equations. By solving this algebraic system natural frequencies of circular cylindrical shells made of fibrous composite materials with different fibre angles are evaluated. The results thus obtained are then compared with some available results and a good agreement is observed. In all the cases studied here efficiency, ease and usefulness of the DQM are well illustrated.

ABSTRACT: In this paper, the thermal buckling of piezoelectric composite shells of revolution under uniform and linear thermal distributions and selected boundary conditions is investigated by using the semi-analytical finite element. The effects of different parameters such as the type of temperature distributions through the thickness, fiber angles, arrangements of piezoelectric patches and amount of displacement feedback control gain are examined. The results obtained from the present analysis are validated, where possible, with those available in the literature.

ABSTRACT: The paper is focused on the elastic buckling behavior of piezocomposite elliptical cylindrical shell finite element formulation. The formulation is based on the shear deformation theory, and the serendipity quadrilateral eight-node element is used to study the elastic behavior of elliptical cylindrical shells. The strain-
displacement relations are accurately accounted for in the formulation. The contributions of work done by the applied load are also incorporated. A constant gain displacement control algorithm coupling the direct and inverse piezoelectric effect is applied to provide active control of composite non-circular shells in a self-monitoring and self-controlling system. The governing equations obtained using the principle of minimum potential energy are solved through an eigenvalue approach. The influences of elliptical cross-sectional parameter and displacement feedback gain \((G_d)\) values on the critical buckling loads of elliptical cylindrical shells are examined.

ABSTRACT: The present paper is concerned with the free vibration analysis of double-walled carbon nanotubes embedded in an elastic medium and based on Eringen's nonlocal elasticity theory. The effects of the transverse shear deformation and rotary inertia are included according to the Timoshenko beam theory. The governing equations of motion which are coupled with each other via the van der Waals interlayer forces have been derived using Hamilton's principle. The thermal effect is also incorporated into the formulation. Using the statically exact beam element with displacement fields based on the first order shear deformation theory, the finite element method is employed to discretize the coupled governing equations which are then solved to find the natural frequencies. The effects of the small scale parameter, boundary conditions, thermal effect, changes in material constant of the surrounding elastic medium, and geometric parameters on the vibration characteristics are investigated. Furthermore, our analysis includes nonlocal double-walled carbon nanotubes with different boundary conditions between inner and outer tubes which seem to be scarcely considered in the literature, and the corresponding given results for this case can be considered as a benchmark for further studies. Comparison of the present numerical results with those from the open literature shows an excellent agreement.

ABSTRACT: Minute concentrations of suspended particles can dramatically alter the behavior of a drying droplet. After a period of isotropic shrinkage, similar to droplets of a pure liquid, these droplets suddenly buckle like an elastic shell. While linear elasticity is able to describe the morphology of the buckled droplets, it fails to predict the onset of buckling. Instead, we find that buckling is coincident with a stress-induced fluid to solid transition in a shell of particles at a droplet's surface, occurring when attractive capillary forces overcome stabilizing electrostatic forces between particles.

D.A. Head (Department of Applied Physics, Faculty of Engineering, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan), “Modeling the elastic deformation of polymer crusts formed by sessile droplet evaporation”, Phys. Rev. E, Vol. 74, 021601 (2006) [8 pages], doi: 10.1103/PhysRevE.74.021601

ABSTRACT: Evaporating droplets of polymer or colloid solution may produce a glassy crust at the liquid-vapor interface, which subsequently deforms as an elastic shell. For sessile droplets, the known radial outward flow of solvent is expected to generate crusts that are thicker near the pinned contact line than the apex. Here we investigate, by nonlinear quasistatic simulation and scaling analysis, the deformation mode and stability properties of elastic caps with a nonuniform thickness profile. By suitably scaling the mean thickness and the contact angle between crust and substrate, we find that data collapse onto a master curve for both buckling pressure and deformation mode, thus allowing us to predict when the deformed shape is a dimple, Mexican hat, and so on. This master curve is parameterized by a dimensionless measure of the nonuniformity of the shell. We also speculate on how overlapping time scales for gelation and deformation may alter our findings.

ABSTRACT: Motivated by observing the buckling of glassy crusts formed on evaporating droplets of polymer and colloid solutions, we numerically model the deformation and buckling of spherical elastic caps controlled by varying the volume between the shell and the substrate. This volume constraint mimics the incompressibility of the unevaporated solvent. Discontinuous buckling is found to occur for sufficiently thin and/or large contact angle shells, and robustly takes the form of a single circular region near the boundary that 'snaps' to an inverted shape, in contrast to the externally pressurized shells case. Scaling theory for shallow shells is shown to approximate well the critical buckling volume, the subsequent enlargement of the inverted region and the contact line force.

ABSTRACT: Drying of a sessile drop of a complex liquid can lead to intriguing complex shapes. We report here a study dealing with a model system, made of a hydrophilic polymer that is glassy when pure. Under solvent evaporation, polymers accumulate near the vapor/drop interface and may form a glassy skin, which bends as the volume of liquid it encloses decreases. The conditions for the occurrence of this buckling instability have been investigated; the experimental results are well explained by a model that compares the characteristic times for drying and for the formation of a glassy skin. Depending on the experimental conditions, different types of shape distortion take place; secondary instabilities that break the axisymmetry are also observed.

ABSTRACT: Spray drying of complex liquids to form solid powders is important in many industrial applications. One of the challenges associated with spray drying is controlling the morphologies of the powders
produced; this requires an understanding of how drying mechanics depend on the ingredients and conditions. We demonstrate that the morphology of powders produced by spray drying colloidal polystyrene (PS) suspensions can be significantly altered by changing the molecular weight of dissolved poly(ethylene oxide) (PEO). Samples containing high-molecular-weight PEO produce powders with more crumpled morphologies than those containing low-molecular-weight PEO. Observations of drying droplets suspended by a thin film of vapor suggest that this occurs because the samples with high-molecular-weight PEO buckle earlier in the drying process when the droplets are larger. Earlier buckling times are likely caused by the decreased stability, demonstrated by bulk rheology experiments, of PS particles in the presence of high-molecular-weight PEO at elevated temperatures. We present a consistent picture in which decreased particle stability hastens droplet buckling and leads to more crumpled powder morphologies; this underscores the importance of interparticle forces in determining the buckling of particle-laden droplets.

ABSTRACT: We visualize the drying of droplets of colloids suspended in a mixture of two miscible solvents, namely water and ethanol. After a period of isotropic shrinkage, droplets suddenly buckle like elastic shells. For a fixed colloid solid fraction, the buckling threshold evolves as a function of ethanol content, due to changes of the solvent mixture physical properties, such as viscosity and evaporation rate. A simplified model predicting the qualitative behavior of the buckling threshold as a function of the initial ethanol mass fraction has been developed that fits well experimental results.

ABSTRACT: The origin of the buckling of micrometer-sized colloidal droplets during evaporation-induced self-assembly (EISA) has been elucidated using electron microscopy and small-angle neutron scattering. Doughnut-like assembled grains with varying aspect ratios are formed during EISA at different physicochemical conditions. It has been revealed that this phenomenon is better explained by an existing hypothesis based on the formation of a viscoelastic shell of nanoparticles during drying than by other existing hypotheses based on the inertial instability of the initial droplets and hydrodynamic instability due to thermocapillary forces. This conclusion was further supported by the arrest of buckling through modification of the colloidal interaction in the initial dispersion.

ABSTRACT: Micrometric grains of anisotropic morphology have been achieved by evaporation-induced self-assembly of silica nanoparticles. The roles of polymer concentration and its molecular weight in controlling the buckling behavior of drying droplets during assembly have been investigated. Buckled doughnut grains have been observed in the case of only silica colloid. Such buckling of the drying droplet could be arrested by attaching poly(ethylene glycol) on the silica surface. The nature of buckling in the case of only silica as well as modified silica colloids has been explained in terms of theory of homogeneous elastic shell under capillary pressure. However, it has been observed that colloids, modified by polymer with relatively large molecular weight, gives rise to buckyball-type grains at higher concentration and could not be explained by the above theory. It has been demonstrated that the shell formed during drying of colloidal droplet in the presence of polymer becomes inhomogeneous due to the presence of soft polymer rich zones on the shell that act as
buckling centers, resulting in buckyball-type grains.

ABSTRACT: The structural evolution in the center of a droplet of a dialyzed styrene–n-butyl acrylate copolymer latex dispersion on a solid surface during drying was studied by means of an in situ synchrotron ultra small-angle X-ray scattering technique. During water evaporation, as the droplet shrinks the shell yields and thickens, as evidenced by the appearance of diffraction peaks at the early stage combined with TGA measurement. As the droplet dried further, colloidal crystalline structure transformation is identified. The transition is attributed to the collapse of the thin shell made of densely packed particles at the surface of the droplet caused by capillary forces that drive the deformation of the shell. As there is a small amount of water remaining beneath the surface layer, charged particles are able to explore new configurations to reestablish a stable structure after leaving the initially formed face-centered cubic structure. Finally, a torus-shaped solid film with a central flat thin film is produced.

ABSTRACT: Arrays of half-symmetric Fabry-Perot micro-cavities were fabricated by controlled formation of circular delamination buckles within a-Si/SiO$_2$ multilayers. Cavity height scales approximately linearly with diameter, in reasonable agreement with predictions based on elastic buckling theory. The measured finesse ($F > 10^3$) and quality factors ($Q > 10^4$ in the 1550 nm range) are close to reflectance limited predictions, indicating that the cavities have low roughness and few defects. Degenerate Hermite-Gaussian and Laguerre-Gaussian modes were observed, suggesting a high degree of cylindrical symmetry. Given their silicon-based fabrication, these cavities hold promise as building blocks for integrated optical sensing systems.

ABSTRACT: A nonlinear structural mechanics based approach for modeling the structure and the deformation of single-wall and multiwall carbon nanotubes (CNTs) is presented. Individual tubes are modeled using shell finite elements, where a specific pairing of elastic properties and mechanical thickness of the tube wall is identified to enable successful modeling with shell theory. The effects of van der Waals forces are simulated with special interaction elements. This new CNT modeling approach is verified by comparison with molecular dynamics simulations and high-resolution micrographs available in the literature. The mechanics of wrinkling of multiwall CNTs are studied, demonstrating the role of the multiwalled shell structure and interwall van der Waals interactions in governing buckling and postbuckling behavior.

A. Pantano, M. C. Boyce, and D. M. Parks (Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA), “Mechanics of Axial Compression of Single and Multi-Wall
ABSTRACT: A recently developed procedure for modeling the deformation of single and multi-wall carbon nanotubes [13,14] is applied to nanotube buckling and post-buckling under axial compression. Critical features of the model, which is grounded in elastic shell theory, include identification of (a) an appropriate elastic modulus and thickness pair matching both the wall stretching and bending resistances of the single atomic layer nanotube walls, and (b) a sufficiently stiff interwall van der Waals potential to preserve interwall spacing in locally buckled MWNTs, as is experimentally observed. The first issue is illustrated by parametric buckling studies on a SWNT and comparisons to a corresponding MD simulation from the literature; results clearly indicating the inadequacy of arbitrarily assigning the shell thickness to be the equilibrium spacing of graphite planes. Details of the evolution of local buckling patterns in a nine-walled CNT are interpreted based on a complex interplay of local shell buckling and evolving interwall pressure distributions. The transition in local buckling wavelengths observed with increasing post-buckling deformation is driven by the lower energy of a longer-wavelength, multiwall deformation pattern, compared to the shorter initial wavelength set by local buckling in the outermost shell. This transition, however, is contingent on adopting a van der Waals interaction sufficiently stiff to preserve interlayer spacing in the post-buckled configuration.

ABSTRACT: Wrinkling (buckling) during a sheet forming process is a major consideration when designing part shape, die geometry and processing parameters. In most instances, the sheet metal is constrained to some extent between binders and/or matching dies at some stage during processing. In this paper, we will examine the wrinkling behavior of both elastic and elastic-plastic sheet subjected to edge compression and lateral constraint. A criterion for wrinkling under such constraint is established using a combination of finite element analysis and energy conservation. Various methods of incorporating imperfections into a finite element model in order to capture buckling and post-buckling behavior are discussed. A simple and practical form of imperfection for predictive modeling of buckling is given along with a discussion of the sensitivity of the solution to the magnitude and distribution of imperfections. Using the proposed form of imperfection, we are able to accurately simulate the wrinkling behavior under complicated boundary conditions in a predictive manner.

ABSTRACT: In the sheet metal forming industry, there is increasing demand to lower manufacturing costs while also providing a decrease in product development turnaround period as well as lighter weight products. These demands have put increasing pressure on the development and use of predictive numerical simulations and in the design and optimization of new forming technologies. In this paper, two of the primary in-process failure modes of sheet metal, wrinkling and tearing, are examined followed by construction of an advanced forming technology – Variable Binder Force – using numerical tools. Specifically, a methodology of capturing the onset of wrinkling and postbuckling behavior proposed in Cao and Boyce (1997) is used to predict wrinkling failure in conical and square cup forming. The results obtained from simulations and experiments demonstrate that the proposed method is not only accurate, but also robust. A tearing criterion based on Forming Limit Diagrams of
non-proportional loading paths is then developed and again shows excellent predictability. Finally, a Variable Binder Force (VBF) trajectory for conical cup forming is designed using simulations which incorporate feedback control to the binder based on the predictions of wrinkling and tearing of the sheet. Experiments using this predefined VBF trajectory show a 16 percent increase in forming height over the best conventional forming method, that is, constant binder force. The uniqueness of this paper is that numerical simulation is no longer utilized only as a verification tool, but as a design tool for advanced manufacturing process with the help of the predictive tools incorporated directly into the numerical model.

ABSTRACT: Wrinkling is one of the major defects in sheet metal forming. The ability to accurately predict the occurrence of wrinkling is critical to the design of tooling and processing parameters. An analytical approach for predicting the onset of flange wrinkling is presented. This method is based on the wrinkling criterion proposed by Cao and Boyce for predicting the buckling behavior of sheet metal under normal constraint. Using a combination of energy conservation and plastic bending theory, the analysis provides the critical buckling stress and wavelength as functions of normal pressure. The results are in excellent agreement with those obtained from Cao and Boyce’s numerical approach, and also match well with the experimental results of a square cup forming. In addition, the effects of material properties on the wrinkling behavior are also discussed. The analytical method significantly reduces computational time and is suitable for direct engineering application.

ABSTRACT: Thin-walled tube bending has found many of its applications in the automobile and aerospace industries. This paper presents an energy approach to provide the minimum bending radius, which does not yield wrinkling in the bending process, as a function of tube and tooling geometry and material properties. A doubly-curved sheet model is established following the deformation theory. This approach provides a predictive tool in designing/optimizing the tooling parameters in tube bending.

ABSTRACT: The prediction and prevention of wrinkling during a sheet metal forming process have been challenging issues on the design of part shape, die geometry, and processing parameters. In an effort to provide a reliable and efficient tool to assess the onset of wrinkling, analytical models for flange wrinkling and straight side-wall wrinkling are presented here. Using a combination of energy conservation and plastic bending theory, the critical buckling wavelength and stress are calculated as functions of the boundary conditions (displacement constraint and binder pressure). Comparisons between the numerical and experimental results are given for both cases and excellent agreement is obtained.

ABSTRACT: Prediction and prevention of side-wall wrinkling are extremely important in the design of tooling and process parameters in sheet metal forming processes. The prediction methods can be broadly divided into two categories: an analytical approach and a numerical simulation using finite element method (FEM). In this paper, a modified energy approach utilizing energy equality and the effective dimensions of the region undergoing circumferential compression is proposed based on simplified flat or curved sheet models with approximate boundary conditions. The analytical model calculates the critical buckling stress as a function of material properties, geometry parameters and current in-plane stress ratio. Meanwhile, the sensitivities of various input parameters and integration methods of FEM models on the prediction of wrinkling phenomena are investigated. To validate our proposed method and to illustrate the sensitivity issue in the FEM simulation, comparisons with experimental results of the Yoshida buckling test, aluminum square cup forming and aluminum conical cup forming are presented. The results demonstrate excellent agreements between the proposed method and experiments. Our model provides a reliable and effective predictor for the onset of side-wall wrinkling in sheet metal forming processes.

ABSTRACT: The prediction and prevention of wrinkling have been challenging issues in sheet metal forming processes. In an effort to provide the design and process engineers a reliable and efficient tool in assessing the onset of flange wrinkling, an analytical model, based on the wrinkling criterion proposed by Cao and Boyce [1], is presented here. The critical buckling stress and wavelength as functions of normal pressure are calculated using a combination of energy conservation and plastic bending theory. The present results are in excellent agreement with those obtained from Cao and Boyce’s numerical approach which has demonstrated its excellent predictive capability by comparing the experimental study of a conical cup [1] and a square cup forming [2]. Additionally, the effects of the tension in the plane of sheet and material properties on the initiation of flange wrinkling are investigated.

ABSTRACT: Flanging is a commonly used sheet forming operation to increase the stiffness of a sheet panel and/or to create the mating surface for subsequent assemblies. This paper presents an energy approach to predict the onset of wrinkling during a shrink flanging operation. A curved sheet model is established to obtain the critical buckling stress in terms of stress state, geometry properties and material properties. The predictions of wave number agree well with the experimental results. The results indicate that the sensitivity of wave number on the plan view radius (PVR) increases as PVR decreases, and the wave number decreases with the increase of flange length. The critical flange length is significantly influenced by PVR, sheet thickness and material work-hardening, and is not sensitive to material strength and anisotropy.

ABSTRACT: A corner type constitutive equation is developed using the general quadratic anisotropic yield function. The wrinkling point of square plates subjected to diagonal tension was obtained by the bifurcation and Mindlin type plate theories, in conjunction with the finite element approximation. The growth of wrinkles was traced by a three-dimensional analysis in flanging terms of an isoparametric shell element. The numerical investigation was performed for the thin plates characterized by Hill's anisotropic yield function. The effects of such material characteristics as yield stress, hardening rate, orthotropy and normal anisotropy on the wrinkling limit and wrinkle height have been clarified.

ABSTRACT: The onset of wrinkling in sheet metals is first analysed as an elastic–plastic bifurcation for thin and shallow shells with compound curvatures. Plastic yielding is described using a criterion recently proposed for transversely anisotropic materials. A local analysis is developed, which allows us to define wrinkling limit curves depending on material properties and local geometry. Finite element (FE) simulations of the conical cup test are also performed using the Abaqus/Explicit code. The FE results relating to the initiation of wrinkling in the wall are compared with the predictions of the bifurcation model. In addition to the intrinsic effect of anisotropy on wrinkling tendencies, it is shown that the attainment of critical wrinkling conditions is significantly affected by the influence of anisotropy on the stress state and sheet curvature developed in the wall prior to bifurcation.

ABSTRACT: An analysis of the onset of wrinkling is first developed for a doubly curved, elastic–plastic shell element submitted to a biaxial plane stress loading. Plastic yielding is described using a criterion recently proposed for anisotropic sheet metals. The wrinkling limit curves obtained with this analysis are compared with previous results based on different yield criteria. Finite element (FE) simulations of a deep-drawing experiment are also performed using the Abaqus/Explicit code with the aim of comparing the FE results relating to the initiation of wrinkling with the predictions of the analytical model and with experiments from the literature.

ABSTRACT: Stamping industries tend to use thin, high-strength metallic sheets, in an effort to lighten the weight of structures. As a result wrinkles frequently develop during stamping processes. In practice wrinkling can occur on the flange or on the wall of the blank. The aim of this paper is to forecast the occurrence of wrinkling on the wall of the blank. Two methods have been developed to capture the onset of wrinkling. The first method is based on a bifurcation analysis for a doubly curved sheet. Wrinkling limit curves are determined by this analytical study. The second method uses finite element (FE) simulations. Two deep drawing tests are simulated using the dynamic explicit FE code ABAQUS/Explicit. FE results combined with analytical predictions allow us to outline the influence of normal anisotropy on the onset of wrinkling. The analytical and the numerical predictions are in fair agreement with experiments from the literature.

ABSTRACT: The onset of wrinkling in sheet metal forming is investigated using an analytical approach and
finite element (FE) simulations. In both cases the yield criterion proposed by Ferron et al. [Int. J. Plast. 10 (1994) 431] for orthotropic sheets is employed. The analytical approach is developed on the basis of the bifurcation criterion developed by Hutchinson [J.W. Hutchinson, Plastic buckling, in: C.-S. Yih (Ed.), Advances in Applied Mechanics, vol. 14, 1974, pp. 67–144] for thin and shallow shells submitted to a biaxial plane stress loading. Wrinkling limit curves obtained with the bifurcation analysis are drawn for different orientations of the orthotropic axes with respect to the principal stress axes, assuming also different orientations with respect to the geometric axes of principal curvatures. The numerical simulations are performed with the FE code ABAQUS/Explicit. Experimental results of deep-drawing processes taken from the literature are also analysed to check the reliability of the wrinkling predictions obtained with the bifurcation analysis and with the FE simulations. Both analytical and numerical predictions compare reasonably well with experiments.

ABSTRACT: A number of researchers have studied the mechanical properties of skin and developed constitutive models to describe its behaviour. Typically, many of these studies have concentrated on the uniaxial tensile behaviour of the skin, on the grounds that it will wrinkle under in-plane compression and have minimal stiffness. However, although there is a substantial body of literature on wrinkling models, the practical implementation of such a model of skin in a finite element setting has not been widely addressed. This paper presents computational details of a wrinkling, hyperelastic membrane model and aspects of its implementation and areas requiring further research are discussed. The model is based on an Ogden constitutive model, which provides accurate results at moderate strains, but it would be straightforward to implement other constitutive models such as the Fung or Arruda-Boyce models using a similar approach. Example results are presented which demonstrate that the model can provide a good approximation to experimental data. The model has many other possible applications, both for biological materials and for other thin hyperelastic membranes.

ABSTRACT: We apply the two-dimensional elastic continuum model to describe the wrinkling of elastic Langmuir layers (membranes) subjected to unidirectional compression. The effects of the dilatational, shear, and bending elasticities are taken into account. Among the numerous solutions of the generalized Laplace equation, corresponding to different membrane tensions, we determine the membrane shape as the profile that minimizes the energy of the system. In the case of small deformations, the problem can be linearized. Its solution predicts a wavelike shape of the compressed membrane. At negligibly small bending elasticity, the energy of the system is minimal for a sinusoidal profile, whose amplitude and wavelength tend to zero. In the opposite limiting case, where the effect of bending elasticity prevails over the effect of gravity, the membrane has a half-wave profile. When the two effects are comparable, the membrane shape exhibits multiple periodic wrinkles (ripples). An expression is derived for calculating the bending elasticity (rigidity) from the wavelength, and reasonable values are obtained from available experimental data. To determine the membrane shape at larger out-of-plane deformations, we solved numerically the respective nonlinear problem. Depending on the values of the physical parameters, the theory predicts various shapes: nonharmonic oscillations, toothed profiles, and profiles with two characteristic wavelengths. The results can be used for determining the bending
elastic modulus of Langmuir films (membranes) as well as for the interpretation of buckling and collapse of monolayers.

ABSTRACT: The mechanical response to compression of a self-assembled gold nanoparticle monolayer and trilayer at the air-liquid interface is examined. Analysis of the film's buckling morphology under compression reveals an anomalously low bending rigidity for both the monolayer and the trilayer, in contrast with continuum elastic plates. We attribute this to the spherical geometry of the nanoparticles and poor coupling between layers, respectively. The elastic energy of the trilayers is first delocalized in wrinkles and then localized into folds, as predicted by linear and nonlinear elastic theory for an inextensible thin film supported on a fluid.

ABSTRACT: The nanomechanical properties of micropatterned nanomembranes containing gold nanoparticle microarrays were investigated with the buckling instability method. An unusual, complex pattern of buckling instability was observed for the nanoscale polymeric films under compressive stresses. An intriguing two-stage wrinkling was observed for these nanoscale films with spatially correlated instabilities. Two concurrent strain-dependent buckling modes were observed above a certain critical strain. Transformation from conventional transversal buckling mode to zigzag buckling is attributed to the development of the biaxial stress along the boundary lines for micropatterned areas. The binary buckling pattern observed here allowed the "one-shot" evaluation of the elastic moduli of two compositionally different regions (with and without gold nanoparticles).

ABSTRACT: We study shape and buckling transitions of particle-laden sessile and pendant droplets that are forced to shrink in size. Monodisperse polystyrene particles were placed at the interface between water and decane at conditions that are known to produce hexagonal, crystalline arrangements on flat interfaces. As the volumes of the drops are reduced, the surface areas are likewise diminished. This effectively compresses the particle monolayer coating and induces a transition from a fluid film to a solid film. Since the particles are firmly attached to the interface by capillary forces, the shape transitions are reversible and shape/volume curves are the same for drainage and inflation. Measurements of the internal pressure of the drops reveal a strong transition in this variable as the buckling transition is approached.

ABSTRACT: We introduce a new experimental approach to study the structural transitions of large numbers of nanoparticle-coated droplets as their volume is reduced. We use an emulsion system where the dispersed phase is slightly soluble in the continuous phase. By adding a fixed amount of unsaturated continuous phase, the volume of the droplets can be controllably reduced, causing them to buckle or crumple, thereby becoming nonspherical. The resultant morphologies depend both on the extent of volume reduction and the average droplet size. The buckling and crumpling behavior implies that the droplet surfaces are solid.

ABSTRACT: Finite element solutions for the steady-state buckle propagation pressure in a pipeline with non-uniform thickness are given. The results are useful in finding buckle propagation pressures in corroded pipelines. It has been found that when corrosion is equal to or less than 10% of the original pipeline thickness, the pipeline collapses in an overall shell buckling mode; otherwise, the pipeline experiences local buckling. The propagation pressure decreases with both the thickness and angular extent of the reduced section, but the rate of decrease with thickness reduction is almost independent of the angular extent of corrosion when it is greater than 90°.

ABSTRACT: Rigid–plastic solutions for the steady-state, quasi-static buckle propagation pressure in corroded pipelines are derived and compared to finite element predictions (ABAQUS). The corroded pipeline is modeled as an infinitely long, cylindrical shell with a section of reduced thickness that is used to describe the corrosion. A five plastic hinge mechanism is used to describe plastic collapse of the corroded pipeline. Closed-form expressions are given for the buckle propagation pressure as a function of the amount of corrosion in an X77 steel pipeline. Buckles that propagate down the pipeline are caused by either global or snap-through buckling, depending on the amount of corrosion. Global buckling occurs when the angular extent of the corrosion is greater than 90°. When the angular extent is less than 90° and the corrosion is severe, snap-through buckling takes place. The buckle propagation pressure and the corresponding collapse modes also compare well to finite element predictions.

ABSTRACT: Analytical solutions for elastic buckling of a non-uniform, long cylindrical shell that is subjected to external hydrostatic pressure are presented in this paper. The non-uniform shell has two regions: one with a nominal thickness and the other with reduced thickness. Symmetric and anti-symmetric buckling modes have been found to occur depending on the relative thickness of the two different regions and the angular extent of
the section with the reduced thickness. A diagram showing the ranges of relative thickness and angular extent of the section with the reduced thickness is given for the occurrence of symmetric and anti-symmetric modes. In general, the buckling pressure decreases when either the relative thickness or the angular extent of the section with the reduced thickness increase. Finite element solutions for the elastic buckling pressure and modes are also found using ABAQUS and the results from analytical solutions are found to be in close agreement with finite element predictions.

ABSTRACT: Solutions for the steady-state buckle propagation modes and pressures in a corroded pipeline subjected to external hydrostatic pressure are presented. The buckle propagation pressure of a corroded pipeline is obtained analytically with a rigid-plastic analysis and numerically from finite element analysis (ABAQUS). Both the rigid-plastic analysis and ABAQUS program reveal symmetric and anti-symmetric buckling modes, depending on the depth and angular extent of the corrosion. Snap-through and global buckling of the pipeline are also distinguished in both solutions. The rigid-plastic solutions for buckle propagation pressure and corresponding collapse modes are found to be within 15% with numerical solutions.

ABSTRACT: A non-linear finite-element analysis for the steady-state buckle propagation phenomenon in subsea corroded pipelines subjected to external hydrostatic pressure is presented. The corroded pipeline is modeled as an infinitely long, cylindrical shell with a non-uniform thickness region. Using Maxwell's theory of two coexisting phases and principle of virtual work, the buckle propagation pressures for the corroded pipeline are calculated from pressure–volume change relations obtained from ABAQUS. The corresponding collapse modes of the corroded pipeline are generated from ABAQUS post-analysis. Symmetric and anti-symmetric collapse modes are found to occur, depending on the depth and angular extent of the corrosion. In addition, snap-through and global collapses are also identified. A parametric study shows how the buckle propagation pressures decrease when either the ratio of corrosion depth to the normal thickness or the angular extent of the corrosion increases. The finite-element model is validated using Timoshenko's classical solutions.

ABSTRACT: This paper deals with the buckling phenomenon of undersea corroded pipelines. The corrosion degree of the pipelines is characterized by two parameters: the angular extension and the corrosion depth. Previous work has shown that symmetric and antisymmetric buckling modes occur in pipelines when the corrosion is uniformly extended over part of pipelines along the circumferential direction. The presented research analyzes the stability condition in pipelines with generalized corrosion. Using WKB theory for
asymptotic expansion, the buckling mode and the eigenfunctions are derived for the corroded pipelines subjected to external hydrostatic pressure. Furthermore, asymptotic solutions are derived for pipelines with constant corrosion and compared with validated solutions obtained in previous work using equilibrium analysis. It shows that the buckling modes and buckling pressure from asymptotic analysis are identical to the exact solutions. Symmetric and antisymmetric buckling modes are found to occur for pipelines when the corrosion is not uniform but symmetric about its centerline.

ABSTRACT: This paper presents a unique approach to analyze the steady-state buckle propagation phenomenon in underwater pipelines. In previous work, we restudied the buckling of a very long pipeline subjected to external pressure and found that buckling happens only over a certain length of the pipeline. In this paper, the collapse mode of the pipeline obtained in previous studies is taken as the transition zone during steady-state buckle propagation. Kinematics in the transition zone is analyzed based on von Kármán–Donnell type of nonlinearity. Assuming linear elastic rigid plastic material properties, the mechanical responses in the transition zone are examined using the deformation theory. Two parameters, the yield coefficient and the membrane stretching factor, are introduced to depict the effects of transversal bending and the membrane stretching, respectively. Analytical solution of buckle propagation pressure is derived by considering the energy conversation calculated from shell theory. It is found that the buckle propagation performance is governed by the transversal bending, including the circumferential bending and longitudinal bending. The membrane stretching is significant only for thick wall pipeline, in particular when the ratio of radius-to-thickness is small than ten. The analysis is in effect by comparing the obtained solutions with the well-established predictions and the experimental results.

China), “A comprehensive study on a propagating buckle in externally pressurized pipelines”, Journal of Mechanical Science and Technology, Vol. 28, No. 12, pp 4907-4919, December 2014

ABSTRACT: Buckle propagation is a unique phenomenon occurring in deep-sea pipelines. In previous works, this phenomenon was investigated using a ring technique in which the pipeline was assumed to be in plane strain condition and the energies absorbed in membrane stretching and longitudinal bending were ignored. This paper presents a three-dimensional analysis of the buckle propagation phenomenon with an emphasis to address more complete factors that were not accounted for in the ring analysis. The analyses are based on the available solutions of the transition zone obtained in our previous works. A comprehensive mechanism for buckle propagation phenomenon is described from the point view of plastic stability theory for shells which enables the incorporation of the effects of transverse and longitudinal bending, membrane stretching and material strain hardening. The nondimensionalized buckle propagation pressure is represented in terms of yield coefficient, strain hardening coefficient and membrane stretching factor. It is found that a buckle once initiated in a pipeline may or may not propagate along the pipeline depending on its radius-to-thickness ratio. By comparing with various experimental results the theoretical predictions from this analysis are shown to provide very accurate estimations of the buckle propagation pressure for different materials with diverse geometric parameters and material properties. This paper points to the need for more complete information regarding the effects of transverse bending, membrane stretching and material strain-hardening on the buckle propagation pressure.
Upon the requirement of application variations of the yield coefficient, strain hardening coefficient and membrane stretching factor with respect to the radius-to-thickness ratio are sketched out. This eliminates the need for recourse the curves and allows a fast and convenient resolution of buckle propagation pressure for certain pipeline. Most importantly, the present analysis offers the potential for future design of pipelines being at once more rationally and parametrically complete, and yet compact and simple to apply.

ABSTRACT: Dynamic pulse buckling of woven E-Glass/Vinyl Ester and laminated E-Glass/Epoxy cylindrical shells subjected to uniform overpressure and asymmetric pressure pulse (side-on explosion) were examined. The solutions for the radial shell deformations were represented by Mathieu differential equations. The dynamic instability of the shells was determined from a Mathieu stability diagram. It was found that the stability of the shells depended on lay-up, aspect ratio as well as impulse distribution. The stable vibration response of the shells with side-on explosion compared well with finite element solutions using a Dynamic, Implicit analysis in ABAQUS Standard. First-ply failure of the woven E-Glass/Vinyl Ester shell with side-on explosion was predicted using a modified Hashin–Rotem failure criterion. It was shown that the thinner woven E-Glass/Vinyl Ester shells were more likely to fail by dynamic instability, whereas the thicker woven E-Glass/Vinyl Ester shells were more likely to fail by first-ply failure.

Jianghong Xue (Dept. of Mechanical & Civil Engineering, Jinan University, Guangzhou, China), “Perturbation analysis of instability for non-uniform cylindrical shells with initial imperfection”, Control and Decision Conference (CCDC), 2011, 23-25 May 2011, pp 661-665, DOI: 10.1109/CCDC.2011.5968265

ABSTRACT: Buckle propagation in subsea corroded pipelines is one of the most concerned problems in offshore industries, while locating the plastic hinges in the corroded pipeline is the crux in determining the buckle propagation pressure. This paper presents a methodology to determine the locations of plastic hinges in non-uniform shells subjected to external pressure. The non-uniform shell used to model the corroded pipeline has two Regions: Region 1 of reduced, inconstant thickness and Region 2 of nominal thickness. Analytical formulas for the bifurcation load, radial deformation, initial yield pressure and stress distribution in the non-uniform shell are derived from perturbation analysis using WKB expansion. The locations of plastic hinges are identified at the stress peaks by taking the derivative of the stress with respect to circumferential coordinate. Imperfection sensitivity of the non-uniform shell is assessed with an emphasis on the role of initial yield pressure and the locations of plastic hinges. Special case when the thickness of Region 2 is constantly reduced is examined. It is found that both the initial yield pressure and the locations of plastic hinges depend on the non-uniform conditions of the cylindrical shell.

ABSTRACT: First-order generalized beam theory describes the behaviour of prismatic structures by ordinary uncoupled differential equations, using deformation functions for bending, torsion and distortion. In second-order theory, the differential equations are coupled by the effect of deviating forces. The basic equations for second-order generalized beam theory are outlined. Solutions for pin-ended supports are presented, demonstrating the coupling effect by modes and by loads. In the different ranges of length, the individual modes are sufficient approximations for the critical load. The application to a thin-walled bar with C-section under eccentric normal force demonstrates the quality of the single-mode compared to the exact solution.

ABSTRACT: For thin-walled sections, lateral and lateral-torsional buckling are often affected by distortion of the section and this can severely reduce the critical stress. A calculation method for the critical stress which takes account of distortional effects, based on Generalised Beam Theory (GBT), is presented in this paper. The limiting slenderness at which distortional effects begin to take effect is evaluated for channel- and hat-sections on the basis of parametric studies. Approximate formulae for the limiting slenderness are then given.

ABSTRACT: Following the intention of this special issue the most important contributions of Kloppel to light weight steel constructions are presented, A short history of the development of Generalized Beam Theory (GBT) is given. Applications of GBT are shown in the fields of distortion (batten plates, cold-rolled purlins and trapezoidal sheeting), stability (buckling and ultimate loads of special sections) and thin-walled cylinders (joint stiffness and buckling).

ABSTRACT: A previous paper presented a method of analysis for any open unbranched thin-walled section considering both rigid body movement and cross-section distortion (including local buckling). It described briefly the calculation procedures required in order to obtain section properties related to each of a number of cross-section distortion modes. These properties were generally calculated using first-order theory. This paper describes in full how second-order theory can be used to calculate the section properties for all modes, including each of the four rigid body modes. In the process of developing the second-order generalized beam theory, additional section properties evolve which enable the first-order equilibrium equation to be modified to consider second-order elastic critical load problems.

ABSTRACT: This paper introduces the second-order terms associated with geometric nonlinearity into the basic equation of Generalised Beam Theory. This gives rise to simple explicit equations for the load to cause buckling in individual modes under either axial load or uniform bending moment. It is then shown how the explicit procedure can be extended to consider the interaction between local, distortional and global buckling modes. More general load cases require the use of numerical methods of analysis and the finite difference method offers a suitable procedure. The success of Generalised Beam Theory for a wide range of situations is demonstrated by comparing the results obtained using it with both test results and other analyses. It is shown that it offers particular advantages in the analysis of buckling problems in cold-formed sections.

ABSTRACT: Previous papers (Refs 1–4) have presented a method of analysis for any open unbranched thin walled section considering both rigid body movement and cross section distortion (including local buckling). Reference 1 described how the Generalized Beam Theory (GBT) can be used to calculate generalized section properties for all modes, including each of the four rigid body modes and the distortional modes. The additional section properties evolved from GBT were then used in Ref. 2 to consider second order elastic critical buckling problems. This paper compares the critical buckling predictions of GBT with the results obtained in two series of tests carried out on lipped and unlipped channels subject to a major axis bending moment. These predictions are then combined with the yield criteria of EC3 to allow a comparison with the analysis of these tests carried out by Lindner and Aschinger (Ref. 5). The paper concludes that the Generalized Theory is a powerful and effective analysis tool for the solution of interactive buckling problems where both local and overall buckling can occur.

“Elastoplastic behavior of longitudinally stiffened girder webs subjected to patch loading and bending”, DYNA.rev.fac.nac.minas, Vol. 82, No. 189, January/February 2015

ABSTRACT: This paper is aimed at studying the elastoplastic behavior of longitudinally stiffened girder webs subjected to patch loading and bending. The investigation is carried out by means of nonlinear finite element analysis to study the structural behavior of the girder components (flanges, web and stiffener) at ultimate limit state. Initial geometrical imperfections, plastic material behavior and large deflection effects are considered in the model. For the numerical model validation, the computer results from the simulations are compared with experimental results taken from the literature. A parametric study was carried out in order to investigate the influence of the applied bending moment and the relative location of the stiffener on the ultimate strength to patch loading.

ABSTRACT: Finite element analysis of pinned cold-formed plain channel columns of different width-to-
thickness ratios is presented in this paper. The study is focused not only on axially loaded columns, but also on eccentrically loaded columns. The general purpose finite element software ABAQUS 6.12 was used, and the force controlled loading was adopted. Geometric and material nonlinearities were incorporated in the finite element model. The ultimate loads are compared with the direct strength method (DSM) for axially loaded columns. Also, a parametric study is done by varying the length of the column and width of the unstiffened element. It is observed that the results correlate better with the DSM values for columns having unstiffened elements of lower b/t ratios. The change in ultimate load is studied only in ABAQUS, as the position of load moves towards the free edge and the supported edge of the unstiffened element. A parametric study is done by varying the nonuniform compression factor for the columns. It is observed that the ultimate load increases as the position of load moves towards the supported edge and it is influenced by the b/t ratio of the unstiffened element.

ABSTRACT: This paper presents an experimental investigation of short cold-formed lipped channel columns compressed between pinned ends. The short columns are subjected to pure axial compressive loading. Twelve column specimens are tested and the columns are categorised into three groups, depending on the length and thickness. The buckling modes of failure that occurred include local buckling and distortional buckling. A comparison of the experimental results with the loads predicted by the South African standard for the design of cold-formed steelwork (SANS 10162-2) shows that the code is not conservative enough to cater for these columns.

ABSTRACT: This paper presents both the analytical and theoretical investigations on ultimate load carrying capacity and behaviour of CFS unlipped channels with their ends fixed and subjected to axial compression. The numerical studies have been carried out in the elastic as well as in the plastic ranges of loading. The slenderness ratio of the channels chosen is 40, 80,100 and 120. Three different web depths [shallow, medium and deep] with five thicknesses have been chosen. In addition to the numerical studies, comparison with the design strengths predicted by using North American Standards for CFS structures. It is observed that the design strength predicted by the specifications are conservative for axially loaded columns. In the present investigation, an attempt is made to study the ultimate load carrying capacity and the mode of failure. Load versus axial shortening behaviour has been studied for various slenderness ratios for a few specimens.

Cheng Yu and Benjamin W. Schafer, “Distortional buckling of cold-formed steel members in bending”, Ph.D. dissertation by Cheng Yu, Advisor B.S. Schafer, American Iron and Steel Institute Final Report, Baltimore, Maryland, January 2005

ABSTRACT: Laterally braced cold-formed steel beams generally fail due to local and/or distortional buckling in combination with yielding. For many cold-formed steel (CFS) studs, joists, purlins, or girts, distortional buckling may be the predominant buckling mode. However, distortional buckling of CFS beams remains a largely unaddressed problem in the current North American Specification for the Design of Cold-Formed Steel Structural Members (NAS). Further, adequate experimental data on unrestricted distortional buckling in bending is unavailable. Therefore, two series of bending tests on industry standard CFS C and Z-sections were performed and presented in this dissertation. The testing setup was carefully designed in the first series of tests (Phase 1) to allow local buckling failure to form while restricting distortional and lateral-torsional buckling. The second series of tests (Phase 2) used nominally identical specimens to Phase 1 tests, and a similar testing setup. However, the corrugated panel attached to the compression flange was removed in the constant moment region so that distortional buckling could occur. The experimental data was used to examine current specifications and new design methods. Finite element modeling in ABAQUS was developed and verified by the two series of bending tests and then applied to analyze more CFS beams. An analytical method was derived to determine the elastic buckling stress of thin plates under longitudinal stress gradient. And finite element analysis was used to study the stress gradient effect on the ultimate strength of thin plates. It was found that the stress gradient increases the buckling stress of both stiffened and unstiffened elements, and current design methods can include
the stress gradient effect if an appropriate elastic buckling coefficient is used. The moment gradient effect on the distortional buckling of CFS beams was also studied by the finite element analysis. The results show that the moment gradient increases both the elastic buckling moment and ultimate strength of distortional buckling of CFS beams. A draft design provision was proposed to account for the moment gradient effect. Research was conducted to explore the distortional buckling of CFS beams with partial restraint on the compression flange. A simple numerical model was proposed to calculate the elastic buckling moment of the CFS section-panel system. It was found that partial restraint has significant influence on distortional buckling, and that the influence could be considered by using a modified elastic buckling moment. For design purposes, simplified closed-form solutions for the elastic buckling moment of CFS C and Z-sections were proposed and verified. In the end, conclusions and recommendations for future research are presented.

ABSTRACT: A nonlinear finite element (FE) model is developed to simulate two series of flexural tests, previously conducted by the authors, on industry standard cold-formed steel C- and Z-section beams. The previous tests focused on laterally braced beams with compression flange details that lead predominately to local buckling failures, in the first test series, and distortional buckling failures, in the second test series. The objectives of this paper are to (i) validate the FE model developed for simulation of the testing, (ii) perform parametric studies outside the bounds of the original tests with a particular focus on variation in yield stress and influence of moment gradient on failures, and (iii) apply the study results to examine and extend the Direct Strength Method of design. The developed FE model shows good agreement with the test data in terms of ultimate bending strength. Extension of the tested sections to cover yield stresses from 228 to 506 MPa indicates that the Direct Strength Method is applicable over this full range of yield stresses. The FE model is also applied to analyze the effect of moment gradient on distortional buckling. It is found that the distortional buckling strength of beams is increased due to the presence of moment gradient. Further, it is proposed and verified that the moment gradient effect on distortional buckling failures can be conservatively accounted for in the Direct Strength Method by using an elastic buckling moment that accounts for the moment gradient. An empirical equation, appropriate for use in design, to predict the increase in the elastic distortional buckling moment due to moment gradient, is developed.
number of sample simulations. In an attempt to curtail the need for multiple sample calculations, an alternative first-order perturbation expansion is proposed for approximating the mean and variance of the post-buckling behavior. However, the limitations of this first-order perturbation approximation are demonstrated to be significant. The simulations indicate that deterministic characteristics of the post-buckling response can be inadequate in the face of input randomness. In one case, a frame that is stable symmetric in the deterministic case is found to be asymmetric when randomness in the input is incorporated; therefore, this frame has real potential for imperfection sensitivity. The importance of random field models for the member stiffness as opposed to random variable models is highlighted. The simulations indicate that the post-buckling response can magnify input randomness, as variability in the post-buckling parameters can be greater than the variability in the input parameters.

“Simplified methods for predicting elastic buckling of cold-formed steel structural members with holes”, 19th International Specialty Conference on Cold-Formed Steel Structures, St. Louis, Missouri, USA, October 14-15, 2008

ABSTRACT: Simplified methods for approximating the local, distortional, and global critical elastic buckling loads of cold-formed steel columns and beams with holes are developed and summarized. These methods are central to the extension of the Direct Strength Method (DSM) to members with holes, as DSM employs elastic buckling properties to predict ultimate strength. The simplified methods are developed as a convenient alternative to shell finite element eigenbuckling analysis, which requires commercial software not always accessible to the engineering community. A variety of simplified methods are pursued including (a) hand methods founded primarily on classical plate stability approximations and (b) empirical extensions to the semi-analytical finite strip method (i.e., modifying and using the freely available, open source software, CUFSM). The proposed methods are verified with shell finite element eigenbuckling studies. The developed simplified methods are intended to be general enough to accommodate the range of hole shapes, locations, and spacings common in industry, while at the same time also defining regimes where explicit use of shell finite element analyses are still needed for adequate accuracy.

ABSTRACT: Closed-form expressions for approximating the influence of single or multiple holes on the critical elastic buckling stress of plates in bending or compression are developed, validated and summarized. The expressions are applicable to plates simply supported on 4 sides and plates simply supported on 3 sides, commonly called stiffened and unstiffened elements in design. The expressions serve as a convenient alternative to shell finite element eigen-buckling analysis, which requires commercial software not typically accessible to the engineering design community. The forms of the expressions are founded on classical plate stability approximations, and are developed and validated with parametric studies employing shell finite elements. The finite element parametric studies demonstrate that holes may create unique buckling modes, and can either decrease or increase a plate's critical elastic buckling stress depending on the hole geometry and spacing. The validated closed-form expressions and their associated limits are intended to be general enough to accommodate the range of hole shapes, locations, and spacings common in engineering practice, while at the same time also defining regimes where explicit use of shell finite element analyses is still needed for adequate accuracy.

ABSTRACT: In this study, a vibration analysis was carried out of symmetric angle-ply laminated composite
plates with and without square hole when subjected to compressive loads, numerically. A buckling analysis is also performed to determine the buckling load of laminated plates. For each fibre orientation, the compression load is taken equal to 50% of the corresponding buckling load. In the analysis, finite element method (FEM) was applied to perform parametric studies, the effects of degree of orthotropy and stacking sequence upon the fundamental frequencies and buckling loads are discussed. The results show that the presence of a constant compressive load tends to reduce uniformly the natural frequencies for materials which have a low degree of orthotropy. However, this reduction becomes non-uniform for materials with a higher degree of orthotropy.

ABSTRACT: The objective of this paper is to provide a method for applying modal identification (i.e. the separation of general deformations into fundamental modal deformation classes: local, distortional, global, shear, and transverse extension) to the collapse analysis of thin-walled members modeled using material and geometric nonlinear shell finite element analysis. The advantage of such a modal identification is the ability to categorize and reduce the complicated deformations that occur in a shell finite element model—and ultimately to (a) quantitatively associate failures with particular classes, e.g. state a model as a local failure, and (b) track the evolution of the classes, e.g., mixed local and distortional buckling leading to a distortional failure in a given model. Ultimately, this capability will aid Specification development, which must simplify complicated behavior down to strength predictions in isolated buckling-induced limit states. The modal identification method is enabled by creating a series of base vectors, consistent with the fundamental deformation classes, that are used to categorize the general finite element displacements. The base vectors are constructed using the constrained finite strip method for general end boundary conditions, previously developed by the authors. A fairly sizeable minimization problem is required for assigning the contributions to the fundamental deformation classes. The procedure is illustrated with shell finite element examples of cold-formed steel members modeled to collapse with geometric or/and material nonlinearity. The failure modes of the member are tracked (i.e., identified as a function of displacement), and the collapse mechanism is investigated. The provided examples provide both proof of concept for the modal identification and demonstrate the potential of using such information to better understand the behavior of thin-walled members.

ABSTRACT: In this paper, flexural buckling of pin-ended thin-walled columns is discussed. The classical formulae for the critical force are based on a beam model. The simplest formulae use the classical Euler–Bernoulli beam theory, but solutions based on the shear-deformable beam theory are also known. In the presented research alternative formulae are derived. The column is modeled as a set of flat plane elements, and the in-plane membrane shear deformations are explicitly considered. The derivations can be carried out in various, slightly different ways, leading to different formulae. The derived critical force formulae are discussed through theoretical considerations and numerical studies.

Kremer, K., Liszkiewicz, A. and Adkins, J., “Development of steel foam materials and structures”, October 2004, Fraunhofer, Center for Manufacturing and Advanced Materials, Newark, Delaware

ABSTRACT: In the past few years there has been a growing interest in lightweight metal foams. Demands for weight reduction, improved fuel efficiency, and increased passenger safety in automobiles now has
manufacturers seriously considering the use of metal foams, in contrast to a few years ago, when the same materials would have been ruled out for technical or economical reasons. The objective of this program was to advance the development and use of steel foam materials, by demonstrating the advantages of these novel lightweight materials in selected generic applications. Progress was made in defining materials and process parameters; characterization of physical and mechanical properties; and fabrication and testing of generic steel foam-filled shapes with compositions from 2.5 wt. % to 0.7 wt. % carbon. A means of producing steel foam shapes with uniform long range porosity levels of 50 to 60 percent was demonstrated and verified with NDE methods. Steel foam integrated beams, cylinders and plates were mechanically tested and demonstrated advantages in bend stiffness, bend resistance, and crush energy absorption. Methods of joining by welding, adhesive bonding, and mechanical fastening were investigated. It is important to keep in mind that steel foam is a conventional material in an unconventional form. A substantial amount of physical and mechanical properties are presented throughout the report and in a properties database at the end of the report to support designer’s in applying steel foam in unconventional ways.

ABSTRACT: Steel tubes have an efficient shape with large second moment of inertia relative to their light weight. One of the main problems of these members is their low buckling resistance caused from having thin walls. In this study, steel foams with high strength over weight ratio is used to fill the steel tube to beneficially modify the response of steel tubes. The linear eigenvalue and plastic collapse FE analysis is done on steel foam filled tube under pure compression and three point bending simulation. It is shown that steel foam improves the maximum strength and the ability of energy absorption of the steel tubes significantly. Different configurations with different volume of steel foam and composite behavior is investigated. It is demonstrated that there are some optimum configurations with more efficient behavior. If composite action between steel foam and steel increases, the strength of the element will improve, in a way that, the failure mode change from local buckling to yielding.

ABSTRACT: Offshore wind turbine (OWT) support structures are subjected to non-proportional environmental wind and wave load patterns with respect to increases in wave height and with respect to wind and wave combined loading. Traditional approaches to estimating the ultimate capacity of offshore support structures are not ideally suited to analysis of OWTs. In this paper, the concept of incremental wind-wave (IWWA) analysis of the structural capacity of OWT support structures is proposed. The approach uses static push-over analysis of OWT support structures subject to wind and wave combined load patterns corresponding to increasing mean return period (MRP). The IWWA framework can be applied as a one-parameter approach (IWWA1) in which
the MRP for the wind and wave conditions is assumed to be the same or a two-parameter approach (IWWA2) in which the MRPs associated with wind and wave conditions are related to a joint probability density function characterizing the wind and wave conditions at the site. Example calculations for monopile and jacket supported OWTs at Atlantic marine sites are performed under both one parameter and two parameters IWWA framework. The analyses illustrate that: the results of an IWWA analysis are site specific; and structural response can be dominated by either wind or wave conditions depending on structural characteristics and site conditions. Finally, reliability analyses for both examples excluding uncertainties in structural resistance are estimated based on their IWWA results and probabilistic models for site environmental conditions.

Paper 1, http://scholarsmine.mst.edu/iscss/21icfss/21icfss-session1/1, August 24, 2012

ABSTRACT: This paper illustrates new capabilities for modal identification of shell Finite Element Method (FEM) models of thin-walled cold-formed steel members. The separation of general deformations into fundamental buckling deformation classes: local, distortional, global, shear, and transverse extension, originated with the constrained Finite Strip Method (cFSM) and is extended here to shell element based FEM analysis. The cFSM base vectors for general end boundary conditions, previously developed by the authors, provide a series of general base functions capable of separating displacements into classes. FEM displacements are identified by minimizing error between the actual FEM displacements and those predicted by the cFSM base functions. This leads to the ability to quantify (i.e., modally identify) the global, distortional, and local participation in a FEM model. The ability to categorize the complicated deformations of a FEM model into simple classes is of great importance because of the different post-buckling and collapse behavior associated with each class. Further, the extension to general FEM models allows for modal identification of members with geometric changes along the length, such as holes, as well as concentrated loads and other characteristics difficult to capture in the finite strip formulation. The method is demonstrated for modal identification of FEM linear elastic analysis, FEM elastic buckling analysis (including highly coupled modes) and FEM nonlinear collapse analysis. Further, the examples include members with holes. The dominance of distortional buckling deformations in collapse regimes of lipped channel members is observed and provides new insight on the interaction of buckling modes in cold-formed steel members. Limitations of the method and future directions for the work are discussed.

ABSTRACT: The objective of this paper is to provide the theoretical background and illustrate the capabilities of the constrained finite strip method (cFASM) for thin-walled members with general end boundary conditions. Based on the conventional finite strip method (FSM), cFASM provides a mechanical methodology to separate the deformations of a thin-walled member into those consistent with global, distortional, local, and other (e.g., shear and transverse extension) modes. For elastic buckling analysis, this enables isolation of any given mode (modal decomposition) or quantitative measures of the interactions within a given general eigenmode (modal identification). Existing cFASM is only applicable to simply supported end boundary conditions. In this paper, FSM is first extended to general end boundary conditions, including simply–simply, clamped–clamped, simply–clamped, clamped–guided, and clamped–free. Next, with the conventional FSM for general end boundary conditions in place, the derivation of the constraint matrices for global, distortional, local, and other modes that play a central role in cFASM are summarized. Several bases (i.e., the constraint matrices) are presented for general end boundary conditions involving, in particular, different orthogonalization conditions. For modal identification, normalization schemes for the base vectors as well as the summation method employed for the modal participation calculation are also provided. Numerical examples of modal decomposition and identification are illustrated for a thin-walled member with general end boundary conditions. Recommendations on the choice of basis, orthogonalization, and normalization are provided.

CURRENT PRACTICE AND FUTURE RESEARCH NEEDS

ABSTRACT: The goal of this paper is to highlight promising methods in current thin metallic shell design practice and to define a future needs framework from which research can launch. Thin shell structural members are a staple in many industries – from aerospace, ship building, to offshore oil and gas to residential and commercial buildings. Shell types and geometries are numerous including ship hulls, silos, tanks, pipelines, chimneys and wind turbine towers. Despite large research investments there is still wide debate and uncertainty when designing thin shell structural members. Failure modes are complex and sensitive to initial geometric imperfections. The types of loadings vary widely – including axial, shear, flexure combined with internal or external pressure – making calculation-based methods challenging. Shell geometry – including longitudinal and transverse stiffeners and conical, tapered along a member – compound the complexity. This paper synthesizes these current approaches and organizes the most promising ideas into a framework for future research. A specific focus will be on research needed to expand current GMNIA (geometrically and materially nonlinear analysis with imperfections included) capabilities.

ABSTRACT: Thin-walled stiffened or unstiffened, metallic or composite shells are widely used structural elements in aeronautical and space applications. These structures are often highly sensitive to initial imperfections and therefore have buckling loads much lower than those computed for perfect structures. Analysis and testing of imperfect shells have been a major research area during the last century. The proposed paper will present the results of the buckling analysis of small cylindrical shells, i.e. beer cans, with length of 100 mm, radius of 33 mm, and thickness 0.1 mm, and their comparison with experimental results. For the analytical work, a hierarchical multi-fidelity approach is used to solve the buckling problem. As a first level analysis some simple programs are used to investigate the behavior of perfect shells. The deformation in both axial and circumferential direction is described using goniometric functions. This is followed by more advanced analytical programs where the deformation in circumferential direction is still described using goniometric functions, but in axial direction the deformation is solved from the differential equations. Finally, the local buckling phenomena as observed during the experiment is looked at more carefully by investigating the energy behaviour.

ABSTRACT: This study reports the experimental investigation of the elastic, buckling and post-buckling response of unidirectional laminated and $0^\circ$ oriented E-glass/epoxy composite rectangular plate subjected to compressive load and liquid environment exposure. The plates were exposed to liquid rocket propellants like kerosene oil, hydrogen peroxide and hydrazine hydrate for different duration. The effects of liquid fuels, moisture concentration, fiber damage and plate parameters on elastic, buckling and post buckling response of the plate were studied. The effect of corrosion on composite plate and reduction in properties like weight changes, elastic, buckling and post-buckling strength were observed and found as a time dependent. The theoretical evaluation using classical thin plate theory showed the significant buckling load variation with response to experimental observation. In addition, hydrogen peroxide and hydrazine hydrate are found more corrosive compared to kerosene oil and reduced one fourth of the total strength of the composite plate.

Ali Fatemi and Shawn Kenny (Memorial University of Newfoundland and Labrador), “Continuum modeling framework for local buckling response of plain and girth welded pipes”, Offshore Technology Conference, 2-5 May 2011, Houston, Texas, USA

ABSTRACT: In this paper, the significance of boundary conditions (L/D ratio), initial geometric imperfections, anisotropic material properties, and material constitutive model on the local buckling response of plain and girth welded pipes was evaluated using continuum finite element modelling procedures. A numerical model was developed, using the finite-element simulator ABAQUS/Standard, to predict the local buckling and post-buckling response of high strength pipelines subject to combined state of loading. The numerical procedures were calibrated using test data from large-scale experiments examining the local buckling of high strength linepipe. The moment and strain response estimates, predicted by the numerical simulation tool, was consistent with the experimental data well into the post-yield range. As the models with high L/D ratio exhibit global Euler-type response, a numerical algorithm was developed to calculate the local section moment response based on FE predictions.
ABSTRACT: The elastic buckling and ultimate capacity of thin-walled steel circular hollow sections manufactured with spiral welding and subjected to axial force or pure bending are studied numerically in ABAQUS and experimentally validated to provide a numerical modeling protocol. This effort, focused on shell finite element analysis and the development of validated modeling protocols, is a part of a larger effort to definitively understand the limit-states and provide design standards for spirally welded steel wind turbine towers. The modeling protocol incorporates fundamental modeling parameters including element type, mesh aspect ratio, mesh style including structured mesh versus spiral mesh along the spiral welds, mesh size along the length, mesh size on the circular cross-section, material modeling, geometrical imperfections, and weld imperfections. The geometrical dimensions in the parametric analyses were selected in accordance with reasonable archetype dimensions and practical plate thicknesses and cross-sectional diameters applicable to wind turbine towers. An eigen-buckling convergence study including both buckling shapes and capacities was performed under pure bending and compressive axial force to find a base-line modeling protocol. To validate the base-line modeling protocol, a spirally welded tube specimen recently tested at Northeastern University was simulated via geometric and material nonlinear shell finite element analysis. The validated protocol will be applied to a larger parametric collapse analyses to generalize the experimental results and to develop reliability based design methods for spirally welded wind turbine towers.

ABSTRACT: Current design of cold-formed steel members is unduly complicated. Part of this complication arises from the need to perform elastic buckling calculations by hand. Also, complications occur in determining the effective width and resulting effective properties of members. Further, as cross-sections become more optimized (e.g., through the introduction of longitudinal stiffeners) both the elastic buckling and effective width calculations become markedly more complex. In order to investigate alternatives to current design a large amount of experimental data on flexural members of varying geometry is collected. The use of numerical elastic buckling solutions for the entire member is investigated as an alternative to current practice. Employing strength curves on the entire member, similar to the effective width strength curves for an element, it is found that a “direct strength” approach is a reliable alternative to current design. Such an approach leads to complete flexibility in cross-section geometry, thus greatly increasing the ability to optimize cold-formed steel members. Conservative limitations of the direct strength approach are also addressed.

ABSTRACT: Global stability of an innovative dome comprising of double-layer space frame sections together with curved flexural members has been studied. The dome had both an outer flat and an inner spherical double-layer grid space frames and formed the roof over a joint ballroom and meeting space of 3,100 square metres. The relatively wide spans between the outer and the inner space structures were covered using thirty six curved flexural pipe members laid on a synclastic surface. These members were employed for architectural purposes to provide a clear glazed area for the roof. Introducing relatively large span flexural members joining the two lattice space frames together complicated the overall structural response of the dome. It also made the dome susceptible to different premature instability modes. The non-linear FE program ABAQUS [1] was utilised to study the global stability of the dome and to investigate fully both its pre and post failure behaviour. Different member configurations were considered for the dome and their effects on the behaviour; stability, snap through buckling and the collapse load of the structure were investigated. In the dome responses, several failure modes such as overall torsional buckling, in-plane ring buckling and symmetrical and non-symmetrical vertical snap through were identified. It was noted that the presence of restraints placed between the flexural members could prevent the occurrence of premature torsional and vertical snap through buckling in the dome. The global behaviour of the dome appeared to be very sensitive to both the type and configuration of the restraints applied along the flexural members. The dome was also found to be remarkably sensitive to non-symmetric loads.

M. Zeinoddini (Dept. of Civil Engineering, University of Technology, Tehran, Iran), “In-situ quasi-static and dynamic behavioural response of steel tubular frames subjected to lateral impact loads”, Latin American Journal of Solids and Structures, Vol. 9, No. 3, June 2012

ABSTRACT: Steel tubular members are widely used as primary and secondary structural framing members in offshore oil and gas platforms. A platform is inherently liable to collisions from ships which can create severe structural damages in the rig. The effect of this damage has been studied by a number of researchers through investigating the impact behaviour isolated tubular members. This is while, the in-situ response of a member located in a structural frame, to lateral impact loads, is not necessarily the same as the response of an individual isolated impacted member. In this paper the behaviour of a chord member forming part of a tubular frame, subjected to impact loads, has been investigated. The tubular frame was tested experimentally by other researchers and reported in the literature. The non-linear numerical models of the frame presented by the authors have been validated against the experimental results. These validated models have been examined under both quasi-static and dynamic impact loads with operational pre-loading applied. It has been found that, in a pre-loaded frame, quasi-static impact loading results in the failure of the impacted member. Interestingly, dynamic modelling of the impact results in the dynamic instability of an adjacent bracing member. It has been noticed that, under a dynamic impact, the impacted in-situ member (located in the frame) behaves rather similarly to a pin ended isolated member. With a quasi-static impact, the impacted in-situ member follows fairly closely the response obtained for a fixed ended isolated member.

ABSTRACT: The application of the finite element method to thin-walled structures often requires non-linear analysis. Whereas in linear finite element analyses errors are easily made, this is even more so in the non-linear analyses. This paper focuses on possible sources of error in linear and non-linear finite element solutions, and gives suggestions how to check and prevent these errors.

ABSTRACT: Thin-walled, cold-formed steel members exhibit a complicated post-buckling regime that is difficult to predict. Today, advanced computational modeling supplements experimental investigation. Accuracy of computational models relies significantly on the characterization of selected inputs. No consensus exists on distributions or magnitudes to be used for modeling geometric imperfections and for modeling residual stresses of cold-formed steel members. In order to provide additional information existing data is collected and analyzed and new experiments performed. Simple rules of thumb and probabilistic concepts are advanced for characterization of both quantities. The importance of the modeling assumptions are shown in the examples. The ideas are summarized in a preliminary set of guidelines for computational modeling of imperfections and residual stresses.

ABSTRACT: Traditionally numerous physical tests have been required to develop and verify newly proposed design procedures. The availability of powerful computers and software makes the finite element method an essential tool in such research. Analysis types, material models, elements and initial conditions that are taken into account in the finite element analysis of thin-walled structures are discussed. A list of programs developed in recent studies and example problems of the finite element method application to thin-walled structures are given.

“Understanding and Classifying Local, Distortional and Global Buckling in Open Thin-Walled Members”, Annual Conference: Structural Stability Research Council, Montreal, Canada, 2005
ABSTRACT: Cross-section instability greatly complicates the behavior of thin-walled members. Current computational stability techniques do little to add clarity. The terms “global,” “distortional,” and “local buckling” permeate the literature, but there are no satisfactory definitions for the three characteristic modes. Despite this, design standards require the calculation of buckling stresses, as each characteristic mode has a differing degree of post-buckling capacity, and may trigger a different collapse response. Further, interaction
between all modes is possible, but poorly understood. This paper proposes a new approach for buckling mode definitions of open cross-section thin-walled members, which, unlike the existing heuristic definitions, are based on simple mechanical assumptions which can easily be applied in the context of any numerical method. The application of the proposed definitions to the Finite Strip Method is briefly demonstrated. The technique may be used either to classify results after performing an analysis (including the extent of interaction) or to constrain a model to a particular characteristic mode or modes before performing the analysis. Numerical examples are provided to justify the applicability and efficiency of the proposed classification

ABSTRACT: This paper provides the first detailed presentation of the derivation for a newly proposed method which can be used for the decomposition of the stability buckling modes of a single-branched, open cross-section, thin-walled member into pure buckling modes. Thin-walled members are generally thought to have three pure buckling modes (or types): global, distortional, and local. However, in an analysis the member may have hundreds or even thousands of buckling modes, as general purpose models employing shell or plate elements in a finite element or finite strip model require large numbers of degrees of freedom, and result in large numbers of buckling modes. Decomposition of these numerous buckling modes into the three buckling types is typically done by visual inspection of the mode shapes, an arbitrary and inefficient process at best. Classification into the buckling types is important, not only for better understanding the behavior of thin-walled members, but also for design, as the different buckling types have different post-buckling and collapse responses. The recently developed generalized beam theory provides an alternative method from general purpose finite element and finite strip analyses that includes a means to focus on buckling modes which are consistent with the commonly understood buckling types. In this paper, the fundamental mechanical
assumptions of the generalized beam theory are identified and then used to constrain a general purpose finite strip analysis to specific buckling types, in this case global and distortional buckling. The constrained finite strip model provides a means to perform both modal identification relevant to the buckling types, and model reduction as the number of degrees of freedom required in the problem can be reduced extensively. Application and examples of the derivation presented here are provided in a companion paper.

ABSTRACT: This paper derives a new method for fully decomposing the elastic stability solution, of a thin-walled single-branched open cross-section member, into mechanically consistent buckling classes associated with global, local, distortional, and shear and transverse extension buckling modes. The method requires a set of formal mechanical definitions for each of the buckling classes. For global and distortional buckling the definitions employed successfully by generalized beam theory are utilized herein, while for local and other (shear and transverse extension) buckling, new definitions are provided. The mechanical definitions for a given buckling class represent a series of constraint conditions on the general deformations that the thin-walled cross-section may undergo. These constraint conditions are derived as explicit constraint matrices within the context of the finite strip method, and provide the desired decomposition of the buckling deformations of the member. The decomposition is full in the sense that the union of the deformation spaces of the decomposed buckling classes is the same as the general deformation space in the original finite strip method. The resulting method is termed the constrained finite strip method (cFSM). The two primary applications for cFSM are modal decomposition and modal identification. Modal decomposition reduces the general finite strip solution to a desired set of buckling classes and performs a useful model reduction that allows the results to focus on a particular buckling class, e.g., distortional buckling. Modal identification provides a means to quantify the extent to which a given buckling class is contributing to a general buckling deformation. Application of cFSM, including graphical representation of the buckling classes, and the advantages of modal decomposition and modal identification, are provided in a series of numerical examples.

ABSTRACT: The aim of this report is to give a review of some recent progresses in the field of cold-formed steel members. Particular emphases are given to progresses in the field of distortional buckling and in recent development of new types of joints.

F. Kolcu, T. Ekmekyapar and M. Özakça (Department of Civil Engineering, University of Gaziantep, Gaziantep, Turkey), “Linear buckling optimization and post-buckling behavior of optimized cold formed steel members”, Scientific Research and Essays Vol. 5(14), pp. 1916-1924, 18 July, 2010  
ABSTRACT: Today's high-strength materials allow for significant increases in working and limit stresses. To
fully exploit material improvements as weight savings on structures, it is desirable to enhance the performance of structural components. The work presented in this paper proposes that the buckling behavior of cold form steel columns may be effectively improved without increased material volume. In order to achieve this goal, optimization algorithm which integrates finite strip analysis, geometric modeling, semi analytical sensitivity analysis and sequential quadratic mathematical programming methods can be used to find an optimum cross section of cold-formed steel columns under axial compression. The objective is the maximization of the critical buckling load with constraints on the volume of material used. Several examples are included to illustrate advantage of the optimization. The post buckling performance of optimized cold form steel columns was also investigated using nonlinear variable thickness finite strip analysis. Non-linear finite strip analysis helped to understand the behaviour of these cold form steel columns and select the most promising designs. The optimum forms found in this paper can be used to develop improved designs for cold formed steel columns.

structure increases. Thus this study presents coupled computational and experimental analyses, aimed at developing relationships between modelling fidelity and the size of the modelled structure, when the global static load to cause initial buckling is the required analysis output. Small, medium and large specimens representing welded lap-joined fuselage panel structure are examined. Two element types, shell and solid-shell, are employed to model each specimen, highlighting the impact of idealisation on the prediction of welded stiffened panel initial skin buckling.

ABSTRACT: This work presents a new metamodel for reinforced panels under compressive loads, typically used in light-weight aircraft structures. The metamodel represents a replicable cell structure of integrally machined panels. The presented formulation for conception is based on the synthesis of four stability criteria: section crippling, web buckling, flange buckling and column collapse. The aluminum alloy, a typical choice in modern aircraft industry, is selected and the structure is expected to work in the linear elastic domain. In order to evaluate the accuracy and to validate the analytical tool, the procedure is applied in the pre-sizing of the fuselage basic structural components of a 9-passenger executive aircraft. The pull-up maneuver, one of the critical load conditions in most of aircrafts, causes the maximum compressive stresses in lower fuselage panels. Finite element models are presented to the resulting fuselage configuration. The optimal configuration achieved through the application of the analytical tool yields to an innovative structure from those usually adopted in the aeronautical industry. This structural configuration is presented and discussed. The developed metamodel proved to be effective, presenting satisfactory results with adequate accuracy for the initial stages of light-weight aircraft structure.

ABSTRACT: Recent developments in the practical utilisation of cold-formed sections in building construction have taken place on three related fronts. There have been significant developments in the technology which result in more complex shapes with a higher yield stress so that cold-formed sections represent a particularly high-tech form of constructional steelwork. Developments in technology would be of little consequence unless there were parallel developments in practical applications and this is illustrated by the continual increase in the market share of cold-formed sections. This, in turn, makes demands on design procedures and requires parallel development in calculation models and design codes. In particular, sections have tended to become more highly stiffened and this necessitates a more sophisticated treatment of local buckling, distortional buckling and the interactions between them. The latest trend is to move from simplified design models to design procedures based on “whole section” analysis. In this paper, recent developments in technology and application are outlined and this is followed by more detailed consideration of the related design procedures.

ABSTRACT: A modular structure is one which is formed from a repeated module, most commonly a regular truss. These are often reduced to equivalent uniform continua so that standard beam theory can be applied. This paper examines the basis of standard beam theory, demonstrating it to be a particular case of a more general theory. It is shown that more accurate results can be obtained by a proper application of the theory to both discrete modular systems and to normal continuous beams.

ABSTRACT: The process of prediction of distortional buckling stress of cold-formed steel members is often cumbersome and it is also difficult to perform parametric studies in this field to investigate the effect of geometric parameters on Elastic Distortional Buckling Stress (EDBS). To overcome this difficulty a neural network based model and formulation which was presented in a companion paper by the author [Pala M. A new formulation for distortional buckling stress in cold formed steel members. Journal of Constructional Steel Research 2006;62:716–22] is proposed as an alternative approach to investigate the effect of geometric parameters on distortional buckling stress. The model considers the effect of web height, flange width, angle of lip, lip length and flange thickness. The results of the Neural Network model are quite satisfactory and are consistent with the literature.

ABSTRACT: The main purpose of the research is to develop formulations for estimating the Elastic distortional buckling stress (EDBS) of cold-formed steel member under compressive loading using Genetic programming (GP) which has not been applied so far. The required data used for the training and testing is collected from the literature. Two GP-based formulations are proposed to predict the elastic distortional buckling of cold formed steel C sections. The results of proposed GP formulations are compared with experimental and analytical results of different researchers and methods and found to be accurate. The results obtained from the formulas have shown that GP is a promising technique for predicting EDBS of cold-formed steel C sections.

B.W. Schafer (Department of Civil Engineering, Johns Hopkins University, Baltimore, MD, 21218, United States), “Review: The Direct Strength Method of cold-formed steel member design”, Journal of Constructional Steel Research, Vol. 64, Nos. 7-8, July-August 2008, pp. 766-778, Special Issue: International Colloquium on Stability and Ductility of Steel Structures 2006, doi:10.1016/j.jcsr.2008.01.022
ABSTRACT: The objective of this paper is to provide a review of the development and current progress in the Direct Strength Method for cold-formed steel member design. A brief comparison of the Direct Strength Method with the Effective Width Method is provided. The advantage of methods that integrate computational stability analysis into the design process, such as the Direct Strength Method, is highlighted. The development of the Direct Strength Method for beams and columns, including the reliability of the method is provided.
Current and ongoing research to extend the Direct Strength Method is reviewed and complete references provided. The Direct Strength Method was formally adopted in North American cold-formed steel design specifications in 2004 as an alternative to the traditional Effective Width Method. The appendices of this paper provide the Direct Strength Method equations for the design of columns and beams as developed by the author and adopted in the North American Specification.

Z. Li and B.W. Schafer, “Application of the finite strip method in cold-formed steel member design”, Journal of Constructional Steel Research, Vol. 66, Nos. 8-9, August-September 2010, pp 971-980
ABSTRACT: The objective of this paper is to explore solutions and provide design recommendations for two practical issues that develop when integrating computational member analysis with the conventional finite strip method (FSM) into cold-formed steel member design utilizing the direct strength method (DSM). First, FSM often fails to uniquely identify the relevant local and distortional member buckling modes. These elastic buckling loads (or moments) are required inputs for predicting the design strength. Second, the recently developed constrained finite strip method (cFSM) which can uniquely identify local and distortional buckling in all cases suffers from its own limitations, specifically (a) cFSM does not yield the same exact solution as FSM even when unique minima exists in the FSM solution, and (b) cFSM cannot include rounded corners in the model of the cross-section. Two methods are examined herein for overcoming these limitations, both of which utilize cFSM in an augmented form. The proposed methods are explored for lipped channel cross-sections both for elastic buckling and for ultimate strength prediction via DSM. Particular attention is paid to methods for handling cross-sections with rounded corners (in both elastic buckling and strength) since cFSM cannot include rounded corners and still meaningfully identify the modes. Finally, based on the study of lipped channel members a recommendation is provided for a methodology that enables automated analysis of cold-formed steel member elastic buckling modes for use in DSM.

ABSTRACT: This paper presents an isoparametric finite element for reinforced shells and plates. The formulation is based on general beam theory and takes into account both transverse shear deformation and torsional warping. The element exhibits complete two-line compatibility. Numerical examples are presented in order to demonstrate the validity of the formulation and the possibilities of application.

ABSTRACT: Consistent and simple lumped mass matrices are formulated for the dynamic analysis of beams with arbitrary cross section. The development is based on a general beam theory which includes the effect of flexural-torsion coupling, the constrained torsion warping and the shear center location. Numerical tests are presented to demonstrate the importance of torsion warping constraints and the acceptable accuracy of the lumped mass matrix formulation.

Gábor M. Vörös (Dept. of Applied Mechanics, Budapest University of Technology and Economics, Budapest,

ABSTRACT: The paper presents the development of a new plate/shell stiffener element and the subsequent application in determine frequencies, mode shapes and buckling loads of different stiffened panels. In structural modelling, the plate and the stiffener are treated as separate finite elements where the displacement compatibility transformation takes into account the torsion - flexural coupling in the stiffener and the eccentricity of internal (contact) forces between the beam - plate/shell parts. The model becomes considerably more flexible due to this coupling technique. The development of the stiffener is based on a general beam theory, which includes the constraint torsional warping effect and the second order terms of finite rotations. Numerical tests are presented to demonstrate the importance of torsion warping constraints. As part of the validation of the results, complete shell finite element analyses were made for stiffened plates.

ABSTRACT: This paper presents a displacement based finite element model for predicting the constraint torsion effect of stiffeners. In structural modelling, the plate/shell and the stiffeners are treated as separate elements where the displacement compatibility transformation between these two types of elements takes into account the constraint torsional warping effect in the stiffeners. The development is based on a general beam theory which includes flexural-torsion coupling, constrained torsion warping, and shear-centre location. The virtual work principle includes the second order terms of finite beam rotations. For finite element analysis, cubic Hermitian polynomials are used as shape functions of the straight space frame element with two nodes. Elastic stiffness and geometric stiffness matrices for an arbitrary cross-section are evaluated in a closed form, and load correction stiffness for eccentric stiffener loads are considered. To demonstrate the importance of torsion warping constraints and to illustrate the accuracy of this formulation, finite element solutions are presented and compared with available solutions.

ABSTRACT: The paper presents the development of a new plate/shell stiffener element and the subsequent application in determine buckling loads and modes of different stiffened panels. The formulation of the stiffener is based on a general beam theory, which includes the constraint torsional warping effect and the second order terms of finite rotations. As part of the validation of the method, complete shell finite element analyses were made for stiffened plates.

References listed at the end of the paper:

ABSTRACT: The paper presents the application of the new stiffener element with seven degrees of freedom per node and the subsequent application in determining frequencies, mode shapes and buckling loads of different stiffened panels. In structural modelling, the stiffener and the plate/shell are treated as separate elements where the displacement compatibility transformation between the seven and six degrees of freedom nodes of these two types of elements takes into account the torsion–flexural coupling in the stiffener and the eccentricity of internal (contact) forces between the beam–plate/shell parts. The model becomes considerably more flexible due to this coupling technique. The development of the stiffener is based on a general beam theory, which includes the constraint torsional warping effect and the second-order terms of finite rotations. Numerical tests are presented to demonstrate the importance of torsion warping. As part of the validation of the results, complete shell and the usual six degrees of freedom per node shell–beam finite element analyses were made for stiffened panels.

ABSTRACT: In recent years, the post-buckling behavior of thin walled cold-formed steel members under compressive or bending loads has been the object of several research studies. For the most relevant situations in practice the problem is assumed to be conservative, so that the system’s behavior can be described from a total potential energy (TPE) function. In order to apply the Rayleigh-Ritz method, a discretization procedure is needed and the TPE becomes a function of a load parameter P and of a set of nC generalized coordinates ia. The post-buckling analysis concerns the search of alternative equilibrium paths in the neighborhood of the critical states – the one associated with the lowest critical load parameter having physical interest. The paper presents a set of numerical techniques required to study the stability behavior of thin-walled members in the context of an extended formulation of GBT (Generalized Beam Theory). An application to the study of the equilibrium and buckling behavior of cold-formed members is also presented.

linear shallow shell equations are discretized by the Galerkin method. The shell is considered to be initially at rest, in a position corresponding to a pre-buckling configuration. Then, a harmonic excitation is applied and conditions to escape from this configuration are sought. By defining steady state and transient stability boundaries, frequency regimes of instability may be identified such that they may be avoided in design. Initially a steady state analysis is performed; resonance response curves in the forcing plane are presented and the main instabilities are identified. Finally, the global transient response of the system is investigated in order to quantify the degree of safety of the shell in the presence of small perturbations. Since the initial conditions, or even the shell parameters, may vary widely, and indeed are often unknown, attention is given to all possible transient motions. As parameters are varied, transient basins of attraction can undergo quantitative and qualitative changes; hence a stability analysis which only considers the steady-state and neglects this global transient behavior, may be seriously non-conservative.

ABSTRACT: The aim of this paper is to investigate the influence of internal resonances on the nonlinear dynamics and instabilities of a parametrically excited cylindrical shell. The case of a 1:1:1:1 internal resonance, a problem not treated in the technical literature, is investigated. For this, a modal solution that takes into account the modal interaction between two modes with the same frequency and their companion modes (modes with rotational symmetry) and satisfies the boundary and continuity conditions of the shell is derived. The shell is modeled using the Donnell nonlinear shallow shell theory and the discretized equations of motion are obtained by applying the Galerkin method. Solving numerically the governing equations of motion, a detailed parametric analysis is conducted to clarify the influence of the internal resonances on the bifurcations, stability boundaries and nonlinear vibration modes of the structure.

References listed at the end of the paper:

ABSTRACT: The buckling phenomenon of prismatic column is experimentally investigated in this work, being major structural design concern. A number of tests were performed on aluminum made prismatic columns with slenderness index \( \lambda_{ef} \) remaining within range of 15 to 460 submitted to programs of multiple in time compressive loads – force and displacement controlled. The experimental evidence obtained here for stocky and slender columns confirm already well known information that column failure results from structural material plastic flow deformation or lateral buckling, respectively. A new, interesting observation has been made for intermediate slenderness columns that “drop” of buckling load takes place (reaching in some cases over 20% of early critical force value) after the very initiation of elasto-plastic buckling process. The observation is in contradiction to adopted in elasto-plastic buckling models assumption of constant (Engesser model) or growing (Shanley model) buckling load during buckling process. The obtained experimental evidence indicates that mysterious scatter in buckling loads for apparently identical columns with intermediate slenderness index can be attributed to minute residual stresses, which easily and in hardly controlled manner can be introduced during industrial production processes.

References listed at the end of the paper:

ABSTRACT: The buckling and post-buckling behaviour of prismatic aluminium columns from stocky to very slender shapes is investigated. The unconventional, in terms of buckling tests, displacement control of compressive load and a series of loadings provided an enhanced insight into the buckling process. A phenomenon of buckling load drop has been detected in columns of intermediate slenderness, reaching over 20% of the load early critical value. This newly observed occurrence resembles finite disturbance instability, which until recently was commonly believed to only appear in cases of thin walled cylindrical shells, but not columns. The observation is in contradiction to predicted results from the elasto-plastic buckling models of Engesser or Shanley, with constant or growing values of load during the post-buckling process. Further tests on columns of intermediate slenderness, with strain gauges glued at node and anti-node locations of the buckled profiles, revealed that even minute buckling results in fields of highly non-symmetric residual microplastic strain. The results of the present study indicate that running column buckling tests under displacement control is worthy of being adopted as common practice. The envelope of column post-buckling states can be conveniently determined. This information will in turn allow for the quick and reliable estimation of the safety of a column, which has undergone accidental or deliberate damage in the form of limited buckling when under operational load.

“Simplified analytical model and numerical simulations of finite-disturbance buckling of columns”,

ABSTRACT: Phenomenon of finite-disturbance buckling (FDB) is commonly attributed to thin elastic cylindrical and spherical shells and it has been rarely associated with columns. Ziolkowski and Imielowski’s, Experimental Mechanics 51(8), (2011) 1335–1345, recent experimental study, revealing appearance of FDB in aluminum columns with slenderness remaining within specific range only, raises questions about its physical sources and mechanism. The main objective of the presented work is to provide a theoretical explanation and quantitative evaluation on the phenomenon of finite-disturbance buckling of columns undergoing elasto-plastic deformation and expressing itself in the form of critical load drop. Elucidation of the issue may have some implications to the hitherto design procedures. The paper presents a coherent analytical model of the phenomenon supported by comprehensive finite element results, compared with experimental data.

References listed at the end of the paper:

ABSTRACT: The first scientific direction, “Buckling analysis of thin-walled members”, represents the
dominant part of the candidate’s research activity, it started with the scientific work developed during the
candidate’s PhD programme entitled “Stability aspects for metallic structures”, supervisor: prof. Cornel BIA,
and since then it has significantly evolved by new theoretical formulations in the field of thin-walled structures.
In this area, the candidate’s work is related to the Generalised Beam Theory (GBT), a specialised theory for
the analysis of thin-walled members, which is thoroughly presented in this thesis. The candidate extended GBT for
special cases of thin-walled members and analysis types, and his personal contributions of theoretical nature,
published in ISI and conference papers, can be summarised as follows:

- GBT formulation to analyse the behaviour of thin-walled members with variable cross-section. This
  formulation added new equations to GBT in order to handle tapered thin-walled members with small
  tapering slopes.
- GBT formulation to analyse the buckling behaviour of isotropic conical shells. GBT was already developed
  for cylindrical shells and tubes and through the candidate’s work, that formulation was extended for
  conical shells, yielding very promising results even for large values of the tapering slope.
- Buckling mode decomposition from Finite Element Analysis (FEA) of thin-walled members. The candidate
  proposed a method capable to quantify the modal participation of the pure deformation modes (of
  Global, Distortional and Local nature) in a general buckling mode. Even if similar methods were very
  recently reported by other researches, the method developed by the candidate is, at present time, the
  fastest and the most stable, due to a special algorithm based on the orthogonality features of the pure
  deformation modes.

The second scientific direction entitled “Vibration analysis of civil engineering structures” contains theoretical
and also experimental work. The theoretical work started under the topic “Vibration mode decomposition from
FEA of thin-walled members” and is mainly concentrated on the applicability of the modal decomposition
method (brieﬂy described above, at point c.) to the modal shapes derived from FEA, associated with the natural
frequencies of thin-walled members. The topics of the experimental work are (i) Experimental modal analysis,
and (ii) Tension estimation of cables based on vibration analysis. The candidate was recently (2011) nominated
as coordinator of the laboratory “Actions in Buildings and Structures”, Department of Structural Mechanics,
Faculty of Civil Engineering, Technical University of Cluj-Napoca. The laboratory contains Bruel&Kjaer and
PCB Piezotronics equipment and dedicated software suited to perform experimental vibration analyses. At
present time, under the candidate supervision, successful experimental modal analyses were performed on real-
world structures (beam and suspension bridges, metallic structures, tall concrete buildings, hollow-core slabs
etc.) and also on small elements inside laboratory. The candidate conducted many vibrations measurements and
analyses in time/frequency domain for bridges and other civil engineering structures (acceleration, velocity,
displacement, level of vibrations) with the purpose of: optimisation of structure’s dynamic characteristics (mass,
stiffness, damping), risk assessment of having the resonance phenomenon, prediction of dynamic behaviour,
evaluating the damping for inclusion in FE models, correlation of FE models with real structures, damage
detection and assessment, long term building monitoring, experimental assessment of traffic or other human
activities induced vibrations.

The tension estimation of cables by means of vibration response is another recent scientiﬁc area in which the
candidate obtained very promising results. The vibration method uses the experimental modal analysis to
extract the natural frequencies of the cable and next, the tension force is determined by using appropriate
analytical closed-form or numerical algorithm-form relationship between natural frequencies and the cable
tension. The cable response is mainly affected by its ﬂexural stiffness, sag-extensibility and the rotational
stiffness of the end-supports. Until present time, the candidate considered hinged supports for his experiments,
and the “sag” effect was neglected, but all the inﬂuencing terms were analysed in numerical studies.

The main achievements and results are presented in detail in Chapter (b-i): Scientiﬁc, professional and
academic achievements.
In what concerns the future research and development plans of the candidate, related to the fields of research presented above, the following research topics will continue or will be developed:

**Analysis of thin-walled members:**
- buckling/vibration analysis of tapered thin-walled members with arbitrary cross-sectional variation
- buckling/vibration analysis of conical shells based on GBT
- improving the modal decomposition method
- buckling/vibration mode decomposition for tapered thin-walled members, cylindrical and conical shells
- buckling/vibration mode decomposition for thin-walled members with arbitrary holes
- the effect of imperfections in non-linear analysis of thin-walled members

**Experimental vibration analyses:**
- perform new experimental modal analyses on real complex structures such as civil and industrial constructions and also on small structures and scale models inside laboratory
- tension estimation of cables by means of vibration response taking into consideration the “sag” effect and the real rotational stiffness of the end-supports

A short description of each topic has been done in Chapter (b-ii): Scientific, professional and academic future development plans.

Mihai Nedelcu (Faculty of Civil Engineering, Technical University of Cluj-Napoca, Str. C. Daicoviciu nr. 15, 400020 Cluj-Napoca, Romania), “GBT formulation to analyse the behaviour of thin-walled members with variable cross-section”, Thin-Walled Structures, Vol. 48, No. 8, August 2010, pp. 629-638, doi:10.1016/j.tws.2010.03.001

ABSTRACT: The generalised beam theory (GBT) provides a general solution for the linear/non-linear analysis of prismatic thin-walled structures, using bar elements capable of describing the cross-section rigid-body motions and distortions. Nowadays GBT is fully developed for thin-walled members having a large variety of constant cross-sections. This paper provides the extension of GBT for the special case of thin-walled members with variable open cross-section and the limits of its applicability. This offers a new analysis method for structures as box shaped bridges, beams, pylons of variable cross-section, conical shell towers, hyperbolic towers, etc. Regarding the 2nd order analysis, the effect of pre-buckling shear stresses is neglected.

ABSTRACT: The paper presents the formulation and illustrates the application of a second order Generalized Beam Theory (GBT) developed to analyze the stability behavior of thin-walled members displaying arbitrary orthotropy. After reviewing and physically interpreting the 2nd order GBT equations, a brief description of the main steps involved in performing a member GBT linear stability analysis is presented. Next, the paper addresses the issue of whether the critical stress value obtained from a member linear stability analysis corresponds to a “true bifurcation” or simply provides an “asymptotic limit load” and, in particular, a systematic procedure to detect true bifurcations is proposed. Finally, the application and capabilities of the 2nd order GBT are illustrated, by means of an investigation of the local and global buckling behavior of lipped channel columns and beams exhibiting asymmetric orthotropy.

ABSTRACT: A geometrically nonlinear Generalized Beam Theory (GBT) is formulated and its application leads to a system of equilibrium equations which are valid in the large deformation range but still retain and take advantage of the unique GBT mode decomposition feature. The proposed GBT formulation, for the elastic post-buckling analysis of isotropic thin-walled members, is able to handle various types of loading and arbitrary initial geometrical imperfections and, in particular, it can be used to perform "exact" or "approximate" (i.e., including only a few deformation modes) analyses. Concerning the solution of the system of GBT nonlinear equilibrium equations, the finite element method (FEM) constitutes the most efficient and versatile numerical technique and, thus, a beam FE formulation is reported in some detail and then employed to obtain numerical results, which validate and illustrate the application and capabilities of the theory.
This paper provides an overview of the Generalised Beam Theory (GBT) fundamentals and
its Applications, edited by M. Pandey, Wei-Chau Xie and Lei Xu, Springer, 2006, pp 187-204
ABSTRACT: This paper provides an overview of the Generalised Beam Theory (GBT) fundamentals and
reports on the novel formulations and applications recently developed at the TU Lisbon: the use of conventional
GBT to derive analytical distortional buckling formulae and extensions to cover (i) the buckling behaviour of
members with (i) branched, closed and closed/branched cross-sections and (ii) made of orthotropic and elastic-
plastic materials, and (ii) the vibration and post-buckling behaviours of elastic isotropic/orthotropic members. In

“Gbt-Based Analysis and Design of Thin-Walled Metal and Frp Members: Recent Developments”, Proc. Int. Workshop Recent Advances and Future Trends in Thin-Walled Structures Technology (Loughborough, 25/6), 2004

ABSTRACT: This paper provides an overview of the Generalised Beam Theory (GBT) applications and formulations recently developed at the TU Lisbon. The conventional GBT is (i) applied to derive analytical distortional buckling formulae and (ii) extended to cover (ii1) orthotropic and elastic-plastic materials, (ii2) closed and branched cross-sections and (ii3) vibration and post-buckling analyses. In order to give an idea about the potential of the new GBT formulations, a few numerical results are presented and briefly discussed.

SUMMARY: Most cold-formed steel members display slender thin-walled open cross-sections, a feature making them highly susceptible to local buckling phenomena, characterised by the sole occurrence of cross-section (in-plane) deformations and classified into two major categories: (i) local-plate buckling and (ii) distortional buckling. The former concerns flexural displacements alone and the latter involves flexural and membrane displacements, including fold-line motions leading to cross-section distortions. Figures 99.1(a) and 99.1(b) show the deformed configurations of rack-section column segments experiencing local-plate and distortional buckling, respectively. Moreover, whenever cold-formed steel members display cross-section geometries and length values leading to similar local and/or global (flexural-torsional or flexural) critical buckling stresses, their structural behaviour is affected by mode interaction effects, namely coupling between (i)
local-plate and distortional or (ii) local and global buckling modes (the cross-section geometry determines the nature of the local mode). In the presence of relevant mode coupling and/or spread of plasticity effects, the "exact" structural behaviour of thin-walled steel members can only be determined by employing sophisticated numerical methods, such as the FEM, which require a computer power only routinely available in (well equipped) research institutions. Although this situation is rapidly changing, as attested by the number of commercial computer codes which are now readily available to perform complex geometrically and physically non linear structural analyses, it was only recently that it became feasible to use FEM analyses to investigate local buckling effects in slender thin-walled members. They will be very useful to validate and/or calibrate easy-to-use design methodologies, thus paving the way to a progressive replacement of several experimental tests by much more convenient computer simulations. Moreover, the above design methodologies are only rational (physically based) and efficient if the member local-plate and/or distortional post-buckling behaviour are accurately known. This paper presents, discusses and illustrates the application and efficiency of an unified approach to the use of FEM analyses to investigate the local buckling, post-buckling and mode interaction behaviour of cold-formed steel thin-walled members, both in the elastic and elastic-plastic ranges. Initially, a number of relevant modelling and numerical implementation issues are briefly addressed, namely related to (i) the finite element and mesh discretisation choice, (ii) the incorporation of the initial geometrical imperfections, (iii) the modelling of the local boundary conditions or (iv) the numerical solution techniques. Next, in order to assess how the FEM approach is able to handle the aforementioned problems, several aspects dealing with the non linear structural behaviour of rack section members are investigated. At this point, one should mention that all the numerical results displayed are obtained by means of analyses performed using the commercial code ABAQUS. Moreover, in order to validate such FEM results, some of them are compared with values available in the literature, most of which have been obtained by means of finite strip analyses. The different types of (non linear) analyses dealt with are:

(i) Elastic buckling (linear stability) analyses, involving the solution of standard eigenvalue problems and yielding critical stress values and buckling mode configurations. Attention is paid to the influence of the applied stress distribution and local support conditions.

(ii) Elastic and elastic-plastic local post-buckling analyses, concerning members which bifurcate in either the local-plate or distortional buckling modes. Such analyses account for the influence of initial geometrical imperfection, can only be performed by resorting to incremental-iterative numerical techniques and lead to the determination of non linear (post-buckling) equilibrium paths, which relate the evolutions of the applied stress value and the displacement component better suited to describe the member deformed configuration.

(iii) Elastic and elastic-plastic (local) mode interaction analyses, concerning the behaviour of members with similar local-plate and distortional buckling stress values. Such analyses also yield non linear equilibrium paths and particular attention is paid to identifying the configuration of the (elastic) coupled buckling mode and the nature of the elastic-plastic deformed configuration.

ABSTRACT: A non-linear elastic Generalised Beam Theory (GBT) is formulated and used to investigate the
buckling behaviour of aluminium and stainless steel thin-walled columns. The modifications that must be incorporated in the conventional GBT, in order to handle the material non-linearity, are addressed and particular attention is paid to the need to define the stability problem in terms of instantaneous elastic moduli. After validating the proposed GBT, by means of its application to compressed rectangular plates, the unique features and capabilities of the theory are illustrated through the presentation and discussion of results concerning C-section and RHS columns. Stress–strain laws of the Ramberg–Osgood type are used to model the uniaxial behaviour and both J2-flow and J2-deformation plasticity theories are implemented.

Pedro Borges Dinis and Dinar Camotim (Civil Engineering Department, ICIST/IST, Technical University of Lisbon, Av. Rovisco Pais, 1049-001, Lisbon, Portugal), “Local-plate and distortional post-buckling behavior of cold-formed steel columns: Elastic and elastic-plastic FEM analysis”, (publisher and date not given in the pdf file; Proceedings of SSRC Annual Stability Conference, 2004?)

ABSTRACT: Following a brief discussion of a few relevant aspects dealing with the finite element modeling of the geometrically and materially non-linear behavior of thin-walled members, the paper presents an investigation on the elastic and elastic-plastic local-plate and distortional post-buckling behavior of rack-section (mostly) and lipped channel cold-formed steel columns. The FEM results displayed and discussed, obtained using the code ABAQUS and discretizing the columns with 4-node shell elements, consist of (i) post-buckling equilibrium paths, (ii) diagrams showing the evolution, along those paths, of the normal stresses acting on the most deformed cross-section and (iii) the column collapse mechanisms. All the columns analyzed contain critical-mode geometrical imperfections with small amplitudes and the issues addressed include the influence of the column (i) yield-to-critical stress ratio and (ii) support conditions (end section warping and rotation restraints). For validation purposes, some of the FEM (elastic) results presented are compared with values reported by other authors and obtained by means of finite strip analyses.

ABSTRACT: A general variational formulation to analyze the elastic lateral–torsional buckling (LTB) behavior of singly symmetric thin-walled tapered beams is presented, numerically implemented, validated and illustrated. It (1) begins with a precise geometrical definition of a tapered beam; (2) extends the kinematical assumptions traditionally adopted to study the LTB of prismatic beams; (3) includes a careful derivation of the beam total potential energy; and (4) employs Trefftz’s criterion to ensure the beam adjacent equilibrium. In order to validate and illustrate the application and capabilities of the proposed formulation, several numerical results are presented, discussed and, when possible, also compared with values reported by other authors. These results (1) are obtained by means of the Rayleigh–Ritz method, using trigonometric functions to approximate the beam critical buckling mode, and (2) concern the critical moments of doubly and singly symmetric web-tapered I-section simply supported beams and cantilevers acted by point loads. In particular, one shows that modeling a tapered beam as an assembly of prismatic beam segments is conceptually inconsistent and may lead to rather inaccurate (safe or unsafe) results. Finally, it is worth mentioning that the paper includes a state-of-the-art review concerning one-dimensional analytical formulations for the LTB behavior of tapered beams.

Pedro B. Dinis and Dinar Camotim, “On the Use of Shell Finite Element Analysis to Assess the Local Buckling and Post-Buckling Behaviour of Cold-Formed Steel Thin-Walled Members”, III European Conference on Computational Mechanics, p. 689, 2006, DOI: 10.1007/1-4020-5370-3_689

ABSTRACT: This paper deals with the use of shell finite element analyses to assess the (i) elastic bifurcation and (ii) elastic and elastic-plastic local-plate and distortional post-buckling behaviours of cold-formed steel thin-walled members (mostly columns, i.e., uniformly compressed members) all the geometrically and physically non-linear analyses are performed using the code ABAQUS and adopting 4-node isoparametric shell elements to discretise the members. First, one addresses several relevant issues concerning (i) the member discretisation (shell element type and mesh refinement), (ii) the simulation of the member end support conditions (a key aspect in numerical structural analysis), (iii) the modelling of the applied loading and material behaviour, (iv) the incorporation of member initial geometrical imperfections and residual stresses, (v) the assessment of buckling mode interaction effects and (vi) the methods employed to solve either the eigenvalue problem or the system of non-linear algebraic equilibrium equations. Then, in order to illustrate the concepts and issues mentioned above and, at the same time, illustrate the power and versatility of the shell finite element analyses, one presents and thoroughly discusses a fairly large number of numerical results concerning the buckling and post-buckling behaviour of lipped channel (mostly), Zed-section and Rack-section cold-formed steel members some of the post-buckling analyses include interaction effects between local-plate and distortional buckling modes. These results consist of (i) buckling curves providing the variation of the critical stress with the member length (see Fig. 1(a)), (ii) elastic and elastic-plastic non-linear (post-buckling) equilibrium paths (see Figs. 1(b)-(c)), (iii) figures providing the evolution, along those equilibrium paths, of the elastic and elastic-plastic member deformed configurations, and (iv) figures showing the spread of plasticity along the members up to failure (see Fig. 1(d)) and conveying relevant information about the nature of their collapse mechanisms.

ABSTRACT: This paper presents the derivation, validates and illustrates the application of a Generalised Beam Theory (GBT) formulation developed to analyse the buckling behaviour of thin-walled members with arbitrarily ‘branched’ open cross-sections. Following a brief overview of the conventional GBT, one addresses in great detail the modifications that must be incorporated into its cross-section analysis procedure, in order to be able to handle the ‘branching’ points — they concern mostly issues related to (i) the choice of the appropriate ‘elementary warping functions’ and (ii) the determination of the ‘initial flexural shape functions’. The derived formulation is then employed to investigate the local-plate, distortional and global buckling behaviour of (i) simply supported and fixed asymmetric E-section columns and (ii) simply supported I-section beams with unequal stiffened flanges. For validation purposes, several GBT-based results are compared with ‘exact’ values, obtained by means of finite strip or shell finite element analyses.

“Thin-walled member plastic bifurcation analysis using generalised beam theory”, Advances in Engineering
ABSTRACT: This paper presents the formulation and illustrates the application of a non-linear Generalised Beam Theory (GBT), which makes it possible to calculate bifurcation load factors of thin-walled members made of non-linear elastic–plastic materials and subjected to general loading conditions. This formulation is an extension of the non-linear GBT recently derived by the authors, which was valid for uniformly compressed members only. In order to illustrate the application of the proposed non-linear GBT, a beam finite element is formulated and some numerical results are presented and discussed. These results concern rectangular plates and thin-walled hat-section beams. The material instantaneous elastic moduli are determined on the basis of both the well known J2-flow and J2-deformation small strain plasticity theories.

ABSTRACT: This paper reports on the use of a recently developed Generalised Beam Theory (GBT) formulation, and corresponding finite element implementation, to analyse the local and global buckling behaviour of thin-walled members with arbitrary loading and support conditions — this formulation takes into account longitudinal normal stress gradients and the ensuing pre-buckling shear stresses. After presenting an overview of the main concepts and procedures involved in the performance of a GBT-based (beam finite element) member buckling analysis, one addresses in detail the incorporation of non-standard support conditions, such as (i) full or partial localised displacement or rotation restraints, (ii) rigid or elastic intermediate supports or (iii) end supports corresponding to angle connections. In order to illustrate the application and capabilities of the proposed GBT-based approach, one presents and discusses numerical results concerning cold-formed steel (i) lipped channel beams and (ii) lipped I-section beams and columns with various “non-standard” support conditions — while the beams are acted by uniformly distributed or mid-span point loads, applied at the shear centre axis, the columns are subjected to uniform compression. In particular, it is possible to assess the influence of the different support conditions on the beam and column buckling behaviour (critical buckling loads and mode shapes). For validation purposes, most GBT-based results are compared with values yielded by shell finite element analyses carried out in the code ANSYS.

ABSTRACT: This paper presents an investigation on the buckling behaviour of single-walled carbon nanotubes under various loading conditions (compression, bending and torsion) and unveils several aspects concerning the dependence of critical measures (axial strain, bending curvature and twisting angle) on the nanotube length. The buckling results are obtained by means of an atomistic-scale generalized beam theory (GBT) that incorporates local deformation of the nanotube cross-section by means of independent and orthogonal deformation modes. Moreover, some estimates are also obtained by means of non-linear shell finite element analyses using Abaqus code. After classifying the buckling modes of thin-walled tubes (global, local and distortional), the paper addresses the importance of the two-wave distortional mode (flattening or ovalization mode) in their structural
behaviour. Then, the well known expression to determine the critical strain of compressed nanotubes, which is based on Donnell theory for shallow shells, is shown to be inadequate for moderately long tubes due to warping displacements appearing in the distortional buckling modes. After that, an in-depth study on the buckling behaviour of nanotubes under compression, bending and torsion is presented. The variation of the critical kinematic measures (axial strain, bending curvature and twisting angle) with the tube length is thoroughly investigated. Concerning this dependence, some uncertainties that exist in the specific literature are meticulously explained, a few useful expressions to determine critical measures of nanotubes are proposed and the results are compared with available data collected from several published works (most of them, obtained from molecular dynamics simulations).

ABSTRACT: This paper presents some remarks on the use of shell models to analyse the stability behaviour of single-walled NTs under compression. It is shown that there are three different categories of critical buckling modes of NTs under compression: while the axi-symmetric mode is critical for very short NTs, the flexural buckling mode is critical for long tubes. While the former exhibits cross-section contour deformation but no warping deformation, the later is characterised by the opposite situation (warping deformation but no contour deformation). Additionally, a third category exists (distortional buckling): it takes place for NTs with moderate length, it is related to the transitional buckling behaviour between the shell (axi-symmetric mode) and the rod (flexural mode) and it is characterised by both cross-section contour deformation and warping deformation. Concerning the distortional buckling behaviour of moderately long NTs, it is also shown that the well known Donnell-type theory of shells leads to erroneous results.

ABSTRACT: This paper presents the development and illustrates the application of semi-analytical solutions for plastic buckling (bifurcation) problems involving perfectly straight and uniformly compressed thin-walled metal members. These solutions are derived on the basis of a non-linear Generalised Beam Theory (GBT) formulation, recently proposed by two of the authors, that resorts to a linearised buckling analysis that adopts Hill’s hypo-elastic comparison solid method to obtain the plastic bifurcation loads and associated buckling mode shapes. Moreover, both J2 small-strain incremental and deformation plasticity theories are employed. Several numerical illustrative examples are presented and discussed throughout the paper and closed-form analytical formulae are also derived. The accuracy of the GBT-based semi-analytical plastic bifurcation predictions is assessed through the comparison with (i) available theoretical solutions and/or (ii) results yielded by a special shell finite element model developed by one of the authors.

ABSTRACT: This paper presents the derivation, validation and illustration of a generalised beam theory (GBT) formulation intended to perform first-order and buckling analyses of arbitrary thin-walled members, namely members with cross-sections that combine closed cells with open branches. Following a brief overview of the so-called “conventional GBT formulation”, as well as of the available extensions for different specific cross-section types, the paper addresses in detail the modifications that must be incorporated into the GBT cross-section analysis procedure to handle the simultaneous presence of closed cells and open branches. The proposed formulation is then employed to analyse the first-order and buckling behaviours of thin-walled members (mostly beams) with complex cross-sections. For validation purposes, the GBT-based numerical results are compared with values yielded by shell finite element and finite strip analyses.

ABSTRACT: In this paper, the dynamic responses of the open cross section columns with intermediate stiffeners subjected to in-plane pulse loading of a rectangular shape were concerned. Columns made of isotropic material were assumed to be simply supported at both loaded ends. The problem of the interactive
buckling was solved by finite element method (FEM) – ANSYS 9. The critical dynamic load factors DLF has been determined using the most popular Budiansky–Hutchinson’s criterion and they have been verified with author’s versions of the phase portraits criterion.

ABSTRACT: The structural components of an aircraft consist mainly of thin plates stiffened by arrangements of ribs and stringers. Thin walled structure is a structure whose thickness is small compared to its other dimensions but which is capable of resisting bending in addition to membrane forces. Which is basic part of an aircraft structure, Thin plates (or thin sections or thin walled structures) under relatively small compressive loads are prone to buckle and so must be stiffened to prevent this. The determination of buckling loads for thin plates in isolation is relatively straightforward but when stiffened by ribs and stringers, the problem becomes complex and frequently relies on an empirical solution. The buckling of the thin plates is a phenomenon which could lead to destabilizing and failure of the aircraft structure; in this paper it is considered C cross section with variable geometry and length. The critical buckling loads have been studied for several combinations of the geometry parameters of the beam with the help of ANSYS and drawn the result plots

ABSTRACT: This paper presents the formulation of a Generalised Beam Theory (GBT) developed to analyse the structural behaviour of composite thin-walled members made of laminated plates and displaying arbitrary orthotropy. The main concepts and procedures involved in the available isotropic first-order GBT are revisited and adapted/modified to account for the specific aspects related to the member orthotropy. In particular, the orthotropic GBT fundamental equilibrium equations and corresponding boundary conditions are derived and their terms are physically interpreted, i.e., associated with the member mechanical properties. Moreover, different laminated plate material behaviours are dealt with and their influence on the GBT equations is...
investigated. Finally, in order to clarify the concepts involved in the formulated GBT and illustrate its application and capabilities, a thin-walled orthotropic beam is analysed and the results obtained are thoroughly discussed.

ABSTRACT: This paper presents the derivation and illustrates the application of a non-linear orthotropic GBT formulation, which is intended to perform post-buckling analyses of laminated plate FRP open-section thin-walled members. Different types of loading and end support conditions can be dealt with and the theory can handle the presence of arbitrary initial geometrical imperfections. One is able to determine “exact” and “approximate” (only a few modes) post-buckling equilibrium paths and the evolution, along those paths, of (i) displacements and stresses and, using the GBT unique mode decomposition feature, also of (ii) the deformation mode participation in the member deformed configuration. To validate and illustrate the application and capabilities of the formulated GBT, numerical results, concerning the post-buckling behaviour of laminated plate FRP lipped channel members exhibiting different orthotropic behaviours, are presented and discussed. Some of them are compared with values obtained from finite element analyses, performed in the code ABAQUS and adopting shell element meshes to discretise the member.

ABSTRACT: This paper provides an overview of the Generalised Beam Theory (GBT) fundamentals and reports on the novel formulations and applications recently developed at the TU Lisbon: the use of conventional GBT to derive analytical distortional buckling formulae and extensions to cover (i) the buckling behaviour of members with (i1) branched, closed and closed/branched cross-sections and (i2) made of orthotropic and elastic-plastic materials, and (ii) the vibration and post-buckling behaviours of elastic isotropic/orthotropic members. In order to illustrate the usefulness and potential of the new GBT formulations, a few numerical results are presented and briefly discussed. Finally, some (near) future developments are briefly mentioned.

ABSTRACT: A formulation of generalised beam theory (GBT) developed to analyse the elastic buckling behaviour of circular hollow section (CHS) members (cylinders and tubes) is presented in this paper. The main concepts involved in the available GBT are adapted to account for the specific aspects related to cross-section geometry. Taking into consideration the kinematic relations used in the theory of thin shells, the variation of the strain energy is evaluated and the terms are physically interpreted, i.e., they are associated with the geometric properties of the CHS. Besides the set of shell-type deformation modes, the formulation also includes axisymmetric and torsion deformation modes. In order to illustrate the application and capabilities of the formulated GBT, the local and global buckling behaviour of CHS members subjected to (i) compression (columns), (ii) bending (beams), (iii) compression and bending (beam-columns) and (iv) torsion (shafts), is analysed. Moreover, the GBT results are compared with estimates obtained by means of shell finite element analyses and are thoroughly discussed.

ABSTRACT: This paper presents several issues that characterize the buckling behaviour of elliptical cylindrical shells and tubes under compression. First, a formulation of Generalised Beam Theory (GBT) developed to analyse the elastic buckling behaviour of non-circular hollow section (NCHS) members is presented. Since the radius varies along the cross-section mid-line, the main concepts involved in the determination of the deformation modes are adapted to account for the specific aspects related to elliptical cross-section geometry. After that, two independent sets of fully orthogonal deformation modes are determined: (i) local-shell modes satisfying the null membrane shear strain but exhibiting transverse extension and (ii) shell-type modes satisfying both assumptions of null membrane shear strain and null transverse extension. In order to illustrate the application, capabilities and versatility of the formulation, the local and global buckling behaviour of elliptical hollow section (EHS) members subjected to compression is analysed. In particular, in-depth studies concerning the influence of member length on the variation of the critical load and corresponding buckling mode shape are presented. Moreover, the GBT results are compared with estimates obtained by means of shell finite element analyses and are thoroughly discussed. The results show that short to intermediate length cylinders buckle mostly in local-shell modes, exhibiting only transverse extension, while intermediate length to long cylinders buckle mostly in shell-type modes (distortional and global modes), which are characterized by transverse bending and primary warping displacements. It is also shown that the present formulation is very efficient from the computational point of view since only three deformation modes (one local-shell, one distortional and one global) are required to evaluate the buckling behaviour of EHS cylinders for a wide range of lengths.

ABSTRACT: This paper presents a formulation of Generalised Beam Theory (GBT) developed to analyse the influence of non-classical effects on the structural behaviour of FRP composite circular hollow section members. Unlike other existing beam theories, the present GBT formulation incorporates non-classical effects.
comprising (i) elastic material couplings, (ii) deformation of cross-section contour, (iii) warping deformation and (iv) shear deformation. With the purpose of solving the GBT system of differential equilibrium equations, a finite element formulation is briefly presented. In order to clarify the concepts involved in the formulated GBT and illustrate its application and capabilities, the linear (1st order) behaviour of two composite members exhibiting elastic couplings is analysed and the results obtained are thoroughly discussed and compared with estimates available in the literature. It is shown that accurate solutions can only be achieved if these non-classical effects are incorporated in the analysis.

ABSTRACT: This paper presents a state-of-the-art report on the use of Generalised Beam Theory (GBT) to assess the buckling behaviour of plane and space thin-walled steel frames. After a very brief overview of the main concepts and procedures involved in performing a GBT buckling analysis, one addresses the development and numerical implementation of a GBT-based beam finite element formulation that is able (i) to unveil local, distortional and global buckling modes, (ii) to handle arbitrary loadings (namely those causing non-uniform member internal force and moment diagrams) and (iii) to incorporate the presence of several frame joint configurations and arbitrary end and/or intermediate support conditions (including those associated with the modelling of bracing systems). In particular, one describes the procedures employed to establish the frame linear and geometric stiffness matrices – special attention is paid to the constraint conditions adopted to ensure the local displacement compatibility at the frame joints. The paper closes with the presentation and discussion of a number of numerical results that make it possible to illustrate the application and show the potential of the GBT-based approach to perform frame buckling analyses – they concern both plane and space frames. In order to validate and assess the numerical efficiency and accuracy of the GBT analyses and results (critical buckling loads and mode shapes), the frames are also rigorously analysed in the commercial code Ansys – both the members and joints are discretised by means of fine shell finite element meshes.

ABSTRACT: Following the Eurocode 3 philosophy, it is expected that the design of elliptical hollow section (EHS) tubes will be based on the slenderness concept, which requires the calculation of the EHS critical stress. The critical stress of an EHS tube under compression may be associated with local buckling, distortional buckling or flexural buckling. The complexity in deriving analytical expressions for distortional critical stress from classical shell theories, led us to apply Artificial Neural Networks (ANN). This paper presents closed-form expressions to calculate the distortional critical stress and half-wave length of EHS tubes under compression, using ANN. Almost 400 EHS geometries are used and based solely on three parameters: the outer EHS dimensions (A and B) and its thickness (t). Two architectures are shown to be successful. They are tested for several statistical parameters and proven to be very well behaved. Finally, some simple illustrative examples are shown and final remarks are drawn concerning the accuracy of the closed-formed formulas.

“Examination Of Cylindrical Shell Theories For Buckling Of Carbon Nanotubes”, International Journal of Structural Stability and Dynamics”, Vol. 11, No. 6, December 2011, p. 1035,
DOI: 10.1142/S0219455411004464
ABSTRACT: This paper examines the validity and accuracy of cylindrical shell theories in predicting the critical buckling strains of axially loaded single-walled carbon nanotubes (CNTs). The shell theories considered are the Donnell thin shell theory (DST), the Sanders thin shell theory (SST), and the first-order shear deformation (thick) shell theory (FSDST). Molecular dynamic (MD) simulation solutions for armchair and zigzag CNTs with clamped ends were used as reference results to assess the shell models. The MD simulations were carried out at room temperature to eliminate the thermal effect on the buckling behavior. By adopting Young’s modulus of 5.5 TPa, Poisson’s ratio of 0.19, and tube thickness of 0.066 nm, it was found that DST is not able to capture the length dependency of the critical buckling strains and thus it should not be used for buckling analysis of CNTs. On the other hand, SST and FSDST are able to predict the critical buckling strains of armchair and zigzag CNTs reasonably well for all aspect ratios, especially the results produced by the FSDST are found to be closer to the MD simulation results, because it allows for the effect of transverse shear deformation that becomes significant for CNTs with small aspect ratios. Thus, FSDST is recommended as a very suitable and convenient continuum mechanics model for buckling analysis of CNTs. The superior FSDST model is used to generate critical buckling strains of axially loaded single-walled CNT with different boundary conditions. These results should be useful for designers of nanodevices that make use of CNTs as axially loaded members. It is worth noting that for long and moderately long CNTs, the Timoshenko beam model may be used instead due to its simplicity.

M. O. Oyesanya (Department of Mathematics, University of Nigeria, Nsukka, Nigeria), “Secondary bifurcation
ABSTRACT: The primary and secondary bifurcation states of a simply supported cylindrical shell of finite length subjected to lateral or hydrostatic pressure is studied using formal perturbation procedures. The effect of arbitrary stress-free initial displacement (imperfections) on the buckling load is studied following standard procedures. It is shown that the buckling load of the imperfect structures depends asymptotically only on the classical buckling load and a measure of the imperfection and not on the secondary bifurcation load.

ABSTRACT: We consider non-linear bifurcation problems for elastic structures modeled by the operator equation $F[w;a]=0$ where... are Banach spaces and ... We focus attention on problems whose bifurcation equations are of the form…. which emanates from bifurcation problems for which the linearization of $F$ is Fredholm operators of index 0. Under the assumption of $F$ being odd we prove an important theorem of existence of secondary bifurcation. Under this same assumption we prove a symmetry condition for the reduced equations and consequently we got an existence result for secondary bifurcation. We also include a stability analysis of the bifurcating solutions.

ABSTRACT: The bifurcation of a toroidal shell segment with initial imperfection which are subjected to lateral or hydrostatic pressure is studied under the assumption that the initial imperfection are Gaussian random stress-free displacement whose mean and autocorrelation function are given. We use a perturbation scheme developed by Amazigo [Amazigo, J.C., 1971. Buckling of stochastically imperfect columns on nonlinear elastic foundation. Quart. Appl. Math. 403–491]. A simple approximate asymptotic expression is obtained for the bifurcation load for small magnitudes of the imperfection. The result is compared with results obtained earlier under secondary bifurcation analysis for the imperfections in the shape of the buckling mode and the results in the literature, which shows some significant differences as a result of inclusion of extra terms in the buckling equation.

ABSTRACT: The result of the study of dynamic response of an elastic circular plate to blast load is presented in this research work. Finite element method is used to derive the equation of motion for the circular plate element under the influence of exponential impulse forces. System stiffness and mass matrices were drive. The effects of transverse shear deformation and rotatory inertia were included. From the numerically simulated
results it is observed that the amplitude dies out quickly due to the effect of damping. The pulse duration is also one of the most important parameter because it gives serious influence to the vibration amplitude. It gives rise to the vibration amplitude on any small decrease on the pulse duration. It is also observed that the exponential blast loading brings faster rate of amplitude decay than those of triangular and sinusoidal blast loading.

ABSTRACT: Improved fabrication techniques and the availability of higher strength steels have encouraged greater use of thin-walled containment vessels in recent years. A major increase in computing capability to analyse these structures for buckling modes has also occurred and this paper considers two recently constructed steel water towers. In particular, the effect of door cut-outs on buckling capacity is examined. The analysis techniques used in the paper provide powerful tools for readily estimating buckling modes and assessing the effects of various stiffener arrangements. By far the most effective stiffening element in the stem of a water tower is a horizontal diaphragm which maintains a circular cross-section.

ABSTRACT: The paper deals with an analysis of the bifurcation and initial post-buckling behaviour of highly imperfection-sensitive large spherical shells, such as cargo tanks for ship transportation of liquefied natural gas and large spherical containment shells for nuclear power plants. The numerical analysis procedure has sufficient generality to treat shells of revolution with arbitrary curved generators and with arbitrary variation of the thickness. The shells can be subjected to non-axisymmetric time-varying loadings. The purpose of the paper is to present simple procedures for scantling selections in the initial design phase and to propose an analysis procedure for verification of the final design of optimized thin-walled spherical shells.

ABSTRACT: The buckling characteristics of some composite stiffened plates are determined in this paper using a finite strip approach. The finite strip formulation is able to predict the complex buckling modes associated with in-plane shear loading and the method of approach can allow for other loading configurations whose associated pre-buckling stresses are not so obviously realised. Two loading conditions have essentially been considered in the paper, that of in-plane shear and that of partial edge loads being reacted by shear. The strip displacement fields before and after buckling are represented by algebraic polynomials across the strip and trigonometric functions along the strip length. The inclusion of sufficient harmonics in the appropriate
displacement representations thus allows the distorted nodal lines of the shear buckling mode and the complex pre-buckled stresses associated with partial edge loads to be determined with relative ease.

ABSTRACT: In this paper a study is made of the buckling behaviour of some composite stiffened panel structures subjected to in-plane compression and shear load combinations. The finite strip method, a computer aided engineering analysis procedure, is employed to determine the buckling solutions. Since the prediction of structural performance is quickly and accurately determined through computer simulation, the analysis capabilities of the finite strip method promotes the examination of many design alternatives. The designer is encouraged and indeed readily aided to make the most efficient use of materials and thus the development of highly reliable structural components, which are able to operate at optimised performance levels, can be achieved. A basic strip formulation for composite material construction is presented which is able to predict the complex buckling modes associated with in-plane load combinations. The buckling displacement fields are represented by algebraic polynomials across the strip and trigonometric functions along the strip length. The inclusion of sufficient harmonics in the appropriate displacement representations provides the required flexibility of the strip formulation to accommodate the more elaborate buckling modes associated with the presence of in-plane shear loading. The results presented in the paper are those pertaining to the buckling capabilities of stiffened panels manufactured from high strength carbon-epoxy composite material. The results illustrate, graphically, the effect on buckling performance of changes in stiffener geometry. Interaction curves are presented in the paper which detail the limiting boundaries for critical load combinations of specific structural configurations.

ABSTRACT: The presence of in-plane shear loading in thin plates is destabilising in nature and will cause buckling at a certain critical intensity. As a result of the shear, the buckling mode will have a complex configuration and will be associated with distorted nodal lines. A finite strip formulation is presented which is able to predict this behaviour for practical structural geometries and due to the considerable flexibility of the strip any flat sided, thin-walled structural configuration can be modelled with relative ease. The structural configuration considered is that of the transversely stiffened shear web manufactured from long fibre composite material and whose stiffeners take the form of plain flat outstands attached to one side of the thin composite skin. Results are presented in the paper which show the effect on the buckling capacity of composite stiffened shear webs of varying the stiffener size and pitch and of particular interest, the effect of fibre orientation in the stiffeners is highlighted in some detail. It is shown that for a given structural weight, shear buckling performance can be enhanced through favourable orientation of the stiffener fibres.

J. Loughlan (Structures and Materials Technology Group, College of Aeronautics, Cranfield University, Cranfield MK43 0AL, UK), “The influence of bend–twist coupling on the shear buckling response of thin

ABSTRACT: The finite strip method of analysis has been used in this paper to examine the effect of bend–twist coupling on the shear buckling behaviour of laminated composite constructions. The distorted nodal lines of the shear buckling mode and its complex deformation state in general are readily accounted for in the analysis procedure through the multi-term nature of the finite strip buckling displacement field and the appropriate level of structural modelling. The degree of bend–twist coupling in the laminated composite plates is varied by changing the level of anisotropy in the plies and by altering the lay-up configuration of the plies in the laminated stack. Symmetric laminates of a balanced and unbalanced nature are given consideration. It is shown that, for a given degree of anisotropy in the plies of a laminate and for a given laminate thickness, the stacking sequence of the plies significantly alters the degree of bend–twist coupling. The shear buckling performance of composite plates having the same dimensions and being made from the same material are therefore shown in the paper to be quite different. The preclusion of the bend–twist coupling coefficients in the solution procedure of the finite strip method allows the shear buckling orthotropic solution to be determined. Comparisons between the coupled and orthotropic solutions are shown in the paper to be markedly different.

ABSTRACT: Restoration forces, associated with embedded activated pre-strained shape memory alloy wires, have successfully been employed to enhance the post-buckling behaviour of various laminated plate structures. An extensive experimental and numerical programme has been conducted, the results of which will be presented. The manufacturing methodology of the hybrid SMA/carbon/epoxy plates is outlined. Such specimens feature 0.4-mm diameter shape memory alloy wires located within tubing at desired locations. Numerical thermal analysis has been employed to predict the non-uniform temperature profile, attributed to shape memory alloy activation through resistive heating, within the laminates. Structural finite element analysis has been employed to determine the hybrid plates' adaptive response while under the influence of a uniaxial compressive load in excess of its critical buckling value. It is shown that, utilising the considerable control authority generated, even for a small actuator volume fraction, the out-of-plane displacement of the post-buckled laminates can be significantly reduced. Such displacement alleviation allows for load redistribution away from the specimens' unloaded edges. With the increase in use of composite materials within aerospace platforms, it is envisaged that the hybrid adaptive SMA/laminate configuration will extend the operational performance over conventional materials and structures, particularly when the structure is exposed to an elevated temperature.

ABSTRACT: Restoration forces, associated with embedded activated pre-strained shape memory alloy wires, have successfully been employed to enhance the post-buckling behaviour of a laminated panel structure. An extensive experimental and numerical programme has been conducted, of which, results will be presented. The manufacturing methodology of the hybrid SMA/carbon/epoxy panel is outlined. The panel specimen features 0.3 mm diameter shape memory alloy wires embedded and partially consolidated to the host matrix at desired
locations. Numerical thermal analysis has been employed to predict the non-uniform temperature profile, attributed to shape memory alloy activation through resistive heating, within the laminate. Structural finite element (FE) analysis has been employed to determine the hybrid panel's adaptive response while under the influence of the uniaxial compressive load in excess of its pseudo-critical buckling value. It is shown that, utilising the control authority generated from the small SMA actuator volume fraction employed, the out-of-plane displacement of the post-buckled laminated panel can be reduced. With the increase in use of composite materials within aerospace platforms, it is envisaged that the hybrid adaptive SMA/laminate configuration will extend the operational performance over conventional materials and structures, particularly when the structure is exposed to an elevated temperature.

ABSTRACT: The compressive stability of anti-symmetric angle-ply laminated plates with particular reference to the degrading influence of membrane–flexural coupling is reported in this paper. The degree of membrane–flexural coupling in the laminated composite plates is varied, essentially, by altering the ply-angle and the number of plies in the laminated stack for a given composite material system. The coupled compressive buckling solutions are determined in the paper using the finite strip method of analysis and the buckling displacement fields of the strip formulation are those which are able to provide zero in-plane normal movement at the edge boundaries of the laminated plates. Results are given for anti-symmetric angle-ply laminated plates subjected to uniaxial compression and these have been obtained from fully converged finite strip structural models. Validation of the finite strip formulation is indicated in the paper through comparisons with exact solutions where appropriate. Increasing the number of plies in the laminated system is seen to reduce the degree of coupling and the critical stress levels are noted to tend towards the plate orthotropic solutions. The ply-angle corresponding to the optimised buckling stress for any particular laminate is noted in the paper to be influenced by the support boundary conditions at the plates unloaded edges. For any particular laminate the minimum critical buckling stress and corresponding natural half-wavelength of the buckling mode are shown to be highly sensitive to ply-angle variation. Some post-buckling results are presented in the paper and these have been determined using the finite element method of analysis. The influence of membrane–flexural coupling is shown to be significant throughout the compressive post-buckling history of the laminated plates. The optimised ply-angle with regard to the critical compressive buckling stress of square simply supported anti-symmetric angle-ply laminates is shown to be less effective in the post-buckling range with regard to post-buckled compressional stiffness.

ABSTRACT: In this paper experimental tests are described and discussed which illustrate the feasibility of buckling control in composite structural elements using induced strain actuation in a smart technological manner. Compressive tests on simply supported square composite plates which utilise the shape memory effect for buckling control are shown to exhibit substantially reduced post-buckling deflections when under activated control in comparison to those experienced for the uncontrolled case. The alleviation of the post-buckling deflections is shown to result in reduced non-linear stress levels in the post-buckling range and thus it is intimated that the ultimate failure levels of the composite plates can be improved through the application of shape memory control. The influence of temperature, from ohmic heating of the actuated shape memory alloy wires, on the mechanical performance of the composite laminated plates is discussed and the analysis procedures for the determination of the resulting non-uniform stress profiles in the composite plates are duly outlined. It was found that temperature effects could be significant and that these in turn depended to a large extent on laminate lay-up configuration. Particular attention is paid in the paper to tests carried out to ascertain the characteristic behaviour of the Nickel–Titanium shape memory material employed for actuation purposes. The cyclic recovery force capabilities of the actuator wires utilised in the compressive plate tests is highlighted and a detailed account of the determination of the alloys characteristic transformation temperatures is given. The paper discusses, in some detail, the feasibility of the proposed smart structural concept and gives some thought to the implementation of smart advanced composite materials within the marketplace with particular reference to future aerospace applications.

ABSTRACT: The numerical simulation analyses were performed on the buckling and postbuckling behavior of laminated composite shells with embedded shape memory alloy (SMA) wires. These analyses using ABAQUS code were conducted to investigate the effect of embedded SMA wires on the characteristics of buckling and postbuckling caused by external and thermal loads. The nonlinear buckling analysis showed that the activation of eccentrically embedded SMA wires increased the critical buckling load when phase transformation of SMA wires occurred. The activated SMA wires embedded in the direction of buckling resulted in a sudden increase of the critical buckling load when both edges were simply supported. However, activated SMA wires embedded in the opposite direction of buckling, resulted in a sudden decrease of the buckling load. The thermal buckling analyses of the composite shells with embedded SMA wires showed that the critical buckling temperature increased and the thermal buckling deformation decreased by using the activation force of embedded SMA wire actuators.

ABSTRACT: An experimental study is presented of the dynamical behaviour of a cylindrical shell within a coaxial rigid cylindrical pipe, with flow in the annulus. The shell could be clamped at both ends or clamped at one end and free at the other. The frequencies of some of the principal modes of the shell were monitored with fibre-optic sensors as the flow velocity was incremented, and the signals were analyzed on a FFT Signal Analyzer, up to the point of loss of stability. It was found in these experiments that a clamped-clamped shell
loses stability by divergence (buckling) in its second or third circumferential mode, depending on the length/radius ratio and the internal pressure in the shell. The experimental observations are extensively compared with a previously developed theoretical model. The qualitative dynamical behaviour in general and the mode associated with instability are in good agreement with theory; the critical flow velocity for divergence, however, is substantially smaller than theoretically predicted, presumably as a result of imperfections. Clamped-free shells, on the other hand, lose stability by flutter, in these experiments in the third or fourth circumferential mode of the shell, depending on the annular-gap/radius ratio and the length/radius ratio.

ABSTRACT: The unstable region of a circular cylindrical aluminium shell subjected to internal leakage flow was investigated experimentally, changing the gap shape and leakage flow velocity. The changes in the natural frequency, damping ratio, and displacement were also investigated to clarify the type of instability that occurred and to obtain the vibration characteristics needed for predicting instability. Flutter-type instability was observed and for an unstable gap condition, the damping ratio decreased to zero, as is known to occur with flutter-type instability. Moreover, the natural frequency increased with the flow velocity. The change in the natural frequency was small and the damping ratio increased with the leakage flow velocity when the gap shape was stable. The repeatability of the flutter occurrence was good. Leakage flow through a straight gap did not cause instability, and the critical ratio of the size of the stepped annular gap for the unstable region was obtained.

ABSTRACT: The dynamic buckling of a finite damped imperfect circular cylindrical shell which is subjected to step-loading in the form of lateral or hydrostatic pressure is examined by means of a perturbation method. The imperfection is assumed to be small. An asymptotic expression for the dynamic buckling load is obtained in terms of the damping coefficient and the Fourier component of the imperfection in the shape of the classical buckling mode. A simple relation which is independent of the imperfection is then obtained between the static and dynamic buckling loads.

ABSTRACT: A circular cylindrical shell, periodically supported and subjected to step-loading in the form of lateral or hydrostatic pressure, is studied. Using the time-dependent von Kármán-Donnell equations, its imperfection sensitivity is examined and a simple asymptotic expression for the dynamic buckling load, valid for small imperfections, is obtained. There is a simple relation, independent of the imperfection, between the dynamic and static buckling loads.
ABSTRACT: In this paper, the axisymmetric dynamic behavior and snap-through buckling of thin elastic shallow spherical shells under harmonic excitation is investigated. Based on Marguerre kinematical assumptions, the governing partial differential equations of motion for a pre-loaded cap are presented in the form of a compatibility equation and a transverse motion equation. The continuous model is reduced to a finite degree of freedom system using the Galerkin method and a Fourier–Bessel approach. Results show that pre-loaded shells may exhibit co-existing stable equilibrium states and that with the application of sufficiently large dynamic loads the structure escapes from the well corresponding to pre-buckling configurations to another. This escape load may be much lower than the corresponding quasi-static buckling load. Indeed, complex resonances can occur until the system snaps-through, often signalling the loss of stability. As parameters are slowly varied, steady state instabilities may occur; these can include jumps to resonance, subharmonic period-doubling bifurcations, cascades to chaos, etc. Moreover a sudden pulse of excitation may lead to a transient failure of the system. In this paper, we examine how spherical caps under harmonic loading may be assessed in an engineering context, with a view to design against steady state instabilities as well as the various modes of transient failure. Steady state and transient stability boundaries are presented in which special attention is devoted to the determination of the critical load conditions. From this theoretical analysis, dynamic buckling criteria can be properly established which may constitute a consistent and rational basis for design of these shell structures under harmonic loading.

PARTIAL ABSTRACT: The problem is to determine the effect of axial compressive and tensile forces on the stability of a circular cylinder in torsion.….

ABSTRACT: A consistent methodology for the analysis of buckling phenomena in three dimensional solids developed in Part 1 is applied to a simple structure, i.e., the externally pressurized cylindrical shell structure. The primary state of the shell is investigated analytically, using asymptotic technique, and then the straightforward buckling analysis is followed up to the third order, adopting the general stability theory in Part 1. The full analysis is done through the analytical manner. Hence, the closed form solution is obtained. Finally, the result is compared with the classical one.

ABSTRACT: Bifurcation instability modes of axially compressed circular cylindrical shell are investigated in the limit of zero thickness (i.e., h (thickness) 0) analytically, adopting the general stability theory developed by Triantafyllidis and Kwon(1987) and Kwon(1992). The primary state of the shell is obtained in a closed form using the asymptotic technique, and then the straightforward bifurcation analysis is followed according to the general stability theory to obtain the bifurcation modes in the limit of zero thickness in a full analytical manner. Hence, the closed form bifurcation solution is obtained. Finally, the result is compared with the classical one.

ABSTRACT: A non-linear, large deformation, finite element analysis is presented for the general instability of ring stiffened shells of revolution subjected to combined end compression and circumferential pressure loading. The circumferential pressure loading is treated as a follower force. A combined load-increment and iteration method is used for solving the resulting equilibrium equations. Effect of varying degrees of initial imperfection in shell geometry on the load-displacement behaviour is reported.

ABSTRACT: The lattice cylindrical shells wound from the planar lattice plates, which have significant applications in aerospace engineering, exhibit different deformation modes with their planar counterparts because of the curvature of the cell wall. In this paper, deformation mechanisms are systematically investigated and failure analyses are conducted for the lattice cylindrical shells with various core topologies. Analytical models are proposed to predict the axial stiffness, critical elastic buckling load or effective yield strength of these shells. Finite element simulations are carried out to identify the validity of the models. The models can be employed for the optimal design. As an example, we construct the failure map for the Kagome lattice cylindrical shell made from an elastic ideally-plastic material. Various failure mechanisms, including yielding, global elastic buckling and local elastic buckling are taken into account. Moreover, optimizations are performed to minimize the weight for a given stiffness or load-carrying capacity for three types of lattice cylindrical shells. It is found that the Kagome and triangular lattice cylindrical shells have almost equivalent load-bearing capacity and both significantly outperform the hexagonal one under axial compression.

ABSTRACT: We consider very large periodic trusses called lattice structures. In classical calculus, the periodic truss character and its global geometry are forgotten. With the homogenization method that we have developed, the lattice is replaced by a continuum model which approaches, in a certain sense, the real structure. This is true when the number of constitutive cells becomes large. The homogenization method has been developed in linear static cases and in free vibration. This paper generalises it for the large displacement assumption. The truss equilibrium is written on the unknown deformed configuration.

ABSTRACT: New techniques have been developed to make materials with a periodic three-dimensional lattice structure. The high stiffness per unit weight and multifunction of such lattice structures make them attractive for use in aeronautic and astronautic structures. In this paper, epoxy-soaked continuous carbon fibres were first introduced to make lattice composite structures, which maximize the specific load carrying capacity. A micromechanical analysis of several designs, each corresponding to a different manufacturing route, was carried out, in order to find the optimized lattice structure with maximum specific stiffness. An intertwining method was chosen and developed as the best route to make lattice composite materials reinforced by carbon fibers. A sandwich-weaved sample with a three-dimensional intertwined lattice structure core was found to be best. The manufacturing of such a composite lattice material was outlined. In addition to a high shear strength of the core and the integral manufacturing method, the lattice sandwich structure is expected to possess better mechanical
ABSTRACT: Fiber reinforced lattice composites are light-weight attractive due to their high specific strength and specific stiffness. In the past 10 years, researchers developed three-dimensional (3D) lattice trusses and two-dimensional (2D) lattice grids by various methods including interlacing, weaving, interlocking, filament winding and molding hot-press. The lattice composites have been applied in the fields of radar cross-section reduction, explosive absorption and heat-resistance. In this paper, topologies of the lattice composites, their manufacturing routes, as well as their mechanical and multifunctional applications, are surveyed.

ABSTRACT: Studies on the static stability and the ultimate bearing capacity of vierendeel latticed shells have been carried out. The buckling modal and the whole course of instability are shown using the Finite Element Method. The ultimate bearing capacity is compared with that of the single-layer latticed shell structure. The results show that the ultimate bearing capacity of the vierendeel latticed shells is 2.87 times more than that of the single-layer lattice shell in the condition of consuming the same steel. The vierendeel lattice shell structure not only has the advantages of concision and transparency like the single layer latticed shell structure, but also has the stability and carrying capacity like double-layer latticed shell structure.

“Analytical study on dynamic buckling of reactor containment vessel”, Nuclear Engineering and Design,
ABSTRACT: The dynamic buckling of a reactor containment vessel under earthquake conditions is evaluated using a nonlinear finite element method. It is based on the four-node MITC (mixed interpolated tensorial components) shell element originally proposed by K.J. Bathe, which has been modified by the authors to include the effect of large rotational increments. At first, the buckling modes for a thin cylindrical shell under a simplified base excitation were classified, then the dynamic buckling analysis of a typical PWR steel containment vessel was carried out, considering both geometrical and material nonlinearities, to compare the results with those of a conventional static analysis. It was found that the global shear buckling of a steel containment vessel occurred under a load level several times greater than the design earthquake, and the buckling load estimated by the conventional analysis was smaller than the buckling load estimated by the dynamic analysis.

ABSTRACT: In this paper, we establish a homogenization framework to analyze the microscopic symmetric bifurcation buckling of cellular solids subjected to macroscopically uniform compression. To this end, describing the principle of virtual work for infinite periodic materials in the updated Lagrangian form, we build a homogenization theory of finite deformation, which satisfies the principle of material objectivity. Then, we state a postulate that at the onset of microscopic symmetric bifurcation, microscopic velocity becomes spontaneous, yet changing the sign of such spontaneous velocity has no influence on the variation in macroscopic states. By applying this postulate to the homogenization theory, we derive the conditions to be satisfied at the onset of microscopic symmetric bifurcation. The resulting conditions are verified by analyzing numerically the in-plane biaxial buckling of an elastic hexagonal honeycomb. It is thus shown that three kinds of experimentally observed buckling modes of honeycombs i.e., uniaxial, biaxial and flower-like modes, are attained and classified as microscopic symmetric bifurcation. It is also shown that the multiplicity of bifurcation gives rise to the complex cell-patterns in the biaxial and flower-like modes.

ABSTRACT: In this study, microscopic buckling of elastic square honeycombs subject to in-plane compression is analyzed using a two-scale theory of the up-dated Lagrangian type. The theory allows us to analyze microscopic bifurcation and post-bifurcation behavior of periodic cellular solids. Cell aggregates are taken to be periodic units so that we can discuss the dependence of buckling stress on periodic length. Then, it is shown that microscopic buckling occurs at a lower compressive load as periodic length increases, and that long-wave buckling occurs just after the onset of macroscopic instability if the periodic length is sufficiently long. It is
further shown that the macroscopic instability is of the shear type, leading to a simple formula to evaluate the lowest in-plane buckling stress of elastic square honeycombs.

ABSTRACT: In this study, a method to evaluate sensitivities in post-buckling analysis is developed. The gradients of load values obtained under several constraint conditions are discussed. Unlike other methods for sensitivity analysis, the present method can cope with both snap-through and bifurcation problems without eigenvalue analysis. In addition, the load sensitivity at arbitrary points on an equilibrium path can be calculated. Using the MITC4 shell element, several numerical examples, such as a bifurcation buckling and a snap-through analysis of shell structures, are solved to show the performance of this sensitivity analysis method.

ABSTRACT: An analysis method for evaluating the sensitivity of buckling load in geometrically nonlinear finite element methods is developed. By searching for the pseudo critical point in the perturbed system on the surface of the hyper-cylinder where the original critical point exists, the sensitivity of buckling load is estimated. Compared with other methods, the present method can cope with both snap-through and bifurcation problems without an eigenvalue analysis. In addition, the load sensitivity at arbitrary points on the equilibrium path can be calculated under the total-displacement constraint condition. Two examples of sensitivity buckling analysis of shell structures are demonstrated to examine the validity of this method, and satisfactory results are obtained.

ABSTRACT: To reveal the local buckling strength of periodic lattice composites, an important factor in optimal material design, analytical method based on the classical beam-column theory was applied. Buckling modes were decided according to the condition that the curvature of the strut columns is the smallest. Characteristic equations were built according to the equilibrium equations. The buckling strengths and constraint factors of various grids under uniaxial compression and tension were achieved. The strut network supports stronger rotation restrictions than pin-jointed nodes but weaker than the built-in ends. With more stacks of struts and connectivity at nodes, the restriction must be stronger and the buckling load is greater. Commonly, the constraint factors of isogrids and mixed triangle grids are greater than Kagome grids. The regular honeycomb and square grids possesses smaller buckling loads.

ABSTRACT: The purpose of this paper is to present a general theory for analysis of the effect of initial geometrical imperfections on vibration frequencies of undamped, conservatively loaded, linear elastic beam and shell structures. The theory will be restricted to single mode vibrations with imperfections in the same shape as the vibration modes. The mathematical tool is a perturbational procedure developed with the aid of the principle of virtual work. The approach is illustrated by applications to beams, plates and axisymmetric shell structures. The examples show that the vibration frequency of these structures may be significantly raised or lowered due to imperfections.

ABSTRACT: An initial buckling analysis for cylindrically curved panels made of generally layered composite materials is presented. Four kinds of boundary conditions and the combination of axial compression and shear forces are considered. Two coupled, fourth-order partial differential equations are solved by the use of multiple Fourier series, in which more exact constants within the characteristic beam functions are introduced so that better orthogonality of the series and, therefore, more exact buckling loads are obtained. The influence of curvature, fibre angles, stacking sequence and panel aspect ratios is investigated. An interesting relationship between the critical axial load and shear forces is found for mid-plane symmetric panels. Comparison of present work with experimental results shows fairly good agreement.

ABSTRACT: An analysis for the postbuckling behaviour of compressively loaded, cylindrically curved panels of generally layered anisotropic composite materials is presented. The 36 coefficients in the constitutive relations of the panels are all taken into account. A pair of coupled non-linear differential equations are solved in conjunction with simply supported boundary conditions. Both double sine series and double sine-squared series are used for the deflection function, while characteristic beam function series are used to express the stress function. Numerical computations are performed for a number of panels with different lay-ups, different curvatures and different materials. Comparison between the present work and available theoretical and experimental data is carried out for the special case of a flat plate.

ABSTRACT: In this paper, the performance under compressive static load of I-section stiffened panels is reported. A pristine panel is compared with panels containing simulated damage and repaired panels. Modes of failure, stiffness and strains are studied and it is shown that the significant decreases in strength caused by the damage are almost fully recovered by the repair scheme used.

ABSTRACT: In this paper the finite element modelling under compressive static load of I-section stiffened panels is reported. A pristine panel is compared with panels containing simulated damage and repaired panels. Predicted stiffness, stress distributions and strength of the panels are compared with experimental results.

ABSTRACT: The buckling behaviour of a liquid storage tank built up of circular cylindrical shell-sections with different thicknesses is investigated. In any partially filled state the critical vacuum for bifurcation is determined taking into account the weight of the structure. For a storage tank with small geometrical imperfections the behaviour is analysed asymptotically using Koiter's general post-buckling theory. The initial post-buckling analysis based on the assumption of linear pre-buckling behaviour indicates that the storage tank is imperfection-sensitive in any partially filled state. Finally, bifurcation analyses accounting for nonlinear pre-buckling show that the assumption of linear pre-buckling is a good approximation even at high liquid levels.

ABSTRACT: Delamination buckling analysis of composite panels is of considerable interest to aerospace industries. In this paper, finite element modelling of delamination buckling of composite panels is discussed. ANSYS 5.4 has been used for modelling the delamination buckling. A 3-D model with 8-node composite shell element is used. The panel is hypothetically divided into two sub-laminates by a plane containing the delamination. The two sub-laminates are modelled separately using 8-node composite shell element. Appropriate constraint conditions are added for the nodes in the undelaminated region using Coupled Nodes facility of ANSYS. The nodes in the delaminated region, whether in the top or bottom laminate, are left free. Using this modelling approach, a few typical test problems have been solved. The computed buckling loads and
strain energy release rate values for the test problems tally closely with that of thoery and other researchers. In addition to the test problems, some results on delamination buckling of a woven-fabric carbon-epoxy composite panel are also presented. The two sub-laminate model discussed here provides a convenient approach to delamination buckling analysis.

ABSTRACT: Hot-rolled and cold-formed structural steel tubular members of elliptical cross-section have recently been introduced into the construction sector. However, there is currently limited knowledge of their structural behaviour and stability, and comprehensive design guidance is not yet available. This paper examines the elastic buckling response of elliptical hollow sections in compression, which has been shown to be intermediate between that of circular hollow sections and flat plates. The transition between these two boundaries is dependant upon both the aspect ratio and relative thickness of the section. Based on the results of numerical and analytical studies, formulae to accurately predict the elastic buckling stress of elliptical tubes have been proposed, and shortcomings of existing expressions have been highlighted. Length effects have also been investigated. The findings have been employed to derive slenderness parameters in a system of cross-section classification for elliptical hollow sections, and form the basis for the development of effective section properties for slender elliptical tubes.

ABSTRACT: The elastic local post-buckling behaviour of elliptical tubes under compression is analysed in this
paper. A brief outline of the local, distortional and global buckling behaviour of EHS tubes is firstly provided, where it is shown that local buckling modes govern the stability of short to intermediate length tubes while distortional modes control the stability of intermediate length to moderately long tubes and global buckling dominates the behaviour of longer tubes. Following this, an in-depth numerical study employing shell finite element modelling, of the elastic local post-buckling behaviour of compressed elliptical hollow section (EHS) tubes is presented. It is concluded that EHS tubes with a low to moderate aspect ratio can support loads up to their limit loads but are imperfection sensitive (shell-type behaviour), while EHS tubes with a moderate to high aspect ratio can carry loads higher than their limit loads (plate-type behaviour) and are imperfection insensitive. The slope of the ascending post-buckling path increases with the EHS aspect ratio and can reach values up to 40% of the slope of the linear primary path. The bound imperfection amplitude concept, separating the imperfection amplitude ranges where the EHS tube is sensitive and insensitive, is proposed. It is also found that, for increasing EHS aspect ratio, the compressive stresses grow and accumulate near the zones of minimum radius of curvature while the zones of maximum radius of curvature possess an approximately uniform and relatively low compressive stress level. Therefore, it is expected that an approach based on the effective width concept widely used for the evaluation of the strength of flat plates may be adapted to the design of EHS tubes with moderate to high aspect ratios.

ABSTRACT: The plastic collapse response of structural steel elliptical hollow section (EHS) profiles in compression is examined in this paper. As an initial step, a parametric study to identify the factors that determine which plastic mechanisms would arise has been carried out using finite element (FE) results from the current work and experimental data from the literature. All investigated EHS had a cross-sectional aspect ratio of two. The parametric study revealed four plastic collapse mechanisms and showed that the “split flip disc” plastic collapse mechanism is the most likely to appear in compressed EHS. Thus, the present work is focussed on this failure mechanism, for which an analytical model to describe the relationship between load and deformation is developed. Coupled with the consideration of the elastic, yielding and strain hardening characteristics of steel, the derived analytical model enables construction of the full load–deformation behaviour of compressed EHS to be established. The parameters controlling the shape and size of the plastic hinges have been investigated and found to be of key importance; hence, special care has been taken in their definition. Finally, the developed load–displacement curves have been compared with both finite element results and experimental data. The comparisons have revealed good agreement, confirming the ability of the analytical model to predict the collapse response of elliptical tubes.

ABSTRACT: A one-dimensional model is presented in order to predict (a) delamination buckling loads of an across the width delaminated and axially loaded laminated plate and (b) the ultimate load-carrying capability of the above geometry, when delamination growth can take place. In order to study the possibility of spreading of the damaged (delaminated) area to the undamaged area, the post-buckling solution is employed. The energy release rate has been used to determine whether the delamination growth is stable or unstable. The results reveal that for a relatively small delamination length the buckling loads serve as a measure of the load-carrying
capacity of the damaged plate, while for a relatively large delamination length, the plate could carry larger loads depending on the fracture toughness of the plate material. Moreover, the present model can be used to study the effect of the presence of coupling between bending and stretching on delamination growth. Note that for such geometries the possibility of bifurcational buckling does not exist, regardless of the level of the applied load.

ABSTRACT: The influence of initial geometric imperfections is analysed at buckling and crack growth in compressed composite plates with delaminations present. First, initial buckling based on bifurcation theory and postbuckling is considered for initially flat laminates with appropriate crack parameters determined. For initially deflected plates, Marguerre shallow shell theory is drawn upon and by a scaling procedure pertinent results in the case of imperfections may be generated directly from those of perfect plates. The method is based on the assumption of affinity between initial and postbuckling transverse deflections. In particular for inextensible buckling states, the method is exact while in more general cases estimates are obtained. Illustrations of the method and procedures are given for several representative cases and especially the associated accuracy of the method is delineated.

ABSTRACT: A theoretical and experimental investigation of a laminated plate with an embedded, initially circular delamination, loaded in uniaxial compression is described. The main issue concerns the combined postbuckling and crack growth behaviour in general situations at arbitrary crack contours and applied to fibre-reinforced carbon-epoxy composite plates. In a numerical procedure a standard FE-code is used to solve the structural postbuckling problem and extended to account also for contact effects. To predict interlaminar crack growth an automatic finite element procedure was employed for the purpose. Delamination growth in laminates was detected by the aid of acoustic emission. After successive crack increments, the evolution of the delamination front was mapped using an ultrasonic C-scan technique and also for comparison by X-ray. Predicted and observed results are compared as regards postbuckling behaviour and in particular the magnitude and shapes of delamination growth fronts.

ABSTRACT: A theoretical study of a buckling-driven, initially circular, delaminated thin film loaded in equal bi-axial compression is presented. The main objective of this investigation is to study the configurational
instability phenomena frequently observed for thin debonded coatings loaded in compression. The analyses are done with the aid of a kinematically non-linear finite element formulation of the plate problem to model the film, supplemented with a method to account automatically for the redistribution of the stress field as the shape of the advancing delamination is changing. By this procedure, not only the shape of the delaminated film but also the stability properties of the growth follow automatically. The configurational stability properties of the initially circular delamination are assessed by slightly perturbing the delamination front. The configurational instability is strongly related to the fracture mode dependence in the crack growth law. Finite growth of the buckling-driven thin film was also investigated. A load perturbation was employed as well as a front perturbation. It was found that the two perturbation methods can result in quite different shapes of the advancing buckled thin film. A few examples of extensive growth are also presented, and in some cases it was observed that a part of the delamination front may start tunnelling in the interface.

“Delamination buckling and growth for delaminations at different depths in a slender composite panel”,
doi:10.1016/S0020-7683(00)00189-X

ABSTRACT: A numerical and experimental investigation for delamination buckling and growth for slender composite panels loaded in compression is presented. The investigated panels consisted of 35 plies in a cross-ply layup with artificially embedded delaminations inserted after three, five or seven plies from the upper surface. The tests clearly and consistently showed that for all delamination depths, delaminated panels failed by delamination growth slightly below the global buckling load of the undamaged panel, whereas the undelaminated panels failed in compression at global buckling. The analysis was done with a finite element based computational model that accounts for contact between delaminated members and fracture mode separation and where crack propagation was simulated with a moving mesh scheme. For all delamination depths, the analysis showed a dramatic increase in the energy release rate when global buckling takes place. Features seen in the tests were captured in the computational analysis. Excellent agreement with tests was found for loads at which delaminated members buckle, the load for onset of delamination growth and the evolution of delamination, e.g., delamination shape and out-of-plane displacements.

“Delamination growth of laminated composite cylindrical shells”, Theoretical and Applied Fracture Mechanics,

ABSTRACT: The local buckling may occur in delaminated cylindrical shells under axial compression. This often causes delamination growth and structure failure. Based on the variational principle of moving boundary, in this paper, the postbuckling governing equations for the laminated cylindrical shells are derived, and the corresponding boundary and matching conditions are given. At the same time, according to the Griffith criterion, the formulas of energy release rate along the delamination front are obtained and the delamination growth is studied. In the numerical calculation, the delamination growth of axisymmetrical laminated cylindrical shells is analyzed, and the effects of delamination sizes and depths, the boundary conditions, the material properties and the laminate stacking sequences on delamination growth are discussed.

ABSTRACT: It is shown that a simple method may be applied in order to determine the first order change of eigenmodes and critical loads at bifurcation buckling of slender structures when cavities or reinforcements are introduced. The perturbation procedure developed is applicable whenever a characteristic diameter of the structural geometry perturbation is one order less than the wave length of the unperturbed eigenmode and necessary computations involve at most the solution of two linear boundary value problems. Situations when the procedure may be further simplified are discussed and statements are made regarding requisite conditions for the buckling load definitely to increase or decrease due to geometry perturbations. Application of the method is illustrated by means of four cases of engineering interest, which involve perforated and reinforced beams and plates with holes and cracks.

ABSTRACT: A finite element modeling is presented to study the buckling and postbuckling behavior of composite laminates with an embedded delamination. The buckling and postbuckling behavior of graphite/epoxy composite laminates with an embedded delamination are investigated for various delamination sizes, stacking sequence and boundary conditions. Three different possible modes of instability are identified at the critical load, which is global, mixed, and local buckling mode. The buckling load and postbuckling behavior depend on the buckling mode that is determined by the delamination size, stacking sequence and boundary conditions. It is found that the presence of a delamination in composite laminates may induce couplings, which have significant effects on the buckling and postbuckling behavior of composite laminates.

ABSTRACT: A finite element modeling is presented to study the effect of delamination on the buckling behavior of quasi-isotropic laminates. The effects of delamination on the buckling and postbuckling behavior of graphite/epoxy composite laminates are investigated for various delamination sizes, stacking sequence and boundary conditions. Three different possible modes of instability are identified at the critical load, which is global, mixed, and local buckling mode. The buckling load and postbuckling behavior depend on the delamination buckling mode that is determined by the delamination size, stacking sequence and boundary conditions. ABSTRACT: In this paper, to investigate the buckling characteristics of carbon nanotubes, an equivalent beam model is first constructed. The molecular mechanics potentials in a C–C covalent bond are transformed into the form of equivalent strain energy stored in a three dimensional (3D) virtual beam element connecting two carbon atoms. Then, the equivalent stiffness parameters of the beam element can be estimated from the force field constants of the molecular mechanics theory. To evaluate the buckling loads of multi-walled carbon nanotubes, the effects of van-der Waals forces are further modeled using a newly proposed rod element. Then, the buckling characteristics of nanotubes can be easily obtained using a 3D beam and rod model of the traditional finite element method (FEM). The results of this numerical model are in good agreement with some previous results, such as those obtained from molecular dynamics computations. This method, designated as molecular structural mechanics approach, is thus proved to be an efficient means to predict the buckling characteristics of carbon nanotubes. Moreover, in the case of nanotubes with large length/diameter, the validity of Euler’s beam buckling theory and a shell model with the proper material properties defined from the results of present 3D FEM beam model is investigated to reduce the computational cost. The results of these simple theoretical models are found to agree well with the existing experimental results.

ABSTRACT: A theoretical and computational study has been carried out for compressive loading of a thin circular embedded delamination located below a cylindrical surface. The delaminated member is subjected to nominally uniaxial and balanced biaxial loading with the main objective to analyze its influence on surface curvature especially as regards imminent crack growth. The analysis is based on nonlinear shell theory combined with linear fracture mechanics. A finite element program earlier developed for delaminated plates has been generalized to apply also for shells and used to determine energy release rates and mode intensities along the delaminated front. A parameter study is made of the influence of curvature of the delaminated shell in particular as regards initiation and stability of crack growth.

ABSTRACT: In this paper, a theory for the analysis of large deflection of squarely-latticed shallow spherical shells is constructed by adopting the equivalent continuum method. The von Kármán type non-linear differential equations of such latticed shells under actions of axisymmetrically distributed loads are derived. An approximate boundary value problem for a uniformly-loaded latticed shallow spherical shell is formulated with variational principles. A practical case of a latticed cap of a petroleum vessel subject to external uniform loads is investigated with this theory, and corresponding buckling loads are numerically presented.

ABSTRACT: The static stability capacity is the main index to measure the whole mechanical performance of single-layer latticed shells. Three single-layer cylindrical latticed shells with different height to span ratio were modeled, and their seismic damage were assessed by the degradation of static stability capacity incurred by earthquakes. Two different static load patterns were considered: dead load and the combination of dead load and half span live load. The results show that the damage assessment method is applicable to single-layer cylindrical latticed shells, and the static load patterns have no big influence on the damage assessment of the single-layer cylindrical latticed shells.

PARTIAL ABSTRACT: In this study the flexural and shear behaviour of large diameter fabricated steel cylinders have been experimentally investigated, and the results are compared with those obtained from existing design equations. The first part of the experimental program consisted of testing an unstiffened cylinder (R/t = 174) in pure flexure. The objective was to add to the scarce data base on cylinders in flexure. The results were compared to predictions made using the semi-empirical design equations of others for axially loaded cylinders…

J. Mok and A.E. Elwi (Department of Civil Engineering, The University of Alberta, Edmonton, Alberta, Canada), “Shear behavior of large diameter fabricated steel cylinders”, Structural Engineering Report No. 136, June 1986,

ABSTRACT: The shear behavior of large diameter fabricated steel cylinders is investigated analytically. The analysis is based on a nonlinear geometric finite element formulation coupled with a von Mises elastic-perfectly-plastic material response. The effects of initial imperfections as well as the boundary conditions on the shear behaviour of the cylindrical shells are examined. The development of a tension field in certain cases is also investigated. The study relies on the program NISA (“Nonlinear Incremental Structural Analysis”) a description of which is included….

ABSTRACT: Columns, stacks, conveyor galleries, and other similar civil engineering structures are often constructed in the form of an unstiffened tube or as a discretely stiffened tube that behaves in an essentially unstiffened manner. Tubes of this type are used extensively in the materials-handling operations of industrial plants. These are fabricated circular steel cylinders, typically 2.4 - 4 m in diameter, with radius-to-thickness ratios in the range of 150 - 400. They support and enclose conveyor systems, and they customarily span distances up to about 50 m. The task of the designer is similar to that faced with plate girders: the bending capacity, shear capacity, and the combined effects of shear and bending all must be examined. The results of a test program established to examine the flexural strength of large diameter fabricated steel tubes is reported herein. Although the number of tests is not great, the program is distinguished by the fact that the tests were done using relatively large specimens made in a way similar to that which would be employed in full-size tubes. These tests are believed to represent the best information currently available, and the results should be useful to both designers and other researchers who are approaching the problem using analytical tools.
ABSTRACT: Based on a blind spot in the current design standard of steel structures, the large diameter thin-walled tube beam-columns are analyzed using nonlinear finite element method in this paper. The influence of several factors on stability capacity of the large diameter thin-walled tube beam-columns is taken into account. Thus, according to the correlative design standard of steel structures, and on the basis of the numerical analytical results by the finite element methods, the calculation formulas of the stability bearing capacity are presented for beam-column members of the large diameter thin-walled tubes. Three tests of thin-walled steel tube beam-columns were reported. Test results for deformations and ultimate strength are found to be in a good agreement with the corresponding values predicted by the calculation formulas, and the proposed methods can be used in design practice.

PARTIAL ABSTRACT: The behavior of thin steel cylinders under transverse shear is investigated using a 16-node three dimensional degenerated plate shell element in the context of the nonlinear finite element analysis program NISA80, with an elastic-perfectly plastic material model. The analysis is carried out along the prebuckling and the postbuckling equilibrium paths for cylinders with initial measured imperfections, initial residual stresses due to longitudinal seam weld shrinkage and initial locked-in stresses due to the cold forming….

ABSTRACT: The decrease in lateral stiffness with increase in current and subsequent buckling of a flexible superconducting coil in a three coil partial torus is reported. The instability was observed for both clamped and clamped-pinned constraints on circular coils. Tests on the in-plane stability show an increase in stiffness with current in contrast with the out of plane or lateral buckling behavior. Along with the decrease in lateral natural frequencies of the coils, a significant increase in damping was observed. The critical buckling current was found to be in good agreement with theoretical calculations based on the authors’ previous work.

ABSTRACT: A 16 coil superconducting torus is used to study magnetoelastic instabilities in a set of current carrying elastic rings. The torus is a 1/75th model of a proposed magnetic fusion reactor. Up to 130 KA-turns were placed in the 30-cm-dia torus. Three different lateral constraint conditions on the elastic magnets are discussed. Both dynamic and static methods are used to determine the critical buckling currents. The coils are observed to pair up during buckling. A series of snap-type instabilities were observed near the critical buckling current for the lowest mode. A fair to good comparison between experimental and theoretical values of the buckling currents for all three modes is obtained when tension stiffening corrections are included.

ABSTRACT: This paper describes tests that have been performed on the buckling behaviour of symmetrical four ply laminated carbon fibre epoxy shells loaded in axial compression. Six shells were tested, two each of three lay up orientations, +30/-30/-30/+30, +45/-45/-45/+45, and +60/-60/-60/+60 (angles measured from the cylinder axis). Testing procedure was to firstly load the shell to collapse, reload to ensure collapse was elastic and no significant damage had been done during the buckling process, impose a defect and retest to determine the degrading effect. During all tests the deformations were monitored by a purpose built optical system based on the reflective moire technique. This inspection technique allowed the entire shell surface to be monitored all times. The degrading effect of the relatively large geometric defects appeared to be more dependent upon geometry than lamina orientation although the 45 degree shells generally exhibited slightly less defect sensitivity.

ABSTRACT: The static deformation of micromachined beams under prescribed in-plane compressive stress is studied by analytical and experimental means over the pre-buckling, transition, and post-buckling load ranges. The finite amplitude of the beam in its post-buckled state is predicted by modeling the non-linear dependence of its compressive stress on the out-of-plane deformation. In addition, the model explicitly considers the net effect of slight imperfections, which can include fabrication defects, geometric irregularities, or non-ideal loading, on the beam's behavior in the near-buckling regime. As an application, clamped-clamped silicon dioxide beams are fabricated through conventional bulk micromachining, and their deflected profiles are measured through three-dimensional optical profilometry. The measurements are compared to the post-buckled amplitudes and shapes that are predicted by the model, and by existing simpler models that do not include the effects of both non-linearity and imperfection. As borne out by the data, when imperfections are considered, the beams exhibit continuous growth of the out-of-plane amplitude during transition from the prebuckled state to a post-buckled one, in contrast to sudden bifurcation at a critical load. By accounting for this behavior, the estimate of residual stress in the thin film from which the beams are fabricated can be improved, and the amplitude of common post-
buckled micromachined structures can be predicted.

ABSTRACT: Fabricated steel cylinders with large R/t ratios are often used in conveyor galleries, offshore platforms, storage tanks, towers, vessels, and the like. The use of longitudinal stiffeners in these large cylinders has proven to be an efficient way to promote structural stability. The increase of load capacity is significant. However, the attachment of the stiffeners complicates the problem by introducing additional buckling modes and new design parameters. Four large-scale specimens were tested. The collected data included the load versus deformation behavior, as well as the geometric imperfections and welding residual stresses of the specimens. The objective of the research program was to investigate the local buckling behavior and ultimate load capacity of longitudinally stiffened steel cylinders subjected to bending. The results showed two failure modes, a shell buckling mode and a general buckling mode. The occurrence of both modes and the corresponding capacity...
depend on the shell properties, as well as on the spacing and angle of arc covered by the stiffeners. The general buckling mode has strength and ductility much higher than those predicted by existing design guidelines.

ABSTRACT: Fabricated steel cylinders are often used as conveyor galleries, stacks or masts, or as members in offshore structures. The cylinders are fabricated by first cold rolling steel plates to form short cans and then joining these together by circumferential girth welds to yield long spans. Circumferential stiffeners are almost always present, in order that the circular shape of the tube is maintained and as an assistance when the cylinder is being handled. Longitudinal stiffeners may be used as well. If they are present, they will be welded to the cylinder surface, thereby improving the behaviour under axial compression or beam bending. The paper addresses the design of the type of cylinder commonly used as a conveyor gallery. In this application, diameters of from 2.5 to 4.0 m are typical and the radius to thickness ration, R/t, ranges from about 100 to 400. Spans can reach 60 m. The results of four large-scale flexural tests on large diameter fabricated steel cylinders that had longitudinal stiffeners and a parametric study of hypothetical cylinders of this configuration are used as the basis of the study. The paper reviews current design standards in the light of those test results, presents the results of the parametric study and makes recommendations for the design of longitudinally-stiffened fabricated steel cylinders.

ABSTRACT: In structural design, the preliminary synthesis stage derives judgmental knowledge from engineering heuristic and experience which are usually expressed in symbolic form. On the other hand, detailed design involves extensive numerical processing. An integrated computer-aided design system should be able to handle both symbolic and numerical processings. It must also be able to integrate engineering databases and CAD packages within a single environment. The knowledge-based system approach provides a venue for achieving all these requirements. This paper presents a prototype knowledge-based system for lattice design that can perform several essential tasks including preliminary synthesis, numerical model generation, nonlinear finite element analysis, code compliance checking and member sizing. The system user is guided throughout the design session by interactive graphical user interfaces which facilitate the design process.

ABSTRACT: This work develops a framework for SIMP-based topology optimization of a metallic panel structure subjected to design-dependent aerodynamic, inertial, elastic, and thermal loads. Multi-physics eigenvalue-based design metrics such as thermal buckling and dynamic flutter are derived, along with their adjoint-based design derivatives. Locating the flutter point (Hopf-bifurcation) in a precise and efficient manner is a particular challenge, as is outfitting the optimization problem with sufficient constraints such that the critical flutter mode does not switch during the design process. Results are presented for flutter-optimal topologies of an unheated panel, thermal buckling-optimal topologies, and flutter-optimality of a heated panel (where the latter case presents a topological compromise between the former two). The effect of various
constraint boundaries, temperature gradients, and (for the flutter of the heated panel) thermal load magnitude are assessed. Off-design flutter and thermal buckling boundaries are given as well.

ABSTRACT: Many structural bifurcation buckling problems exhibit a scaling or power law property. Dimensional analysis is used to analyze the general scaling property. The concept of a new dimensionless number, the response number-Rn, suggested by the present author for the dynamic plastic response and failure of beams, plates and so on, subjected to large dynamic loading, is generalized in this paper to study the elastic, plastic, dynamic elastic as well as dynamic plastic buckling problems of columns, plates as well as shells. Structural bifurcation buckling can be considered when Rn(n) reaches a critical value.

ABSTRACT: This paper is concerned with the geometrical optimum design and the aseismic analysis of double-layer reticulated shell structures. The characteristic of free vibration of reticulated shell structures, with respect to geometric parameter, is investigated. The variations of the eigenfrequency of shell structures, with respect to the ratio of height-to-span, span, grid division frequency and thickness of shell, are discussed. The Newmark method is used to calculate the stresses and displacements of the reticulated shell structure under earthquake action. The analysis results show that under a specified span, the eigenfrequency of the structure increases with the increase of the height-to-span ratio and then decreases afterwards. Therefore, there exists an optimum height-to-span ratio resulting in an optimum stiffness at the specified span. The optimum value of the ratio is found to be between 1/3 and 1/4 from the simulation study presented in this paper. At a specified height-to-span ratio, the increase of the value of structural span greatly reduces the eigenfrequency of the structure and then decreases the global stiffness of the structure. At the specified span and the specified height-to-span ratio, the eigenfrequency of the structure has a minor increase with the increase of the thickness and the grid division frequency of the reticulated shell structure. The partial double-layer reticulated shell structures have less stability compared with double-layer reticulated shell structures, but more stability in comparison with single-layer reticulated shell structures. The 1/6 partial double-layer reticulated shell structure has a best performance-to-price ratio. In other words, it has a higher buckling load, with smaller material consumption, compared with other partial double-layer reticulated shell structures. It is proposed to adopt the 1/6 partial double-layer reticulated shell structure in engineering if a double layer reticulated shell structure is required.

ABSTRACT: In this study a kind of buckling-restrained braces (BRBs) as energy dissipation dampers is attempted for seismic performance of large span double-layer reticulated shell and the effectiveness of BRBs to protect structures against strong earthquakes is numerically studied. The hysteretic curve of such members is obtained through the simulation of the cyclic-loading test, and the equations of motion of the system under earthquake excitations are established. BRBs are then placed at certain locations on the example reticulated shell to replace some normal members, and the damping effect of the two installation schemes of BRBs is
investigated by non-linear time-history analyses under various ground motions representing major earthquake events. Compared with the seismic behavior of the original structure without BRBs, satisfactory seismic performance is seen in the upgraded models, which clarifies the BRBs can reduce the vibration response of spatial reticulated structure effectively and the new system has wide space to develop double layer reticulated shell.

ABSTRACT: Plate-cone reticulated shell is a new type of space structures with good mechanical behavior and technical economy. In this paper, local buckling and influence factors of composite plates in plate-cone reticulated shell are analyzed with theory of composite plate and shell through composite structure finite element method, and the mechanical characteristics of composite plate-cone reticulated shell are studied, some important conclusions were obtained, which can provide theoretical foundation for practical design of composite plate-cone reticulated shell and composite plates.

ABSTRACT: In this paper some stability problems of reticulated shells are studied. Adequate mathematical models for the analysis of shell instability, using a direct method and a shell analogy method, are presented. It is assumed that the members of the analysed shells consist of a homogeneous, isotropic elastic material. The theoretical results, obtained from some numerical examples, are also presented.

Adrian Ivan and Marin Ivan (Politehnica University of Timisoara, Romania), “Typical failure modes of some single layered reticulated shells”, (publisher and date not given in the pdf file. The most recent citation is dated 2001)

ABSTRACT: The paper reveals the main cases of possible failure of some single layered reticulated shells working in the elastic domain. The structural members are pinned jointed everywhere, and all are of tubular cross section.

CONCLUSIONS: In order to predict stability for complex reticulated structures it is necessary to analyze the elastic buckling loads of these domes using geometrical nonlinear analysis. Unfortunately this should be followed by mode shape analysis. Both will reveal the sensitivity to certain coupled modes of instability. Attention should be focused on these ones. The lowest critical load is obtained in the vicinity of a coupled instability on the reticulated shells affected by geometrical imperfections. The initial imperfection pattern should be affine to the mode shape. Not always this represents the most unfavorable imperfection pattern. The
stability of reticulated shells requires a large computing effort.

ABSTRACT: We present a study on buckling of colloidal particles, including experimental, theoretical and numerical developments. Oil-filled thin shells prepared by emulsion templating show buckling in mixtures of water and ethanol, due to dissolution of the core in the external medium. This leads to conformations with a single depression, either axisymmetric or polygonal depending on the geometrical features of the shells. These conformations could be theoretically and/or numerically reproduced in a model of homogeneous spherical thin shells with bending and stretching elasticity, submitted to an isotropic external pressure.

ABSTRACT: The multiple complexities inherent to living objects have motivated the search for abiotic substitutes, able to mimic some of their relevant physical properties. Hydrogels provide a highly monitorable counterpart and have thus found many applications in medicine and bioengineering. Recently, it has been recognized that their ability to swell could be used to unravel some of the universal physical processes at work during biological growth. However, it is yet unknown how the microscopic distinctions between swelling and biological growth affect macroscopic changes (shape, stresses) induced by volume variations. To answer this question, we focus on a clinically motivated example of growth. Some solid tumors such as melanoma or glioblastoma undergo a shape transition during their evolution. This bifurcation appears when growth is confined at the periphery of the tumor and is concomitant with the transition from the avascular to the vascular stage of the tumor evolution. To model this phenomenon, we consider in this paper the deformation of an elastic ring enclosing a core of different stiffness. When the volume of the outer ring increases, the system develops a periodic instability. We consider two possible descriptions of the volume variation process: either by imposing a homogeneous volumetric strain (biological growth) or through migration of solvent molecules inside a solid network (swelling). For thin rings, both theories are in qualitative agreement. When the interior is soft, we predict the emergence of a large wavelength buckling. Upon increasing the stiffness of the inner disc, the wavelength of the instability decreases until a condensation of the buckles occurs at the free boundary. This short wavelength pattern is independent of the stiffness of the disc and is only limited by the presence of surface tension. For thicker rings, two scenarios emerge. When a volumetric strain is prescribed, compressive stresses accumulate in the vicinity of the core and the deformation localizes itself at the boundary between the disc and
the ring. On the other hand, swelling being an instance of stress-modulated growth, elastic stretches near the core saturate and the instability occurs primarily at the free boundary. Besides its implications for the mechanical stability of avascular tumors, this work provides important results concerning layered tissues growth and the role of hydrogels as biological tissues substitutes.

ABSTRACT: An overview is given on a new buckling instability that arises following the osmotically driven swelling of a polymer film. This instability yields a simple route to produce wells 10–100 nm deep and with a diameter on the order of micrometers. It is shown that by using a simple surface pretreatment, it is possible to create an ordered array of these wells.

ABSTRACT: The objective of this thesis is to develop an efficient multi–scale finite element frame-work to capture the macroscopic localization due to the micro–buckling of cell walls and the size effect phenomena arising in structures made of cellular materials.

Under the compression loading, the buckling phenomenon (so–called micro–buckling) of the slender components (cell walls, cell faces) of cellular solids can occur. Even if the tangent operator of the material of which the micro–structure is made, is still elliptic, the presence of the micro–buckling can lead to the loss of ellipticity of the resulting homogenized tangent operator. In that case, localization bands are formed and propagate in the macroscopic structure. Moreover, when considering a cellular structure whose dimensions are close to the cell size, the size effect phenomenon cannot be neglected since deformations are characterized by a strain gradient.

On the one hand, a classical multi–scale computational homogenization scheme (so– called first–order scheme) loses accuracy with the apparition of the macroscopic localization or the high strain gradient arising in cellular materials because the underlying assumption of the local action principle, in which the stress state on a macroscopic material point depends only on the strain state at that point, is no–longer suitable. On the other hand, the second–order multi–scale computational homogenization scheme proposed by Kouznetsova et al. (2004b) exhibits a good ability to capture such phenomena. Thus this second–order scheme is improved in this
thesis with the following novelties so that it can be used for cellular materials. First, at the microscopic scale, the periodic boundary condition is used because of its efficiency. As the meshes generated from cellular materials exhibit a large void part on the boundaries and are not conforming in general, the classical enforcement based on the matching nodes cannot be applied. A new method based on the polynomial interpolation without the requirement of the matching mesh condition on opposite boundaries of the representative volume element (RVE) is developed.

Next, in order to solve the underlying macroscopic Mindlin strain gradient continuum of this second-order scheme by the displacement–based finite element framework, the presence of high order terms (related to the higher stress and strain) leads to many complications in the numerical treatment. Indeed, the resolution requires the continuities not only of the displacement field but also of its first derivatives. This work uses the discontinuous Galerkin (DG) method to weakly impose these continuities. This proposed second–order DG–based FE2 scheme appears to be easily integrated into conventional parallel finite element codes.

Finally, the proposed second–order DG–based FE2 scheme is used to model cellular materials. As the instability phenomena are considered at both scales, the path following technique is adopted to solve both the macroscopic and microscopic problems. The micro–buckling leading to the macroscopic localization and the size effect phenomena can be captured within the proposed framework.

ABSTRACT: We present a modified version of a strain–induced buckling instability technique that relies on the analysis of a two–plate composite film deposited on an elastomeric poly(dimethylsiloxane) (PDMS) substrate. We have previously shown that the “strain–induced elastic buckling instability for mechanical measurements” (SIEBIMM) technique is suitable for testing polyelectrolyte multilayers (PEMs) that are amenable to deposition directly on the testing substrate. The method presented in this paper broadens the applicability of the SIEBIMM technique through the transfer of a thin layer of polystyrene (PS) to the PDMS surface prior to film deposition, which creates a deposition surface that can be treated to promote adhesion of films not amenable to transfer or assembly directly onto PDMS. Multilayers assembled onto the PS-coated PDMS substrates yield thin two-plate PS–PEM composite films on the surface of the PDMS substrates that buckle like their homogeneous counterparts. The mechanical contribution of the PS layer is mathematically deconvoluted from the behavior of the composite film to arrive at a Young’s modulus value for the PEM part of the two-plate film. We test the new method by comparing results from two systems evaluated with both conventional SIEBIMM and the two-plate technique. Following this, we use the two-plate method to perform measurements on two PEM assemblies comprised of poly(allylamine hydrochloride) (PAH) and poly(acrylic acid) (PAA) that could not be measured by the conventional SIEBIMM approach. In addition to confirming the accuracy of the two-plate approach, our results yield new insights into the mechanical properties of PEM films. We find that the dry-state stiffness of PEM films is affected primarily by the choice of polyelectrolytes and the ambient humidity and secondarily by assembly conditions. In addition, films assembled from PAH and PAA have moduli on the order of 10 GPa at low (20%) ambient humidities, an unusually high value for a nonreinforced cross-linked polymer network.

Jun Y. Chung, Adam J. Nolte and Christopher M. Stafford (Polymers Division at the National Institute of Standards and Technology, 100 Bureau Drive, Gaithersburg MD 20899, USA), “Surface wrinkling: a versatile

ABSTRACT: Surface instabilities in soft matter have captivated the scientific community for decades. Recently, surface wrinkling has received a great deal of attention due to its simplicity and well-established mechanics of formation. Particularly, the use of surface wrinkling as a measurement platform for material properties has gained widespread momentum in the material science community. In this article, we will review several applications of surface wrinkling for the measurement of thin film mechanical properties, highlighting particularly challenging materials systems such as ultrathin films, polymer brushes, polyelectrolyte multilayer assemblies, and ultrasoft materials. We will also offer a perspective on the future directions of this maturing field, both as a metrology for material properties as well as a route for robust surface patterning.

ABSTRACT: Nanocapsules that can be tailored intelligently and specifically have drawn considerable attention in the fields of drug delivery and bioimaging. Here we conduct a theoretical study on cell uptake of a spherical nanocapsule which is modeled as a linear elastic solid thin shell in three dimensions. It is found that there exist five wrapping phases based on the stability of three wrapping states: no wrapping, partial wrapping and full wrapping. The wrapping phase diagrams are strongly dependent on the capsule size, adhesion energy, cell membrane tension, and bending rigidity ratio between the capsule and membrane. Discussion is made on similarities and differences between the cell uptake of solid nanocapsules and fluid vesicles. The reported results may have important implications for biomedical applications of nanotechnology.

Jincheng Lv, Shike Zhang and Xinsheng Yuan (School of Civil Engineering and Architecture, Anyang Normal University, Anyang, Nenan, China), “A Green’s function approach for dynamic stress analysis of spherical shell under the isotropic impact load”, Mathematical Problems in Engineering, Vol. 2015, Article ID 169468

ABSTRACT: A Green’s function approach is developed for the analytic solution of thick-walled spherical shell
under an isotropic impact load, which involves building Green’s function of this problem by using the appropriate boundary conditions of thick-walled spherical shell. This method can be used to analyze displacement distribution and dynamic stress distribution of the thick-walled spherical shell. The advantages of this method are able to avoid the superposition process of quasi-static solution and free vibration solution during decomposition of dynamic general solution of dynamics, to well adapt for various initial conditions, and to conveniently analyze the dynamic stress distribution using numerical calculation. Finally, a special case is performed to verify that the proposed Green’s function method is able to accurately analyze the dynamic stress distribution of thick-walled spherical shell under an isotropic impact load.

ABSTRACT: The three-dimensional patterns of surface wrinkling on a core-shell soft sphere are investigated through buckling and postbuckling analyses under differential tissue growth or shrinkage. With increasing deformation, the sphere first exhibits a buckyball-like wrinkling pattern and then undergoes a wrinkle-to-fold transition into labyrinth folded patterns, in agreement with experimental observations. This transition involves dynamic movement, rotation, and coalescence of polygons formed during the initial buckling.

ABSTRACT: The linear bifurcation theory is used to investigate the stability of soft thin films bonded to curved substrates. It is found that such a film can spontaneously lose its stability due to van der Waals or electrostatic interaction when its thickness reduces to the order of microns or nanometers. We first present the generic method for analyzing the surface stability of a thin film interacting with the substrate and then discuss several important geometric configurations with either a positive or negative mean curvature. The critical conditions for the onset of spontaneous instability in these representative examples are established analytically. Besides the surface energy and Poisson’s ratio of the thin film, the curvature of the substrate is demonstrated to have a significant influence on the wrinkling behavior of the film. The results suggest that one may fabricate nanopatterns or enhance the surface stability of soft thin films on curved solid surfaces by modulating the mechanical properties of the films and/or such geometrical properties as film thickness and substrate curvature. This study can also help to understand various phenomena associated with surface instability.

Cao, G., Chen, X., Li, C., Ji, A., Cao, Z., 2008. Self-assembled triangular and labyrinth buckling patterns of thin films on spherical

ABSTRACT: A freely floating polymer film, tens of nanometers in thickness, wrinkles under the capillary force exerted by a drop of water placed on its surface. The wrinkling pattern is characterized by the number and length of the wrinkles. The dependence of the number of wrinkles on the elastic properties of the film and on the capillary force exerted by the drop confirms recent theoretical predictions on the selection of a pattern with a well-defined length scale in the wrinkling instability. We combined scaling relations that were developed for the length of the wrinkles with those for the number of wrinkles to construct a metrology for measuring the elasticity and thickness of ultrathin films that relies on no more than a dish of fluid and a low-magnification microscope. We validated this method on polymer films modified by plasticizer. The relaxation of the wrinkles affords a simple method to study the viscoelastic response of ultrathin films.

ABSTRACT: Symmetry-breaking transitions associated with the buckling and folding of curved multilayered surfaces—which are common to a wide range of systems and processes such as embryogenesis, tissue differentiation and structure formation in heterogeneous thin films or on planetary surfaces—have been characterized experimentally. Yet owing to the nonlinearity of the underlying stretching and bending forces, the transitions cannot be reliably predicted by current theoretical models. Here, we report a generalized Swift–Hohenberg theory that describes wrinkling morphology and pattern selection in curved elastic bilayer materials. By testing the theory against experiments on spherically shaped surfaces, we find quantitative agreement with analytical predictions for the critical curves separating labyrinth, hybrid and hexagonal phases. Furthermore, a comparison to earlier experiments suggests that the theory is universally applicable to macroscopic and microscopic systems. Our approach builds on general differential-geometry principles and can thus be extended to arbitrarily shaped surfaces.

ABSTRACT: Using the nonlinear elastic stability theory and its applications to shells, we have investigated the post-buckling behaviour and imperfection sensitivity of spherical shells with amplitude modulation. For this purpose, we assume that the buckling modes have the form of Legendre polynomials with an exponential function as a modulating factor. Since the expressions of the second and the third variation of the energy functional of the spherical shell in the fundamental state are too complicated to obtain a closed form, we use a numerical analysis technique with high precision. The amplitudes of the post-buckling modes and the critical loading factors of the spherical shell with various imperfection modes are presented.

ABSTRACT: In this paper the effect of the interaction between two or more simultaneous buckling modes on the postbuckling behaviour of uniformly compressed thin-walled members (TWM) is analysed by means of the general theory of elastic stability. The analysis is restricted to third-order terms of the energy expansion and therefore can be fruitfully applied to the investigation of structures with asymmetric postbuckling behaviour only. Initial imperfection effect is taken into account. A simplified procedure is suggested for solving the nonlinear equations relative to the evaluation of the bifurcated paths. By using the finite strip method an extensive parametric analysis is performed. It is found that when the flexural-torsional (FT) buckling interacts with a local symmetric and antisymmetric mode, sensitivity to initial imperfections is remarkable and is comparable to the one arising from the interaction between the Euler (E) and any local buckling.

ABSTRACT: Different perturbation methods for the analysis of non-linear interaction between simultaneous buckling modes of nearly symmetric structures are discussed. First, the perturbation method employed by Budiansky for a single buckling mode, is extended to consider modes interaction of a perfect structure, by determining both the slope and the curvature of the bifurcated paths. It is shown that the solution diverges, when a properly defined parameter which characterizes the asymmetry of the structure approaches zero, thus preventing to recover results of symmetric systems. A modified perturbation method which permits to surmount this drawback is then suggested; this method applies only to a class of structures and furnishes asymptotic series valid in a wide region around bifurcation. The two methods are applied to investigate the post-buckling behavior of a two-degree-of-freedom system. Finally, a novel perturbation method which follows to some extent the lines of the Galerkin method and is particularly powerful in the investigation of nearly symmetric systems is presented.

ABSTRACT: Localization phenomena in one-dimensional imperfect continuous structures are analyzed, both in dynamics and buckling. By using simple models, fundamental concepts about localization are introduced and similarities between dynamics and buckling localization are highlighted. In particular, it is shown that strong localization of the normal modes is due to turning points in which purely imaginary characteristic exponents assume a non zero real part; in contrast, if turning points do not occur, only weak localization can exist. The possibility of a disturbance propagating along the structure is also discussed. A perturbation method is then illustrated, which generalizes the classical WKB method; this allows the differential problem to be transformed into a sequence of algebraic problems in which the spatial variable appears as a parameter. Applications of the method are worked out for beams and strings on elastic soil. All these structures are found to have nearly-defective system matrices, so their characteristic exponents are highly sensitive to imperfections.

ABSTRACT: A method is derived for the analysis of mode interaction in thin walled elastic beams. A nonlinear plate theory is employed for the plate segments of the beam, in which the exact nonlinear expressions are used for the middle surface strain measures, but the bending measures are linearized. The beam is subjected to a combination of axial compression and a constant bending moment, and it is assumed to be simply supported at the ends. In the calculation of the total potential energy, the influence of the prebuckling deformations is neglected. The finite strip method is used with the transverse variation of all three displacement components described by cubic polynomials in the arc length. The nonlinear mode interaction is analysed by means of Koiter's asymptotic theory of stability. Some applications of the method to representative problems are presented in a subsequent paper by the authors. This shows that significant mode interaction and imperfection sensitivity occur in these structures.

ABSTRACT: Mode interaction between local and global buckling modes is studied for two types of thin-walled beam structures, using a method of analysis presented in Part I of the author's paper [Mollmann and Goltermann (1989). Int. J. Solids Structures 25, 715–728]. This method involves a combination of the finite strip method and Koiter's asymptotic theory of stability. It appears that the interaction essentially involves three buckling modes (one global and two local modes), and that the inclusion of additional nearly simultaneous local buckling modes in the analysis does not alter the results perceptibly (in the case of local imperfections). In both examples, substantial reductions of load-carrying capacity due to mode interaction and imperfection sensitivity (up to about 50%) are observed. Some of the 2nd order fields and 4-index coefficients exhibit a marked dependence on the value of the load factor at which they are evaluated. For both structures, the load-carrying capacities have been determined for different values of the ratio between global and local critical loads. When this ratio is greater than one (i.e. when the local critical load is smaller than the global), the load carrying capacity will exceed the local critical load if the imperfections are sufficiently small.

ABSTRACT: A consistent method for the analysis of bifurcation instabilities in shells of arbitrary thickness has been proposed. The advantages of this method, as compared to the classical approach followed so far, are the independence of the results on the nonlinear shell theory employed as well as the possibility of finding the dependence of the critical load and eigenmode on the shell's thickness up to any degree of accuracy desired. A brief description of the general method, which is asymptotic with respect to the shell's thickness, is followed by its application to the case of an internally or externally pressurized infinite cylindrical tube for which an analytical solution of the resulting asymptotic problem is possible. Critical loads and modes compare very favorably with a numerical solution of the exact three dimensional problem even for relatively thick tubes. The presentation is concluded with a short discussion on the application of this technique to the general wrinkling instability problem in metal forming.

ABSTRACT: The bifurcation problem of thin walled structures in contact with rigid surfaces is formulated by adopting the multiple scales asymptotic technique. The general theory developed in this paper is very useful for the bifurcation analysis of waviness instabilities in the sheet metal forming. The formulation is presented in a full Lagrangian formulation. Through this general formulation, the bifurcation functional is derived within an error of O(E^3) (E: shell’s thickness parameter). This functional can be used in numerical solutions to sheet metal forming instability problem.

ABSTRACT: Devices with feature size on the order of one micrometer have found widespread applications in
science and engineering. MEMS, is a rapidly growing technology for the fabrication of miniature devices which provides a way to integrate mechanical, fluidic, optical, and electronic functionality on very small devices, ranging from 0.1 microns to one millimeter. Recently, it has been proposed that regular patterns can be generated through the mechanical buckling of a thin film. In this thesis, we focus on the buckling mechanism. The wavy patterns are generated when the thin elastic film is subjected to an in-plane compressive stress and by the application of controlled heating. We first introduce the mechanism of developing wave patterns through buckling using beam buckling as an example and then the finite element formulation and the commercial analysis package Algor. Our study includes the "stress stiffening" component, which is not usually included in most finite element analyses. Both the "Critical Buckling Load" and the "Natural Frequency with Load Stiffening" analyses are made use of to determine the buckling loads. Finally, the buckling load for each case is determined through the analysis and a comparison with the theoretical values is made.

ABSTRACT: The fracture mechanics of a straight-sided, thin film delamination at stress levels, which are high compared to the stress required to initiate the delamination is investigated. Buckling at a bifurcation point of the delaminated region, resulting from incompletely relieved stresses in this region, is analysed by a semi-analytical approach for delaminations of infinite extent. The results are compared to numerical predictions based on finite element calculations for finite sized delaminations. The finite element calculations are carried out in the post-buckling regime showing that parts of the crack front will close as a result of bifurcation buckling, while other parts will experience enhanced energy release rate and mode I stress intensity factor. The mode III stress intensity factor is shown to be negligible at the stress levels analysed.

ABSTRACT: The transition from a straight-sided wrinkle to a periodic distribution of bubbles has been experimentally studied by atomic force microscopy for a stressed thin film relying on a substrate. A non-linear numerical analysis has been carried out and the different steps of the wrinkle evolution have been characterized. Different parameters of the buckling structure such as the shape parameter of the blisters and the stress relaxation have been determined and compared to the experimental data. The comparison of elastic strain energies has highlighted the possible coexistence of structures with different wavelengths.
ABSTRACT: The post-critical regime of straight-sided wrinkles on compliant substrates of polycarbonate has been observed by atomic force microscope and investigated by means of finite element simulations. The effect of coupling between the film and its substrate has revealed a global buckling phenomenon, characterized by critical loads lower than those found in the case of a rigid substrate. Characteristic shapes of the buckled structure have been also found to spread over a region wider than the delaminated zone itself. A law relating the film deflexion to the stress has finally been established for any film/substrate system.

ABSTRACT: The postbuckling transition from an initially straight-sided wrinkle to a distribution of bubbles has been investigated by means of finite element simulations in the case of a thin film relying on a rigid substrate. The calculations show that a snapthrough occurs when the buckling wavelength exceeds a critical value. Experimental atomic force microscopy observations of this transition have been reported and found to be in good agreement with the calculations.

ABSTRACT: We establish a quantitative mechanics framework of elastic buckling of a spheroidal thin film/substrate system, which is highly relevant to the morphologies of quite a few natural and biological systems. The anisotropic stress-driven bifurcation is governed by the ratios between the effective size/thickness, the equatorial/polar radii, and the substrate/film moduli. The possibilities of manipulating the undulations through external constraints, anisotropic growth/material properties, and substrate geometry/structure are discussed. Analytical equations correlating the undulation characteristics with the geometry/material properties are derived. The quantitative mechanics framework established herein not only has important implications on the morphogenesis of various fruits, vegetables, nuts, eggs, tissues, and animal body parts, but also could guide the three-dimensional micro-fabrications via controlled self-assembly on curved substrate surfaces.

ABSTRACT: Mechanical buckling principles of conical film/substrate systems are explored in this study using extensive finite element simulations. The effects of geometrical and material parameters, including cone angle, normalized cone size, film/substrate thickness ratio, and modulus ratio between film and substrate, are explored systematically in terms of the resulting stress anisotropy (in particular the ratio between hoop and longitudinal stresses) and buckling morphology (longitudinal ridges, latitudinal stripes and reticular/herringbone patterns, as well as their transition and branching behaviours). The trends of buckling shape and wave numbers are also explored through analytical solutions of similar hollow cylindrical film/substrate systems. Finally, the mechanical buckling principles are employed to reproduce the morphological features of several types of mollusks, where each distinctive appearance corresponds to certain ranges of material and geometrical parameters. In addition to shedding some light on the morphogenesis of certain natural and biological systems, the study may also provide some useful insights on biomedical engineering and three-dimensional micro-fabrications.

ABSTRACT: The present paper deals with dynamic, coupled buckling of long, prismatic columns simply supported at the ends. This investigation concerns thin-walled structures of a square cross-section with or without intermediate stiffeners under in-plane pulse loading. The dynamic load of a rectangular shape has been assumed in the analysis. The structures are composed of rectangular plates interconnected along longitudinal edges. A plate model is adopted in the analysis. The material of the structure is isotropic. The problem has been investigated on the basis of the disturbance theory. The dynamic critical load factor DLF has been determined using the Budiansky and Hutchinson criterion. The results obtained with the analytical–numerical method (ANM), which employs the asymptotic perturbation theory, have been compared with the finite element method (FEM).

ABSTRACT: The dynamic coupled buckling loads were determined for the columns with intermediate stiffener subjected to in-plane pulse loading. The pulse loading of a rectangular shape was concerned. Columns made of isotropic material were assumed to be simply supported at loaded ends. A plate model was adopted in the analysis. The discussed problem of interactive buckling is solved by the analytical–numerical method (ANM) using Koiter’s perturbations method. The differential equations of motion were obtained from Hamilton’s Principle, taking into account all components of inertia forces. In this study, the interactions of two global modes with two local ones were presented. The results obtained by the analytical–numerical method (ANM) were compared with finite element method (FEM)—ANSYS. The dynamic critical loads using the most popular Budiansky–Hutchinson’s criterion, the Kleiber–Kotula–Saran’s criterion with Kubiak’s modifications and the phase plane criterion were determined. New versions of criteria: Kleiber–Kotula–Saran’s quasi-bifurcation
dynamic criterion and the phase plane criterion were proposed.

ABSTRACT: The double singularities induced by bifurcation point and boundary layer in non-dimensionalized nonlinear boundary-layer Kármán-Donnell equations for axially compressed stiffened cylindrical shells can be treated by Koiter-boundary layer singular perturbation method in this paper. It is demonstrated that the method has high computing efficiency and accuracy based on the analysis of AS-2 shell, and some new conclusions can be directly obtained from the perturbation formulas which are very well in agreement with experimental phenomenon of axially compressed stiffened cylindrical shells.

Yi Zhu and Tim Wilkinson, “Finite Element Analysis of Structural Steel Elliptical Hollow Sections in Compression”, Research Report No R874, The University of Sydney, School of Civil Engineering Sydney NSW 2006 AUSTRALIA

ABSTRACT: This paper presents a finite element investigation of the local buckling behaviour of the structural steel Elliptical Hollow Section (EHS) in compression. The theoretical elastic buckling load of an EHS is similar to that of a Circular Hollow Section (CHS) except that the diameter term, D, is replaced by D12/D2, representing the major and minor diameters of the ellipse. The overall aim is to examine whether an “equivalent CHS” can be used to model the local buckling of EHS when considering imperfections and non-linear material properties. The finite element program ABAQUS was used to examine the local buckling behaviour of EHS with a range of aspect ratios from 1:1 (CHS) to 10:1 to examine the transitional behaviour. Three types of analysis were considered. The first stage was elastic buckling with no material imperfection. The second stage considered inelastic material properties, followed by measured material properties. The final stage was to investigate how geometric imperfection affected the buckling modes. The results are benchmarked against experimental results. It was found that the use of an equivalent CHS was a reasonably good predictor of capacity of slender sections and the deformation capacity of compact sections. However, further benchmarking against experimental results is recommended.

ABSTRACT: The most up-to-date research in the mechanics of delaminations and related crack-like defects in laminate and fiber composites is discussed. Both internal and near-surface delaminations are considered. In the latter case, local buckling of delaminations and the interaction between buckling, damage accumulation, crack growth and global buckling are considered. The problem of the evaluation of the residual load-carrying capacity of delaminated structural components is discussed, including the assessment of the fracture toughness with respect to impact loading.

ABSTRACT: (not available)

ABSTRACT: Optimal structural design of a noncircular cylindrical shell under overall bending and axial force is considered. The material is assumed to be governed by the Norton nonlinear steady creep law. Minimal cross-sectional area is the design objective, the middle line of the profile and the wall-thickness are the design variables and the constraints refer to local stability of the wall according to Gerard's criterion and to brittle creep rupture as described by the Kachanov-Robinson hypothesis. In view of bending, optimal design requires some concentrated areas (longitudinal ribs) located at the outer fibres of the cross-section.

ABSTRACT: The paper shows the effects of behaviour of loading during the buckling process on the value of critical force and initial stability of post-buckling path for elastic, non-prismatic columns. Perturbation method combined with Croll's manoeuvre makes it possible to derive general formulae for the first or the second correction of the force, and hence to analyze stability in the post-buckling range. The effects of behaviour of active and reactive forces may be essential: in numerous examples the boundary values of structural parameters separating stability and instability are evaluated. Pre-buckling geometry changes are analyzed as well.

ABSTRACT: An efficient numerical algorithm is created on the basis of the method of curvilinear meshes, the method of basis reduction, and the asymptotic Koiter theory. It enables us to study load curves to reveal singular (limit and bifurcation) points and to analyze their behavior at branch points. Such an approach allows analyzing the nonlinear deformation of shell structures of arbitrary form and their sensitivity to imperfections. The technique is illustrated by an example of a conic panel with imperfections in the shape.

E. A. Gotsulyak (National University of Building and Architecture, Kiev, Ukraine), “Mesh Discretization of the

ABSTRACT: Mesh methods for discretization of the differential vector relations are generalized as applied to problems of shell theory. In the finite-difference method, covariant derivatives are replaced by vector differences, which are then projected on the vectors of a local basis. In the finite-element method, vector functions are approximated by a Taylor series with tensor coefficients. It is shown that such schemes satisfy the condition of rigid displacement for a deformable body, which improves considerably the convergence of the solution. The proposed schemes, which are sensitive to approximation uncertainties, were tested by solving problems on deformation of shells.

ABSTRACT: Using detailed finite element models, compressive failure mechanisms of composite structures consisting of many laminae are analyzed. It is assumed that the structures contain interlaminar delamination and their failure mode to be characterized by either buckling or delamination growth. Our primary goal is to identify the effects of delamination and ply-arrangement on the multi-layered structures. Up to 32 laminae are distinctly modeled in this investigation. Our study considers two most basic geometry; one is flat panels under compressive load and the other is cylindrical shells subjected to external pressure. In both cases, the energy release rate and mixed-mode stress intensity factors are computed to quantify the crack driving force. The results are used to determine dominant failure initiation mode, structural buckling or delamination growth. Regardless of the structural type and total number of layers, a significant reduction in the load carrying capacity may occur when interlaminar delamination exists. In the flat panels, interlaminar delamination can generate unstable post-buckling behavior and lower the steady-state post-buckling load. However, delamination growth does not likely to occur during the pre-buckling stage. For the cylindrical shells, delamination growth may initiate prior to structural buckling. The location of delamination also plays an important role in defining the critical crack initiation load. When the delamination is located within 25% to 40% of shell thickness measured from the outer surface, the crack initiation load can be as low as half of the buckling load. In both types of structures, as the total number of plies increases, the layer effect diminishes. The overall deformation and failure behaviors of panels with large number of layers approach those of the infinite-layer model with homogenized material properties.

ABSTRACT: The thin-walled composite columns with an open cross-section reinforced by intermediate stiffener under axial compression have been considered. The finite element method is employed to study the buckling behaviour of the thin-walled composite column. Eigenvalue analyses are carried out first to predict the buckling load and buckling mode shapes of the column, and then the geometric nonlinear analyses are performed to investigate the nonlinear buckling properties and post-buckling behaviour of the thin-walled
structures. The type of angle ply symmetric laminate is used. The investigation is performed over several values of ply arrangement angle and various values of stiffener parameter. The numerical results show a significant effect of the intermediate stiffeners and composite ply angle on loading capacity and buckling behaviour of the thin-walled composite column. The research provides insight into the thin-walled structure and composite laminate, which is employed to enhance the loading capacity of thin-walled composite structures.

ABSTRACT: Based on the J_2 flow theory, an analysis is presented of the initial postbuckling behavior of circular cylindrical shells subjected to external pressure by using Hutchinson's general method. The elastic-plastic material forming the shells is taken to have an arbitrary strain-hardening exponent. It is shown that plastic deformation must be taken into account if the shells have a diameter-thickness ratio of less than 40. This kind of shell has a different postbuckling behavior from thin cylindrical shells and its imperfection-sensitivity is strong.

ABSTRACT: A model of a column is proposed in order to analyse the post-buckling behaviour of a structural element in the elastic-plastic deformation range. The ideal two point I-section applied here simplifies the deformation analysis, that is, the problem of development of plastic zones in a section is eliminated, but still
gives the possibility for qualitative analysis and optimization of the post-critical equilibrium paths. The coefficients of linear or parabolic variability of thickness of the flanges and their distance (web width) are accepted as model parameters and hence could be used for design variables in the optimization procedure. Moreover, the stiffness of an additional elastic support of the free end of the beam is also included as a parameter or design variable. A material model is employed with non-linear asymptotic isotropic hardening without the Bauschinger effect. Change of the tangent modulus is continuous and smooth during the transition from the elastic to plastic deformation range. The main goal of the analysis is to determine the values of the design variables for which the post-critical equilibrium paths are stable at least in the specified range of a generalized displacement. The constraints for the constant volume of the flanges and web material are applied. The inequality constraints are imposed on the flange thickness and web width. Various formulations of the optimization problem are proposed for all types of non-linear behaviour, including elastic or plastic buckling and elastic or elastic-plastic post-buckling deformation.

ABSTRACT: A perturbation method based on the static stability criterion associated with the vanishing of the total potential energy on a certain equilibrium point on the unstable postbuckling path is presented for the determination of lower bound dynamic buckling loads of imperfection-sensitive structures under step load of infinite duration. Attention is focused on the effect of various possible sources of structural imperfections on the dynamic buckling strength of perfect structures. Under the assumption that the effect of structural imperfections is of the first order, the method can give any desired higher-order approximation to the lower bound dynamic buckling loads and the corresponding displacements without solving the system of differential equations of motion numerically. Especially, the method applies to finite-degree-of-freedom systems as well as continuous ones. The application of the method is illustrated on two examples. The results demonstrate the significant effect of other imperfection sources, besides the shape imperfections having the shape of the classical buckling mode.

“A Simplified Model to Simulate Crash Behavior of Honeycomb”, Proceedings of the International conference on Advanced Design and Manufacture 8th-10th January, 2006, Harbin, China
ABSTRACT: Although to have an accurate result of Finite Element analysis of a system is always enviable, on most of engineering problems it is worthwhile to find simpler models with less required time to solve and acceptable degree of accuracy those keep the general characteristics of system. Available numerical methods, however consider effect of different characters like air drainage and adhesive influence on crash behavior of honeycomb, but usually these assumptions are not applicable on big models especially when a complicated geometry is appraised. This paper validates a simple Finite Element model for honeycomb witch has an acceptable accuracy in crash analysis and is easily applicable on intricate problems. This model is desirable not only for simple honeycomb systems but also for sophisticated samples such as multi-layer or multi-material honeycomb based structures. A comparison with experimental results shows good rate of exactitude for new

ABSTRACT: In the aeronautical field, sandwich structures are widely used for secondary structures like flaps or landing gear doors. The modeling of low velocity/low energy impact, which can lead to a decrease of the structure strength by 50%, remains a designer’s main problem. Since this type of impact has the same effect as quasi-static indentation, the study focuses on the behavior of honeycomb cores under compression. The crushing phenomenon has been well identified for years but its mechanism is not described explicitly and the model proposed may not satisfy industrial purposes. To understand the crushing mechanism, honeycomb test specimens made of Nomextrade, aluminum alloy and paper were tested. During the crushing, a CCD camera showed that the cell walls buckled very quickly. The peak load recorded during tests corresponded to the buckling of the common edge of three honeycomb cells. Further tests on corner structures to simulate only one vertical edge of a honeycomb cell show a similar behavior. The different specimens exhibited similar load/displacement curves and the differences observed were only due to the behavior of the different materials. As a conclusion of this phenomenological study, the hypothesis that loads are mainly taken by the vertical edge can be made. So, a honeycomb core subjected to compression can be modeled by a grid of nonlinear springs. A simple analytical model was then developed and validated by tests on Nomextrade honeycomb core indented by different sized spherical indenters. A good correlation between theory and experiment was found. This result can be used to satisfactorily model using finite elements the indentation on a sandwich structure with a metallic or composite skin and honeycomb core.

ABSTRACT: Presented in the following pages is an experimental and numerical study of dynamic local buckling of skin on foam core. Impact tests on sandwich-type structures with skins stabilized by foam demonstrated that rupture appears by debonding of skins due to a local buckling phenomenon, and that the maximum stress in the skin, obtained at rupture, grows with the increase of the loading rate of the skin. A finite element analysis allows this phenomenon to be analyzed and understood, and a mass-spring-dashpot model is proposed to model the skin debonding initiation.

ABSTRACT: This paper investigates the non-linear dynamic behavior and stability of the internal membrane of a ventricular assist device (VAD). This membrane separates the blood chamber from the pneumatic chamber, transmitting the driving cyclic pneumatic loading to blood flowing from the left ventricle into the aorta. The membrane is a thin, nearly spherical axi-symmetric shallow cap made of polyurethane and reinforced with a cotton mesh. Experimental evidence shows that the reinforced membrane behaves as an isotropic elastic material and exhibits both membrane and flexural stiffness. So, the membrane is modeled as an isotropic pressure loaded shallow spherical shell and its dynamic behavior and snap-through buckling considering different types of dynamic excitation relevant to the understanding of the VAD behavior is investigated. Based on Marguerre kinematical assumptions, the governing partial differential equations of motion are presented in the form of a compatibility equation and a transverse motion equation. The results show that the shell, when subjected to compressive pressure loading, may lose its stability at a limit point, jumping to an inverted position. If the compressive load is removed, the shell jumps back to its original configuration. This non-linear behavior is the key feature in the VAD behavior.

ABSTRACT: A combined experimental/finite element effort is carried out to elucidate the post buckling response of unilaterally constrained plates under monotonically increasing edge thrust. Real time observations, together with a wide range of plate aspect ratio and a large load level facilitate deep physical insight into the general behavior of this class of problems. The interaction of the plate with the rigid restraining plane following
buckling leads to interesting deformation sequences, characterized by the development of asymmetric bulges and contact zones following by a possible plate snapping. The latter is motivated by a secondary buckling evolving gradually from a contact zone(s) or a bulge(s). These two instability mechanisms are competitive, being dictated by the plate aspect ratio and other system parameters. The critical load for plate snapping agrees well with a finite element prediction based on an asymmetric deformation choice that minimizes the strain energy in the plate. A semi analytic relation for predicting the onset of secondary instability in the contact area and subsequent plate snapping is developed based on the numerical results. Finally, the present work seems to add a new dimension into the fracture of coatings and laminated composites containing near-surface defects.

ABSTRACT: Thin wall steel-concrete composite wall panels can be used as bearing member and also as maintenance structural plates, which can satisfy functional requirements of building including bearing capacity, heat insulation and preservation. The problem relating unilateral contact buckling of thin wall steel composite panels has received attention from many construction engineers. The investigation progress is analyzed in general and the investigation questions are illustrated. The research approach and technical routes of delaminated critical load are also presented.

ABSTRACT: This paper comprises results which have been obtained in the course of studies on a unified approach to a variety of current static and dynamic problems of inelastic solids and structures. The objective of the first part of the paper is to review some concepts of constitutive and finite element modelling for novel plasticity applications. The specific topics covered here are: large elastic-plastic strains with infinitesimal or finite elastic strain contribution, non-associated viscous and non-viscous plasticity as applied to void-containing metals, and temperature and creep effects. The discussion to follow is aimed at showing the great potential of finite-element time stepping schemes in solving problems of structural and mechanical engineering. The numerical illustrations encompass a diversity of large scale computations such as geometrically and materially nonlinear analysis of frames and shells and bifurcation analysis in void-containing metals.

ABSTRACT: The general problem of sizing, material selection, load parameter and shape sensitivity of non-linear structural response is considered. The non-linear sensitivity path is followed by an incremental strategy employing the continuum-based updated Lagrangian description. The resulting finite element equations are derived. Both the direct differentiation and adjoint structure strategies are considered. The merits of using the consistent tangent matrix for sensitivity calculations are indicated. The formulation employs the so-called reference volume concept and may be seen as a further attempt to unify the shape and non-shape sensitivity analysis procedures.

ABSTRACT: This paper is concerned with recent sensitivity results for buckling and post-buckling problems. The article starts with an overview of the FEM-based approach to inelastic structural mechanics systems with singular points along the equilibrium path. The existing sensitivity techniques are reviewed, their inherent drawbacks are indicated and a new methodology is suggested. The discretized formalism is mainly employed throughout but a continuum formulation appropriate for this class of problems is also given. Numerical studies illustrate the presentation.

ABSTRACT: The Canadian Forces (CF) and the US Interagency Ship Structure Committee (SSC) jointly sponsored a full-scale testing project to study the load-carrying characteristics of single stiffened panels under different load combinations and with various types of damage. A full-scale testing system was designed and constructed, in which the stiffened panel was simply supported by cylindrical bearings at both ends and restrained by discrete carriages along the sides to simulate the boundary conditions resulting from a grillage environment in ship hull structures. Twelve full-scale panels, including seven “as-built”, two “dented” and three “corroded” specimens, were tested in this set-up. In the meantime, a series of nonlinear finite element analyses were conducted to simulate the test procedure and predict the collapse loads and buckling behavior of these stiffened panels. The finite element models were established by a direct mapping of measured imperfections to nodal points. Residual stresses were introduced using a thermal stress analysis procedure. For models with spatial discontinuities, locally refined meshes and the branch shifting technique were used to achieve the desired failure modes. In this paper, the finite element solutions are presented in detail and compared with the test observations. The good agreement between the experimental and numerical results indicates that the nonlinear finite element method is capable of predicting plastic post-buckling behavior of stiffened panel structures.

doi: 10.1002/nme.157
ABSTRACT: A method to analyse and solve symmetric bifurcations by establishing the bifurcation equations using an asymptotic expansion method is presented. The bifurcation equations are obtained using a decomposition of the spaces by means of the theory of Lyapunov–Schmidt. To solve the bifurcation equations an asymptotic expansion method along the lines of Koiter is applied. The expansion is presented in a form suited for implementation in a finite element context. The present paper is focused on the treatment of symmetric multiple bifurcations where new forms of the bifurcation equations are established. The accuracy of
the method is verified with three examples.

ABSTRACT: A nonlinear finite strip method of analysis is described for the post-local buckling of geometrically imperfect plate assemblies. The method is used to provide an accurate alternative to the Winter effective width formula for obtaining the effective section of a simply supported I-beam in the post-local buckling range of structural response. The effective section of a locally buckled beam with thin flange outstands is used to investigate the resistance of the beam to flexural-torsional buckling. The analytical methods developed to assess the nonlinear interaction of local and lateral buckling are compared with experimental tests performed by Cherry.

ABSTRACT: A finite strip method of analysis is presented for the inelastic local buckling of I-beams fabricated by welding. Stiffness and stability matrices for the section are developed at a monotonically increasing load factor, and the critical moment is that for which the buckling determinant vanishes. Critical moments determined in this way are shown to agree well with test results. The limiting depth-to-thickness ratios for the web which correspond to compact and semi-compact sections are investigated, and it is shown that the values given in BS 5950: Part I are unconservative for an extensive range of section geometries. Based on a parametric study, alternative and more accurate formulations for the critical web slendernesses are proposed.

ABSTRACT: The semi-analytical complex finite strip method is used to study the elastic local buckling of I-sections in bending containing a longitudinal stiffener attached to the web. The optimum position of this stiffener is calculated to maximise the web local buckling stress. The local buckling of the stiffener is then considered, and recommendations are made regarding the stiffener proportions that would cause yield of the stiffener before it buckled locally.

ABSTRACT: A complex finite strip method of analysis that includes inelasticity is described. The finite strip displacement functions are augmented with so-called bubble functions, which are extra modes associated with internal or nodeless degrees-of-freedom. It is shown that the use of bubble functions significantly improves the convergence of the inelastic finite strip method. The analytical procedure is then used to study the inelastic local buckling of plates in compression and shear, stiffened plates in compression and I-section beams in shear.

ABSTRACT: A modified semi-analytical finite strip method of buckling analysis in which the usual restriction of two, opposite, simply supported ends is removed by assuming appropriate longitudinal functions is described. Two sets of basic functions (denoted I and II) are used in the buckling study and the accuracy of these basic functions is evaluated. It is shown that the use of so-called bubble functions significantly improves the convergence of the finite strip method for local buckling problems. The analytical procedure is used to investigate the local buckling behaviour of isotropic plates with different boundary conditions along all edges under both uniaxial and biaxial compression, and the buckling of stiffened plates under compression. The bubble formulation provides a powerful tool for the efficient analysis of a variety of local buckling problems.

ABSTRACT: This paper is concerned with the inelastic local buckling of flat plate structures that contain plates with variable thicknesses. Use is made of the semi-analytical complex finite strip method, which is augmented with transverse bubble functions. Stiffness and stability matrices are derived for inclusion in the finite strip method, which is based on the deformation theory of plasticity. The numerical scheme is programmed, and several numerical examples are presented to illustrate the prowess and scope of the procedure. The inelastic local buckling of tapered plates subjected to compression and shear with different boundary conditions is studied first, and the method is then applied to the inelastic local buckling of channel sections with tapered flanges and stiffened plates with variable thickness and different geometries. Slenderness limits for channels that delineate between local buckling and yield (and that define the transition from non-compact to slender cross-sections) are discussed.

ABSTRACT: Reinforced concrete cooling towers of hyperbolic shell configuration find widespread application in utilities engaged in the production of electric power. In designing critical civil infrastructure of this type, it is imperative to consider all of the possible loading conditions that the cooling tower may experience. One important loading condition in many nations is that of earthquake excitation, whose influence on the integrity and stability of cooling towers is profound. Previous research has shown that the columns supporting a cooling tower are sensitive to earthquake forces, as they are heavily loaded elements that do not possess high ductility,
and understanding the behaviour of columns under earthquake excitation is vital in structural design because they provide the load path for the self weight of the tower shell. This paper presents the results of a finite element investigation of a representative “dry” cooling tower, using realistic horizontal and vertical acceleration data obtained from the recent and widely-reported Tabas, Nahgan and Bam earthquakes in Iran. The results of both linear and nonlinear analyses are reported in the paper, the locations of plastic hinges within the supporting columns are identified and the ramifications of the plastic hinges on the stability of the cooling tower are assessed. It is concluded that for the (typical) cooling tower configuration analysed, the columns that are instrumental in providing a load path are influenced greatly by earthquake loading, and for the earthquake data used in this study the representative cooling tower would be rendered unstable and would collapse under the earthquake forces considered.

ABSTRACT: Elliptical tubes may buckle in an elastic local buckling failure mode under uniform compression. Previous analyses of the local buckling of these members have assumed that the cross-section is hollow, but it is well-known that the local buckling capacity of thin-walled closed sections may be increased by filling them with a rigid medium such as concrete. In many applications, the medium many not necessarily be rigid, and the infill can be considered to be an elastic material which interacts with the buckling of the elliptical tube that surrounds it. This paper uses an energy-based technique to model the buckling of a thin-walled elliptical tube containing an elastic infill, which elucidates the physics of the buckling phenomenon from an engineering mechanics basis, in deference to a less generic finite element approach to the buckling problem. It makes use of the observation that the local buckling in an elliptical tube is localised with respect to the contour of the ellipse in its cross-section, with the localisation being at the region of lowest curvature. The formulation in the paper is algebraic and it leads to solutions that can be determined by implementing simple numerical solution techniques. A further extension of this formulation to a stiffness approach with multiple degrees of buckling freedom is described, and it is shown that using the simple one degree of freedom representation is sufficiently accurate for determining the elastic local buckling coefficient.

ABSTRACT: Elliptical tubes may buckle in an elastic local buckling failure mode under uniform compression. Previous analyses of the local buckling of these members have assumed that the cross-section is hollow, but it is well-known that the local buckling capacity of thin-walled closed sections may be increased by filling them with a rigid medium such as concrete. In many applications, the medium many not necessarily be rigid, and the infill can be considered to be an elastic material which interacts with the buckling of the elliptical tube that surrounds it. This paper uses an energy-based technique to model the buckling of a thin-walled elliptical tube containing an elastic infill, which elucidates the physics of the buckling phenomenon from an engineering mechanics basis, in deference to a less generic finite element approach to the buckling problem. It makes use of the observation that the local buckling in an elliptical tube is localised with respect to the contour of the ellipse in its cross-section, with the localisation being at the region of lowest curvature. The formulation in the paper is algebraic and it leads to solutions that can be determined by implementing simple numerical solution techniques. A further extension of this formulation to a stiffness approach with multiple degrees of buckling freedom is described, and it is shown that using the simple one degree of freedom representation is sufficiently accurate for determining the elastic local buckling coefficient.

ABSTRACT: The accuracy of stability analysis depends on the accuracy of both the element stiffness matrix and geometry stiffness matrix. Therefore, when carrying out the stability analysis of thin cylindrical shells using the finite element methods will require, firstly, a refined non-conforming rectangular curved cylindrical shell element RCSR4 is proposed according to the refined non-conforming FE method, in which both the C1 and C0 weak continuity conditions are satisfied and as a result, can ensure the convergence of computation. At the same time, a refined geometrical stiffness matrix is introduced to replace the standard consistent geometrical stiffness matrix. Simple expressions of the refined constant strain matrices with adjustable constants are introduced with respect to the weak continuity conditions. Numerical examples are presented to show that the present method can indeed improve the performance and the accuracy in stability analysis.

ABSTRACT: A refined non-conforming triangular plate/shell element for geometric non-linear analysis of plates/shells using the total Lagrangian/updated Lagrangian approach is constructed in this paper based on the refined non-conforming element method for geometric non-linear analysis. The Allman's triangular plane element with vertex degrees of freedom and the refined triangular plate-bending element RT9 are used to construct the present element. Numerical examples demonstrate that the accuracy of the new element is quite high in the geometric non-linear analysis of plates/shells.

ABSTRACT: A refined non-conforming triangular plate/shell element for linear and geometrically nonlinear analysis of plates and shells is developed in this paper based on the refined non-conforming element method (RNEM). A conforming triangle membrane element with drilling degrees of freedom in Cartesian coordinates and the refined non-conforming triangular plate-bending element RT9, in which Kirchhoff kinematic assumption was adopted, are used to construct the present element. The displacement continuity condition along the interelement boundary is satisfied in an average sense for plate analysis, and the coupled displacement continuity requirement at the interelement is satisfied in an average sense, thereby improving the performance.
of the element for shell analysis. Selectively reduced integration with stabilization scheme is employed in this paper to avoid membrane locking. Numerical examples demonstrate that the present element behaves quite satisfactorily either for the linear analysis of plate bending problems and plane problems or for the geometrically nonlinear analysis of thin plates and shells with large displacement, moderate rotation but small strain.

ABSTRACT: We present in this research article, the improvements that we made to create a four nodes flat quadrilateral shell element for geometrically nonlinear analysis, based on corotational updated lagrangian formulation. These improvements are initially related to the improvement of the in-plane behaviour by incorporation of the in-plane rotational degrees of freedom known as “drilling degrees of freedom” in the membrane displacements field formulation. In the second phase, a co-rotational spatial local system of axes which adapts well to the problems of quadrilateral elements is adopted, while ensuring simplicity and effectiveness at numerical level. The required goal being mainly to have a robust thin shell element associated with a simplified formulation. The obtained element remains economic, and showing a robust behaviour in delicate situations of tests.

ABSTRACT: This paper proposes a simple and accurate 4-node, 24-DOF layered quadrilateral flat plate/shell element, and an efficient nonlinear finite element analysis procedure, for the geometric and material nonlinear analysis of reinforced concrete cylindrical shell and slab structures. The model combines a 4-node quadrilateral membrane element with drilling or rotational degrees of freedom, and a refined nonconforming 4-node 12-DOF quadrilateral plate bending element RPQ4, so that displacement compatibility along the interelement boundary is satisfied in an average sense. The element modelling consists of a layered system of fully bonded concrete and equivalent smeared steel reinforcement layers, and coupled membrane and bending effects are included. The modelling accounts for geometric nonlinearity with large displacements (but moderate rotations) as well as short-term material nonlinearity that incorporates tension, cracking and tension stiffening of the concrete, biaxial compression and compression yielding of the concrete and yielding of the steel. An updated Lagrangian approach is employed to solve the nonlinear finite element stiffness equations. Numerical examples of two reinforced concrete slabs and of a shallow reinforced concrete arch are presented to demonstrate the accuracy and scope of the layered element formulation.

“Recent developments in finite element analysis for laminated composite plates”, Composite Structures, Vol.88,
ABSTRACT: A review of the recent development of the finite element analysis for laminated composite plates from 1990 is presented in this paper. The literature review is devoted to the recently developed finite elements based on the various laminated plate theories for the free vibration and dynamics, buckling and postbuckling analysis, geometric nonlinearity and large deformation analysis, and failure and damage analysis of composite laminated plates. The material nonlinearity effects and thermal effects on the buckling and postbuckling analysis, the first-ply failure analysis and the failure and damage analysis were emphasized specially. The future research is summarised finally.

Zora Vrcelj and Mark Andrew Bradford (School of Civil and Environmental Engineering, The University of New South Wales, Sydney, Australia), “A simple method for the inclusion of external and internal supports in the spline finite strip method (SFSM) of buckling analysis”, Computers & Structures, Vol. 86, No. 6, March 2008, pp. 529-544, Special Issue: Civil-Comp, doi:10.1016/j.compstruc.2007.05.001

ABSTRACT: The SFSM is an attractive numerical technique for the buckling analysis of folded-plate structures where general loading regimes and boundary conditions need to be modelled. In implementing splines as interpolation functions in the longitudinal direction of the strip, amended splines have been used conventionally to model the variety of end conditions that may occur. These amended splines are fairly difficult to implement, particularly so if internal restraints are also to be specified. A simple technique for replacing the specification of dedicated amended splines is presented in this paper. The method is then employed to study the local buckling of flat plates under longitudinally and transversely varying compression and bending with different boundary conditions at the ends.

PARTIAL ABSTRACT: This paper presents a nonlinear inelastic analysis of the biaxial bending and torsion of thin-walled steel beam-columns based on the principle of virtual work. The effect of geometric nonlinearity is developed using position vector analysis. Approximations are not made in the early stage of the development, and thus some significant terms for buckling and postbuckling analysis are retained. The von Mises yield criterion, the associated flow rule, and the hardening rule are used in formulating the elastic-plastic constitutive matrix for the ...

PARTIAL ABSTRACT: This paper investigates the non-linear in-plane buckling and postbuckling behaviour of elastic arches using a curved finite element model for the non-linear analysis of elastic arches, which includes the effects of prebuckling deformations and second-order terms in the deformed curvatures and bending strains. It is found that the effects of prebuckling deformations on the buckling of shallow arches are significant, that the existence of a linear bifurcation buckling load is not a sufficient condition for linear bifurcation buckling to occur, ...

ABSTRACT: Many design codes do not give methods for designing steel arches against in-plane failure. The
few that do provide methods that are essentially based on a linear interaction equation for the in-plane strengths of an equivalent beam-column, which uses the maximum elastic bending moment and axial compression in the arch. However, the linear interaction equation for a beam-column may not be suitable for an arch because it does not consider the strength characteristics of steel arches. This paper studies the in-plane buckling of arches in uniform compression and uses a nonlinear inelastic finite-element model to develop a method for designing steel arches against uniform compression, and also to develop an interaction equation for the design of steel arches against nonuniform in-plane compression and bending. Analytical solutions for the buckling loads of shallow arches in uniform compression are obtained. It is found that the design equation for steel columns cannot be used directly for steel arches in uniform compression, nor can the design interaction equations for steel beam-columns be used directly for steel arches under nonuniform compression and bending. The proposed design equations provide close predictions for the in-plane buckling strengths of both shallow and nonshallow steel arches in uniform compression. The modified interaction equation proposed provides good lower bounds for the in-plane strengths of both shallow and nonshallow steel arches in bending and compression because it considers the nonuniform distributions of the bending moment and axial compression around the arch, the behavior of shallow arches, and the favorable moment redistribution after the first hinge forms.

PARTIAL ABSTRACT: Classical buckling theory is mostly used to investigate the in-plane stability of arches, which assumes that the pre-buckling behaviour is linear and that the effects of pre-buckling deformations on buckling can be ignored. However, the behaviour of shallow arches becomes non-linear and the deformations are substantial prior to buckling, so that their effects on the buckling of shallow arches need to be considered. Classical buckling theory which does not consider these effects cannot correctly predict the in-plane buckling load.

ABSTRACT: When a shallow arch is subjected to an in-plane load that is applied suddenly, the arch will oscillate about an equilibrium position due to the kinetic energy imparted to the arch by the sudden load. If the suddenly applied load is sufficient large, the motion of the arch may reach an unstable equilibrium position, leading to dynamic buckling of the arch. This paper presents a study of the dynamic in-plane buckling of a shallow pin-ended circular arch under a central radial load that is applied suddenly with infinite duration. The method of conservation of energy is used to establish the criterion for dynamic buckling of the shallow pin-ended arch and analytical solutions for the lower and upper dynamic buckling loads of the arch under this sudden central load with infinite duration are obtained. It is found that the dynamic buckling loads of a shallow pin-ended arch under a sudden central load with infinite duration are lower than its static buckling loads, and that the dynamic buckling load increases with an increase of a dimensionless arch geometric parameter that is introduced. The effect of static preloading on the dynamic buckling of a shallow pin-ended arch is also investigated. It is found that the pre-applied static load decreases its dynamic buckling loads, but increases the sum of the pre-applied load and the dynamic buckling load.
ABSTRACT: The nonlinear long-term buckling behaviour (creep buckling) of spherical shallow, thin-walled concrete shells of revolution (including domes) subjected to sustained loads is investigated herein. A thorough understanding of their nonlinear time-dependent behaviour, as well as the development of comprehensive analytical models for their analysis, has hitherto not been fully established and further studies are required. A nonlinear axisymmetric theoretical model, which accounts for the effects of creep and shrinkage, and which considers the ageing of the concrete material and the variation of the internal stresses and geometry in time, is developed for this purpose. The governing field equations are derived using variational principles, equilibrium requirements, and integral-type constitutive relations. A systematic step-by-step procedure is used for the solution of the integral-type governing equations. First, the nonlinear short-term behaviour is studied to provide a benchmark for the long-term analysis. Different theories for the analysis of the shell structure are examined for this purpose and compared with results obtained by the finite element method. A numerical study, which highlights the capabilities of the nonlinear theoretical model and which provides insight into the nonlinear long-term behaviour of shallow concrete domes, is presented. The results show that long-term effects are critical for the design and structural safety of shallow, thin-walled concrete domes, and so these effects need to be fully understood and quantifiable.

ABSTRACT: Ultimate strength tests on stiffened plates simply supported on all four edges and sub jetted to the combined action of axial and lateral loads are reported. A series of 10 stiffened plates having two different plate slenderness values were tested to failure under different combinations of axial and lateral loads. A description of test procedure is also presented. The test specimens were analysed by using the elasto-plastic finite element package to determine the behaviour and ultimate load capacity of stiffened panels and the comparison of these results with those obtained experimentally established the accuracy of the finite element modelling. In addition, stiffened plates tested by other researchers have been analysed to examine the behaviour of stiffened plates under combined loading.

ABSTRACT: From the mathematical standpoint one has a partial differential equation with variable coefficients. Perturbation procedure gives the possibility for an analytical solution of this eigenvalue problem. Self-adjoint equations and Padé approximants are used for improving the obtained results.
ABSTRACT: The coupled system of three partial differential equations governing a flexible shallow shell dynamics is analysed. No any prior assumptions about the temperature distribution through the shell thickness are applied. The efficiency of the method used here when applied to the solution of integral–differential equations with different dimensions (three-dimensional equations related to the Kirchhoff–Love model) and of different type (heat transfer equations and the hyperbolic equations of shell theory) is demonstrated. Many computational results are reported and discussed.

INTRODUCTION: The widest class of shells used in the civil and mechanical engineering is the class of shells with developable principal surface. The stress-strain state of shell structures under loads, which corresponds to buckling, is inhomogeneous, significantly bended, and nonlinear. Permanent interest of researchers in the problem of inhomogeneous compression of shells of zero Gaussian curvature has not led so far to a correct solution. Therefore, there is a need for the development and application of new methods that allow considering...
the problem in a complex setting, the most appropriate to study real behavior of structures. The approximate analytic integration of nonlinear differential equations of the theory of flexible elastic shells in most practical cases is based on the method of continuation of solution on the artificially introduced parameter. They can be satisfactorily applied only with an effective method of summation. The most natural analytical continuation method is that using Padé approximants (PAs). PAs effectively solves the problem of analytical continuation of power series, and this is a basis of their successful application in the study of applied problems. Currently, the method of PAs is one of the most promising non-linear methods of summation of power series, and the localization of its singular points. Recently, the method of PAs for single-variable functions has been successfully extended to the approximation of two variable functions (2D PAs). A method that provides polynomial asymptotics of the exact solution of the general form and its meromorphic continuation based on 2D Padé approximants is proposed in this work. Several examples of displacements, stability and vibration calculations for inhomogeneous loaded shells with developable principal surface are presented. The accuracy of 2D PAs theoretical results are confirmed by experiments with stainless steel specimens based on holographic interferometry. It is shown that the application of PAs provides sufficient accuracy in the studied area that confirms the advantage of our proposed approach.

ABSTRACT: Nonlinear behaviour of flexible shallow rectangular spherical panels subjected to a uniformly distributed transversal load is analysed. Detection of bifurcation points and construction of bifurcation branches on a ‘load–deflection’ characteristic are mainly addressed. The proposed algorithm is based on a set-up method. Geometrical parameters of shallow shells bifurcations are estimated numerically, and an evolution of bifurcation diagrams vs geometrical parameters kx, ky is traced. An increase of geometrical parameters yields an increase of the set of solutions. Besides symmetrical ones, unsymmetrical solutions are detected, illustrated, and discussed as well.

ABSTRACT: By the variational principle, the chaotic vibrations of deterministic geometrically nonlinear elastic spherical and conical axially symmetric shells with non-homogeneous thickness subjected to a transversal harmonic load are analyzed. The material of the shells is assumed to be isotropic and of the Hookean type. Inertial forces tangent to the averaged surface and inertia of rotation of the cross-section are neglected. By the Ritz procedure, the original PDEs are transferred to the ODEs (Cauchy problem), which are then solved by the fourth-order Runge–Kutta method. In the numerical studies, scenarios of transitions from harmonic to chaotic states for vibrations of flexible spherical and conical shells are detected. Various vibrational states for different combinations of the following control parameters: shell's deflection arrow, the amplitude and frequency of the exciting force, number of modes considered, boundary conditions, and the thickness and shape of the shell cross-section are studied. By adjusting the above parameters, we can detect the transition of a continuous system to the lumped one, and the transition from the harmonic to chaotic vibrations.

ABSTRACT: A geometrically non-linear theory is presented for the dynamic analysis of thin, circular cylindrical shells which have wafer, stronger or ring stiffening. An asymptotic procedure is followed which separates the solution of the non-linear equations of motion into two parts, an inner part which applies to the boundary layer, and an outer part. The resulting approximate equations are relatively simple to deal with. A numerical example is solved for the free vibrations of a simply supported, stringer-stiffened shell.

I.V. Andrianov (1), V.M. Verbonol (2) and J. Awrejcewicz (3)
ABSTRACT: Engineering approach for computation of stringer stiffened cylindrical shells is realized mainly using the structurally orthotropic theory with momentless pre-buckling state. On the other hand, experimental results suggest that in many cases the mentioned theory provides excessive values of buckling load. The influence of imperfections for stringer stiffened shells seems to be less important than in an isotropic case. Considering axially symmetric momentous components of pre-buckling state cannot essentially improve theoretical results. Specific experiments showed a significant influence of stringer discreteness on the buckling loads of reinforced shells. The mentioned influence can be divided into two parts: excitation of essentially non-axially symmetric pre-buckling and buckling states. Usually, only the latter phenomenon is taken into account. In this paper we show that the first factor dominates. We propose simple analytical expressions governing non-axially symmetric pre-buckling state components. We also propose an asymptotic simplification of the buckling boundary value problem. Results obtained are compared numerically with the known theoretical and experimental data.

ABSTRACT: This paper provides a state-of-the-art review of asymptotic methods in the theory of plates and shells. Asymptotic methods of solving problems related to theory of plates and shells have been developed by many authors. The main features of our paper are: (i) it is devoted to the fundamental principles of asymptotic approaches, and (ii) it deals with both traditional approaches, and less widely used, new approaches. The authors have paid special attention to examples and discussion of results rather than to burying the ideas in formalism, notation, and technical details.

ABSTRACT: The method of asymptotic expansions, with the thickness as the parameter, is applied to the nonlinear, three-dimensional, equations for the equilibrium of a special class of elastic plates under suitable loads. It is shown that the leading term of the expansion is the solution of a system of equations equivalent to those of von Kármán. The existence of solutions of this system is established. It is also shown that the displacement and stress corresponding to the leading term of the expansion have the specific form generally assumed in the usual derivations of the von Kármán equations; in particular, the displacement field is of Kirchhoff-Love type. This approach also clarifies the nature of admissible boundary conditions for both the von Kármán equations and the three-dimensional model from which these equations are obtained. A careful discussion of the limitations of this approach is given in the conclusion.

ABSTRACT: Complex vibrations of closed cylindrical shells of infinite length and circular cross-section subjected to transversal local load in the frame of the classical non-linear theories are studied. A transition from partial differential equations (PDEs) to ordinary differential equations (ODEs) is carried out using a higher-order Bubnov-Galerkin approach and Fourier representation. On the other hand, the Cauchy problem is solved using the fourth-order Runge-Kutta method. In the first part of this work, static problems of the theory of closed cylindrical shells are studied. Reliability of the obtained results is verified by comparing them with the results taken from literature. The second part is devoted to the analysis of stability, bifurcation and chaos of closed cylindrical shells. In particular, an influence of sign-changeable external pressure and the control parameters
such as magnitude of pressure measured by \( \phi_0 \), relative linear shell dimension \( \lambda = \frac{L}{R} \), frequency \( \omega \), and amplitude \( q_0 \) of external transversal load, on the shell's non-linear dynamics is studied.

"A mechanical basis for chromosome function", Proceedings of the National Academy of Sciences of the United States of America (PNAS), PNAS August 24, 2004 vol. 101 no. 34 12592-12597, 10.1073/pnas.0402724101

ABSTRACT: We propose that chromosome function is governed by internal mechanical forces generated by programmed tendencies for expansion of the DNA/chromatin fiber against constraining features. Chromosomal processes are generally considered to comprise the simple sum of a large number of individual biochemical changes. We present here a different idea in which internal mechanical forces play a governing role.

CONCLUSION: We propose that basic chromosome function is governed by internally generated mechanical forces generated by tendencies for DNA/chromatin expansion. An attractive feature of this model is that the DNA plays a governing role not only via its information content but also via its intrinsic mechanical properties.

ABSTRACT: Design formulas for calculating the critical stresses of unreinforced and reinforced cylindrical shells in axial compression are derived by analyzing experimental data. The curves obtained with the formulas bound the experimental data from below.

ABSTRACT: The report outlines the methodology and procedures used to manufacture the thin walled cylinder with its axial imperfections using a NUM 1060 CNC Lathe machine. By introducing the known geometries imperfections, the thin cylinder manufactured could be analyzed under different load conditions and with different type of applications. The cylinders manufactured were to have minimum thickness set up with their flat end were machined to follow a periodic sinusoidal wave’s function of specified amplitude and frequency. In addition, the flat end cylinder circumference surface was also required to have a constant chamfer angle either from the outside or inside cylinder surface. A number of experiments were attempted to determine the minimum thickness, the sinusoidal wave's function and the constant chamfer angles required. At the end of the project, the machining techniques and procedures used to manufacture the cylinder were successfully established as well as the CNC part programs which played a major role in producing the imperfections required. A result of a satisfactory final thin cylinder was manufactured even though some difficulties had occurred throughout the whole project. Finally, all the information contained were vital for understanding the concept of manufacturing the cylinders with axial imperfections. It indicates some essential findings for the clear description of the project purposes and the necessary works that undertaken through the completion of the project.

ABSTRACT: This paper presents numerical results on chaotic vibrations of a shallow cylindrical shell-panel under harmonic lateral excitation. The shell, with a rectangular boundary, is simply supported for deflection and the shell is constrained elastically in an in-plane direction. Using the Donnell--Mushtari--Vlasov equation, modified with an inertia force, the basic equation is reduced to a nonlinear differential equation of a multiple-degree-of-freedom system by the Galerkin procedure. To estimate regions of the chaos, first, nonlinear responses of steady state vibration are calculated by the harmonic balance method. Next, time progresses of the chaotic response are obtained numerically by the Runge--Kutta--Gill method. The chaos accompanied with a dynamic snap-through of the shell is identified both by the Lyapunov exponent and the Poincaré projection onto the phase space. The Lyapunov dimension is carefully examined by increasing the assumed modes of vibration. The effects of the in-plane elastic constraint on the chaos of the shell are discussed.

ABSTRACT: This paper presents effects of a concentrated mass on chaotic oscillations of a shallow cylindrical shell under gravity and periodic acceleration. The rectangular shell is simply supported and is elastically in-plane constrained. Assuming mode functions, the Donnell equation with inertia force is reduced to non-linear coupled differential equations by the Galerkin method. The chaotic response is calculated numerically and is examined by the maximum Lyapunov exponent. Dominant chaotic responses are generated within restricted frequency regions of sub-harmonic resonance of 1/2 order. As the concentrated mass increases, the chaotic response is shifted to the lower frequency region. The increment of the concentrated mass decreases the
maximum Lyapunov exponent.

ABSTRACT: Detailed experimental results and analytical results are presented on chaotic vibrations of a shallow cylindrical shell-panel subjected to gravity and periodic excitation. The shallow shell-panel with square boundary is simply supported for deflection. In-plane displacement at the boundary is elastically constrained by in-plane springs. In the experiment, the cylindrical shallow shell-panel with thickness 0.24 mm, square form of length 140 mm and mean radius 5150 mm is used for the test specimen. All edges around the shell boundary are simply supported by adhesive flexible films. First, to find fundamental properties of the shell-panel, linear natural frequencies and characteristics of restoring for the shell-panel are measured. These results are compared with the relevant analytical results. Then, geometrical parameters of the shell-panel are identified. Exciting the shell-panel with lateral periodic acceleration, nonlinear frequency responses of the shell-panel are obtained by sweeping the frequency of periodic acceleration. In typical ranges of the exciting frequency, predominant chaotic responses are generated. Time histories of the responses are recorded for inspection of the chaos. In the analysis, the Donnell equation with lateral inertia force is introduced. Assuming mode functions, the governing equation is reduced to a set of nonlinear ordinary differential equations by the Galerkin procedure. Periodic responses are calculated by the harmonic balance method. Chaotic responses are integrated numerically by the Runge–Kutta–Gill method. The chaotic responses, which are obtained by the experiment and the analysis, are inspected with the Fourier spectra, the Poincaré projections, the maximum Lyapunov exponents and the Lyapunov dimension. It is found that the dominant chaotic responses of the shell-panel are generated from the responses of the sub-harmonic resonance of 1/2 order and of the ultra-sub-harmonic resonance of 2/3 order. By the convergence of the maximum Lyapunov exponent to the embedding dimension, the number of predominant vibration modes which contribute to the chaos is found to be three or four. Fairly good agreements are obtained between the experimental results and the analytical results.

ABSTRACT: To clarify chaotic behavior of thin walled beams, detailed experimental results are presented on chaotic vibrations of a post-buckled beam subjected to periodic lateral acceleration. A thin steel beam of thickness 0.198 mm, breadth 12.7 mm and length 106 mm is used as a test beam. Both ends of the beam are clamped for deflection. One end of the beam is elastically constrained by an axial spring. The beam is compressed to the post-buckled configuration by the axial spring. First, characteristics of restoring force and natural frequency of the beam are obtained. Dynamic nonlinear responses of the beam are measured under periodic acceleration. In specific frequency regions, chaotic responses are generated. The chaotic responses are examined carefully with the Poincaré maps, the Fourier spectra, the maximum Lyapunov exponents and the
principal component analysis. The post-buckled beam shows the soften-and-hardening characteristics of restoring force. The dominant chaotic responses of the beam are bifurcated from the sub-harmonic resonances of 1/2 and 1/3 orders with the lowest mode of vibration. Changing the exciting frequency gradually, dynamical transition behaviors from these steady-state sub-harmonic response to the chaotic responses are precisely inspected by the Poincaré projection. The maximum Lyapunov exponent of the former chaotic response of 1/2 order is larger than that of the latter chaotic response of 1/3 order. The principal component analysis predicts that the contribution of the lowest mode of vibration to the chaos is dominant among other contributions of multiple vibration modes.

ABSTRACT: Experimental results and analytical results are presented on chaotic vibrations of a shallow double-curved shell-panel subjected to gravity and periodic excitation. Modal interactions in the chaotic responses are discussed. The shell-panel with square boundary is simply supported for deflection. In-plane displacement at the boundary is elastically constrained. In the experiment, time histories of the chaotic responses at the spatial multiple positions of the shell-panel are measured for the inspection of modal interaction. In the analysis, the shallow shell-panel is assumed to have constant curvatures along to orthogonal directions and geometric initial imperfection. The Donnell–Mushtari–Vlasov type equation is used as governing equation with lateral inertia force. Assuming deflection with multiple modes of vibration, the governing equation is reduced to a set of nonlinear ordinary differential equations by the Bubnov–Galerkin procedure. Chaotic responses are integrated numerically. The chaotic responses, which are obtained by the experiment and the analysis, are inspected with the Fourier spectra, the Poincaré projections, the maximum Lyapunov exponents and the Lyapunov dimension. Contribution of modes of vibration to the chaotic responses is analyzed by the principal component analysis, i.e., Karhunen–Loève transformation.

ABSTRACT: Composite laminates are widely used in construction of mechanical, aerospace, marine and automotive structure. These structures exhibit inherent random dispersion in material properties, as absolute control of production process is neither feasible nor economical. Some composite structures are subjected to large amplitude vibration during their working life that may lead to non-linearity in the response. The present paper analyses the effect of material parameter dispersion on the large amplitude free vibration of especially orthotropic laminated composite plates. The basic formulation of the problem has been developed based on the classical laminate theory and Von-Karman non-linear strain–displacement relation. The system equations have been obtained by using Hamilton's principle and the solution has been found by term wise series integration. Perturbation technique has been used to obtain the second order response statistics. Typical results have been presented for a plate with all edges simply supported. Effects of side-to-thickness ratio, aspect ratio, oscillation
amplitude and mode shape along with change in standard deviation of material properties have been investigated for cross-ply symmetric and antisymmetric laminates.

ABSTRACT: This paper addresses nonlinear flexural vibrations of shallow shells composed of three thick layers with different shear flexibility, which are symmetrically arranged with respect to the middle surface. The considered shell structures of polygonal planform are hard hinged simply supported (i.e. all in-plane rotations and the bending moment vanish) with the edges fully restraint against displacements in any direction. The kinematic field equations are formulated by layerwise application of a first-order shear deformation theory. A modification of Berger's theory is employed to model the nonlinear characteristics of the structural response. The continuity of the transverse shear stress across the interfaces is specified according to Hooke's law, and subsequently the equations of motion of this higher order problem can be derived in analogy to a homogeneous single-layer shear deformable shallow shell. Numerical results of rectangular shallow shells in nonlinear steady-state vibration are presented for various ratios of shell rise to thickness, and non-dimensional load amplitude.

ABSTRACT: This paper is concerned with the non-linear free periodic vibrations of thin, open, cylindrical and shallow shells vibrating in the geometrically non-linear regime. A multi-degree-of-freedom model with hierarchical basis functions is adopted and the principle of the virtual work is used to define the time domain equations of motion. These equations are transformed into the frequency domain by the harmonic balance method and are finally solved by an arc-length continuation method. Shells of different thicknesses and of different curvature radius are analysed, and the variation of the non-linear natural frequencies of these shells with the vibration amplitude are investigated in some detail. The variation of the mode shapes with the vibration amplitude is demonstrated. It is found that both softening and hardening spring effects occur and that the number of couplings between vibration modes is rather large in undamped shells.

ABSTRACT: The geometrically non-linear vibrations of linear elastic composite laminated shallow shells under the simultaneous action of thermal fields and mechanical excitations are analysed. For this purpose, a model based on a very efficient p-version first-order shear deformation finite element, with hierarchical basis functions, is employed. The equations of motion are solved in the time domain by a Newmark implicit time integration method. The model and code developed are partially validated by comparison with published data.
Parametric studies are carried out in order to study the influence of temperature change, initial curvature, panel thickness and fibre orientation on the shells’ dynamics.

ABSTRACT: The chaotic vibrations of a bimetallic shallow shell of revolution under time-varying temperature excitation are investigated in the present study. The governing equations are established in forms similar to those of classical single-layered shell theory by re-determination of reference surface. The nonlinear differential equation in time-mode is derived by variational method following an assumed spatial-mode. The Melnikov function is established theoretically to estimate regions of the chaos, and the Poincaré map, phase portrait, Lyapunov exponent, and Lyapunov dimension are used to determine if a chaotic motion really appears. Further investigations are developed by means of detailed numerical simulation, and both the bifurcation diagrams and corresponding maximum Lyapunov exponent are illustrated. The influence of static and time-dependent temperature parameters, height parameter of the shell, and damping parameter on the dynamic characteristics is examined. Interesting phenomena such as the onset of chaos, transient chaotic motion, chaos with interior crisis and period window, period-doubling scenario and reversed period-doubling bifurcation leading to chaos, jump phenomena, and chaos suddenly converting to period orbit have been observed from these figures.

ABSTRACT: The axisymmetrically nonlinear free vibration of a bimetallic shallow shell of revolution under uniformly distributed static temperature changes is investigated. Based on the nonlinear bending theory of thin shallow shells, the governing equations are established in forms similar to those of classical single-layered shells theory by redetermination of reference surface of coordinate. These partial differential equations are reduced to corresponding ordinary ones by elimination of the time variable with Kantorovich averaging method following an assumed harmonic time mode. The resulting equations, which form a nonlinear two-point boundary value problem, are then solved numerically by shooting method, and the temperature-dependent characteristic relations of frequency vs. amplitude are obtained successfully. A detailed parametric study is conducted involving shell geometry and temperature parameters. The effects of these variables on the frequency–amplitude characteristics are plotted and discussed.

ABSTRACT: The non-linear free vibration of a functionally graded doubly-curved shallow shell of elliptical plan-form is investigated using the p-version of the finite element method in conjunction with the blending function method. The effects of transverse shear deformations, rotary inertia, and geometrical non-linearity are taken into account. It is assumed that the material properties vary through the thickness according to a power
law distribution. The harmonic balance method is used to derive the equations of free motion. The resultant non-linear equations are solved iteratively using the linearized updated mode method. The efficiency of the method is demonstrated through convergence study and comparison with published results. Three types of functionally graded doubly-curved shallow shells of elliptical plan-form are considered. The effects of the volume fraction exponent and thickness ratio on the linear and non-linear frequencies are discussed. It is shown that these parameters influence the hardening behaviour.

“On the accuracy of the multiple scales method for non-linear vibrations of doubly curved shallow shells”,
International Journal of Non-Linear Mechanics, Vol. 46, No. 1, January 2011, pp. 170-179,
doi:10.1016/j.ijnonlinmec.2010.08.006

ABSTRACT: Non-linear free and forced vibrations of doubly curved isotropic shallow shells are investigated via multi-modal Galerkin discretization and the method of multiple scales. Donnell’s non-linear shallow shell theory is used and it is assumed that the shell is simply supported with movable edges. By deriving two different forms of the stress function, the equations of motion are reduced to a system of infinite non-linear ordinary differential equations with quadratic and cubic non-linearities. A quadratic relation between the excitation and the fundamental frequency is considered and it is shown that, although in case of hardening non-linearities the results resemble those found via numerical integration or continuation softwares, in case of softening non-linearity the solution breaks down as the amplitude becomes larger than the thickness. Results reveal that, expressing the relation between the excitation and fundamental frequency in this form, which was considered by many researchers as a useful tool in analyzing strong non-linear oscillators, yields in spurious results when the non-linearity becomes of softening type.

Kathleen Mae Gelera and Jong Sup Park (Sangmyung University, Korea), “Elastic lateral torsional buckling strength of monosymmetric stepped I-beams”, KSCE Journal of Civil Engineering, Vol. 16, No. 5, July 2012,
DOI: 10.1007/s12205-012-1255-8

ABSTRACT: This paper reports the results of parametric analyses for the lateral torsional buckling strengths of singly symmetric stepped I-beams with constant depth subjected to general loading conditions. Simply supported beams with varying monosymmetric ratios from 0.1 to 0.9 were analyzed using a finite element program ABAQUS and a regression program MINITAB. Stepped length ratios, flange width ratios and flange thickness ratios were taken from the geometry of real bridges. The beams were first subjected to pure bending to take account for the effect of steps in beams. And then ten-different loading conditions were applied to the beams to study the effect of varied moment along the unbraced span. Design solutions were suggested based on the results of the parametric analyses. The use of equations for beams with inflection point of zero and one is recommended for stepped beams with monosymmetric ratios from 0.1 to 0.9. In specialty, the use of new equation for beams with inflection point of two is recommended for doubly stepped beams with monosymmetric ratios between 0.1 and 0.9 and for singly stepped beams with monosymmetric ratios between 0.1 and 0.7.

ABSTRACT: We consider modeling of a nonlinear thin plate and a nonlinear thin shell under the following assumptions: (a) the materials are nonlinear; (b) the deflections are small (linear strain displacement relations). For a plate with a planar middle surface, we consider the bending of the plate to establish the strain energy, the equilibrium equations, and the motion equations. For a shell with a curved middle surface in IR3, we derive a nonlinear model where a deformation in three-dimensions is concerned.

ABSTRACT: On the basis of the nonlinear plate-shell and piezoelectric theory, the governing equations of motion for axisymmetrical piezoelectric delaminated cylindrical shell under hygrothermal conditions were derived. The governing equation of transverse motion was modified by contact force and thus the penetration between two delaminated layers could be avoided. The whole problem was resolved by using the finite difference method. In calculation examples, the effects of delamination length, depth and amplitude of load on the nonlinear dynamic response of the axisymmetrical piezoelectric delaminated shell under hygrothermal conditions were discussed in detail.

ABSTRACT: The vibrations of the shallow shell with geometrical nonlinearity submerged in a fluid are considered. Interaction of the shell with a fluid is described by linear hypersingular integral equation, which is solved by the boundary element method. The vibrations of the shell are described by the nonlinear finite-degree-of-freedom system. The vibrations are studied by the Shaw–Pierre nonlinear modes.
DOI: 10.1007/s00707-011-0556-1

ABSTRACT: The system of three partial differential equations with respect to displacements (Donnell equations) is used to analyze nonlinear vibrations of a cylindrical shell. The Galerkin method is applied to every partial differential equation to obtain a finite-degree-of-freedom model of the shell. The system of ordinary differential equations with respect to the general coordinates of the radial shell displacements is derived. The nonlinear modes of free vibrations are calculated using the harmonic balance method. The stability analysis of periodic motions is performed.

ABSTRACT: In this study, the homotopy analysis method (HAM) is used to obtain an approximate analytical solution for geometrically non-linear vibrations of thin laminated composite plates resting on non-linear elastic foundations. Geometric non-linearity is considered using von Karman’s strain–displacement relations. Then, the effects of the initial deflection, ply properties, aspect ratio of the plate and foundation parameters on the non-linear free vibration is studied. Comparison between the obtained results and those available in the literature demonstrates the potential of HAM for the analysis of such vibration problems, whose governing differential equations include the quadratic and cubic non-linear terms. This study shows that only a first-order approximation of the HAM leads to highly accurate solutions for this type of non-linear problems.

ABSTRACT: In this work, chaotic vibrations of shallow sector-type spherical shells are studied. A sector-type shallow shell is understood as a shell defined by a sector with associated boundary conditions and obtained by cutting a spherical shell for a given angle thetak, or it is a sector of a shallow spherical cap associated with the mentioned angle. Both static stability and complex nonlinear dynamics of the mentioned mechanical objects subjected to transversal uniformly distributed sign-changeable load are analyzed, and the so-called vibration charts and scales regarding the chosen control parameters are reported. In particular, scenarios of transition from regular to chaotic dynamics of the mentioned shells are investigated. A novel method to control chaotic dynamics of the studied flexible spherical shells driven by transversal sign-changeable load via synchronized action of the sign-changeable antitorque is proposed and applied. All investigations are carried out within the fields of qualitative theory of differential equations and nonlinear dynamics.
ABSTRACT: The buckling strength of a delaminated ring subjected to hydrostatic pressure is sought. The problem is solved by applying a weighted residual solution technique to the equation of the second variation of the potential energy for the ring. The effect of the position and the size of the delamination is investigated using a numerical example. The buckled mode shapes are analyzed and the contact problem between the adjacent layers is discussed.

ABSTRACT: The buckling and post-buckling behavior of arches is very sensitive to their geometric imperfections. The purpose of this paper is to develop a refined curved finite element that might accurately represent the actual geometry of arches so that the imperfection effects on their buckling behavior could be properly investigated. For an arch with known geometric imperfections, the element stiffness matrix is precisely formulated in terms of Lagrangian variables for a perfect arch from a general incremental variational principle. In general, the element stiffness matrix contains Lagrangian strain, first and second order incremental strain and imperfection terms. For any general planar imperfect arch with a variable curvature, the element stiffness matrix is evaluated by numerical integration; however, for a nominally circular arch, it can be represented in closed form. Numerical results in terms of load-deformation curves are presented for a number of circular arches with and without imperfections and compared with existing solutions.

J. I. Craig and M. F. Duggan (School of Aerospace Engineering, Georgia Institute of Technology), “Nondestructive shell-stability estimation by a combined-loading technique” (The variation of specimen lateral stiffness with compressive axial loading is studied experimentally and it is demonstrated that buckling loads can be predicted for monocoque shells for such data.), Experimental Mechanics, Vol. 13, No. 9, 1972, pp. 381-388, doi: 10.1007/BF02324040
ABSTRACT: Accurate nondestructive procedures for cylindrical-shell-stability investigations have long been a goal of experimentalists and practicing engineers. Stability criteria based on stress and deflection have been investigated intensively by researchers, but lateral-stiffness variation has been largely ignored. It is this aspect which is the foundation of the present work. The variation of specimen lateral stiffness with compressive axial loading is studied experimentally and it is demonstrated that buckling loads can be predicted for monocoque shells from such data. A study of the initial specimen geometry is presented and an evaluation is made of its effect on the distribution of stiffness at zero axial load. When the lateral test force used to determine the stiffness is considered as a destabilizing load in combination with the axial compression, it is shown that critical values of the force can be estimated by the “Southwell plot” procedure. These critical forces can be correlated with axial load and extrapolated to yield an accurate estimate of the buckling load. The approach greatly reduces the compressive load necessary for stability predictions over that required for other techniques.

ABSTRACT: A theoretical investigation of the effect of general imperfections on the buckling of a cylindrical shell under axial compression was carried out. A limit point analysis was performed to determine the buckling loads using a simplified imperfection and displacement model consisting of one axisymmetric and two asymmetric components with the same circumferential wave number. The wave number dependence of imperfections for a class of shells obtained by the same manufacturing processes was characterized by using an imperfection model to fit the experimental imperfection coefficients available. Buckling load calculations were performed using both experimental and fitted data as imperfection coefficients. For the experimental data available the three-mode solution was found to have only a small additional effect with respect to the two-mode solution. In addition, by extrapolating imperfection coefficients for high wave numbers by means of the imperfection model, it was found that a strong interaction effect would exist between a low wave number axisymmetric mode and two classical asymmetric modes.

ABSTRACT: A scheme for treating so-called floating rings is recommended for use in the buckling analysis of stiffened cylindrical shells. Critical stresses are calculated and compared to those for integral rings, for a design representative of the unpressurized Space Shuttle liquid hydrogen (LH2) tank. The ring rigidity required to prevent general instability is found to be much less than that required by the Shanley criterion, with a correspondingly significant weight saving. There is very little difference in total shell weight between floating and internal rings for equal strength designs.

ABSTRACT: The nonlinear flexural vibration behaviour of cylindrical shells has received considerable attention to date. It is pointed out that, although in a well-known reference case there seems to be a reasonable agreement, there are unresolved discrepancies between the results obtained by different authors. In the present paper, the problem is studied using various analytical–numerical models with different levels of accuracy and complexity. The frequency–amplitude curves from the different analysis models developed are compared both for isotropic shells and for an orthotropic composite shell. Secondary modes can play an important role. In more complicated cases modal interactions may significantly influence the nonlinear vibration behaviour, and the results obtained strongly depend on the analysis model chosen.

ABSTRACT: An analytical–numerical method involving a small number of generalized coordinates is presented for the analysis of the nonlinear vibration and dynamic stability behaviour of imperfect anisotropic cylindrical shells. Donnell-type governing equations are used and classical lamination theory is employed. The assumed deflection modes approximately satisfy simply supported boundary conditions. The axisymmetric mode satisfying a relevant coupling condition with the linear, asymmetric mode is included in the assumed deflection function. The shell is statically loaded by axial compression, radial pressure and torsion. A two-mode imperfection model, consisting of an axisymmetric and an asymmetric mode, is used. The static-state response is assumed to be affine to the given imperfection. In order to find approximate solutions for the dynamic-state equations, Hamilton’s principle is applied to derive a set of modal amplitude equations. The dynamic response is obtained via numerical time-integration of the set of nonlinear ordinary differential
equations. The nonlinear behaviour under axial parametric excitation and the dynamic buckling under axial step loading of specific imperfect isotropic and anisotropic shells are simulated using this approach. Characteristic results are discussed. The softening behaviour of shells under parametric excitation and the decrease of the buckling load under step loading, as compared with the static case, are illustrated.

ABSTRACT: A perturbation method is used to analyse the nonlinear vibration behaviour of imperfect general structures under static preloading. The method is based on a perturbation expansion for both the frequency parameter and the dependent variables. The effects on the linearized and nonlinear vibrations caused by geometric imperfections, a static fundamental state, and a nontrivial static state are included in the perturbation procedure. The theory is applied in the nonlinear vibration analysis of anisotropic cylindrical shells. In the analysis the specified boundary conditions at the shell edges can be satisfied accurately. The characteristics of the analysis capability are shown through examples of the vibration behaviour of specific shells. Results for single mode and coupled mode nonlinear vibrations of shells are presented. Parametric studies have been performed for a composite shell.

Hung-Peng Li, “Investigation Of The Stability Of Metallic/Composite-Cased Solid Propellant Rocket MotorsUnder External Pressure”, (Dissertation for Mechanical Engineering Dept. of Virginia Polytechnic Institute and State University, Blacksburg, Virginia, USA), September 1998

ABSTRACT: Solid rocket motors consist of a thin metallic or composite shell filled with a soft rubbery propellant. Such motors are vulnerable and prone to buckling due to sudden external pressures produced by nearby detonation. The stability conditions of rocket motors subjected to axisymmetric, external pressure loading are examined. The outer cases of motors are considered as isotropic (metallic) or anisotropic (composite), thin and high-strength shells, which are the main structures of interest in the stability analyses. The inner, low-strength elastic cores are modeled as linear and nonlinear elastic foundations. A general, refined, Sanders' nonlinear shell theory, which accounts for geometric nonlinearity in the form of von Karman type of nonlinear strain-displacement relations, is used to model thin-walled, laminated, composite cylindrical shells. The first order shear deformable concept is adopted in the analysis to include the transverse shear flexibility of composites. A Winkler-type linear and nonlinear elastic foundation is applied to model the internal foundations. Pasternak-foundation constants are also chosen to modify the proposed elastic foundation model for the purpose of shear interactions. A set of displacement-based finite element codes have been formulated to determine critical buckling loads and mode shapes. The effect of initial imperfections on the structural responses are also incorporated in the formulations. A variety of numerical examples are investigated to demonstrate the validity and efficiency of the proposed theory under various boundary conditions and loading cases. First, linear
eigenvalue analysis is used to examine approximate buckling loads and buckling modes as well as symmetry conditions. An iterative solution procedure, either Newton-Raphson or Riks-Wempner method, is employed to trace the nonlinear equilibrium paths for the cases of stress, buckling and post-buckling analyses. Both ring- and shell-type models are applied for the structural analyses with different internal elastic foundations and initial imperfections.

ABSTRACT: This paper presents the free vibration analysis of arbitrary thin shell structures by using a newly developed spline finite element. The new element has three salient features in its formulation: (i) the use of B-spline shape functions for the interpolations of both in-plane and out-of-plane displacements of a general thin shell element; (ii) the use of “displacement constraints” and “parameters shifting” to construct a finite element model; (iii) that a proposed modified version of the Koiter’s thin shell theory is employed. The element is doubly curved, has nine primary nodes and eight auxiliary nodes, and has a total of 63 degrees of freedom. It is formulated through the conventional C1 displacement approach, and is capable of modeling sharp corners, arbitrary shapes and multiple junctions of thin shell structures. The numerical examples discussed include spherical panels, cylindrical panels and shells of revolution, as well as single- and double-cell boxes. These examples are typical shells of negative, zero and positive Gaussian curvatures. The effects of aspect ratios, distorted meshes and junctions of shells on the performance of the element are studied. It is shown that the new spline finite element is a reliable, versatile, accurate and efficient thin shell element suitable for the analysis of arbitrary thin shell structures.

ABSTRACT: Delamination type failures are often observed in carbon-epoxy composites, where catastrophic failure is generally preceded by constituent level damage accumulation. Out-of-plane loading such as internal pressure in a composite fuselage or out-of-plane deformations in compression-loaded post-buckled panel may lead to debonding of the frame or stiffener from the panel. On other hand, numerous investigations show the ability of stiffened composite structures to work in the post-buckling region, which is considered unsafe in the conventional design procedures. Experimental evaluation of damage influence on post-buckling performance of stiffened shells is essential for development of safe design guidelines that would allow exploitation of these structures in the post-buckling region. The results of this investigation show that a damaged stiffened composite shell can be loaded up to 200% of skin buckling load without any propagation of delaminations. This can serve as the base for more extended studies on the subject, including numerical modelling and improvement of the existing design guidelines.

Edgars Eglitis, Kaspars Kalnins and Olgerts Ozolins (Institute of Materials and Structures, Riga Technical University, Kalku Str. 1, Riga LV 1658, Latvia), “Experimental and numerical study on buckling of axially
PARTIAL INTRODUCTION: Thin shells are efficient structures that can support very high buckling loads. However, unlike columns and plates, shells usually have a very unstable post-buckling behaviour that strongly influences their buckling characteristics. Hence their buckling and post-buckling have presented scientific and engineering challenges for decades. [1] Axially compressed cylinder may be one of the last classical problems in structural mechanics for which it remains difficult to obtain close agreement between careful experiments and the best predictions from numerical modelling, therefore this is a subject of continuous research. Buckling and post-buckling of axially compressed, homogenous isotropic cylinders has been investigated since it was first identified in the beginning of the last century by “wrinkling” or “secondary flexure” in columns. [3] In practice, buckling of cylindrical shells under axial compression became important as their use in aircraft structures broadened as thin-walled columns and stressed-skin construction of fuselages and wings, introduced in the late twenties. Since then the shell buckling phenomena became the central design problem of aerospace structures. According to the well-known and accepted linear classical theory, the linear bifurcation buckling stress for a perfect isotropic cylindrical shell under ideal conditions (of medium length, with pre-buckling stresses by the boundary conditions and boundaries that restrain circumferential displacements during buckling) is...

ABSTRACT: Multiple delaminations are more realistic damage types in the laminated composite structures. In this study, buckling and postbuckling analysis was conducted for the composite laminates with multiple delaminations under compressive loading. In a nonlinear finite element formulation, the updated Lagrangian description and modified arc-length method were adopted. For a finite element modeling of composite laminates, the eight-node degenerated shell element was used. To avoid the overlapping between delaminated areas, the contact node pair was defined by virtual beam element. Numerical results showed that multiple delaminations lower buckling loads and load carrying capacities in the postbuckling region.

ABSTRACT: A model is selected for the study of delamination buckling of a short laminated orthotropic tube under axial compression. Delamination is assumed to exist prior to loading and it spans the entire circumference. On the basis of total Lagrangian description and axisymmetric assumption, a nonlinear finite element method is formulated to examine nonlinear post-buckling behavior. Then, for treating the contact of delamination face caused by the effect of curvature, the nonlinear finite element program is associated with a quadratic programming procedure. Using the path independent J-integral defined for axisymmetric finite deformation, the energy release rate is calculated. The load-carrying capacity of the delaminated tube and the stability of delamination growth are examined in terms of the critical buckling load and the energy release rate, respectively.

ABSTRACT: Delaminations weaken a laminated beam, which then fails prematurely under in-plane compression. An exact buckling analysis is performed for beams with double delaminations. Novel adoption of two coordinates and choice of slope as the unknown function reduce the buckling equations to simple solvable geometric equations. Complex buckling behaviors emerge for different sizes and depths of the delaminations. “Free mode” and “constrained mode” of buckling are identified. Both global and local buckling occurs, depending upon the slenderness ratios of the delaminations. In addition, an upper bound and a lower bound of buckling loads are obtained by assuming totally “constrained” and totally “free” deformation for the delaminated beam. These bounds are easy to compute and provide useful approximations.

ABSTRACT: In the present paper, new nondimensionalized parameters, namely, nondimensionalized axial and bending stiffnesses have been introduced to study analytically the buckling behavior of two-layer beams with separated delaminations. Numerical analysis has been carried out by using ANSYS software to validate the developed analytical model. Delaminations are modeled with gap elements in ANSYS. A detailed parametric study has been carried out and it is found that the buckling behavior strongly depends on these new nondimensionalized parameters. Another nondimensionalized parameter, effective-slenderness ratio is also introduced and it is found to be a controlling parameter of delamination buckling mode configurations.

ABSTRACT: Critical buckling loads of laminated fibre-reinforced plastic square panels have been obtained using the finite element method. Various boundary conditions, lay-up details, fibre orientations, cut-out sizes are considered. A 36 degrees of freedom triangular element, based on the classical lamination theory (CLT) has been used for the analysis. The performance of this element is validated by comparing results with some of
those available in literature. New results have been given for several cases of boundary conditions for $[0\deg./ \pm 45\deg./90\deg.]$s laminates. The effect of fibre-orientation in the ply on the buckling loads has been investigated by considering $[\pm \theta]_s$ laminates.

ABSTRACT: The stability behaviour of fibre reinforced plastic plates containing delaminations is studied. Embedded delaminations in the form of a circle or an ellipse, centrally located in $[0/90^\circ/0]$ square plates are considered. A 36 degrees of freedom triangular finite element based on classical laminated plate theory is utilized to idealize the two sublaminates in the delaminated and the undelaminated part of the laminate. Results are compared with some of those available in the literature. Effects of size, shape, thickness-wise location of delamination and fibre orientation on the buckling load are discussed. Generally, the buckling load reduces with increase in delamination size and three distinct types of buckling modes are possible depending upon the delamination parameters.

ABSTRACT: A study of residual compressive strength in delaminated laminates is presented. A methodology is proposed for simulating the whole compressive failure responses, such as initial buckling, postbuckling, contact of delamination front region, delamination propagation, fiber breakage, and matrix cracking etc. An finite element analysis (FEA) of the residual compressive strength is conducted on the basis of the Von Karman's nonlinearity assumption and the first-order shear deformation plate theory, combined with a stiffness degradation scheme. The numerical analysis models and methods are briefly introduced in this paper and some numerical examples are presented to illustrate it. From numerical results and discussion, it is clear that the compressive failure response involves complex multi-failure modes during compressive process. The method and numerical conclusions provide in this paper should of great value to engineers dealing with composite structures.

ABSTRACT: This study investigates the applicability of scaled models for predicting the buckling behavior of delaminated composites. Such a study is important since it provides the necessary scaling laws, and the factors which affect the accuracy of the scale models. Employment of similitude theory to establish similarity among structural systems can save considerable expense and time, provided that the proper scaling laws are found and
validated. In this study a number of parametric studies are performed. The limitations and acceptable intervals of all parameters and corresponding scale factors are investigated. Particular emphasis is placed on the case of delamination buckling of orthotropic plates. Both complete and partial similarities are discussed. This study indicates that models with a different delamination size, depth and number of delaminations than those of the prototype are capable of predicting buckling loads of the prototypes with good accuracy.

ABSTRACT: This study investigates buckling behaviors of laminated composite structures with a delamination using the enhanced assumed strain (EAS) solid element. The EAS three-dimensional finite element (FE) formulation described in this paper, in comparison with the conventional approaches, is more attractive not only because it shows better accuracy but also it converges faster, especially for distorted element shapes. The developed FE model is used for studying cross-ply or angle-ply laminates containing an embedded delamination as well as through-the-width delamination. The numerical results obtained are in good agreement with those reported by other investigators. In particular, new results reported in this paper are focused on the significant effects of the local buckling for various parameters, such as size of delamination, aspect ratio, width-to-thickness ratio, stacking sequences, and location of delamination and multiple delaminations.

PARTIAL ABSTRACT: In this paper the effect of material impact damage on buckling-driven delamination growth in composite laminates under compression is studied using a finite element method. The initial material damage, e.g. fibre fracture and matrix cracking due to impact, is modeled through a so-called soft-inclusion, in which an area with reduced stiffness is introduced in the analysis of buckling-induced delamination growth with an ADINA-based finite element program…

ABSTRACT: Based on the first order shear deformation theory(FSDT), the nonlinear dynamic equations involving transverse shear deformation and initial geometric imperfections were obtained by Hamilton's philosophy. Geometric deformation of the composite cylindrical shell was treated as the initial geometric imperfection in the dynamic equations, which were solved by the semi-analytical method in this paper. Stiffness reduction was employed for the damaged sub-layer, and the equivalent stiffness matrix was obtained for the delaminated area. By circumferential Fourier series expansions for shell displacements and loads and by using Galerkin technique, the nonlinear partial differential equations were transformed to ordinary differential
equations which were finally solved by the finite difference method. The buckling was judged from shell responses by B-R criteria, and critical loads were then determined. The effect of the initial geometric deformation on the dynamic response and buckling of composite cylindrical shell was also discussed, as well as the effects of concomitant delamination and sub-layer matrix damages.

ABSTRACT: Free vibration, nonlinear dynamic response, buckling and postbuckling, delaminarion buckling of composite circular cylindrical shells with stringer and ring stiffeners have been investigated theoretically, numerically, experimentally in this paper. The effects of the shells and stiffener parameters, delaminarion parameters on the stiffened composite shells are discussed. The aim is to provide appropriate analytical methods and theoretical basis for design of stiffened composite shells. The major work in this paper is as follows: At the beginning, the advances in the research of free vibration, nonlinear dynamic response under axial impact load, buckling and postbuckling under axial compression of the stiffened composite shells are reviewed comprehensively. The main comments are systematically remark on the delaminarion buckling. Research background and involved elementary theory of this thesis are emphatically expatiated. The second part of paper is about the analytical solution for the free vibration of simply supported composite circular cylindrical shells with stringer and ring stiffeners. Using the Love’s theory and the Rayleigh-Ritz energy method, the frequency equations can be deduced, which can be solved. The effects of shells and orthogonal stiffeners parameters such as the shell thickness-to-radius ratio, the shell length-to-radius ratio, the stiffener’s height, lamination angle and forms on the frequencies are studied. In addition, the effect of hydrostatic pressure is also discussed. The third part presents a simple and efficient semi-analytic method to solve the nonlinear dynamic response of composite circular cylindrical shells with circumferential stiffeners under axial impact load. Applying the discrete stiffened shells model, Based on the composite shell’s shear deformation theory, the motion equations of stiffened shells is deduced using Hamilton’s variation principle. The deformation of the shells and the load are expanded in double series. The motion equations expressed by deflection are obtained with the Galerkin method, and numerically solved by R-kutta approach. Examples are given for the nonlinear dynamic response of stiffened composite shells under axial impact. The effects of the stiffener geometric parameters, lamination angle, lamination forms, the numbers of lamination layers on the dynamic response of stiffened composite circular cylindrical shells are discussed. In the forth part, the generalized Donnell-type equations governing large deflection of laminated cross-ply circular cylindrical shells based on first-order shear deformation theory are presented. An asymptotic series solution is constructed by the perturbation technique for postbuckling behavior of the cylindrical shell under axial compression. The boundary layer solutions are also designed to match with the out-of-plane boundary conditions by singular perturbation approach, and then determined the critical buckling loads and postbuckling equilibrium paths. The effects of the stiffener and shell geometric parameters, lamination angle, lamination forms, initial imperfection on the buckling and postbuckling behavior of the shells are discussed. The fifth chapter analyzed the buckling behavior of composite circular cylindrical shells with throughout circumference delamination by using the first first-order shear deformation theory. And establish the buckling model by spanning the entire circumference is divided into multiple sublaminates shell. The deformations are expanded in double series. The variational principle is applied to obtain the governing equations, boundary conditions, the continuous conditions of displacements, the equilibrium conditions of the force and moment. The influences of the shell geometric parameters, lamination angle, lamination forms, length and depth of delamination on buckling load are analyzed. The final part offered an experiment of free vibration, buckling and postbuckling under axial compression of composite circular cylindrical shells with or without delamination. The effects of lamination angle, length and range of delamination on buckling load, postbuckling
behavior and the final damage form are discussed. The comparison between the experiment outcome and the numerical results indicates that those frequency results of the composite circular cylindrical shells are in good agreement with each other. However, the result of the crush experiment is inconsistent with the theoretical outcome. At last, the reasons for those discriminations are presented.

ABSTRACT: The effect of axial shallow groove on the nonlinear dynamic response and buckling of laminated cylindrical shells subjected to radial compression loading was investigated. Based on the first-order shear deformation theory (FSDT), the nonlinear dynamic equations involving the transverse shear deformation and initial geometric imperfections were derived with the Hamilton philosophy. The axial shallow groove of the laminated composite cylindrical shell was treated as the initial geometric imperfections in the dynamic equations. A semi-analytical method of expanding displacements and loads along the circumferential direction and employing the finite difference method along the axial direction and in the time domain is used to solve the governing equations and obtain the dynamic response of the laminated shell. The B-R criterion was employed to determine the critical loads of dynamic buckling of the shell. The effects of the parameters of the shallow groove on the dynamic response and buckling were discussed in this paper and the results show that the axial shallow grooves greatly affect the dynamic response and buckling.

ABSTRACT: Damage tolerance characteristics and results from experimental and analytical studies of a composite fuselage keel sandwich structure subjected to low-speed impact damage and discrete-source damage are presented. The test specimens are constructed from graphite-epoxy skins bonded to a honeycomb core, and they are representative of a highly loaded fuselage keel structure. Results of compression-after-impact (CAI) and notch-length sensitivity studies of 5-in.-wide by 10-in.-long specimens are presented. A correlation between low-speed-impact dent depth, the associated damage area, and residual strength for different impact-energy levels is described; and a comparison of the strength for undamaged and damaged specimens with different notch-length-to-specimen-width ratios is presented. Surface strains in the facesheets of the undamaged specimens as well as surface strains that illustrate the load redistribution around the notch sites in the notched specimens are presented and compared with results from finite element analyses. Reductions in strength of as much as 53.1 percent for the impacted specimens and 64.7 percent for the notched specimens are observed. References listed at the end of the report:

ABSTRACT: The sandwich composites fuselages appear to be a promising choice for the future aircrafts because of their structural efficiency and functional integration advantages. However, the design of sandwich composites is more complex than other structures because of many involved variables. In this paper, the fuselage is designed as a sandwich composites cylinder, and its structural optimization using the finite element method (FEM) is outlined to obtain the minimum weight. The constraints include structural stability and the composites failure criteria. In order to get a verification baseline for the FEM analysis, the stability of sandwich structures is studied and the optimal design is performed based on the analytical formulae. Then, the predicted buckling loads and the optimization results obtained from a FEM model are compared with that from the analytical formulae, and a good agreement is achieved. A detailed parametric optimal design for the sandwich composites cylinder is conducted. The optimization method used here includes two steps: the minimization of the layer thickness followed by tailoring of the fiber orientation. The factors comprise layer number, fiber orientation, core thickness, frame dimension and spacing. Results show that the two-step optimization is an effective method for the sandwich composites and the foam sandwich cylinder with core thickness of 5 mm and frame pitch of 0.5 m exhibits the minimum weight.

ABSTRACT: The present work introduces efficient methodologies based on the finite-element method for a quick evaluation of damage resistance and damage tolerance of composite aerospace structures. Monolithic, stringer-stiffened structures, and sandwich structures are considered. The presented methodologies cover the simulation of the dynamic response of a structure during a low velocity impact event including the prediction of the internal non-visible or barely visible damage that develops during the impact. Additionally, methods for the prediction of the compression-after-impact strength are presented. In order to permit an accurate and efficient calculation of deformations and stresses in sandwich structures, special finite-element formulations have been developed. A comparison of simulation results with experimental data is presented for a two-stringer monolithic panel and for a honeycomb sandwich plate. The examples demonstrate that the presented methodologies can be used to quickly assess the damage tolerance of composite structures.

ABSTRACT: An analysis of the buckling and post-buckling of a delaminated composite strut is presented using a simple 4 degree of freedom nonlinear Rayleigh–Ritz formulation. Bifurcation analysis indicates that instability occurs in general at an asymmetric point of bifurcation. Depending on the depth of delamination both thin-film and overall buckling can occur in the post-buckling range, the transition being seen at a point of secondary bifurcation. For certain combinations of parameters this becomes a stellar bifurcation, associated with a double eigenvalue, where there are three possible subsequent routes for the post-buckling. The method used is fast and reliable and can be readily extended to modelling a composite with several layers.

ABSTRACT: The governing equilibrium equations for strain gradient elastic thin shallow shells are derived, considering non-linear strains and linear constitutive strain gradient elastic relations. Adopting Kirchhoff’s theory of thin shallow structures, the equilibrium equations, along with the boundary conditions, are formulated through a variational procedure. It turns out that new terms are introduced, indicating the importance of the cross-section area in bending of thin plates. Those terms are missing from the existing strain gradient shallow thin shell theories. Those terms highly increase the stiffness of the structures. When the curvature of the shallow shell becomes zero, the governing equilibrium for the plates are derived.

ABSTRACT: The primary thrusts of this dissertation are to develop and test a new quadrilateral layered membrane element with drilling degrees of freedom (DOF) and a quadrilateral thin flat layered shell element for the nonlinear analysis of reinforced concrete walls. The drilling degrees of freedom refers to the incorporation of the in-plane rotation as a degree of freedom at each node of the element. The membrane element consists of a quadrilateral element with a total of 12 DOF, 3 per node, 2 displacements and 1 in-plane rotation, and uses a blended field interpolation for the displacements over the element. This formulation is an extension of the one developed by Xia et al. [151] in 2009. The shell element is created by the combination of the membrane element developed in this dissertation and a Discrete Kirchhoff Quadrilateral Element (DKQ, 12 DOF), formulated by Batoz and Tahar [11] 1982, to model the out of plane bending behavior of the element. The modeling of the section of the membrane and the shell element consists of a layered system of fully bonded, smeared steel reinforcement and smeared orthotropic concrete material with the rotating angle formulation. The layered section for the shell includes the coupling membrane and bending effects. These elements are implemented on a finite element framework using the object oriented programing language under MATLAB [62]. The framework or MATLAB toolbox for Finite Elements developed for this dissertation allows to incorporate, develop and test new elements, materials, sections and analysis algorithms in a easy and quick manner. The proposed elements are evaluated using experimental results that are available in the literature. It is shown that the new elements are in excellent agreement with the experimental results for the different load configuration, monotonic and cyclic loading, and they are able to predict the failure modes for the different wall configurations analyzed in this dissertation.

ABSTRACT: In this paper, we study the temperature’s effect on a plate under global tensile stress. For this aim, the Fourier double scale method is used in order to develop a macroscopic model that is a generalized continuum. This model couples local and global instabilities in wrinkling phenomena. The advantage of this technique is to remain valid away from the bifurcation point while former techniques such as Landau-Ginzburg theory are valid only close to the bifurcation point. Due to its efficiency, this method is extended to plate structures. A finite element formulation of the plate model is made. The model developed was implemented using MATLAB code and a validation test has been conducted, comparing to ABAQUS simulation.

ABSTRACT: Effects of axial forces on beam lateral buckling strength are investigated here in the case of elements with mono-symmetric cross sections. A unique compact closed-form is established for the interaction of lateral buckling moment with axial forces. This new equation is derived from a non-linear stability model. It includes first order bending distribution, load height level and effect of mono-symmetry terms (Wagner’s coefficient and shear point position). Compared to the so-called three-factors (C1–C3) formula commonly employed in beam lateral buckling stability, another factor C4 is added in presence of axial loads. Pre-buckling deflection effects are considered in the study and the case of doubly-symmetric cross sections is easily recovered. The proposed solutions are validated and compared to finite element simulations where 3D beam elements including warping are used. The agreement of the proposed solutions with bifurcations observed on the non-linear equilibrium paths is good. Dimensionless interaction curves are dressed for the beam lateral buckling strength and the applied axial load, where the flexural-torsional buckling axial force is a taken as reference.

Mario M. Attard (School of Civil and Environmental Engineering, University of New South Wales, Sydney, Australia), “Global buckling experiments on sandwich columns with soft shear cores”, Electronic Journal of Structural Engineering, Vol. 11, No. 1, 2011

ABSTRACT: Several failure modes for sandwich columns under compression are said to be possible with shear crimping or shear buckling suggested for short columns with soft shear cores. The buckling formulas and theoretical assumptions of Engesser and Haringx for isotropic columns and soft shear core sandwich columns are reviewed. An important distinction is made between the isotropic column buckling formula attributed to Haringx and the theoretical assumptions underpinning his approach. It is shown that the theoretical approaches of Haringx and Engesser yield the same basic buckling equation for soft shear core sandwich columns when the thickness is very small in comparison to the core thickness, and the shear in the face sheets, the axial force in the core and the bending within the face sheets are ignored. To determine whether shear crimping (shear buckling) is a member or localised type of buckle, tests on low slenderness - short sandwich columns identified as possibly exhibiting shear crimping, were performed. The test specimens were constructed from 10 mm thick Divinycell H45, H80, H100 and H200 foam for the core and 1 mm face sheets made of Aluminum 2024-T3. The lengths of the columns varied from 20 to 500 mm. The columns were end-clamped according to ASTM C 364-99 [1] and placed in a servo-controlled compression testing machine. The width of the specimens was 100 mm and two specimens at each length were tested. The adhesive chosen was a toughened epoxy, trade name “Devcon Epoxy Plus”. Measurements of the mid-span lateral displacement were used in a Southwell type plot to determine the elastic global buckling load. The shear modulus of the core was determined from three point bending tests according to ASTM-C-393 [2]. Some of the very short specimens failed with buckling of the face sheet within the clamped region. None of the tests exhibited shear crimping or shear buckling modes and the
global buckling loads for very short columns were much higher than the shear buckling limit of Engesser. Wrinkling failure was not considered.

Kellermann (Centre for Infrastructure Engineering and Safety, School of Civil and Environmental Engineering, The University of New South Wales, Sydney, 2052, Australia), “In-plane nonlinear buckling of circular arches including shear deformations”, Archive of Applied Mechanics, Vol. 84, No. 12, pp 1841-1860, December 2014

ABSTRACT: A numerical strategy is presented to trace the pre-buckling as well as the post-buckling nonlinear equilibrium paths for elastic circular arches in which the effects of shear deformations and the geometric nonlinearity due to large deformations are taken into account. Timoshenko beam hypothesis is adopted for
incorporating shear. The constitutive relations including shear effects for stress and finite strain are based on a hyperelastic constitutive model. The finite strain equilibrium equations are developed for the circular arches. Based on the derived transformed equilibrium equations and the boundary conditions, the nonlinear buckling behaviour of circular arches is investigated using the trapezoid method with Richardson extrapolation enhancement. The results are validated using available experimental results in the literature, the finite element package ANSYS and other solutions in the literature. Parametric studies are performed on examples to identify the factors that influence the nonlinear buckling of circular arches. The shear deformation effects on the nonlinear buckling behaviour and the buckling mode are investigated for circular arches under many different loading conditions and various boundary conditions.

ABSTRACT: The present paper deals with the application of the finite element method to dynamic contact buckling problems. The penalty function method is applied to incorporate the contact conditions in the equation of motion and a trial-and-error method is employed to obtain the converged contact state. Numerical examples are analysed to show the effectiveness and the validity of the method, and it is applied to a dynamic buckling problem involving contact phenomena.

ABSTRACT: The creep buckling of viscoelastic structures is investigated analytically and experimentally. The theory of linear viscoelasticity is used to model polymeric column specimens subjected to constant compressive end loads. The growth of initial imperfections is calculated using the hereditary integral formulation. Solution techniques are developed for small displacements and also generalized to include the effects of non-linear kinematics. It turns out that the kinematically linear model represents the deformation process closely and conservatively; material non-linearities are not dominant since maximum strains of the order of only 2% are encountered. The analyses are exact with respect to (non-linear) kinematics and linearly viscoelastic material representation. A failure criterion based on maximum deformation allows the column life to be determined from the material relaxation modulus if the initial imperfections are known. A discussion on the possible generalization of the results to include plates and shells is presented. Results of creep buckling experiments performed on PMMA specimens at elevated temperatures (accelerating the creep behavior) are reported. The
relaxation modulus of PMMA is represented by a Prony-Dirichlet series and the model is used to simulate the laboratory experiments. Model and experimental results are compared and discussed especially with respect to uncontrollable material behavior.

ABSTRACT: During the last ten years, the French Research Institute for Nuclear Energy (Commissariat à l'Energie Atomique) achieved many theoretical as well as experimental studies for designing the first large size pool type fast breeder reactor. Many of the sensitive parts of this reactor are thin shells subjected to high temperatures and loads. Special care has been given to buckling, because it often governs design. Most of the thin shells structures of the French breeder reactor are axisymmetric. However, imperfections have to be accounted for. In order to keep the advantage of an axisymmetric analysis (low computational costs), a special element has been implemented and used with considerable success in the recent years. This element (COMU) is described in the first chapter, its main features are:
1. either non axisymmetric imperfection or non axisymmetric load,
2. large displacement,
3. non linear material behaviour,
4. computational costs about ten times cheaper than the equivalent three dimensional analysis.

This paper based on a careful comparison between experimental and computational results, obtained with the COMU element, will analyse three problems:
1. First: design procedure against buckling of thin shells structures subjected to primary loads.
2. Second: static post buckling.
3. Third: buckling under seismic loads.

ABSTRACT: A cylindrical shell with a shape defect is studied. A one DOF modelling is derived. Its nonlinear behaviour is investigated by using both harmonic balance method and normal form theory. Stability domains are computed according to 2 parameters related to the frequency and the amplitude of the external forcing.

ABSTRACT: In this paper, a simplified method is proposed for the prediction of creep buckling. This simplified approach relies upon a model which yields an analytical evaluation of creep buckling times for cylinders under external pressure. This model is fully developed herein, and a ‘closed-form’ solution is given
for the evaluation of the critical creep collapse time. The collapse mechanism is assumed to be due to the formation of a plastic hinge which induces an unstable post-buckling of the ring. The analytical ‘closed-form’ creep collapse time is then compared to finite element buckling predictions using the quasi-axisymmetric COMU shell element in the INCA code of the CASTEM system. The model is then applied to four different cylinders under external pressure and compared to finite element predictions; the cylinders' radius-to-thickness ratio varies between 50 and 550. It is shown that the proposed model performs well for this type of prediction: in all cases, the times to failure predicted by the model are lower than the finite element predictions. These predictions prove to be rather conservative for thicker cylinders. It is shown that creep buckling is a very dangerous failure mode. If the shape of the structure is observed as a function of time, nothing seems to happen during a very long ‘incubation’ period; when the initial imperfection reaches some critical value, buckling then suddenly occurs. This phenomenon is shown by the two methods of evaluation presented herein.

ABSTRACT: In this paper, the simplified method, proposed in (Combescure, 1998), for the prediction of creep buckling is compared to experimental results. The model is applied to predict the buckling time of two sets of experiments on cylinders subjected to uniform external pressure. It is shown that the proposed model is satisfactory for this type of prediction: in all cases, the times up to failure predicted by the model are generally lower than the experimental failure times. The model is rather conservative for thicker cylinders. However, it appears that a very detailed geometrical imperfection survey would be necessary if a highly accurate assessment of the creep failure time were sought. It has been observed experimentally that creep buckling is a very dangerous failure mode: nothing seems to happen during a very long “incubation” period but, when the initial imperfection reaches some critical value, buckling then suddenly occurs. For thin cylinders, the level of creep strain at which the instability starts to develop is much lower than the strain at which the tertiary creep initiates; the instability is thus clearly generated from the interaction between the material and the geometrical nonlinearity.

ABSTRACT: The objective of this paper is to answer the question: "Can a 'shell' model always be used to predict the elastic buckling of a shell?" This paper shows that such a model leads to significantly overestimated critical loads in the case of sandwich shells and gives an explanation for this overestimation. A dependable model is proposed and applied to a few structures of revolution, for which it is shown that shell analyses are sometimes overly on the unsafe side. Of course, in such cases, 3D analysis is possible, but the associated computation cost is several orders of magnitude higher than that of the Fourier series analysis proposed in this paper.

ABSTRACT: This paper proposes a new type of shell, similar to a cylindrical shell, which has significantly higher buckling strength when subjected to an arbitrary combination of uniform external pressure and axial compression. The underlying principle consists in a slight modification of the perfect cylinder in order to counteract the natural deformations which get larger and larger and lead to the collapse of the structure. Such shells are called ASTER shells. The concept has been validated through experiments, then analyzed numerically in order to explain what was observed and to propose avenues for improvements. The shells were made of electrodeposited nickel. The material was characterized. The chosen specimens were carefully measured to characterize their thickness and initial imperfections, then tested under the various types of loading. Then they were analyzed using finite elements. Thus, we were able to compare the finite element predictions with the experimental results. This comparison shows that plasticity has a decisive influence on the critical load and that linear elastic dimensioning leads to a serious overestimation of the experimental critical load. Contrary to perfect cylindrical shells, this type of shell is not significantly affected by geometric imperfections: this is another advantage of this type of design. Finally, we propose a numerical analysis in order to optimize the choice of the shape and propose shapes which resist buckling much better than a smooth cylinder when subjected to uniform external pressure, axial compression or a combination of both.

ABSTRACT: This paper deals with the creep buckling of a circular cylindrical shell subjected to both axial compression and internal or external pressure. The finite element method is applied to a creep deformation analysis to obtain the critical time when the creep buckling occurs. Two types of creep buckling are considered in the present analysis. One is the axisymmetric mode of creep buckling due to the quasi-static instability. The other is the asymmetric mode of creep buckling due to the bifurcation. The effects of internal or external pressure on the creep buckling are clarified by the present analysis.

ABSTRACT: First two equations of equilibrium are utilized to compute the transverse shear stress variation through thickness of a thick laminated plate after in-plane stresses have been computed using an assumed quadratic displacement triangular element based on transverse inextensibility and layerwise constant shear angle theory (LCST). Centroid of the triangle is the point of exceptional accuracy for transverse shear stresses. Numerical results indicate close agreement with elasticity theory. An interesting comparison between the present theory and that based on assumed stress hybrid finite element approach suggests that the latter does not satisfy the condition of free normal traction at the edge. Comparison with numerical results obtained by using constant shear angle theory suggests that LCST is close to the elasticity solution while the CST is closer to classical (CLT) solution. It is also demonstrated that the reduced integration gives faster convergence when the present theory is applied to a thin plate.

ABSTRACT: A method has been presented wherein the surface-parallel stresses in a laminated shell are first computed using standard finite element formulation and then approximate transverse shear stress variation through the shell thickness is obtained utilizing the first two (stress) equations of equilibrium and divergence theorem. Numerical results have been presented for both homogeneous isotropic and laminated anisotropic cylindrical shells using the Cartesian-like Riemann coordinate approximation and compared to the corresponding analytical solutions.

ABSTRACT: A post-processing semi-analytical approach, for prediction of the interlaminar shear stress distribution through the thickness of an arbitrarily laminated general shell, is presented. The starting point of the approach is an assumed displacement finite element analysis, based on the assumptions of transverse inextensibility and layerwise constant shear-angle theory (LCST). First, the problem is posed in the context of Taylor series expansions of the interlaminar shear stresses in terms of the thickness coordinate, dictated by the LCST assumption and the shell curvature. An “exact” (in the context of the problem thus posed) and three progressively approximate semi-analytical methods for prediction of interlaminar shear stresses are then presented. The throughthickness distribution of interlaminar shear stresses in an arbitrarily laminated thick plate can be obtained as a special case of the present solution. Numerical results are presented for two-layer thin and thick tubes with simply-supported edges, using the Cartesian-like local Riemann coordinate (CLRC) approximation and are compared to the corresponding analytical solutions, based on the classical lamination theory (CLT). Results for thin laminated tubes prove the accuracy of the present approach, while hitherto unavailable results for a thick laminated tube are expected to serve as baseline solutions for future comparisons.

ABSTRACT: Hitherto unavailable analytical solutions to the boundary-value problems of static response and free vibration of an arbitrarily laminated doubly-curved panel of rectangular planform are presented. Four classical shallow shell theories (namely, Donnell, Sanders, Reissner and modified Sanders) have been utilized in the formulation, which generates a system of one fourth-order and two third-order partial differential equations with constant coefficients. A novel double Fourier series approach has been developed to solve this system of three partial differential equations with the SS2-type simply supported boundary conditions prescribed at all four edges. The accuracy of the solutions is ascertained by studying the convergence characteristics of the lowest two natural frequencies, deflections and moments of angle-ply panels, and also by comparison with the available FSDT-based analytical and CLT-based Galerkin solutions. Also presented are comparisons of deflections and moments of antisymmetric angle-ply cylindrical panels, computed using the four classical shallow shell theories considered. Comparisons with the available FSDT (first-order shear deformation theory)-based analytical solutions are presented for the purpose of establishing the upper limit (with respect to the thickness-to-length ratio) of validity of the present CLT (classical lamination theory)-based solutions for angle-ply panels. Also studied is the highly complex interaction of bending-stretching type coupling effect with the effects of transverse shear deformation, rotatory inertias, inplane inertias, and membrane action due to shell curvature. Other important numerical results presented include variation of the
response quantities of interest with geometric and material parameters, such as radius-to-length ratio, length-to-thickness ratio and angle of fiber orientation.

ABSTRACT: A hitherto unavailable Fourier series solution to the boundary-value problem of thin cylindrical panels of rectangular planform, subjected to transverse loads, is presented. Sanders' kinematic relations (for classical shell theory) are utilized in the formulation, which generates one fourth-order (in terms of the transverse displacement component) and two second-order (in terms of the surface-parallel displacement components) partial differential equations with constant coefficients. A boundary-discontinuous double Fourier series approach is used to solve the system of three partial differential equations with the SS2-type simply-supported boundary conditions prescribed at all four edges. The final algebraic equations are expressed in terms of the boundary Fourier coefficients, which substantially reduce the size of the matrix, that is inverted using a digital computer. The accuracy of the series solution is ascertained by studying the convergence characteristics, and also by comparison with finite element solutions. Other important numerical results presented include variation of displacement and moment with the radius-to-thickness, length-to-thickness and length-to-width ratios. Also presented are variations of displacement and moment along the center line of the cylindrical panels. These numerical results contribute to our understanding of the complex deformation behavior of finite cylindrically curved panels—especially the influence of the boundary discontinuities on the computed displacements and stresses.

ABSTRACT: A fully nonlinear finite element analysis for prediction of localization/delocalization and compression fracture of moderately thick imperfect transversely isotropic rings, under applied hydrostatic pressure, is presented. The combined effects of modal imperfections, transverse shear/normal deformation, geometric nonlinearity, and bilinear elastic (a special case of hypoelastic) material property on the emergence of interlaminar shear crippling type instability modes are investigated in detail. An analogy to a soliton (slightly disturbed integrable Hamiltonian system) helps understanding the localization (onset of deformation softening) and delocalization (onset of deformation hardening) phenomena leading to the compression damage/fracture at the propagation pressure. The primary accomplishment is the (hitherto unavailable) computation of the mode II fracture toughness (stress intensity factor/energy release rate) and shear damage/crack bandwidth, under compression, from a nonlinear finite element analysis, using Maxwell’s construction and Griffith’s energy balance approach. Additionally, the shear crippling angle is determined using an analysis, pertaining to the elastic plane strain inextensional deformation of the compressed ring. Finally, the present investigation bridges a gap of three or more orders of magnitude between the macro-mechanics (in the scale of mms and up) and micro-mechanics (in the scale of microns) by taking into account the effects of material and geometric nonlinearities and combining them with the concepts of phase transition via Maxwell construction and Griffith-Irwin fracture mechanics.

ABSTRACT: An analytical (strong form) solution to the boundary value problem of moderately thick shallow cylindrical panels, with arbitrary laminations is presented. A double Fourier series approach is used to solve five second-order highly coupled partial differential equations that arise from the shallow shell formulation based on popular Donnell-Mushtari-Vlasov shell theory, and the first-order shear deformation-based through-thickness theory. An admissible boundary condition is considered to obtain numerical results that constitute the study of convergence of displacements, and moments; and spatial variations of them presented in the form of contour plotting for various parametric effects. These, hitherto unavailable, analytically obtained numerical results should serve as base-line solutions for future comparisons of popular approximate methods such as finite element, finite difference, Galerkin approach, Rayleigh-Ritz method, collocation method, least-squares method, and experimental results, for the case of arbitrary laminations.

ABSTRACT: An analytical solution to thermal buckling response of moderately thick symmetric angle-ply laminated, all-edge clamped rectangular plates subjected to a uniformly distributed temperature load is presented. A boundary continuous solution methodology based on double Fourier series functions that satisfy the rigidly clamped boundary conditions is assumed. The through-thickness formulation of the plate considers transverse shear deformation effects by employing the first order shear deformation theory (FSDT) based on Reissner and Mindlin hypothesis that result in three highly coupled partial differential equations. The numerical results are presented for various parametric effects such as length-to-thickness ratio, plate aspect ratio and major-to-minor modulus of elasticity ratio. The results of the analytical method are compared with the results obtained using finite element method. The numerical results that are presented should serve as a benchmark for future comparisons of such popular approximate methods as finite element, finite difference, Rayleigh–Ritz, Galerkin approach, collocation, or experimental methods.

ABSTRACT: Analytical solutions to the boundary-value problems of static response under transverse load and free vibration of a general cross-ply doubly curved panel of rectangular planform are presented. Four classical shallow shell theories (namely, Donnell, Sanders, Reissner and modified Sanders) are used in the formulation, which generates a system of one fourth-order and two second-order (in terms of the transverse displacement) partial differential equations with constant coefficients. A recently developed boundary-discontinuous double Fourier series approach is used to solve this system of three partial differential equations with the SS2-type simply supported boundary conditions prescribed at all four edges. The accuracy of the solutions is ascertained by studying the convergence characteristics of deflections, moments and natural frequencies of cross-ply panels, and also by comparison with the available analytical solutions. Also presented are comparisons of numerical
results predicted by the four classical shallow shell theories considered for cross-ply panels over a wide range of geometric and material parameters. Comparisons with the available FSDT (first-order shear deformation theory)-based analytical solutions are presented for the purpose of establishing the upper limit (with respect to the thickness-to-length ratio) of validity of the present CLT (classical lamination theory)-based solutions for both symmetric and antisymmetric cross-ply panels. Other important numerical results presented include variation of displacements, moments and the two lowest natural frequencies with the shell geometric parameters, such as radius-to-length ratio.

ABSTRACT: A fully nonlinear analysis for prediction of shear crippling (kinkband) type propagating instability in long thick laminated composite cylindrical shells is presented. The primary accomplishment of the present investigation is prediction of equilibrium paths, which are often unstable, in the presence of interlaminar shear deformation, and which usually deviate from the classical lamination theory (CLT)-based equilibrium paths, representing global or structural level stability. A nonlinear finite element methodology, based on a three-dimensional hypothesis, known as layerwise linear displacement distribution theory (LLDT) and the total Lagrangian formulation, is developed to predict the aforementioned instability behavior of long laminated thick cylindrical shell type structures and evaluate failure modes when radial/hydrostatic compressive loads are applied. The most important computational feature is the successful implementation of an incremental displacement control scheme beyond the limit point to compute the unstable postbuckling path. A long (plane strain) thick laminated composite [90/0/90] imperfect cylinder is investigated with the objective of analytically studying its premature compressive failure behavior. Thickness effect (i.e. interlaminar shear/normal deformation) is clearly responsible for causing the appearance of limit point on the postbuckling equilibrium path, thus lowering the load carrying capability of the long composite cylinder, and localizing the failure pattern, which is associated with spontaneous breaking of the periodicity of classical or modal buckling patterns. In analogy to the phase transition phenomena, Maxwell construction is employed to (a) correct the unphysical negative slope of the computed equilibrium paths encountered in the case of thicker cylinders modeled by the finite elements methods that fail to include micro-structural defects, such as fiber waviness or misalignments, and (b) to compute the propagating pressure responsible for interlaminar shear crippling or kinkband type propagating instability. This type of instability triggered by the combined effect of interlaminar shear/normal deformation and geometric imperfections, such as fiber misalignment, appears to be one of the dominant compressive failure modes for moderately thick and thick cylinders with radius-to-thickness ratio below the corresponding critical value. A three-dimensional theory, such as the LLDT, is essential for capturing the interlaminar shear crippling type propagating instability.

“Influence of localized imperfection on the instability of isotropic/cross-ply cylindrical shells/rings under

ABSTRACT: Compressive response of two extreme cases of cylindrical shell type structures weakened by the presence of localized imperfections is investigated. These two extreme cases are (i) thin metallic cylindrical shells, which are characterized by the absence of transverse shear deformation, and (ii) thick laminated advanced fiber reinforced composite rings (very long cylindrical shells), whose response is dominated by the interlaminar or transverse (primarily shear) deformation. A fully nonlinear finite element analysis, that employs a cylindrically curved 16-node layer-element, and is based on the assumption of layerwise linear displacements distribution through thickness (LLDT) or linear displacements distribution through thickness (LDT), is utilized in the analysis of afore-mentioned cross-ply ring or thin homogeneous isotropic cylindrical shell, respectively. Hitherto unavailable numerical results pertaining to the two cases are also presented.

doi:10.1016/j.compstruct.2007.02.006
ABSTRACT: The effect of transverse shear modulus on the compressive response of a thick plane strain cross-
ply ring (very long cylindrical shell) weakened by the presence of a modal imperfection is investigated. The
present study is primarily motivated to obtain the hitherto unavailable results pertaining to the effect of reduced
transverse shear modulus, G, of a lamina weakened by the presence of randomly distributed fiber
misalignments. A simple expression for the reduced transverse shear modulus, G, of a layer material is derived
in terms of the average fiber misalignment angle. A fully nonlinear finite element analysis, that employs a
cylindrically curved 16-node layer-element and is based on the assumption of layer-wise linear displacement
distribution through thickness (LLDT), is utilized in the analysis of the afore-mentioned cross-ply ring. The
interaction of a micro-structural defect in the form of initial fiber misalignments with its macro-structural
counterpart represented by a modal imperfection is a key to understanding this meso-structural level
phenomenon. Hitherto unavailable numerical results pertaining to the influence of this effect on the localization
of buckling patterns and the ensuing shear crippling instability are also presented.

“Admissible boundary conditions and solutions to internally pressurized thin arbitrarily laminated cylindrical
shell boundary-value problems”, Composite Structures, Vol. 86, No. 4, December 2008, pp. 385-400,
ABSTRACT: Admissible boundary conditions are derived for an arbitrarily laminated internally pressurized
cylindrical shell of finite length, under the framework of Donnell’s, Love–Timoshenko’s and Sanders’
ikinematic relations, and the CLT (based on Love’s first approximation theory). Closed-form solutions for
the same cylindrical shell are presented for Love–Timoshenko’s theory, with two sets of asymmetrically placed
prescribed boundary conditions. As the first example, internally pressurized thin hybrid general (asymmetric)
four-layer cylindrical shells with RS2-C4 boundary conditions, made of glass and carbon fiber reinforced
composite layers, are numerically investigated. In the second example, the numerical results for two-layer asymmetrically laminated cylindrical shells, with RS2-SS1 boundary conditions, are compared with those, computed using triangular finite elements based on the layer-wise constant shear-angle theory (LCST), in order to evaluate the limit of applicability of the CLT.

ABSTRACT: The large deflection behavior of a symmetrically laminated thin shallow circular arch subjected to a central concentrated load is studied using the Rayleigh–Ritz finite element method. The shape functions used in the finite element method maintain C1-continuity of the radial displacement (deflection) and C0-continuity of the tangential displacement, respectively. The nonlinear algebraic equations of equilibrium are solved to a high degree of accuracy using Taylor’s expansion technique in conjunction with the Newton–Raphson method. Nonlinear stability analysis provides accurate solutions for the symmetric and antisymmetric buckling of both pin-ended and fixed shallow arches. The stability of the symmetric deformation path is investigated for both pinned and fixed arches, and a detailed analysis is carried out at the point of bifurcation onto an asymmetric deformation path for a pinned symmetrically laminated shallow arch. The slope of this post-buckled path is also computed, and is shown to be accurate for deformations well beyond the point of bifurcation.

ABSTRACT: The present investigation is concerned with the prediction of localization (onset of deformation softening) and post-localization and post-“yield” equilibrium paths for moderately thick and thick cross-ply [90/0/90] imperfect plane strain rings. These paths are often unstable in the presence of modal imperfections and material nonlinearity, and are considered to “bifurcate” from the primary equilibrium paths, representing periodic buckling patterns pertaining to global or structural level stability. The fully nonlinear finite element analysis, based on the total Lagrangian formulation, employs a three-dimensional theory, known as layer-wise linear displacement distribution theory (LLDT), to capture the three-dimensional interlaminar (especially, shear) deformation behavior, associated with the localized interlaminar shear-crippling failure. The combined effects of modal imperfections, interlaminar shear/normal deformation and nonlinear (hypo-elastic) material property for the transverse shear modulus, GTT, on the localization and delocalization (deformation hardening) phenomena are thoroughly investigated, and physically meaningful conclusions are drawn from these numerical results.

M. Farshad and G. Ahmadi (School of Engineering, Pahlavi University, Shiraz, Iran), “Influence of loading

ABSTRACT: In order to investigate the influence of motion-dependency of loading on the form of stability equations of circular cylindrical shells, certain types of deformation-dependent forces are characterized. The stability equations of rings and columns acted upon by motion-dependent (and possibly non-conservative) forces are obtained as special cases. Some new aspects of ring instability such as tension-induced modes of instability and rigid body modes are also studied.

ABSTRACT: The strain energy release rate is calculated for buckled one-dimensional delamination (through-width delamination) in composite laminates subjected to in-plane compression. A crack closure method based on plate finite elements is used in this analysis. For some laminates containing a one-dimensional delamination in cylindrical bending, closed form solutions are available. The present finite element solutions show excellent agreement with the analytical solutions. The strain energy release rate for various types of laminates is also calculated using the present finite element method. The results show that the strain energy release rate strongly depends on the type of laminate.

ABSTRACT: In this paper, numerical methods for the evaluation of the energy-release-rate along a delamination periphery under conditions of local buckling of the delaminate, as well as global buckling of the entire laminate, are presented. A multi-plate model, using independent Reissner-Mindlin plate models for each of the delaminated and undelaminated plies, with Reissner-Mindlin constraints for relating the degrees of freedom of the delaminated plates to those of the undelaminated plate at the crack front, is used to model the laminate with embedded delaminations. Explicit expressions, in terms of finite element nodal or Gauss-point variables, are derived for the pointwise energy release rate in terms of the J-integral and the Equivalent Domain Integral in the context of a typical multi-plate model for characterising the delamination growth. A finite element method with a 3-noded quasi-conforming shell element, and an automated post-buckling solution capability, is used for conducting the numerical analyses in this paper. Using these numerical results, mechanisms of multiple buckling modes and their effect on the propagation of embedded delaminations in plates, are studied.

DTIC Accession Number: ADA327865, Handle / proxy Url : http://handle.dtic.mil/100.2/ADA327865

ABSTRACT: BUCKDEL, performs geometrically nonlinear analysis of stiffened laminated composite plates with and without delaminations. BUCKDEL allows the user to perform: a linear static solution; a linear
buckling (eigenvalue) analysis; and a nonlinear post-buckling analysis through both limit and bifurcation points. There are two finite elements in BUCKDEL: a quasi-conforming triangular laminated plate element based on a refined first order shear theory with seven degrees of freedom per node and a fiber reinforced beam element with seven degrees of freedom per node. The behavior of all materials is assumed to be linearly elastic. The multi-domain modeling method is used for the analysis of laminated plates containing delaminations. In this model, the delaminate, base and the undelaminate are modeled as 3 distinct. On the delamination front, Mindlin's deformation assumption is applied to obtain the relationship between the displacements in the delaminate, base and undelaminate.

ABSTRACT: Delamination reduces an elastic buckling load of the laminated composite structures and lead to global structural failure at loads below the design level. Therefore, the problem of the delamination buckling of laminated composite structures has generated significant research interest and has been the subject of many theoretical and experimental investigations. However, questions still remain regarding a complete understanding and details of the phenomena involved. In this paper an efficient finite element model is presented for analyzing the elastic buckling behavior of laminated composite plates with through-the-width delamination using a solid element based on a three-dimensional theory. The solid finite element, named by EAS-SOLID8, is based on an enhanced assumed strain method. The study for elastic buckling behavior of laminated composite plates with through-the-width delaminations are focused on various parameters, such as size of delamination, support condition, aspect ratio, width-to-thickness ratio, stacking sequences, and location of delamination and multiple delaminations.

References listed at the end of the paper:

ABSTRACT: Compressive buckling stability of composite panels with through-width, equally spaced multiple delaminations are investigated analytically and experimentally. An analytical method is formulated on the basis of Rayleigh-Ritz approximation technique. Timoshenko type shear effects are included. An experiment and a finite element analysis are also conducted on the present model. The analytical results agree very well with the experimental and finite element results. The buckling load, which is the compressive strength of the panel in the case of the present model, reduces significantly due to the existence of multiple delaminations. The mechanism causing the significant loss of the compressive buckling load due to the delaminations is well explained.

ABSTRACT: An experimental and analytical investigation is conducted on the compressive buckling behavior of an orthotropic plate with a free edge delamination. The plate is a simplified model of stiffener plates. In the present paper two loading edges are fixed and a side edge is simply-supported. The delamination locates at the free edge over the whole length. A Rayleigh-Ritz approximation method is adopted in the analysis. A constrained point is used to allow contacts between the two delaminated surfaces. At this point, relative displacement and two relative slopes are constrained through imaginary springs. The buckling load of the geometrically admissible buckling mode is obtained by an ordinary eigenvalue analysis. The analytical results are compared with the experiment and the results agree well. The effects of the width and the location of the delamination on the buckling behavior are studied analytically for the plates with various aspect ratios. Low local delamination buckling can occur at very low load when the delamination locates near the surface and its size is relatively large compared with that of the plate. The constrained point is shown to be effective for the buckling analysis of the delaminated plates.

ABSTRACT: The extended finite element method is applied to stress analyses of composite laminates modeled by shell elements. In the proposed method, a thin-walled structure containing an interface is modeled by shell elements, and the nodes on the interface are enriched in order to model the delamination. The X-FEM code for thin-walled structures based on the proposed method is developed and is applied to buckling analyses of Carbon Fiber-Reinforced Plastic laminate with delaminations. The proposed X-FEM for shell elements was shown to provide appropriate results, which agree well with those obtained by the X-FEM for solid elements and conventional FEM analyses.

ABSTRACT: Delamination growth is a phenomenon known to reduce the integrity of laminated composite structural elements and may lead to premature failures. In the present study, state of the art procedures of delamination growth analysis are overviewed. The energy release rate calculation is formulated for composite
delaminated tubular cross sections and specialized to a finite element model for delamination buckling and growth analysis of long laminated composite tubes taking into account initial geometric imperfections, large deformations, contact between delamination faces and material degradation. It is, then, used to study the potential of delamination growth in a hybrid composite tube. Parametric studies are conducted to assess the effects of delamination length, location and geometric imperfection on growth.

ABSTRACT: The collapse of cylindrical shells under external pressure is known to be controlled by global elastic buckling, material failure, or a combination thereof. In the case of composites, delamination is another factor affecting the stiffness and stability of the structural component. Thin inner delaminated layers are expected to locally buckle inwards, under hoop compression, reducing the effective thickness of the ring wall. This may lead to a premature collapse of composite rings. The problem is numerically treated and parametrically studied. A Fourier series-based finite-element model is formulated for delaminated composite tubular cross sections. A special “chord length” procedure is developed to enable the convergence of the local buckling solution in quasi-static nonlinear analysis. Parametric studies are conducted to assess the influence of delamination length, depth, location, out-of-roundness imperfection, and ring layup on the pressure levels at delamination buckling and collapse.

DOI: 10.1007/s11340-011-9514-z

ABSTRACT: To characterize the materials parameters and deformation of a convex shell of axial symmetry, a hydrogel contact lens is mechanically deformed by two loading configurations: (a) compression between two parallel plates and (b) central load applied by a shaft with a spherical tip. A universal testing machine with nano-Newton and submicron resolutions is used to measure the applied force, F, as a function of vertical displacement of the plate/shaft, w₀, while a homemade laser aided topography system records the in-situ deformed shell profile and the contact radius or central dimple, a. A nonlinear shell theory and an iterative finite difference method are used to account for the large elastic deformation, the central buckling for the central load compression, and the interrelationship between the measureable quantities (F, w₀, a).

ABSTRACT: The present work deals with a generalization of geometrically linear shear deformation theory for multilayered anisotropic shells of general shape. No assumptions are made other than to neglect the transverse normal strain. The results, which include the effects of shear deformations and rotary inertia as well as initial curvature (included in the stress resultants and assumed transverse shear stresses) are deduced by application of the virtual work principle, with displacements and transverse shear as independent variables. These equations are applied to different shell geometries, such as revolution, cylindrical, spherical and conical shells as well as rectangular and circular plates.

ABSTRACT: A general approach, based on shearable shell theory, to predict the influence of geometric non-linearities on the natural frequencies of an elastic anisotropic laminated cylindrical shell incorporating large displacements and rotations is presented in this paper. The effects of shear deformations and rotary inertia are taken into account in the equations of motion. The hybrid finite element approach and shearable shell theory are used to determine the shape function matrix. The analytical solution is divided into two parts. In part one, the displacement functions are obtained by the exact solution of the equilibrium equations of a cylindrical shell based on shearable shell theory instead of the usually used and more arbitrary interpolating polynomials. The mass and linear stiffness matrices are derived by exact analytical integration. In part two, the modal coefficients are obtained, using Green’s exact strain–displacement relations, for these displacement functions. The second- and third-order non-linear stiffness matrices are then calculated by precise analytical integration and superimposed on the linear part of equations to establish the non-linear modal equations. Comparison with available results is satisfactorily good.

“Large amplitude vibrations of anisotropic cylindrical shells”, Computers & Structures, Vol. 82, Nos. 23-26,
ABSTRACT: A semi-analytical method is developed in conjunction with shearable shell theory and modal expansion approach to predict the influence of geometrical non-linearities on free vibrations of anisotropic laminated cylindrical shells. Shear deformation and rotary inertia effects are taken into account in the equations of motion. The hybrid method developed in this theory is a combination of classical finite element approach, shearable shell theory and modal coefficient procedure. The displacement functions are obtained by the exact solution of the equilibrium equations of anisotropic cylindrical shells and thereafter, the mass and linear stiffness matrices are derived by exact analytical integration. Green exact strain–displacement relations are used to obtain the modal coefficients for these displacement functions. The second- and third-order non-linear stiffness matrices are then calculated by precise analytical integration and superimposed on the linear part of equations to establish the non-linear modal equations. The linear and non-linear natural frequency variations are determined as a function of shell parameters for different cases. The comparison shows that the numerical analysis is of good reliability on the prediction of the experimental results.

ABSTRACT: Many papers have been devoted to the panel flutter of shells [1-4], it is used the piston theory formula for pressure of the aerodynamical interactions between the flow and a shell. Inadequacy of such an approach is discussed in papers [5-7]; results of these studies were used in [8-9] for new statements of problems on the flutter of conical shells. In the proposed work, in elaborations of results of [6], it is considered a problem on the truncated conical shell flutter, it is adduced data on evaluative computations and comparison them with analogous ones, obtained by the piston theory.

ABSTRACT: Large amplitude vibration behavior of symmetrically laminated moderately thick doubly curved shallow open shells with simply-supported sides is investigated. The von Karman type nonlinear strains are incorporated into the first-order shear deformation theory. By applying a Galerkin approximation, five governing equations of motion are reduced to a single nonlinear time differential equation which involves the quadratic and cubic nonlinearities. The nonlinear equation is solved by the fourth-order Runge-Kutta time integration scheme. The validity of the present approach is established by comparing the results obtained by the present study with those available in the literature. The effects of curvature, vibration amplitude, degree of orthotropy, aspect ratio and inplane edge support conditions on the nonlinear vibration characteristics of isotropic, orthotropic and laminated anisotropic open shells are examined.

ABSTRACT: The postbuckling behavior of rectangular isotropic stiffened plates under inplane compressive load is investigated considering the phenomenon of buckled pattern change in the postbuckling load range. The finite deformation strains in the von Karman sense are incorporated in the geometrical nonlinear postbuckling analysis. The inplane and out-of-plane displacements are assumed as truncated Fourier series. The principle of minimum potential energy is applied. The total potential energy includes the strain energy due to bending and membrane action of plate, torsion of stiffeners, and the work done by external compressive force. The plates are assumed to be simply supported along the loaded sides and elastically restrained against rotation by longitudinal stiffeners along the unloaded sides. In numerical examples, the postbuckling load end-shortening curves and effective width curves are presented for the rectangular stiffened plates with various aspect ratios, torsional rigidities of stiffeners and inplane boundary conditions along unloaded sides.

ABSTRACT: For the coupled stability analysis of thin-walled composite beam with closed cross-section subjected to various forces such as eccentric constant axial force, end moments, and linearly varying axial force, the efficient numerical method to evaluate the element stiffness matrix is newly presented based on the homogeneous form of simultaneous ordinary differential equations. The general bifurcation type of buckling theory for thin-walled composite box beam is developed based on the energy functional corresponding to semitangential rotations and semitangential moments. The coupled stability equations including variable coefficients and the force–displacement relationships are derived from the energy principle and explicit expressions for displacement functions are presented based on power series expansions of displacement components. The element stiffness matrix is evaluated by applying member force–displacement relationships to these displacement functions. In addition, the finite element model based on the cubic Hermitian interpolation polynomial is presented. In order to verify the accuracy and validity of this study, numerical solutions are presented and compared with the finite element solutions using the Hermitian beam elements and the available results from other researchers. Particularly, the influence of the eccentricity and the force ratio of axial forces, the fiber orientation, and the boundary conditions on the buckling behavior of composite box beam are parametrically investigated. Also the emphasis is given in showing the phenomenon of buckling mode change.

ABSTRACT: Dynamic responses of composite cylindrical shell panels under initial in-plane stress and impacted by a rigid ball are analyzed by the finite element method using nonlinear shell theory based on Donnell's shell theory with von-Karman's large deflection assumptions. The contact force is characterized by
modified indentation laws which account for the effect of curvatures of the composite cylindrical shell and impactor. Dynamic transient responses including deflections, stresses, strains and contact forces are presented and compared with those obtained by linear analysis. In addition, effects of curvature and initial stress in the shells on the impact responses are investigated and discussed.

ABSTRACT: The buckling behavior of multilayer shells is studied for composite structures subjected to combinations of uniform temperature change, applied external pressure, and applied and reactive circumferential edge loads. A stability criterion is established for the class of structures of interest and a transverse loading parameter is identified. Critical parameters are identified, and closed form analytical solutions are obtained for the associated non-linear problems. Numerical simulations, based on these solutions, are performed and the stability criterion is applied, revealing characteristic behavior of the structures of interest. Such behavior includes “sling-shot” buckling, whereby the structure slings from deflections in one direction to deflections in the opposite sense, in an unstable manner, at critical temperatures. The influence of external pressure on the critical temperature change of thermally loaded composite structures is elucidated, as is the influence of temperature change on the buckling behavior of pressure loaded multilayer shells.

ABSTRACT: An overview, unification and review of the mathematical models, stability criteria and critical parameters for two types of structures, patched plates and layered shells, subjected to uniform temperature change are presented. Results of numerical simulations based on analytical solutions are presented and critical behavior is reviewed and compared. In each case, a transverse loading parameter is seen to force the system. For both types of structure, the loading parameter is dependent on both the temperature and the membrane force, and a critical membrane force and critical temperature are identified. When the corresponding critical temperature is achieved, both types of structures considered are seen to exhibit sling-shot buckling, an instability in which the structure dynamically slings from equilibrium configurations associated with deflections in one direction to those associated with deflections in the opposite sense. Conclusions are drawn and explanations are given as to the physical reasons for this phenomenon.

ABSTRACT: The coupling of edge debonding and thermal buckling of patched beam-plates possessing initial edge detachment is examined for the case when the structure is subjected to a uniform temperature change. The geometrically nonlinear analytical model employed is that established by the authors in a prior work. The problem is recast in a mixed formulation in terms of the transverse deflection and the membrane force to aid in the analysis and physical interpretation. The interaction of edge-debond propagation and thermal buckling is studied. The phenomenon of buckle-trapping, originally observed by the authors in a congruent study, as well as the phenomenon of sling-shot buckling, is seen to manifest itself in the debonding behavior. The evolution of the structure is predicted as a function of given material and geometric parameters from numerical simulations based on analytical solutions of the nonlinear problem. A (propagating) contact zone adjacent to the bonded region is accounted for, and its presence or absence, as well as its nature, is seen to be highly influential in the global as well as local behavior of the structure.

ABSTRACT: Combined effects of modal imperfections, transverse shear/normal deformation with/without reduced transverse shear modulus, $G_{LT}$ (caused by distributed fibre misalignments), on emergence of interlaminar shear crippling type instability modes, related to localization (onset of deformation softening), delocalization (onset of deformation hardening) and propagation of mode II compression fracture/damage, in thick imperfect cross-ply very long cylindrical shells (plane strain rings) under applied hydrostatic pressure, are investigated. Of special interest is the question: what are the geometric and/or material parameters that induce localized and delocalized states in imperfect cross-ply (very) long cylindrical shells under hydrostatic compression simultaneously, and what would be the consequences of such occurrences? The primary accomplishment is the (hitherto unavailable) computation of the layer-wise mode II stress intensity factor, energy release rate and kink–crack bandwidth, under hydrostatic compression, from a nonlinear finite-element analysis, using Maxwell's construction and Griffith's energy balance approach. Additionally, the shear crippling angles in the layers are determined using an analysis, pertaining to the elastic inextensional deformation of the compressed (plane strain) ring. Numerical results include effects of (i) thickness-induced transverse shear/normal deformation and (ii) uniformly distributed fibre misalignments, on localization and delocalization, and consequently on compression fracture/damage characteristics of thick imperfect cross-ply very long cylindrical shells.

ABSTRACT: The main objective of this paper is to investigate the validity of the finite element method (FEM) on the buckling and post-buckling behavior of laminated composite cylindrical shells that have been subjected to an external hydrostatic pressure. In addition, a buckling pressure equation that is based on the ASME and
American Bureau of Shipping (ABS) buckling equation and customized to USN125 composite material is also presented. In order to determine an application for composite material under external hydrostatic pressure, material tests were conducted for carbon–epoxy ply composite URN300 and USN125. The strength and stiffness of the fiber and resin of two composites were determined. Cylindrical panel tests were performed to investigate the behavior of post-buckling under vertical line load. Finite element analyses, using ABAQUS 6.6 code, have been performed, using a linear buckling model based on the solution of the eigenvalue problem, and a non-linear model based on the arc-length method for various cases. Furthermore, an external hydrostatic pressure test was conducted to verify numerical analysis. These results were compared with the previous results obtained by FEM on the buckling. Difference between FEM and the test result is expected to be approximately 18%.

“Post-buckling behavior of laminated composite cylindrical shells subjected to axial, bending and torsion loads”, World Journal of Engineering and Technology (WJET), Vol. 3, No. 4, November 2015, DOI: 10.4236/wjet.2015.34019

ABSTRACT: In present work, post-buckling behavior of imperfect (of eigen form) laminated composite cylindrical shells with different L/D and R/t ratios subjected to axial, bending and torsion loads has been investigated by using an equilibrium path approach in the finite element analysis. The Newton-Raphson approach as well as the arc-length approach is used to ensure the correctness of the equilibrium paths up to the limit point load. Post-buckling behavior of imperfect cylindrical shells with different L/D and R/t ratios of interest is obtained and the theoretical knock-down factors are reported for the considered cylindrical shells.

ABSTRACT: The influence of winding pattern on the mechanical response of filament wound glass/epoxy cylinders exposed to external pressure is studied by testing cylindrical specimens having stacked layers with coincident patterns in a hyperbaric testing chamber. Different analytical models are evaluated to predict buckling pressure and modes of thin wall cylinders (diameter to thickness ratio d/h of 25) and satisfactory predictions are obtained which are in the same order of magnitude that those obtained in experimental results. Test results show no evident pattern influence on either strength (implosion pressure) or buckling behavior (buckling modes) of thin wall or thick wall (d/h of 10) cylinders.

ABSTRACT: A refined higher-order displacement model for the study of the behavior of concentrically and eccentrically stiffened laminated plates based on C0 finite element discretization is presented. The model incorporates non-linear variations of longitudinal displacements through the thickness and hence eliminates the need to use shear correction coefficient(s). Transverse shear deformations are included in the formulation making the model applicable for both moderately thick and thin composite stiffened plates. The plate element used is a nine-noded isoparametric one with seven degrees of freedom at each node. The stiffener element is a three-noded isoparametric beam element with four degrees of freedom at each node. The stiffness of a stiffener is reflected at all nine nodes of the plate element in which it is placed. Accordingly, the stiffeners can be positioned anywhere within the plate element along lines of constant natural coordinates and need not necessarily be placed on nodal lines which gives a great flexibility in the choice of mesh size. The integrals are evaluated by a selectively reduced integration (SRI) technique with three and two Gauss quadrature rules for membrane-flexure and shear parts, respectively. The present formulation is checked for different examples of stiffened plates made of isotropic and fiber-reinforced composites, and results are compared with existing analytical and other finite element solutions.

PARTIAL ABSTRACT: A viable aspect of fiber-reinforced composites is their elastic tailoring ability. Anticlastic curvature is one example of elastic tailoring that occurs with an unsymmetrical cross-ply layup. Residual stresses resulting from differences in coefficients of thermal expansion and elastic properties in each lamina can cause large out-of-plane deformations. In the case of thin unsymmetric cross-ply laminates under thermal curing load, a cylindrical shape is observed because of the inherent geometrical non-linearity as opposed to the saddle shape that Classical Lamination Theory predicts. In this paper a finite element approach using ABAQUS is implemented in order to predict the unsymmetric cross-ply laminate shapes under thermal curing stresses…

ABSTRACT: A viable aspect of fiber-reinforced composites is their elastic tailoring ability. Anticlastic curvature is one example of elastic tailoring that occurs with an unsymmetric cross-ply layup. Residual stresses resulting from differences in coefficients of thermal expansion and elastic properties in each lamina can cause large out-of-plane deformations. In the case of thin unsymmetric cross-ply laminates under thermal curing load, a cylindrical shape is observed because of this inherent geometrical nonlinearity as opposed to the saddle shape that classical lamination theory predicts. In this article, a finite element approach, using ABAQUS, is implemented in order to predict the unsymmetric cross-ply laminate shapes under thermal curing stresses and understand the underlying limit point instability. Numerical results for curvatures of the predicted shapes are in agreement with published experimental and analytical data. The stability of the cylindrical laminates is also investigated. Depending on the aspect ratio of the rectangular laminate, a cylindrical shape may snap-through from its current stable configuration to another stable cylindrical shape with a different curvature. In particular, both the critical aspect ratio where snap-through will cease to occur and the buckling load are reported.

ABSTRACT: This research aims at investigating the bistable characteristics of unsymmetric cross-ply laminates resulting from thermally induced stresses while curing. The bistable characteristics are examined with a focus on the change in geometry for a subset of configurations, namely, rectangular, trapezoidal and triangular. To this end, these geometries are systematically investigated leading to a set of non-dimensional parameters establishing the values required for bistable behavior. A new apparatus is designed to measure the magnitude of the force required for snap-through and snap-back. The influence of friction at the supports of the tested panels is minimized by utilizing air cushion for frictionless motion. Predictions from a nonlinear finite element based methodology using the ABAQUS code are validated through comparisons with test data.

ABSTRACT: A composite panel, with a [0/90] unsymmetric layup, exhibits bi-stable anticlastic equilibrium configurations. One way to provide morphing capabilities to such a panel is attained by attaching piezoelectric actuators to its surface. In such a design an electric field is applied to the piezoelectric actuators in order to trigger snap-through behavior of the panel/actuator assembly. A simple cantilever beam configuration is discussed to perform actuator assessment. Results are compared to with predictions from Extended Classical Lamination Theory and finite element analysis. Guidelines are proposed to design a morphing unsymmetric
panel/actuator assembly. The panel/actuator(s) assembly is manufactured accordingly. Snap-through experiments are conducted and the ABAQUS finite element software is used to predict snap-through behavior. Analysis predictions are in good agreement with test results.

ABSTRACT: Composite shells show a rich multistable behaviour of interest for the design of shape-changing (morphing) structures. Previous studies have investigated how the initial shape determines the shell stability properties. For uniform initial curvatures and orthotropic material behaviour, not more than two stable equilibria have been reported. In this paper, we prove that untwisted, uniformly curved, thin orthotropic shells can have up to three stable equilibrium configurations. Cases of tristability are first documented using a numerical stability analysis of an extensible shallow shell model. Including mid-plane extension shows that the shells must be sufficiently curved in relation to their thickness to be multistable. Thus, an inextensible model allows us to perform an analytical stability analysis. Focusing on untwisted initial configurations, we illustrate with simple analytical results how the material parameters of the shell control the dependence of its multistable behaviour on the initial curvatures. In particular, we show that when the bending stiffness matrix approaches a degeneracy condition, the shell exhibits three stable equilibria for a wide range of initial curvatures.

“Multiparametric Actuation of Bistable Plates: A Method to Avoid Snap-Through Instabilities”, 7th EUROMECH Solid Mechanics Conference J. Ambrosio et.al. (eds.) Lisbon, Portugal, 7–11 September 2009

ABSTRACT: Large changes in the shape of a given structural member can be obtained by exploiting geometric nonlinearities or instability phenomena; multistable structures, i.e. structures characterized by two or more stable configurations, can undergo large displacements under moderate actuation forces. This feature turns out to be a major advantage for some actuation problems. The study of multistability and of geometrical nonlinear effects in composite plates and shells has recently gained a relevant interest: it is expected that the industrial applications of multistable structures will encompass a large variety of engineering products from micro-electronics systems to human-scale systems. Previous numerical and experimental [5, 9, 13] studies have analyzed the possibility of using a piezoelectric actuation to drive a bistable composite plate from one stable configuration to the other; other recent contributions [11, 15] have investigated the influence of geometry and material properties on the stability properties of shallow shells. We propose new insights regarding both these aspects.

ABSTRACT: This paper studies the stable equilibrium shapes of free multilayered orthotropic plates loaded by inelastic deformations induced by thermal and piezoelectric effects. Starting with a Von Kármán plate kinematics and an energetic formulation, a discrete intrinsic nonlinear model in terms of curvatures only is deduced. The model has 3 degrees of freedom, namely the components of the symmetric curvature tensor, which is supposed to be uniform in space. Despite of this rough assumption, the analytical results about the equilibrium shapes and their stability show a good agreement with the finite element simulations performed with a commercial code. Literature results about the bistable behavior of isotropic plates under a single-parameter loading are extended to the orthotropic case with two loading parameters. In light of a global stability analysis and a phase portrait as a function of the inelastic curvatures, we study possible actuation techniques for controlling the transition of the plate between its two stable configurations. We show that with a suitable two-parameter actuation, it is possible to get a controlled quasi-static transition, avoiding any instability phenomenon. Numerical simulations on a realistic case study support the technological feasibility of the proposed actuation technique when using active piezoelectric layers to control the inelastic curvature.

ABSTRACT: The paper presents a displacement incrementation procedure to handle multiple loadings in post-buckling analysis of structures by Dynamic Relaxation (DR). This procedure is generalized and a ‘variable-arc-length’ method is proposed to automate the tracing of load-deflection path. The resulting algorithm exactly traces limit points and can handle ‘snap-through’ or ‘snap-back’ problems. The efficiency of the proposed method is demonstrated by typical examples of truss, beam and shell structures.

ABSTRACT: This paper investigates the post-buckling analysis of structures using several proposed three-parameter constrained solution techniques. The family of three-parameter constraint equations is non-dimensional and comprises an elliptic constraint method, hyperbolic constraint method and a second degree polynomial constraint method. The proposed methods are numerically robust and are shown to be quadratically convergent. Their computational performance is demonstrated through various examples of truss, beam, plane stress and shell structures. The scope of the paper is limited only to the tracing of primary equilibrium path of the above structures, and hence the problems of bifurcation are not considered in the present study.

“Postbuckling response and failure of symmetric laminates under in-plane shear”, Composites Science and
ABSTRACT: This paper summarizes a study aimed at understanding the postbuckling behaviour and progressive failure of thin, simply supported symmetric rectangular laminates with various possible in-plane boundary conditions and under the action of in-plane shear loads. First-order shear deformation theory and geometric non-linearity, in the von-Karman sense, is used with a finite-element procedure. The 3D Tsai–Hill criterion is used to predict failure of lamina and the maximum stress criterion is used to predict the onset of delamination at the interface of two adjacent layers. The effect of in-plane boundary conditions, plate lay-ups, plate aspect ratio, fiber orientations and lamina material properties on the load deflection response, buckling load, first-ply failure load, ultimate load and the maximum transverse displacement associated with failure loads is presented.

ABSTRACT: The objective of this work is to study the postbuckling behaviour and progressive failure response of thin, symmetric laminates under uniaxial compression and uniaxial compression combined with in-plane shear loads (positive and negative). First-order shear deformation theory and geometric non-linearity in the von Karman sense are used with a finite-element procedure. The 3-D Tsai–Hill criterion is used to predict failure of a lamina and the maximum stress criterion is used to predict onset of delamination at the interface of two adjacent layers. The effect of plate aspect ratio and ply lay-ups on the load deflection response is presented. Load interaction diagrams for (±45/0/90)2s, (±45)4s and (0/90)4s laminates are obtained in terms of the buckling, the first-ply and the ultimate failure loads. In addition, progressive failure response of the (±45/0/90)2s laminate is also presented to show the buckling loads, failure loads, maximum transverse displacements associated with the failure loads and failure modes and locations at various load ratios.

ABSTRACT: A nonlinear finite element method, which is based on the von Karman–Mindlin plate theory and the principle of minimum total potential energy, is used to study the response and the first-ply failure of thin laminated composite plates under uniform temperature rise. The temperature dependent mechanical and strength properties, their effect on response and failure of laminates and the onset of delamination in the process of first-ply failure computation are some of the features incorporated in the nonlinear formulation. The load–displacement curves for different types of graphite/epoxy laminates are obtained. Stresses are computed to determine the first-ply failure temperature based on the Tsai–Wu failure criterion. The effect of the fiber orientation, the number of lay-ups and the plate aspect ratio on the response as well as the first-ply failure is studied.

“Postbuckling strengths of composite laminate with various shaped cutouts under in-plane shear”, Composite Structures, Vol. 92, No. 12, November 2010, pp. 2966-2978, doi:10.1016/j.compstruct.2010.05.008
ABSTRACT: The aim of present investigation is to study the buckling and postbuckling response and strengths under positive and negative in-plane shear loads of simply-supported composite laminate with various shaped cutouts (i.e., circular, square, diamond, elliptical-vertical and elliptical-horizontal) of various sizes using finite-element method. The FEM formulation is based on the first order shear deformation theory which incorporates geometric nonlinearity using von Karman’s assumptions. The 3-D Tsai-Hill criterion is used to predict the failure of a lamina while the onset of delamination is predicted by the interlaminar failure criterion. The effect of cutout shape, size and direction of shear load on buckling and postbuckling responses, failure loads and failure characteristics of quasi-isotropic [i.e., (+45/-45/0/90)2s] laminate has been discussed. In addition, the effect of composite lay-up [i.e., (+45/-45/0/90)2s, (45/-45)4s and (0/90)4s] has also been reported. It is observed that the cutout shape has considerable effect on the buckling and postbuckling behaviour of the quasi-isotropic laminate with large size cutout. It is also observed that the direction of shear load and composite lay-up have substantial influence on strength and failure characteristics of the laminate.

ABSTRACT: The objective of this paper is to study the interaction curves along with buckling and postbuckling responses of a quasi-isotropic laminate with a centrally placed circular cutout of various sizes under uni-axial compression combined with in-plane shear loads (positive and negative). The present study is carried out using finite element method. The finite element formulation is based on the first order shear deformation theory and von Karman’s assumptions to incorporate geometric nonlinearity. The resulting nonlinear algebraic equations are solved by Newton–Raphson method. The 3-D Tsai-Hill criterion is used to predict the failure of a lamina while the onset of delamination is predicted by the interlaminar failure criterion. It is observed that pure compression-buckling, -first-ply failure and -ultimate failure strengths of the quasi-isotropic laminate with and without circular cutout decreases with increasing accompanying shear load. In addition, it is also noted that for a given uni-axial compression load, a quasi-isotropic laminate with and without a cutout can sustain higher negative shear load in comparison to the positive shear load.

ABSTRACT: Digital fringe projection profilometry (FPP) is suitable to inspect surface profile of object, with some apparent advantages of non-contact, full-field measurement, simple apparatus, high precision, and real-time profile automation. Four phase-shifted sinusoidal fringe patterns are circularly projected onto the surface of a composite laminates panel reinforced with crossed ribs. Phase shifting method is applied to inspect the surface profile variations during compression. The profile results reveal that different local buckling modes appear at different crossed ribs, where the wave villages locate at the middle and the wave peaks occur at the composite panel ends. From the details of the deflection analysis, it can be seen that the local buckling modes couple with the whole bending of the composite panel. The local buckling modes vary with the applied load and
the experimental results are helpful to understand its failure mechanism.

ABSTRACT: Exact elasticity solutions are obtained using the stress function approach, where the radial, circumferential and shear stresses are determined, taking into account the closed ends of the cylindrical shell. The system of the governing algebraic equations is derived to accurately analyse a multilayered pressure vessel with an arbitrary number of layers and any thickness. The approach used is straight-forward compared to other three-dimensional solutions found in the literature. The design of multilayered composite pressure vessels is accomplished using the genetic algorithm and subject to the Tsai–Wu failure criterion. The genetic algorithm is optimized to serve this particular problem.

ABSTRACT: This paper aims to obtain the optimal design of laminated composite structures. The design variables are specified as the ply angles and the laminate thicknesses. The objective is to obtain a structure with minimum weight that is capable of carrying a given set of static external forces without failure. The solution strategy consists of addressing the problem sequentially at two levels, each having a different algorithm and a separate set of design variables. The optimization techniques use a combination of sensitivity analysis combined with optimality criteria and mathematical programming. The adequacy of the solution is assured by constraints limiting stresses and displacements.

ABSTRACT: A design optimisation methodology for beam reinforced composite structures with non-linear geometric behaviour is proposed. The formulation involves displacement, stresses, buckling and size constraints. The Newton–Raphson iterative procedure and the arc-length method are used for tracing equilibrium path and later updating the buckling load and the first ply failure load. The proposed sensitivity analysis model is based on an approach of the adjoint variable method for structures with non-linear geometric behaviour. The optimal design performs on a multilevel scheme based on structural efficiency maximisation exploring the anisotropic properties of the composites and weight minimisation using the ply thickness and the cross-section variables of the stiffeners. To demonstrate the applicability of the proposed developments, optimisation problems considering first ply failure and buckling conditions are presented.

C. A. Conceição António (Faculty of Engineering, University of Porto, Rua Dr. Roberto Frias, 4200-465 Porto, Portugal), “A hierarchical genetic algorithm for reliability based design of geometrically non-linear composite
ABSTRACT: A design optimisation methodology based on structural reliability of beam reinforced composite shell structures with non-linear geometric behaviour is proposed. The formulation involves probabilistic stress, displacement and buckling constraints. The structural integrity is evaluated through the reliability index using a Lind–Hasofer second-order-second-moment approximation method together with the Newton–Raphson iterative procedure and the arc-length method. The random variables are the mechanical properties of the laminates treated as homogeneous orthotropic materials. A new methodology based on an evolutionary strategy searching the global most probable failure point (MPP) for composite structures under non-linear geometric behaviour is proposed. The optimal design performs on a hierarchical genetic algorithm (HGA) based on weight minimisation under prescribed reliability constraints. The design variables are the ply angle, the ply thickness and the geometric variables associated with the cross sections of the stiffeners. To demonstrate the applicability of the proposed developments, optimisation problems are presented.

ABSTRACT: A multilevel genetic algorithm aiming the global optimization of beam reinforced composite structures with nonlinear geometric behaviour is proposed. A unified approach based on load-displacement control for buckling and first ply failure analysis is adopted. The Newton-Raphson iterative scheme and the arc-length method are used for tracing the equilibrium path and later for updating the critical values. The proposed genetic algorithm performs several sequences of two optimization levels resulting from the decomposition of the original optimization problem. Independent genetic searches are implemented for each level where different fitness functions and sub-populations are considered. The genetic operators selection and crossover supported by an elitist strategy are used while the diversity of the sub-populations is guaranteed based on implicit mutation. A genetic material exchange between levels is performed using clones and so the offspring of matured sub-populations is guaranteed. To improve the efficiency of the multilevel genetic optimization a niche of population is induced after the first stage at both levels.

ABSTRACT: The optimum design of laminated composite structures in terms of their strength is a complex task because many different mechanisms are involved in the damage and rupture to which these materials are subject. The great diversity of the damage mechanisms and their patterns of evolution makes it extremely difficult to estimate the strength margins. It is still impossible, for instance, to perform simulations on industrial structures made of unidirectional ply laminates up to rupture. The strategy adopted in this study on designing laminated composite structures is based on the choice of materials (woven or unidirectional plies) and the use of simple models (focusing on the rupture of the first ply) with which industrial structure analyses can be carried out. The choice of materials (woven or unidirectional plies) does not depend only on mechanical criteria but also on the simplicity of the corresponding modelling procedures.
ABSTRACT: Parameter studies, genetic algorithms and Monte Carlo type calculations are examples of pleasantly parallel computational tasks. Pleasantly parallel computational tasks can be effectively calculated in computer clusters or grids. In this work, we consider a weight minimization problem of a laminated composite structure in the post-buckling region. The design variables are the number of layers and the layer orientations given in a discrete set of allowable angles for layer orientations. Optimization is carried out using a deterministic search process, where the lay-up configurations are generated iteratively in the design space from the selected design points of the population at the preceding cycle. Computation is performed using NorduGrid grid computing platform. In this work, we briefly go through some general grid concepts and the use of grid in optimization of laminated composite structures.
ABSTRACT: If major weight saving is to be realised it is essential that composites be used in “primary” structural components, i.e., wing and fuselage skins. To this end it is essential that analytical tools be developed to ensure that composite structures meet the FAA damage tolerance certification requirements. For stiffened composite panels one potential failure mechanism is the separation of the skin from the stiffeners; resulting from excessive “through the thickness” stresses. This failure mechanism is also present in bonded composite joints and composite repairs. Currently failure prediction due to in-plane loading appears to be relatively well handled. Unfortunately, this is not yet true for matrix-dominated failures. Consequently, it is essential that a valid analysis methodology capable of addressing all of the possible failure mechanisms, including failure due to interlaminar failure, be developed. To aid in achieving this objective the present paper outlines the results of a series of experimental, analytical and numerical studies into the matrix-dominated failures of rib stiffened structures.

ABSTRACT: With the introduction of postbuckling lightweight composite structures, adhesively bonded joints with thin skins are susceptible to premature failure due to peel induced loading. This paper reports on the findings of a research programme to investigate the local and global responses of postbuckling rib-stiffened panels under shear loads. C- and I-section ribs, with and without taper in the flanges, have been studied experimentally and analysed numerically to assess their postbuckling behaviour and relative merit with respect to structural integrity of rib-stiffened shear panels. The rib-skin separation loads and locations for the different panels have been evaluated via mechanical tests, and the experimental data have been closely predicted using Finite Element Method models.

ABSTRACT: The buckling behavior of composite laminated square plates is analyzed with the aid of the finite-element method in which a modified isoparametric linear shell element is used. The in-plane and bending displacements are used together in the formulation of the finite-element method in the case of asymmetric laminates. A new method of modifying the constitutive law of composite materials to circumvent the shear-lock effect is also proposed. This new method has the useful property of removing the shear-lock effect in the case of very thin plates. Composite laminates of symmetric and asymmetric stacking sequences, with and without a central circular hole are analyzed. Using the developed program, various laminated cases are analyzed and discussed. The present results show an improvement over those found analytically when compared with experimental results for asymmetric laminates.

ABSTRACT: Analytical solutions for the buckling of anisotropic cylinders and curved panels under arbitrary loadings are presented. Donnell-type equations, laminated shell constitutive relations and the Galerkin method are used to determine critical loads. Correlations to account for unsatisfied boundary conditions are developed. A method for calculating the transverse shear stiffness of a laminated shell is discussed. Numerical correlations between theoretical and experimental buckling loads are presented.

ABSTRACT: The in-plane load-bearing capacity of marine composite plates is an area that has received little attention, in contrast to the significantly larger buckling and post-buckling studies available on aeronautical composites. The aim of this study is to investigate experimentally the strength to failure of large woven composite panels and correlate the results with finite element analyses. The tests performed were able to demonstrate the well-known sensitivity of the panels to boundary conditions and panel imperfection size, which is also reflected in a parametric study carried out in Abaqus/Standard. Two-dimensional stress-based failure criteria were implemented via a user-defined field (USDFLD) subroutine to detect matrix and fiber damage, which allows progressive damage to be modeled. A modification of Hashin’s failure criteria proved to be the most effective in capturing both the size and location of the damage and obtain a good approximation of the load—displacement history and surface strains.

ABSTRACT: The application of a shell/3D technique for the simulation of skin/stringer debond in a specimen subjected to three-point bending is demonstrated. The global structure was modeled with shell elements. A local three-dimensional model, extending to about three specimen thicknesses on either side of the delamination front was used to capture the details of the damaged section. Computed total strain energy release rates and mixed-mode ratios obtained from shell/3D simulations were in good agreement with results obtained from full solid models. The good correlations of the results demonstrate the effectiveness of the shell/3D modeling technique for the investigation of skin-stiffener separation due to delamination in the adherents.

ABSTRACT: The development of an approximate analysis for predicting stresses in the skin-stiffener interface region of composite plates and shallow shells is presented. The analysis determines interlaminar normal stress and transverse shear stresses in the direction of the stiffener axial coordinate and the direction of the in-plane coordinate perpendicular to the stiffener axis. The analysis accounts for skin-stiffener interfaces with nonzero thickness and for curvature in the skin and stiffener. The interlaminar normal stress and transverse shear stresses at the interface are applied to the lower face of the skin and the upper face of the stiffener flange as unknown functions, and the displacements in the skin and flange are related through the deformation of the interface bond layer. The Rayleigh-Ritz method is used to determine the unknown functions that yield the interlaminar stresses at the skin-stiffener interface. The addition of a failure criterion to the stress prediction capability of the analysis results in the prediction of separation failure. After validation of results from the model, the effects of geometric nonlinearities and aspects of the numerical convergence of the analysis are explored and presented. Furthermore, the influence of various design parameters on the interface stress distribution, and therefore on skin-stiffener separation, is presented.

PARTIAL ABSTRACT: Experimental simulation of boundary conditions while carrying out a panel buckling test has been known to be difficult. In this paper, compression buckling tests on 6.0-mm-thick carbon fiber composite (CFC) panels have been described for which a reasonably good simulation of the boundary conditions was achieved, especially under the simple supported condition. Carefully designed test fixtures that provided excellent alignment of the panel with the load axis and adequate lateral stiffness for edge supports during buckling of the CFC panels were used to achieve this goal. Both simply supported and clamped boundary conditions have been studied. Tests in room-temperature-as-received (RT/AR) and hot-wet (H/W) conditions are described. A buckling test on a simply supported panel with prior moisture conditioning was performed under the H/W condition with an environmental test chamber mounted on the test rig to prevent any loss of moisture during the test at 100 degrees C and greater than 85 per cent relative humidity. Based on these results, a test procedure was developed to identify buckling loads through measurement of out-of-plane displacements rather than relying solely upon longitudinal strain measurement...

PARTIAL ABSTRACT: In typical applications such as in the top skin of a wing or in control surfaces of an airframe, laminated composites are often found to be buckling-critical. Under excessive compression loading composite panels may undergo buckling and failure mechanisms that would generally involve delamination or fiber breakage. Tapered composite panels with ply drops, when employed in wing skin, are expected to be more prone to the above mode of failure. This is one important area of concern to the designers of composite structures and both analysis and experimental verification of the buckling behavior are recommended as a part of the design validation effort. However, data from such analyses are scarce in the open literature. In this paper, results of a study on buckling and fracture behavior of laminated carbon fiber composite (CFC) panels containing ply drops are presented. CFC panels of varying thickness with normal and inclined ply drops were tested under compression loading until buckling and ultimate failure. Nearly simply supported boundary conditions at the ends and along the edges were simulated with the help of specially designed test fixtures. Tests were conducted both under room temperature and hot-wet…

ABSTRACT: The response of honeycomb sandwich structure to disbond damage, in a compressive stress field, has been assessed. Two types of disbond were considered; those extending through the full width of a panel (through-width) and those enclosed within the panel boundaries (embedded). For each type of disbond the failure process was established through four-point bend testing of 56 sandwich specimens. For both types of disbond, failure was found to be governed by buckling-driven disbond growth and, consequently, models of buckling and disbond growth were developed. All of the models decoupled the face-sheets of the sandwich and treated the core as a spring foundation having a stiffness determined from equilibrium of a two-dimensional orthotropic solid. A linear Winkler beam model was used to predict buckling of a through-width disbond. The model buckling loads agreed with specimen test results with an average difference of 1.7%. A non-linear Winkler beam model was then developed to predict post-buckling behaviour and the initiation of disbond growth, through a fracture mechanics analysis. A characteristic growth curve, defining the work input required to initiate disbond growth, was developed and agreed with specimen test results with an average difference of 3.3%. The model also verified that disbond growth occurs in discrete increments approximately equal to the diameter of the honeycomb cells. A linear Winkler plate model was used to predict buckling of an embedded disbond. The model buckling loads agreed with specimen test results with an average difference of 3.7%. A non-linear Winkler plate model was then developed to predict post-buckling behaviour of a sandwich panel containing an embedded disbond. The model considered contact conditions and modelled disbond growth by releasing fractured nodes during load incrementation. Disbond growth initiation loads agreed with specimen test results with an average difference of 15.8%. Failure loads consistently over-predicted specimen test results by an average of 13.9%. It was concluded that the growth initiation loads should be used as a conservative estimate of failure. The models developed may be used to assess the criticality of disbond damage in sandwich structure having thin-gauge, composite face-sheets.

ABSTRACT: In the present work, an avant-garde study on Buckling of honeycomb sandwich panel of hexagonal cell has been carried out by considering simply supported boundary constraints explicitly. A novel theoretical formulation has been developed for the buckling of honeycomb panel as per Mil Standard (MIL-HDBK-23A). The laminate element type has been considered for linear static analysis using Lanczos Method (finite element method (FEM)). The buckling analysis carried out by FEM has been compared and validated with theoretical and experimental investigation for different panel aspect ratio under static load.

Zoh Gweon Kim, Chang Sun Hong and Chun Gon Kimt (Department of Aerospace Engineering, Korea Advanced Institute of Science and Technology, 373-1 Kusong-dong, Yusung-gu, Taejon, 305-701, Korea), “Postbuckling Analysis of Stringer- Stiffened Composite Laminated Cylindrical Panels”, Journal of Reinforced Plastics and Composites, August 1995, vol. 14, no. 8, pp. 827-846, doi: 10.1177/073168449501400804 ABSTRACT: The postbuckling behavior of stiffened composite cylindrical panels was studied analytically and experimentally. Progressive failure analysis was implemented for the prediction of failure characteristics and postbuckling ultimate load. For the progressive failure analysis, the maximum stress criterion is applied to the average stress in each layer of all the finite elements. Using the same degenerated three dimensional isoparametric solid element in order to model stiffeners and the skin, the global and the local buckling of the stiffened panel can be depicted exactly. The results show the effects of stiffener location, and various stiffener heights and thickness on the postbuckling behavior of stiffened composite cylindrical panels. The postbuckling ultimate load of stringer-stiffened composite cylindrical panel is not dependent of the initial buckling load, but becomes higher as the stiffener thickness and height increase.

ABSTRACT: The dynamic response and damage of laminated composite cylindrical shell subjected to impact load is numerically investigated using the finite element method. A nine-node isoparametric quadrilateral element based on Sander's shell theory is developed, in which the transverse shear deformation is considered. A semi-empirical contact law that accounts for the permanent indentation is incorporated into the finite element program to evaluate the contact force. The Newmark time integration algorithm is used for solving the time dependent equations of the shell and the impactor. The Tsai-Wu failure criterion is used to estimate the failure of the laminated shell. Numerical results, including the contact force history, interlaminate damage zone, and failure indices in the shell are presented. Effects of curvature, impact velocity and mass of impactor on the composite shell behaviors are discussed.

ABSTRACT: Low velocity impact and compression-after-impact characteristics of a typical plain weave E-glass/epoxy composite are studied experimentally. Atmospheric pressure was maintained on the top surface and different pressures were applied on the rear side during impact experiments. Pressure on the rear side of the impacted plate is referred to as back pressure in further discussion. Effect of back pressure on the impact behavior is studied. It is observed that the variation in peak contact force and maximum central deflection are governed by two opposing phenomena. The parameters influencing the opposing phenomena are: induced curvature because of back pressure, effective pre-stressing and effective thickness. The incident impact energy was the same in all the experiments. Post-impact compressive strength was also investigated.

ABSTRACT: Fibre composite structures have become the most attractive candidate for civil engineering applications. Fibre reinforced plastic polymer (FRP) composite materials have been used in the rehabilitation and replacement of the old degrading traditional structures or build new structures. However, the lack of design standards for civil infrastructure limits their structural applications. The majority of the existing applications have been designed based on the research and guidelines provided by the fibre composite manufacturers or based on the designer’s experience. It has been a tendency that the final structure is generally over-designed. This paper provides a review on the available studies related to the design optimization of fibre composite structures used in civil engineering such as; plate, beam, box beam, sandwich panel, bridge girder, and bridge deck. Various optimization methods are presented and compared. In addition, the importance of using the appropriate optimization technique is discussed. An improved methodology, which considering experimental testing, numerical modelling, and design constrains, is proposed in the paper for design optimization of
composite structures.

Vassilopoulos and Thomas Keller [Composite Construction Laboratory (CCLab), Ecole Polytechnique Federale de Lausanne (EPFL), Lausanne, Switzerland], “Shear wrinkling of GFRP webs in cell-core sandwiches”, Advances in FRP Composites in Civil Engineering, pp 91-94, 2011

ABSTRACT: Slender webs of glass fiber-reinforced polymer (GFRP) beams are sensitive to shear buckling. Shear buckling can be seen as an in-plane biaxial compression-tension buckling problem. The transverse tensile load thereby delays the onset of buckling and increases the ultimate load. Thin-walled GFRP plates of two different fiber stacking sequences, [0/90]S and [90/0]S, were subjected to in-plane biaxial compression-tension loading. The buckling loads were almost duplicated by increasing the tensile load while the ultimate loads were increased by up to 20%. The fiber stacking sequence thereby had significant effects on buckling mode shape and buckling and ultimate loads.

ABSTRACT: Glass fiber-reinforced (GFRP) cell-core sandwich structures are increasingly used in bridge deck and roof construction. GFRP cell-core sandwiches are composed of the outer GFRP face sheets, a foam core and a grid of GFRP webs integrated into the core in order to reinforce the shear load capacity. One of the critical failure modes is shear wrinkling, a local buckling failure in the sandwich webs due to shear loading. Shear wrinkling is a biaxial compression-tension wrinkling problem and, for this reason, the numerous results of pure compressive wrinkling research are not necessarily applicable. The details and results of in-plane biaxial compression-tension wrinkling experiments on GFRP sandwich laminates, stabilized by a polyurethane foam core, are presented. It is shown that an increasing transverse tension load significantly decreases the wrinkling load. These results are confirmed by finite element calculations.

ABSTRACT: The laws of corrugation (wrinkling) that takes place in thin aluminum films on silicon substrates with styrene sublayers under the conditions of thermal treatment have been studied using atomic force microscopy techniques. Measurements of the amplitude and period (wavelength) of wrinkles revealed stages in the viscoelastic corrugation process at various temperatures. It is established that the evolution of wrinkles in the course of annealing is controlled by the periodic distribution of normal and tangential stresses at the film-sublayer interface.

ABSTRACT: The objectives of this research are to investigate the effects of stacking sequence (orientation of plies adjacent to the 0° plies), free surfaces, fiber/matrix interfacial bond strength, initial fiber waviness, resin-rich regions, and nonlinear resin shear constitutive behavior on fiber microbuckling initiation. Three thermoplastic composite material systems are used in this investigation. The materials are the commercial APC-
2 (AS4/ PEEK), QUADRAX Interlaced Tape, and a poor interface experimental material, AU4U/ PEEK. Notched compression specimens are studied at 21°C, 77 °C, and 132°C. Observations indicate that the notch radius controlled fiber microbuckling initiation, and thus compression strength, by dictating the unsupported fiber length at the notch. The numerical results from a companion paper [1] are compared qualitatively with these experimental results. The results show that increasing the test temperature, locating 0° plies at the free surface of the laminate, and degrading the fiber/matrix interfacial bond strength reduce the resistance to fiber microbuckling initiation in these notched laminates. The fiber micro buckling initiation strain is shown to be a constant, regardless of stacking sequence, for these notched laminates. Experimental results show that resin-rich regions also reduced the resistance to fiber microbuckling initiation.

ABSTRACT: Layer waviness was investigated in T300/P1700 carbon/polysulfone com posite laminates under static compression loading. A three-step procedure was used to fabricate isolated layer waves into the central 0° layer of [902/02/902/02]s laminates. Efforts were made to insure that this three-step procedure itself did not degrade the laminate quality. Layer wave geometries up to 1.5 layer thicknesses in amplitude and as short as nine layer thicknesses in length were tested. The more severe wave geometries produced reductions in static strength as high as 36 %, although the wavy 0° layer accounted for only 20% of the load carrying capacity of the laminate. Specimen failures were sudden and catastrophic. Brooming failure, characterized by through-the-thickness splaying of the layers and numerous delaminations near the waviness, was the common failure mode.

ABSTRACT: Four properties of unidirectional fibre composites are shown to be influenced by fibre waviness. Compressive strength (and also modulus) can be related to fibre waviness by relatively simple equations. Loss in strength during fatigue does not lend itself so easily to simple analysis, but seems to be readily explicable if the fibres are not straight. Shear strength parallel to the fibres is greater than the matrix shear strength—and at high temperatures much greater—and simple equations can be used to explain this in terms of fibre waviness. Finally, some features of delamination resistance can be explained in terms of fibre waviness. However, both for shear and delamination resistance, more data is needed on the degree of fibre waviness in test samples.

ABSTRACT: An investigation has been conducted of the effect of fiber waviness on stiffness and strength
reduction of unidirectional composites under compressive loading. Analytical models have been developed for
determining the elastic properties and compressive strength as a function of fiber waviness for three types of
wavy patterns: uniform, graded and localized waviness. Compression tests were conducted to verify the
predictions. Experimental results were in good agreement with predictions based on the analytical models. It is
shown that in unidirectional composites both major Young's modulus and compressive strength are degraded
seriously with increasing fiber waviness. Material anisotropy is also shown to influence the degree of stiffness
and strength reduction. Interlaminar shear failure was found to be the dominant failure mechanism for
unidirectional wavy composites under compressive loading.

“Ply waviness on in-plane stiffness of composite laminates” (publisher and date not given in the pdf file. Latest
reference is dated 1996; perhaps the paper was presented at ICCM12; Stanford University Ph.D. dissertation
with similar title and same author as the first author of this paper is dated 1997)

ABSTRACT: A model was developed to determine the effect of ply waviness on the in-plane stiffness of
composite laminates. On this model, plies containing waviness were mathematically described as in-phase sine-
waves. Several configurations were included as well as generalization for any symmetric lay-up. The effective
properties were calculated using both weighted average and springs in series approaches. A test program was
conducted to validate the model for quasi-isotropic lay-ups. Data from the literature was also compared to
model predictions for unidirectional and cross-ply laminates. These predictions correlated fairly well to test
data. Model can be used as part of a framework to quantitatively access the effects of regions containing ply
waviness on the global in-plane stiffness of structural composite parts. This information can be used to control
quality or to impose operational limitations on such parts.

ABSTRACT: Out-of-plane layer waviness, a manufacturing-induced imperfection in multidirectional composite laminates, can produce significant decreases in compression strength. To date, failure predictions based on initial “first-ply” failure analyses as well as compression strength reductions based on the ply fraction containing waviness have shown limited agreement for compression-loaded cross-ply laminates with idealized formations of layer waviness. The objective of this investigation was to extend previous research by employing progressive failure analysis to predict the ultimate compression strength of carbon/epoxy composite laminates with layer waviness. A finite element modeling methodology was developed using cohesive elements available in the commercial finite element code ANSYS to model the formation and growth of delaminations at layer interfaces. Progressive failure analysis within individual composite layers was performed using the Hashin failure criterion and subsequent reduction of appropriate stiffness properties of the failed elements. Strength predictions were compared to mechanical test results obtained for a variety of layer wave formations intentionally fabricated into otherwise wave-free cross-ply laminates. Results suggest that the computational approach used for progressive failure analysis is well suited for predicting strength reductions due to realistic formations of layer waviness in composite laminates.

ABSTRACT: This paper present the model analysis for the predicating the behaviour of inflatable membrane structure of general L-shape with a thickness in millimetre using the various smart material which optimally within structural member subjected to pre-stressed rather than bending or moments. A numerical solution for membranes may also be found using the finite element method. In this paper flat thin membrane choose to analysis the behavioural effect of the membranes using the properties of different smart material and compare their results in terms of frequency and generalized mass with mode shape. This analysis makes more effective to selects the smart material in the space technology. Geometrically non-linear vibration analysis of arbitrary L-shape membrane is also done using a finite element package, ABAQUS. The analysis shows good agreement between finite element and analytical solutions.

ABSTRACT: The effects of fiber waviness on the nonlinear behavior of unidirectional composites under tensile and compressive loadings have been investigated theoretically and experimentally. Unidirectional composites examined were composed of continuous fibers with sinusoidal waviness in a matrix. As a consequence of material and geometric factors, both the tensile and compressive behavior of these composites was generally nonlinear under finite deformation. Analytical models were proposed for predicting the nonlinear tensile and compressive behavior as a function of fiber waviness for three types of fiber waviness pattern: uniform, graded and localized fiber waviness. The material and geometric nonlinearities due to fiber waviness were incorporated into the models based on complementary energy density and an incremental method. Specimens with various degrees of fiber waviness were fabricated. Tensile and compressive tests were conducted on the specimens to obtain the elastic properties and behaviors of the composite materials with fiber waviness. The experimental results were in good agreement with the predictions.

ABSTRACT: A fiber microbuckling calculation is presented for the effects of fiber misalignment and material nonlinearity on the compressive strength of fiber composites. The role of fiber bending stiffness is included by using a particular form of couple stress theory. In order to examine the effect of a distribution of fiber waviness, the fiber misalignment angle is assumed to vary along the fiber length but is taken to be uniform in the transverse direction. Thus, the effects of wavelength as well as amplitude of fiber waviness are taken into account. A consideration of sinusoidal initial waviness reveals that short wavelength imperfections are much less deleterious than long wavelengths. A statistical analysis is presented for the effect of random fiber waviness on compressive strength, using a Monte Carlo simulation technique. Compressive strength is found to be particularly sensitive to the area under the spectral density curve and to the minimum fiber wavelength.
the form of a finite elliptical region of fibre waviness. The calculations show that the compressive strength decreases with increasing imperfection spatial size from the elastic bifurcation value of Rosen (1965, Fibre Composite Materials, pp. 37–75, American Society Metals Seminar) to the imperfection-sensitive infinite band strength given by Fleck et al. [1995, J. Appl. Mech. 62, 329–337].

ABSTRACT: A model is presented for the dynamic compressive response of polymer matrix fiber composites. The model includes the effects of fiber misalignment and material nonlinearity as well as material inertia. The role of fiber bending stiffness is included via a couple stress formulation. The response of fiber composites to suddenly applied, constant compressive axial load is examined. It is found that under constant load, inertial effects contribute to a reduction in the critical stress for composite failure. This reduction is greatest for composites with long initial fiber imperfection wavelengths. For a given load, there is a range of initial fiber imperfection wavelengths that will result in composite failure. Within this range, there is a preferred wavelength, which results in the shortest failure time.

ABSTRACT: Microbuckle initiation from an open hole, from a filled hole, and from the free surface of a unidirectional fibre composite is examined by a finite element method. The role of fibre bending resistance is included in the formulation so that a hole size effect is predicted. It is found that the open hole knocks-down the compressive strength to the order of 20tauY, while the filled hole reduces the strength to about 40tauY, where tauY is the in-plane shear modulus of the composite. Pre-existing fibre waviness adjacent to the hole gives a further reduction in the compressive strength. The role of in-plane shear stress and transverse stress in reducing the open hole compressive strength is examined: the compressive strength is reduced by the presence of shear and transverse tension, but the effect is less pronounced than that observed previously for the case of a circular patch of waviness. The study concludes with an investigation of the influence of the free surface on microbuckle initiation from a band of waviness and from a semi-circular patch of waviness: a negligible effect of the free surface on the compressive strength is predicted.

ABSTRACT: A finite element couple stress formulation is used to predict microbuckle initiation from a patch of fibre waviness in a unidirectional fibre composite under remote compression and bending. Attention is
focused on the knock-down in strength due to large amplitude waviness, with the effects of the physical size of the imperfection included by incorporating the fibre bending resistance within the formulation. The predicted strengths deviate significantly from the simpler kinking theory which neglects the role of fibre bending. Initial imperfections in the form of an infinite band and a circular wavy patch are considered: when these imperfections are of large spatial extent and possess a large misalignment angle, the compressive strength approximates the steady state band broadening stress for an infinite band. The effect of an imposed spatial gradient of stress within the composite is explored by determining the compressive strength of beams of finite height for the loading cases of pure bending and axial compression. It is found that the compressive strength is sensitive to the magnitude of the imposed stress gradient: the compressive strength of the outer fibres of the beam in bending increases with diminishing height of the beam. This size dependence is much reduced for the case of uniform compression.

ABSTRACT: The compressive strength of unidirectional long fibre composites is predicted for plastic microbuckling from a random two-dimensional distribution of fibre waviness. The effect of the physical size of waviness is addressed by using couple stress theory, with the fibre bending resistance scaling with the fibre diameter d. The predicted statistical distribution of compressive strength is found using a Monte Carlo method. An ensemble of fibre waviness profiles is generated from an assumed spectral density of waviness and the compressive strength for each such realisation is calculated directly by the finite element method. The average predicted strength agrees reasonably with practical values, confirming the hypothesis that microbuckles can be initiated by fibre misalignment. It is found that the probability distribution of strength is well matched by a Weibull fit, and the dependence of the Weibull parameters upon the spectral density of waviness is determined. For the practical range of fibre distributions considered, it is concluded that the strength depends mainly upon the root mean square amplitude of fibre misalignment, with the shape of the power spectral density function playing only a minor role. An engineering model for predicting the compressive strength is proposed, akin to weakest link theory for materials containing flaws. A specimen containing randomly distributed waviness is examined to locate regions of high-fibre misalignment. The strength of each of these weak regions is estimated from a look-up table derived from calculations with idealised circular or elliptical patches of waviness. The strength of the composite is given by the failure stress associated with the weakest such patch. For random distributions of waviness, the predictions using this engineering approach are in good agreement with the direct calculations of strength using the finite element method.

ABSTRACT: An investigation was performed to study the response of cylindrical composite shells subjected to out-of-plane loads. During the investigation, an analytical model was developed to predict the mechanical behavior of the structures from the initial failure, through post-failure, to the final collapse. The model is also capable of predicting the residual stiffness and strength of the structures after a preload. Basically, the model consists of a structural analysis for calculating the global response of the structures, and a failure analysis for
predicting local damage of the structures and their residual stiffnesses and strengths. A nonlinear finite element code based on the updated Lagrangian formulation was developed for the model. To verify the model, experiments were also conducted. An excellent agreement was found between the computer simulations and the test results. It is expected that the model can be extended to more complicated structures with various loading conditions.

ABSTRACT: The aim of the present investigation is to examine the stability characteristics of laminated plates subjected to various types of in-plane loadings. Towards this, a rectangular four node finite element, having fourteen degrees of freedom per node, based on a simple higher-order shear deformation theory is developed. The theory employed herein involves four dependent variables. The element is found to be free of shear lock problems. A series of numerical problems are solved to study the effect of various parameters such as lay-up, side to thickness ratio, aspect ratio, type of loadings (uniaxial/biaxial/positive and negative shear/tension—compression/compression—tension) and boundary conditions. Some interesting observations regarding the considerable difference in the buckling resistance of angle-ply plates when subjected to positive and negative shear loading are made.

ABSTRACT: The objective of this paper is to investigate the buckling behavior of moderately thick laminated plates subjected to various in-plane edge loads. For this purpose, an accurate four noded rectangular plate element based on coupled displacement field is developed. Moment-shear and in-plane equilibrium equations are employed to derive the polynomial displacement field of the element. The resulting element has six degrees of freedom per node namely three translations, two bending rotations and a twist and allows higher-order polynomial description for the field variables. The element is not only lock-free but also yields excellent convergence characteristics. A series of numerical examples are solved to demonstrate the efficacy of the proposed element. The influence of lay-up sequence, side-to-thickness ratios, boundary conditions on the prediction capability of the element is studied in detail.

ABSTRACT: Following Flügge's exact derivation for the buckling of cylindrical shells, the equations of motion for transient dynamic loading of orthotropic circular cylindrical shells under external hydrostatic pressure have been formulated. The normal mode theory is used to provide transient dynamic response for the equations of motion. The effect of shell's parameters, external hydrostatic pressure and material properties on the shell response has been studied in detail. A part of tables and figures are given in this paper.
ABSTRACT: A new method for calculating the free vibration frequencies of a thin circular cylindrical shell is presented, based on Flügge's shell theory equations for orthotropic materials. A general displacement representation is introduced, and a type of coupled polynomial eigenvalue problem is developed in present study. Numerical examples are given for isotropic and orthotropic shells. Comparison with that from classical dynamic approach is studied for frequency of an isotropic shell.

ABSTRACT: Following Flügge's exact derivation for the buckling of cylindrical shells, the equations of motion for dynamic loading of a circular cylindrical shell under external hydrostatic pressure have been formulated. The normal mode theory is used to provide transient dynamic response for the equations of motion. The responses of displacements, strain, and stress are obtained for the area of impact, while those outside the area of impact are also calculated. The accuracy of normal mode theory and Timoshenko shell theory are examined in this paper.

DOI: 10.1109/ICMA.2009.5246529
ABSTRACT: The theoretical analysis of finite element method for buckling phenomenon to finite-sized shell structure is first introduced. Then, a real application using a probe for detecting the pressure inside turboprops is analyzed thoroughly with ANSYS10.0, including section profile, dimensions, and local characteristics. Based on the solved results, several rules between critical load and influence factors are obtained, which would be helpful for similar structures design and application. Finally, several useful conclusions about the best profile and ratio between dimensions are obtained.

ABSTRACT: A theoretical analysis of the buckling problems of anisotropic laminated or sandwich, short or long, circular cylindrical shells under axial loads is presented. The theory is based on Flügge’s equations, improved by using first-order shear deformation theory. Nonlinear partial differential equations of equilibrium and boundary conditions are obtained by using a strain of finite-displacement theory and the principle of virtual work, and these nonlinear partial differential equations of equilibrium are linearized. Solutions that satisfy the partial differential equations of equilibrium and boundary condition are obtained, and the analytical model is verified by presenting some numerical results and comparing them with results from previous studies.
ABSTRACT: The effects of anisotropy, transverse shear stiffness, length, and their interactions on buckling under pure torsion and under combined axial compression and torsion were investigated using a previously derived analytical model based on deep shell theory including anisotropy and transverse shear stiffness. The model was verified only for buckling under pure axial compression, hence results for buckling under torsion have now been compared with the results of previous analyses, and the comparison showed that the model has good accuracy for buckling under torsion. Investigation showed that the buckling loads of a cylindrical shell are affected not only by anisotropy and transverse shear stiffness but also by shell length. This means that the shallow shell theory (Donnell-type theory) is not appropriate and deep shell theory including anisotropy and transverse shear stiffness must be used.

ABSTRACT: Statistical knockdown factors for the axial buckling of anisotropic cylinders were derived for practical design purposes. The solution with the least amount of simplification in the linear bifurcation theory was chosen from the previously published solutions, and it was compared with more than 100 experimental results from the open literature. A-basis values (99% probability with 95% confidence level) and B-basis values (90% probability with 95% confidence level) of knockdown factors were obtained by using inferential statistics, i.e., inference concerning unknown aspects of a population by using a small sample.

ABSTRACT: The results of external air pressure buckling tests of thin-walled, truncated conical steel shells are presented, along with a description of the equipment developed for the testing program. The testing was conducted in support of Sandia National Laboratories Z-Pinch Inertial Fusion Energy Proof-of-Principle power plant design. Optimized stiffening ring locations were determined by using the finite element method, and were then tested, indicating an experimental improvement in initial buckling pressure of more than 300% over the unstiffened cone. An analytical method of determining buckling pressures of stiffened conical shells is also presented, based on the method of the equivalent cylindrical shell. The results of the analytical method agreed very closely to the finite element method for the stiffened cones, but are 20–40% higher than the experimental results.

ABSTRACT: A theoretical investigation of the initial buckling response of laminated composite plates under uniform shear load is presented. The laminates under consideration are generally layered, thin, flat, rectangular and they are clamped along all four edges. Extensive numerical results highlighting the effect of fibre orientation, lay-up, aspect ratio, number of layers, different material properties and combinations of in-plane loading on the buckling response of laminated plates are presented.

ABSTRACT: Stiffened panels are structures that can be designed to efficiently support in-plane compression, bending, and shear loads. Although the stiffeners are usually discrete elements which are fastened or bonded to a flat or continuously curved plate, manufacturing methods such as thermoforming allow integral formation of the stiffeners in a panel. Such a configuration offers potential advantages in terms of a reduced number of parts and manufacturing operations. For thermoplastic composite panels stiffened by integrally formed open-section beads, the effects of bead spacing and bend cross-section geometry on the initiation of buckling under uniaxial compression and uniform shear loading were investigated. Finite elements results for a range of stiffened panel sizes and bead geometries are presented and compared with approximate closed-form solutions based on an effective flat plate size. Experimental verification of analytical predictions for one of the shear panels and one of the compression panels is described. Compensation of the forming tool to reduce the degree of initial curvature of the panels was found to be necessary.

ABSTRACT: The integral formation of stiffeners in a panel is economically attractive in terms of a reduced number of parts and manufacturing operations. For thermoplastic composite panels stiffened by integral formed open-section beads, the effects of bead spacing and bead cross-section geometry on the initiation of buckling under uniaxial compression and uniform shear loading have been investigated. Approximate analytical relationships for buckling of flat, orthotropic plates have been verified by the use of classical solution methods. Finite element results for a range of stiffened panel sizes and bead geometries are presented and compared with closed-form solutions based on an effective flat plate size. Experimental verification of analytical predictions for four of the panels is described.

ABSTRACT: The article presents the solution of symmetrical face sheet wrinkling problem for sandwich panel with composite facings and an orthotropic core. The new model is proposed for elastic core that takes into account compressive and shear stiffnesses as well as nonlinear change of transverse displacement over the core thickness at wrinkling. The governing buckling equation is derived using energy method. Analysis of cylindrical face wrinkling is performed for sandwich strips subjected to compressive loads applied to the two opposite simply supported edges. The effects of elastic and geometric parameters on the critical buckling stresses and wrinkling waves’ formation are examined.

ABSTRACT: The paper deals with the solution of the buckling problem for a rectangular orthotropic plate with two parallel free edges. The other two parallel simply supported opposite edges of the plate are loaded by a linearly distributed in-plane load which is equivalent to the pure in-plane bending. Buckling analysis is performed using the Levy-type solution and subsequent finite-difference approximation of the boundary-value problem. Solution of the corresponding eigenvalue problem yields the critical buckling coefficient and critical load. The problem is solved for isotropic and orthotropic composite plates. The design chart has been obtained for the isotropic plates with various aspect ratios from which the corresponding critical loads can be found. Critical buckling coefficients are determined for composite plates with various aspect ratios and angles of the reinforcement orientation. The optimum material reinforcement structure providing the maximum value of critical load is determined.

ABSTRACT: Solution of the buckling problem for the CCFF orthotropic plate subjected to in-plane pure bending is presented. The two parallel clamped edges of the plate are loaded by linearly distributed in-plane loads statically equivalent to the in-plane bending moments. The problem is solved using method of lines for partial differential equations and Galerkin’s method. The buckling problems are solved for isotropic, orthotropic and multilayered CFRP composite plates with various aspect ratios. Results of calculations of critical loads are compared with those based on finite-element modelling and analyses. The comparisons demonstrate efficiency of the proposed approach to the buckling analysis of composite CCFF plates with various dimensional and stiffness parameters.

ABSTRACT: The paper presents the solution of the buckling problem for an orthotropic rectangular plate having two parallel edges simply supported, one edge clamped and the remaining edge free (the SSCF plate). The plate considered is subjected to a linearly varying in-plane load that can take the form of uniform compression, combination of in-plane bending and uniform compression, or pure in-plane bending. The solution technique involves reduction of the relevant variational buckling equation to a one-dimensional form using the Kantorovich procedure and subsequent application of the generalised Galerkin method. The buckling problems are solved for isotropic and orthotropic plates with various aspect ratios. The analytical solution is verified using the finite-element analysis. The comparisons of computational results demonstrate the appropriateness and efficiency of the approach developed in this work for the calculation of critical loads of composite SSCF plates with various dimensional and stiffness parameters.

“Buckling analysis and design of anisogrid composite lattice conical shells”, Composite Structures, Vol. 93, No. 12, pp. 3150-3162, November 2011, DOI: 10.1016/j.compstruct.2011.06.015

ABSTRACT: Composite lattice anisogrid shells have now become a popular choice in many aerospace applications. Their use in various structural components, such as rocket interstages, payload adapters for spacecraft launchers, fuselage components for aerial vehicles, and parts of the deployable space antennas requires the development of more advanced finite-element models and analysis techniques capable of predicting buckling behaviour of these structures under variety of loadings. A specialised finite-element model generation procedure (design modeller) is developed and applied to the buckling analysis of the composite anisogrid conical shells treated as three-dimensional frames composed of the curvilinear ribs made of unidirectional composite material. Featuring a dedicated control procedure for positioning the beam elements, the design modeller enables a close approximation of the original twisted geometry of the curvilinear ribs. The parametric finite-element buckling analyses of the anisogrid conical shells subjected to axial compression, transverse
bending, pure bending, and torsion showed the robustness and potential of the modelling approach. It was demonstrated that the buckling resistance can be significantly enhanced by either increasing the stiffness of a few hoop ribs located in the close proximity to the section with the larger diameter, or by introducing the additional hoop ribs in the same part of the conical shell. The effectiveness of the design analyses is demonstrated using particular examples. It has been shown that the resultant optimised designs can produce up to 22% mass savings in comparison with the non-optimised lattice shells.

ABSTRACT: An exact solution for buckling of simply supported symmetrical cross-ply composite rectangular plates under a linearly varying edge load is presented. It is developed based on the first-order shear deformation theory for moderately thick laminated plates. Buckling loads of cross-ply rectangular plates with various aspect ratios are obtained and the effects of load intensity variation and layup configuration on the buckling load are investigated. The results are verified using the computer code ABAQUS.

ABSTRACT: The elastic buckling behavior of rectangular perforated plates was studied by using the finite element method in this study. Circular cutout was chosen at different locations along the principal x-axis of plates subjected to linearly varying loading in order to evaluate the effect of cutout location on the buckling behavior of plates. The results show that the center of a circular hole should not be placed at the end half of the outer panel for all loading patterns. Furthermore, the presence of a circular hole always causes a decrease in the elastic buckling load of plates subjected to bending, even if the circular hole is not in the outer panel.

ABSTRACT: A modified Hellinger-Reissner functional for thin shells of revolution is presented. A mixed finite element formulation is developed from this functional which is free from line integrals and relaxed continuity terms. This formulation is applied to the problem of free vibration of spherical and conical shells. Bilinear trial functions are used for all field variables. The quadrilateral curved elements here presented satisfy the C0 continuity requirement of the functional. In all the results obtained the accuracy is quite good even for a reasonable…

ABSTRACT: A mixed finite element formulation is developed from a weak variational principle. This formulation is applied to stability analysis of cylindrical shell structures subjected to follower loading. Bilinear trial functions are used for all field variables. The rectangular curved elements presented here satisfy the continuity requirements for the field variables at the element interface. Two examples of a cantilevered cylindrical shell panel under different kinds of loading are solved.

ABSTRACT: An analysis of vibration and stability of conical and cylindrical shell panels with slight internal damping under follower forces is presented. An extended form of the principle of virtual work is utilized. Examples of cantilevered conical and cylindrical shell panels with and without small internal damping are solved. Plots of these solutions illustrate graphically the influence of internal damping.

ABSTRACT: A study is described which was carried out to investigate the dynamic response of an aircraft-type aluminium alloy plate, with fully clamped boundaries, subjected to combined acoustic excitation and uniaxial in-plane compression. Experiments were conducted in an acoustic tunnel with sound pressure levels up to 150 dB. The non-linear characteristics of the plate have been examined under sinusoidal and broad band random excitation and a study made of the statistical and spectral properties of the response. Theoretical and experimental estimates of the plate natural frequencies and mode shapes are described.

ABSTRACT: Free-vibration characteristics of cantilever non-circular curved panels are analyzed by using the differential quadrature method (DQM) in this paper. The equations of motion of a curved panel are based on the Love's hypothesis and are expressed in an orthogonal curvilinear co-ordinate system. By applying the differential quadrature formulation and the proposed modified relationships for specified boundary conditions, the free-vibration equations of motion of the curved panel are transformed to a set of algebraic equations. Natural frequencies of a cantilever flat plate and a circular curved panel are obtained for verifying the
applicability of the present approach. Good convergent trend and accuracy are observed. Effects of shallowness, thickness and aspect ratios on the natural frequencies of a cantilever curved panel are also investigated. Furthermore, natural frequencies of parabolic curved panels are obtained. In all cases studied, the efficiency and convenience of the DQM are illustrated.

ABSTRACT: The problem described is solved by approximating the displacement function using simple polynomial coordinate functions which identically satisfy the boundary conditions. The numerical determinations of the eigenvalues under investigation are determined using the Rayleigh-Ritz method assuming that the plate thickness varies according to the functional relation h(r) = ho[1 + 2(r/a)n], where n is an integer. It is shown that the frequency coefficients and critical buckling load parameters obtained by means of the analytical procedure are in excellent agreement with the results obtained employing a finite element algorithmic procedure. It is concluded that the value of Poisson's ratio has a significant effect upon the frequency and buckling parameters, especially in the case of plates of nonuniform thickness and with simply supported edges.

ABSTRACT: The lateral buckling of a laminated composite beam with channel section is studied. A general analytical model applicable to the lateral buckling of a channel-section composite beam subjected to various types of loadings is derived. This model is based on the classical lamination theory, and accounts for the material coupling for arbitrary laminate stacking sequence configuration and various boundary conditions. The
effects of the location of applied loading on the buckling capacity are also included in the analysis. A
displacement-based one-dimensional finite element model is developed to predict critical loads and
corresponding buckling modes for a thin-walled composite beam with arbitrary boundary conditions. Numerical
results are obtained for thin-walled composites under central point load, uniformly distributed load, and pure
bending with angle-ply and laminates. The effects of fiber orientation, location of applied load, and types of
loads on the critical buckling loads are parametrically studied.

Davalos JF, Qiao PX. Analytical and experimental study of lateral and distortional buckling of FRP wide-
ABSTRACT: A combined analytical and experimental evaluation of flexural-torsional and lateral-distortional
buckling of fiber-reinforced plastic (FRP) composite wide-flange (WF) beams is presented. Based on energy
principles, the total potential energy equations for instability of FRP WF sections are derived using the
nonlinear elastic theory. For the analysis of lateral-distortional buckling, a fifth-order polynomial shape function
is adopted to model the deformed shape of web panels. The models are validated by testing two geometrically
identical FRP WF beams but with distinct material architectures produced by the pultrusion process. The beams
are tested under midspan concentrated loads to evaluate their flexural-torsional and lateral-distortional buckling
responses. To detect rotations of the midspan cross sections and onset of critical buckling loads, horizontal
transverse bars are attached to the beam's flanges, and the bar ends are connected to linear variable differential
transducers (LVDTs). For the same purpose, we use strain gauges bonded to the upper and lower surfaces near
to the free edges of the top flange. A good agreement between the proposed analytical approach and
experimental and finite-element analyses results is obtained, and simplified engineering equations for flexural-
torsional buckling are formulated. The proposed analytical solutions can be used to predict flexural-torsional
and lateral-distortional buckling loads for other FRP shapes and to formulate simplified design equations.
ABSTRACT: In this paper, a theoretical model is developed for the dynamic analysis of composite thin-walled beams with open or closed cross-sections. The present model incorporates, in a full form, the shear flexibility (bending and warping shear) as well as a state of initial stresses. This allows to study the free vibration and buckling problems in a unified fashion. An analytical solution of the developed equations is obtained for the case of simply supported thin-walled beams. Numerical examples are given to demonstrate the importance of the shear flexibility on the vibration and buckling behavior of the considered structures.

ABSTRACT: In this paper, a theoretical model is developed for the stability analysis of composite thin-walled beams with open or closed cross-sections. The present model incorporates, in a full form, the shear flexibility (bending and non-uniform warping), featured in a consistent way by means of a linearized formulation based on the Reissner’s Variational Principle. The model is developed using a non-linear displacement field, whose rotations are based on the rule of semi-tangential transformation. This model allows to study the buckling and lateral stability of composite thin-walled beam with general cross-section. A finite element with two-nodes and fourteen-degrees-of-freedom is developed to solve the governing equations. Numerical examples are given to show the importance of the shear flexibility on the stability behavior of this type of structures.

ABSTRACT: In this paper, a new theoretical model is developed for the generalized linear analysis of composite thin-walled beams with open or closed cross-sections. The present model incorporates, in a full form, the shear deformability by means of two features. The first one may be addressed as a mechanical aspect where the effect of shear deformability due to both bending and non-uniform warping is considered. The second feature is connected with the constitutive aspects, and it contemplates the use of different hypotheses adopted in the formulation. These topics are treated in a straightforward way by means of the Linearized Principle of Virtual Works. The model is developed by employing a non-linear displacement field, whose rotations are formulated by means of the rule of semitangential transformation. This model allows studying many problems of static's, free vibrations with or without arbitrary initial stresses and linear stability of composite thin-walled beams with general cross-sections. A discussion about the constitutive equations is performed, in order to explain distinctive aspects of the effects included in the theory. This paper presents the theoretical formulation together with finite element procedures that are developed with the aim to obtain solutions to the general equations of thin-walled shear deformable composite beams. A non-locking fourteen-degree-of-freedom finite element is introduced. Numerical examples are carried out in several topics of static's, dynamics and buckling problems, focusing attention in the validation of the theory with respect to experimental data and with 2D and 3D computational approaches. Also, new parametrical studies are performed in order to show the influence of
shear flexibility in the mechanics of the thin-walled composite beams as well as to illustrate the usefulness of the model.

Carlos P. Filipich and Marcelo Tulio Piovan, “The dynamics of thick curved beams constructed with functionally graded materials”, Mechanics Research Communications, Vol. 37, No. 6, pp 565-570, September 2010, DOI: 10.1016/j.mechrescom.2010.07.007
ABSTRACT: During the last two decades materials, that exhibit graded properties, left their spirit of conceptual laboratory specimens to become a technological reality with a well established background. However structural applications of these materials are not a fulfilled research. Models of straight and curved beams are normally reported in the scientific literature as the easiest way to understand some existing aspects in mechanics of structures. Most of these models are formulated appealing to numerical approaches such as the finite element method among others, without taking into account theoretical aspects that can be quite useful to reduce algebraic complexity. In the present work a technical theory for dynamic analysis of thick curved beams is deduced within the context of functionally graded materials. The concept of material neutral-axis shifting is employed in the deduction procedure in order to reduce the algebraic handling and complexity of the motion equations. This leads to find analytical solutions of the governing differential system, even if it has variable coefficients. Parametric studies on the dynamics of curved beams are offered to show the versatility of the adopted formulation by means of solutions handled with the power series method.

ABSTRACT: The dynamic stability of functionally graded thin-walled beams allowing for shear deformability is investigated in this article. The analysis is based on a model that has small strains and moderate rotations which are formulated through the adoption of a second-order non-linear displacement field. The beam is subjected to axial external dynamic loading. The model takes into account thermoelastic effects. The heat conduction equation is solved in order to characterize the temperature in the cross-sectional domain. Galerkin’s and Bolotin’s methods are employed with the scope to discretize the governing equations and to determine the regions of dynamic stability, respectively. Regions of stability are evaluated and expressed in non-dimensional form. The influence of the longitudinal vibration on the unstable regions is investigated. The numerical results show the importance of this effect when the forcing frequency approaches to the natural longitudinal frequency, obtaining substantially wider parametric stability regions. The effects of temperature gradients, shear flexibility and axial inertia, in beams with different cross-sections and different types of graded material are analyzed as well.

ABSTRACT: In this article a non-linear model for dynamic analysis of rotating thin-walled composite beams is introduced. The theory is deduced in the context of classic variational principles and the finite element method is employed to discretize and furnish a numerical approximation to the motion equations. The model considers shear flexibility as well as non-linear inertial terms, Coriolis effects, among others. The clamping stiffness of the beam to the rotating hub is modeled through a set of spring factors. The model serves as a mean
deterministic basis to the studies of stochastic dynamics, which are the objective of the present article. Uncertainties should be considered in order to improve the predictability of a given modeling scheme. In a rotating structural system, uncertainties are present due to a number of facts, namely, loads, material properties, etc. In this study the uncertainties are incorporated in the beam-to-hub connection (i.e. the connection angle and the springs) and the rotating velocity. The probability density functions of the uncertain parameters are derived employing the Maximum Entropy Principle. Different numerical studies are conducted to show the main characteristics of the uncertainty propagation in the dynamics of rotating composite beams.

ABSTRACT: In this paper the dynamic and buckling features of slender structures with curved axis are addressed. A survey on the literature concerning mechanics of beams constructed with non-homogeneous materials or with functionally graded materials reveals only a few papers devoted to the dynamics and buckling of curved beams constructed with such materials. This problem was tackled mainly through 2D or 3D numerical formulations, but comprehensive beam theories on the matter are scarce. In the present paper a model of non-homogeneous and/or FGM curved beams is developed. The model is deduced by adopting a consistent displacement field which incorporates second order rotational terms based on the semi-tangential rule. The model also incorporates the shear flexibility due to bending and warping due to twisting effects. Arbitrary initial stresses and initial off-axis loads are taken into account in the linearized principle of virtual works. The finite element method is employed to discretize the motion equations with the objective to solve problems of dynamics, statics and buckling. The model contains, as particular cases, several straight beam theories as well as curved beam theories. Some comparisons with the available experimental data of the open literature are performed in order to illustrate the predictive features of the model, and comparisons with 2D and 3D finite element approaches are also performed.

ABSTRACT: In this work an analysis is performed on the nonlinear planar vibrations of a functionally graded beam subjected to a combined thermal and harmonic transverse load in the presence of internal resonance. Adopting the direct perturbation MMS technique, the partial differential equations of motion of the beam are reduced to sets of first-order nonlinear modulation equations in terms of the complex modes of the beam. The assumption of steady-state values of centrifugal loads is evaluated. It has to be said that there is a lack of information about modeling of rotating box beams made of functionally graded materials (FGMs) under thermo-mechanical loads. The influence of the transverse load amplitude and the internal detuning parameter on the strength of nonlinear modal interaction is illustrated. It is also shown that the system exhibits periodic and quasiperiodic responses for a typical range of parameter values.

ABSTRACT: This article is concerned with the stochastic dynamic analysis of structures constructed with composite materials. Depending on many aspects (manufacturing process, material uncertainty, boundary conditions, etc.) real composite structures may have deviations with respect to the calculated response (or deterministic response). These aspects lead to a source of uncertainty in the structural response associated with constituent proportions, geometric parameters or other unexpected agents. Uncertainties should be considered in a structural system in order to improve the predictability of a given modeling scheme. In this study a model of shear deformable composite beams is employed as the mean model. The probabilistic model is constructed by adopting random variables for the uncertain parameters of the model. This strategy is called parametric probabilistic approach. The probability density functions of the random variables are constructed appealing to the Maximum Entropy Principle. The continuous model is discretised by finite elements and the Monte Carlo method is employed to perform the simulations, thereafter a statistical analysis is performed. Numerical studies are carried out to show the main advantages of the modeling strategies employed, as well as to quantify the propagation of the uncertainty in the dynamics of slender composite structures.

“Dynamics of magneto electro elastic curved beams: Quantification of parametric uncertainties”, Composite Structures, Col. 133, July 2015

ABSTRACT: The objective of this paper is the evaluation of uncertainty propagation associated to several parameters in the dynamics of magneto-electro-elastic (MEE) curved beams. These MEE structures can be employed as imbedded parts in high performance technological systems to control motions and/or attenuate vibrations, for energy harvesting, etc. Although a lot of research connected with these structures was done for dynamics and statics, it is remarkable the scarcity of articles analyzing random dynamics of MEE structure, provided that many models have uncertainties associated to their parameters: loads and/or material properties, among others. A theory for MEE curved beams is derived and assumed as the deterministic model. The response is calculated by means of a finite element formulation. The probabilistic model is constructed appealing to the finite element formulation of the deterministic approach, by adopting random variables for the uncertain parameters selected. The probability density functions of the random variables are derived with the Maximum Entropy Principle. The Monte Carlo method is used to perform simulations with independent realizations. Studies are carried out in order to evaluate the influence of Magneto-elastic and/or piezoelectric coupling in the dynamics of MEE curved beams in both contexts: the deterministic and the stochastic.

ABSTRACT: In this article we perform a quantification of the uncertainty propagation of the dynamics of slender initially curved structures constructed with fiber reinforced composite materials. Depending on the manufacturing process, composite materials may have deviations with respect to the expected response, often called nominal response in a deterministic sense. The manufacturing aspects lead to uncertainty in the structural response associated with constituent proportions, material and/or geometric parameters among others. Another aspect of uncertainty that can be sensitive in composite structures is the mathematical model that represents the mechanics of the structural member, that is: the assumptions and type of hypotheses invoked reflect the most relevant aspects of the physics of a structure, however in some circumstances these hypotheses are not enough,
and cannot represent properly the mechanics of the structure. Uncertainties should be considered in a structural system in order to improve the predictability of a given modeling scheme. There are two approaches to evaluate the propagation of uncertainties in structural models: The parametric probabilistic approach and the nonparametric probabilistic approach. In the first approach, one quantifies the uncertainty of given parameters (such as variation of the angles of fiber reinforcement, material constituents, etc.) by associating random variables to them. In the second approach, the propagation of uncertainty is quantified by considering uncertain the matrices of the whole system. In this study a shear deformable model of composite curved thin walled beams is employed as the mean or expected model. The probabilistic model is constructed by adopting random variables for the uncertain entities (parameters or matrices) of the model. The probability density functions of the random entities are derived appealing to the Maximum Entropy Principle under given constraints. Once the probabilistic model is discretized in the context of the finite element method, the Monte Carlo method is employed to perform the simulations. Then the statistics of the simulations is evaluated and the parametric and nonparametric approaches are compared.

ABSTRACT: Plane plates subjected to tensile loads are usually not considered to fail due to buckling. However if a plate contains a cut-out, regions of compressive stresses arise under a uniaxial tensile load. In thin-walled orthotropic composite plates these compressive stresses may cause local buckling. In general the stress concentration factors of cut-outs are very high, thus the buckling limits will not be exceeded before fracture. However cut-outs, optimised by a shape optimisation method, run risk to initiate buckling before exceeding the fracture load because the stress concentration factors for these cut-outs are very low. In this paper the influence of the shape of optimised cut-outs on the buckling behaviour is investigated. Besides the critical load the undercritical and post-critical behaviour of geometrical imperfect orthotropic composite plates is analysed. Methods that prevent local buckling under tensile stresses are discussed in order to provide the full advantage of optimised cut-outs.

ABSTRACT: A numerical and experimental study was carried out to determine the effects of antisymmetric laminate configuration, cutout and length/thickness ratio on the buckling behavior of E/glass-epoxy composite plates. The buckling loads were presented for symmetrically and anti-symmetrically laminated plates subjected to axial compression load. The study included two different laminate configurations ([90/45/-45/0]as and [90/45/-45/0]s), two different cutout shapes (circular and semi-circular), two different length/thickness ratios (L/t = 75 and 37.5) and three boundary conditions (clamped-clamped [CC], clamped-pinned [CP] and pinned-pinned [PP]). Firstly, the buckling loads of eight-ply E/glass-epoxy rectangular plates were determined experimentally. Then, the buckling loads of the laminated composites were calculated by ANSYS finite-element computer code. The changing in buckling load of the composites due to the presence of cutout and changing of length/thickness ratio was calculated. Finally, the experimental test results were compared to the buckling loads of plates obtained from the finite element analysis.

References listed at the end of the paper:

ABSTRACT: In this study, the influence of boundary conditions on the buckling load for rectangular plates of various cutout shape, length/thickness ratio, and ply orientation is examined. Boundary conditions consisting of clamped, pinned, and their combinations are considered. Numerical and experimental studies are conducted to investigate the effect of boundary conditions, cutout shape, length/thickness ratio, and ply orientation on the buckling behavior of E-glass/epoxy composite plates under in-plane compression load. Buckling analysis of the laminated composites is performed by using finite element analysis software ANSYS. Tests have been carried out on laminated composites with circular and semicircular cutouts under various boundary conditions. Comparisons are made between the test results and predictions based on finite element analysis. The results show a complex interaction between plate orthotropy and boundary conditions.

ABSTRACT: This paper presents a new curved shell finite element formulation for linear static analysis of laminated composite plates and shells, where the displacement approximation in the direction of the shell thickness can be of an arbitrary polynomial order p, thereby permitting strains of at least (p - 1) order. This is accomplished by introducing additional nodal variables in the element displacement approximation corresponding to the Lagrange interpolating polynomials in the element thickness direction. The resulting element displacement approximation has an important hierarchical property i.e. the approximation functions and the generalized nodal variables corresponding to an approximation order p are a subset of those corresponding to an approximation order (p + 1). The element formulation ensures C0 continuity or smoothness of displacements across the interelement boundaries. The element properties (stiffness matrix and equivalent load vectors) are derived using the principle of virtual work and the hierarchical element approximation. The formulation is extended for generally orthotropic material behaviour where the material directions are not necessarily parallel to the global axes. Further extension of this formulation for laminated composites is accomplished by incorporating the material properties of each lamina by numerically integrating the element stiffness matrix for each lamina. The formulation has no restriction on either the number of laminas or the layup pattern of the laminas. Each lamina can be generally orthotropic, and the material directions and the lamina thicknesses may vary from point to point within each lamina. The geometry of the laminated shell element is described by the co-ordinates of the nodes lying on the middle surface of the element and the lamina thicknesses at each node. The formulation permits any desired order displacement or strain approximation in the shell thickness direction without remodelling. Numerical examples are presented to demonstrate the accuracy,
efficiency, and overall superiority of the present formulation. The results obtained from the present formulation are compared with those available in the literature as well as the analytical solutions.

ABSTRACT: This paper presents a new completely hierarchical three dimensional curved shell finite element formulation for linear static analysis of laminated composite plates and shells. The element displacement approximation can be of arbitrary polynomial orders p xi, p eta and p zeta in the xi, eta, and zeta directions thereby permitting strains of at least (p xi – 1), (p eta – 1) and (p zeta – 1) order. The element approximation functions as well as the nodal variables are hierarchical. The element formulation ensures C0 continuity. The lamina properties are incorporated by numerically integrating the element stiffness matrix for each lamina. The formulation has no restriction on either the number of laminas or the layup pattern of the laminas. The geometry of the laminated shell element is described by the coordinates of the nodes lying on the middle surface of the element and the lamina thicknesses at each node. The element formulation is equally effective for very thin as well as very thick laminated plates and curved shells. The results obtained from the present formulation are compared with those available in the literature as well as available analytical solutions.

ABSTRACT: This paper presents a nine-node three-dimensional laminated composite curved shell finite element formulation for geometrically nonlinear (GNL) analysis of laminated plates and shells where the displacement approximation for the laminate is piecewise hierarchical and is derived based on p-version. The displacement approximation for the element is developed first by establishing a hierarchical displacement approximation for each lamina of the laminate and then by imposing interlamina continuity conditions of displacements at the interfaces between the laminas. The nodal variables for the entire laminate are derived from the nodal variables of the laminas and the interlamina continuity conditions of displacements. The element formulation ensures C0 continuity of displacements across the interelement as well as interlamina boundaries. The lamina stiffness matrices and the equivalent nodal force vectors are derived using the principle of virtual work and the hierarchical displacement approximation for the laminas. Interlamina continuity conditions are used to construct the transformation matrices for the individual laminas which permit transformation of the lamina degrees of freedom to the laminate degrees of freedom. The interlamina behavior incorporated in this formulation is in total agreement with the physics of laminate behavior for composite plates and shells. In formulating the properties of the element, complete three-dimensional stresses and strains are considered, hence the element is equally effective for very thin as well as extremely thick laminated shells and plates. Incremental equations of equilibrium are derived and solved using standard Newton's method. The total load is divided in increments and for each increment of load equilibrium iterations are performed until each component of the residuals and the generalized nodal displacement vector are within preset tolerances. Numerical examples are presented to show the accuracy, p-convergence characteristics and overall advantages of the present formulation.

ABSTRACT: A method is introduced to determine the limit load of thin shells using the finite element method. The method is based on an upper bound limit and shakedown analysis with the elastic-perfectly plastic material model. A nonlinear constrained optimization problem is solved by using Newton’s method in conjunction with a penalty method and the Lagrange dual method. The numerical investigation of a pipe bend subjected to bending moments proves the effectiveness of the algorithm.

ABSTRACT: This paper presents a numerical procedure for reliability analysis of thin plates and shells with respect to plastic collapse or to inadaptation. The procedure involves a deterministic shakedown analysis for each probabilistic iteration, which is based on the upper bound approach and the use of the exact Ilyushin yield surface. Probabilistic shakedown analysis deals with uncertainties originated from the loads, material strength and thickness of the shell. Based on a direct definition of the limit state function, the calculation of the failure probability may be efficiently solved by using the First and Second Order Reliability Methods (FORM and SORM). The problem of reliability of structural systems (series systems) is handled by the application of a special technique which permits to find all the design points corresponding to all the failure modes. Studies show, in this case, that it improves considerably the FORM and SORM results.

ABSTRACT: A spline based method for approximating thin shell dynamics is presented here. While the method is developed in the context of the Donnell-Mushtari thin shell equations, it can be easily extended to the Byrne-Flugge-Lur’ye equations or other models for shells of revolution as warranted by applications. The primary requirements for the method include accuracy, flexibility and efficiency in smart material applications. To accomplish this, the method was designed to be flexible with regard to boundary conditions, material nonhomogeneities due to sensors and actuators, and inputs from smart material actuators such as piezoceramic patches. The accuracy of the method was also of primary concern, both to guarantee full resolution of structural dynamics and to facilitate the development of PDE-based controllers which ultimately require real-time implementation. Several numerical examples provide initial evidence demonstrating the efficacy of the method.

ABSTRACT: In this study, finite element buckling analyses of transversely stiffened isotropic and orthotropic rectangular thin plates under shear loads are presented. Eigenvalue buckling analysis is used to predict critical buckling loads of mild steel and Boron—Aluminium MMC composite stiffened plates with different fiber orientations by using ANSYS. A simply supported boundary condition is applied through the edges of the plates and uniformly distributed shear loads are given to edge nodes. It is demonstrated that by adding more transverse rectangular stiffeners which are made of the same material with the plate, critical buckling stress of the plates increases linearly. The failure tests of unstiffened Boron—Aluminium plates were performed according to Tsai-Hill failure criteria.

ABSTRACT: Local buckling in FRP profiles is analyzed. Some experimental results in compression and bending, where local buckling of the flanges in compression occurred, are described and the critical stresses are summarized. A numerical model by the finite element method (FEM) is introduced and validated by comparison of the numerical results with the experimental ones. This finite element model is applied for a wide parametric analysis in order to individuate a buckling curve for the local buckling of the flange. An analytical expression of the buckling curve is developed, taking into consideration the orthotropy of the material, in which the restraint action of the web on the flange is explicitly introduced as a function of the geometrical and mechanical data of the section sub-components. The reliability of the proposed curve as a design tool is confirmed by comparison with the experimental results.
ABSTRACT: The large-amplitude vibrational behavior of a shallow spherical-cap shell is investigated theoretically using simple arguments. The results of this approximate analysis are expressed in the form of appealingly simple nondimensional quantities. It is shown that the frequency of the fundamental mode of such a shell falls by as much as 50 per cent as the vibration amplitude is increased to approximately the shell depth. For even larger amplitudes the frequency rises, and it exceeds the small-amplitude frequency when the amplitude is more than about twice the shell depth. The influence of shell thickness is considered and increasing thickness is shown to decrease the frequency shift. This analysis is shown to account for the pitch glide behavior of certain Chinese opera gongs.

ABSTRACT: The effect of random initial geometric imperfections on the vibration behavior of rectangular plates is investigated in this paper using a statistical method. The random initial geometric imperfections of plates are described by Gaussian random fields and simulated numerically using Elishakoff's method. Lindstedt-Poincaré's perturbation technique is employed to solve Duffing's Equation with an additional quadratic spring term derived in the vibration analysis of imperfect rectangular plates. A Monte Carlo analysis for simply supported plates is carried out in detail to illustrate the proposed approach. It is shown that the effect of random geometric imperfections on the vibration behavior of the plates can be described quantitatively in terms of the frequency reliability function and the hardening type probability.

China), “Influence of compression-bending coupling on the stability behavior of anisotropic laminated panels”, Applied Mathematics and Mechanics, Vol. 20, No. 1, 1999, pp. 18-26, doi 10.1007/BF02459269
ABSTRACT: Dynamic-Relaxation Method (DRM) is applied to studying the influence of compression-bending coupling on nonlinear behavior of cylindrically slightly curved panels of unsymmetric laminated composite materials subjected to uniform uniaxial compression during loading and unloading. Numerical results are given for cross-ply plates and panels under S4 S4 and S4 S2 boundary conditions. The results show that the effects of absolute value and the sign of the coupling coefficient on the stability behavior of the panels are significant.

ABSTRACT: A method of estimating the manufacturing cost for composite stiffened panels was proposed on the basis of co-curing process. Considering cost as a major design parameter, an approach to optimize the configuration that minimizes the cost and weight of composite stiffened panels under compression and shear was presented, under structural requirements and manufacturing constraints. Based on the case of panel with T
stiffener, the objective function of cost and weight was minimized respectively to verify the cost estimation model. The results estimated are in good agreement with practical process time of lay up. In addition, the stiffened panel cost and weight were discussed for seven stiffener cross-sectional shapes. It is found that T stiffener gives the lowest time configuration while its weight is only 0.5% more than that of the J stiffener, while J is of the lowest weight among seven stiffeners. The optimization conclusion can be applied to guide design of composite stiffened panel.

ABSTRACT: The axial compressive mechanical response of substrate-supported carbon nanotube (CNT) arrays with heights from 35 to 1200 micrometers is evaluated using flat punch nanoindentation with indentation depths to 200 micrometers. The compressive behavior is consistent with that of an open-cell foam material with array height playing a role similar to that of occupation density for traditional foam. Mechanical yielding of all arrays is initiated between 0.03 and 0.12 strain and arises from localized coordinated plastic buckling. For intermediate CNT array heights between 190 and 650 lm, buckle formation is highly periodic, with characteristic wavelengths between 3 and 6 micrometers. Buckle formation produced substantial force oscillations in both the compressive and lateral directions. The compressive elastic modulus of the arrays is obtained as a continuous function of penetration depth and attains a value between 10 and 20 MPa for all arrays during mechanical yield.

A qualitative model based upon concepts of cellular foam geometry is advanced to explain the observed CNT buckling behavior.

ABSTRACT: A continuum mechanics theory is established for the in-surface buckling of one-dimensional nanomaterials on compliant substrates, such as silicon nanowires on elastomeric substrates observed in experiments. Simple analytical expressions are obtained for the buckling wavelength, amplitude and critical buckling strain in terms of the bending and tension stiffness of the nanomaterial and the substrate elastic properties. The analysis is applied to silicon nanowires, single-walled carbon nanotubes, multi-walled carbon nanotubes, and carbon nanotube bundles. For silicon nanowires, the measured buckling wavelength gives Young's modulus to be 140 GPa, which agrees well with the prior experimental studies. It is shown that the energy for in-surface buckling is lower than that for normal (out-of-surface) buckling, and is therefore energetically favorable.

DOI: 10.1016/j.jmps.2011.05.002

ABSTRACT: We carry out axisymmetric, finite deformation finite element analyses of the uniaxial compression of cylindrical bundles of vertically aligned carbon nanotubes (VACNTs) firmly attached to a Si substrate. A compressible elastic–viscoplastic constitutive relation with a piecewise, linear hardening–softening–hardening flow strength is used to model the material. Calculations are performed for VACNTs both with uniform properties and with axially graded properties. We show that, with uniform properties, sequential buckling initiates at the substrate and propagates away from it, in agreement with previous experimental findings. We investigate the dependence of the magnitude and wavelength of the buckles on characteristics of the function defining the flow strength. When a property gradient giving a more compliant response at the end opposite to the substrate is specified, we find that sequential buckling initiates at that end and propagates toward the substrate. Results of the analyses are compared with the experimental observations and capture many of the experimentally obtained stress–strain and morphological features. The proposed model serves as a promising foundation for capturing the underlying energy absorption mechanisms in these systems. Comparison of the model predictions with the experimental results also suggests directions for model improvement.

ABSTRACT: For the first time, carbon nanotube (CNT) forests are fully characterized as transversely isotropic continuum material. Each of the five independent elastic constants is experimentally obtained using a combination of nanoindenter-based uniaxial compression and shear testing, in situ SEM compression, and digital image correlation (DIC) of vertically and laterally oriented CNT microstructure columns. Material properties are highly anisotropic, with an axial modulus (165–275 MPa) that is nearly two orders of magnitude greater than the transverse modulus (2.5–2.7 MPa) and the out of plane shear modulus (0.8–1.6 MPa). The Poisson’s ratios along three mutually orthogonal axes, measured directly by simultaneous in situ DIC evaluation of axial and transverse strain, are found to be similarly anisotropic ($\nu_{12} = 0.35$, $\nu_{23} = 0.1$, $\nu_{21} = 0.005$). A Timoshenko beam model is then developed to accurately predict the critical buckling stress of the vertically oriented columns using a subset of these anisotropic properties and considering inelastic column buckling. These results show that the critical buckling stress of CNT microstructures vary predictably with geometry and that continuum models with appropriate material constants may be applied to analyze CNT microstructures and evaluate their stability for many applications.

ABSTRACT: The investigation of stability of shell structures is a specialty which in its own right deserves a complete separate book. Here just some main aspects are explained, and the correspondence and difference with beam-column buckling is touched. We will successively discuss buckling of uni-axially loaded plates as a limit case of shells, arched beams, arched circular roofs, axially-pressed shells of rotation and domes.

ABSTRACT: We report on the mechanical behavior of a dense brush of small-diameter (1–3 nm) non-catalytic multiwall (2–4 walls) carbon nanotubes (CNTs), with ~10 times higher density than CNT brushes produced by other methods. Under compression with spherical indenters of different radii, these highly dense CNT brushes exhibit a higher modulus (~17–20 GPa) and orders of magnitude higher resistance to buckling than vapor phase deposited CNT brushes or carbon walls. We also demonstrate the viscoelastic behavior, caused by the increased
influence of the van der Waals’ forces in these highly dense CNT brushes, showing their promise for energy-absorbing coatings.

DOI: 10.1016/j.commatsci.2010.08.011

ABSTRACT: Intramolecular junctions (IMJs) formed by connecting two arbitrary carbon nanotubes (CNTs) can act as functional building blocks in circuits and components of CNT-based electronics devices. While extensive studies have been conducted on the atomic structural as well as electrical properties of IMJs and great advances have been achieved, mechanical response of IMJs under large deformation, which may exert significant effects on their electrical properties, are still not fully explored. In this paper, both molecular dynamics (MD) simulation and finite element (FE) analysis are employed to investigate the buckling behavior of IMJs under axial compression. The strain rate effects are firstly studied in the MD simulations. It is found that the critical compressive strain is not sensitive to the strain rate of relatively low range, but it exhibits a strong dependency upon the strain rate under high speed compression. In particular, a different failure mode may occur under ultra-high loading velocities. Based on the discussion on the strain rate effects, a reasonable loading velocity is suggested to be adopted in the subsequent MD simulations. In this study, the results of both the MD simulations and the FE analyses indicate that the critical compressive strain is dependent upon the length, radial dimensions of the IMJ but insensitive to the chirality of the IMJ. The comparison between the results of the MD simulations and the FE analyses also confirms that the FE analysis is able to provide useful insights into the compressive behavior of CNT-based IMJs with a much less computational cost.

ABSTRACT: The paper presents 3D results of a quasi-static buckling analysis of a funnel-flow cylindrical metal bin composed of horizontally corrugated sheets strengthened by vertical columns. A linear buckling and a non-linear analysis with geometric and material non-linearity were carried out with a perfect and an imperfect real silo shell by taking into account axisymmetric and non-axisymmetric loads imposed by a bulk solid following Eurocode 1 and different initial geometric imperfections and load non-uniformities around the circumference. The calculated buckling forces were compared with the permissible one given by Eurocode 3.

Biswarup Ghosh, “Consequences of simultaneous local and overall buckling in stiffened panels”, Master’s Thesis, Virginia Polytechnic Institute and State University, Blacksburg, VA, 2003

ABSTRACT: In this thesis improved expressions for elastic local plate buckling and overall panel buckling of uniaxially compressed T-stiffened panels are developed and validated with 55 ABAQUS eigenvalue buckling analyses of a wide range of typical panel geometries. These two expressions are equated to derive a new expression for the rigidity ratio \( (EI_x/Db)_{co} \) that uniquely identifies “crossover” panels – those for which local and overall buckling stresses are the same. The new expression for \( (EI_x/Db)_{co} \) is also validated using the 55 FE models. Earlier work by (Chen, 2003) had produced a new step-by-step beam-column method for predicting
stiffener-induced compressive collapse of stiffened panels. An alternative approach is to use orthotropic plate theory. As part of the validation of the new beam-column method, ABAQUS elasto-plastic Riks ultimate strength analyses were made for 107 stiffened panels—the 55 crossover panels and 52 others. The beam-column and orthotropic approaches were also used. A surprising result was that the orthotropic approach has a large error for crossover panels whereas the beam-column method does not. Some possible reasons for this are suggested. Collapse patterns for the crossover panels are studied and classified from von Mises stress distribution at collapse. The collapse mechanism and load-deflection diagrams suggest stable inelastic post collapse behavior for most panels and an abrupt drop in load carrying capacity in only nine of the 55.

ABSTRACT: A 48 degrees of freedom (dof) doubly curved quadrilateral thin shell finite element is used for studying the supersonic flutter of cantilevered curved composite panels. The composite material behavior is included using classical lamination theory and supersonic aerodynamic behavior is included using linearized piston theory. To reduce the number of dof of the finite element aeroelastic system, a normal mode approach is adopted. Results are presented to illustrate the behavior of flutter characteristics for composite curved cylindrical panels. The effects of fiber orientation and flow angle on the flutter characteristics are presented for selected examples. The accuracy, efficiency, and applicability of the present finite element method is demonstrated by illustrative examples with some results comparing well with the available alternate solutions in the literature.

ABSTRACT: The use of springs with very large stiffness to model constraints in vibratory systems has been a popular approach to overcome the limitations on the choice of admissible functions in the Rayleigh–Ritz method. The maximum possible error resulting from this asymptotic modelling can be determined by using positive and negative stiffness values, or in general terms using positive and negative penalty functions. This paper illustrates how this method could be used to determine the critical loads of structures.

ABSTRACT: A numerical procedure for analyzing a common and catastrophic failure mode in pultruded composite material I-beams is presented in this paper. Pultruded wide-flange profiles (often referred to as I-beams) exhibit a number of different failure modes when loaded in flexure or axial compression. The particular failure mode of interest to this paper is that due to the local separation of the flange from the web of the profile following local buckling of the flange. A node-separation technique is used to simulate the progressive failure of the joint between the flange and the web of the wide-flange beam in the postbuckled regime. The procedure has been implemented in NIKE3D, a multipurpose nonlinear implicit finite-element code. The fundamentals of the separation algorithm and the mechanics of the implementation in NIKE3D are described. The results of simulations using the proposed procedure are compared with experimental observations.

ABSTRACT: Virtual testing using dynamic finite element simulations is an efficient way to investigate the mechanical behaviour of small- and large-scale structures reducing time- and cost-expensive prototype tests. Furthermore, numerical models allow for efficient parameter studies or optimisations. One example, which is the focus of this paper, is the configurational design of cellular sandwich core structures. From classical honeycomb cores to innovative folded core structures, a relatively large design space is provided allowing for tailoring of the cellular core geometry with respect to the desired properties. The method of determining the effective mechanical properties of such cellular sandwich core structures of different geometries using dynamic compression, tensile and shear test simulations is discussed covering a number of important modelling aspects: the cell wall material modelling, the influence of mesh size and number of unit cells, the inclusion of imperfections, etc. A comparison of numerical and experimental results is given for Nomex honeycomb cores and Kevlar or carbon fibre-reinforced plastic (CFRP) foldcore structures. A good correlation with respect to cell wall deformation mechanisms and stress–strain data was obtained. Therefore, these models not only allow for a complete mechanical characterisation of cellular core structures but also for a detailed investigation of cell wall deformation patterns and failure modes to get a better understanding of the structural behaviour, which can be difficult using solely experimental observations. To show that this efficient virtual testing method is suitable for the development of cellular core geometries for specific requirements, an optimisation study of a CFRP foldcore geometry with respect to its compressive behaviour was performed.

ABSTRACT: Thin-walled members that have one dimension relatively large in comparison to the cross-sectional dimensions are usually modelled by using beam-type one-dimensional finite elements. Beam-type elements, however, are based on the assumption of rigid cross-section, thus they only allow considerations associated with the beam axis behaviour such as flexural-, torsional- or lateral-buckling and cannot consider the effects of local deformations such as flange local buckling or distortional buckling. In order to capture the local effects of this type shell-type finite element models can be used. Based on the Bridging multi-scale approach, this study proposes a numerical technique that is able to split the global analysis, which is performed by using simple beam-type elements, from the local analysis which is based on more sophisticated shell-type elements.
As a result, the proposed multi-scale method allows the usage of shell elements in a local region to incorporate the local deformation effects on the overall behaviour of thin-walled members without necessitating a shell-type model for the whole member. Comparisons with full shell-type analysis are provided in order to illustrate the efficiency of the method developed herein.

ABSTRACT: Structural design codes and standards provide a foundation of good engineering practice. The process of developing probability-based codes has brought the structural reliability research community and engineers in professional practice together and led to research toward a common goal that otherwise would not have been possible. This paper reviews developments in probability-based codified structural design during the past two decades, assesses advantages and shortcomings of the current generation of probability-based codes, and suggests several avenues for new research.

PARTIAL ABSTRACT: Successful planning of complex structures of composite materials is possible only on the basis of reliable determination of the load bearing capacity. Experience shows [1,2] that a characteristic feature of the failure of composite materials is the stochastic growth and cumulation of microdefects in the process of loading (breakage of fibers, plastic deformation of the matrix, destruction of the boundary layer, delamination, etc.), and this leads subsequently to the appearance of zones of failure of the material…

ABSTRACT: The paper describes a method to optimise the thickness balance within a composite laminate with layers oriented according to a limited set of angles. The laminate must be symmetric, balanced and loaded in-plane. The optimisation process is particularly suited to be used in conjunction with a finite element program. It provides the designer with the optimal overall engineering characteristics and a list of all the possible orientation combinations ranked with respect to their safety factor. The optimisation method is based on the first order gradient optimum search method and operates iteratively in the engineering elastic characteristics field. The cost function implemented up to now is the structure stiffness but no conceptual limitations exist for different functions. Some simple applications are listed at the end of the paper in order to verify the capabilities of the method.

ABSTRACT: A review of research in the area of large amplitude vibration of composite plates and shells is presented in this paper. The main focus of this paper is on the effects of geometric nonlinearity, transverse shear deformation and rotatory inertia on the vibration behaviour of single-layered plates and shells. Recent advances made in these areas are reviewed. Some literature on laminated plates and shells made of filamentary composite material is also included. Particular attention is given to the recent developments in the analytical methods of solution. Recent research leading to advances in numerical techniques is also included in the present overview.

“Analysis and design of pultruded FRP shapes under bending”, Composites Part B: Engineering, Vol. 27, Nos.3-4, 1996, pp. 295-305, Special Issue: Structural Composites in Infrastructures, doi:10.1016/1359-8368(95)00015-1
ABSTRACT: A comprehensive approach for the analysis and design of pultruded FRP beams in bending is presented. It is shown that the material architecture of pultruded FRP shapes can be efficiently modeled as a layered system. Based on the information provided by the material producers, a detailed procedure is presented for the computation of fiber volume fraction (Vf) of the constituents, including fiber bundles or rovings, continuous strand mats, and cross-ply and angle-ply fabrics. Using the computed Vfs, the ply stiffnesses are evaluated from selected micromechanics models. The wall or panel laminate engineering constants can be computed from the ply stiffnesses and macromechanics, and it is shown that the predictions correlate well with coupon test results. The bending response of various H and box sections is studied experimentally and analytically. The mechanics of laminated beams (MLB) model used in this study can accurately predict displacements and strains, and it can be used in engineering design and manufacturing optimization of cross-sectional shapes and lay-up configurations. The experimental results agree closely with the MLB predictions and finite element verifications.

ABSTRACT: Fiber-reinforced plastic (FRP) beams are thin-walled or moderately thick-walled open or closed sections consisting of assemblies of flat panels. We present a computational approach with the computer program FRPBEAM (1994) for the response evaluation of pultruded FRP beams in bending. This program combines micro/macro-mechanics analyses with the Mechanics of Laminated composite Beams (MLB) model and an explicit stability solution to analyze, design, and optimize FRP shapes. In FRPBEAM, the ply stiffnesses are predicted by micromechanics formulas, based on the fiber volume fraction of each lamina, and the panel laminate properties are computed from the ply stiffnesses and macromechanics. The MLB model is used to analyze the overall response of FRP beams in bending, and the Tsai–Hill failure criterion is adopted to predict first-ply-failure loads. An example of a laminated box beam is used to demonstrate the accuracy of the computer program for predicting beam displacements and ply stresses in relation to finite element analyses. A stability Rayleigh–Ritz method is included in the program and used to evaluate the critical buckling loads for pultruded I-beams. Through parametric studies with FRPBEAM and a multiobjective optimization scheme, the fiber architecture of an existing I-beam is optimized, and based on a recommended practical design, the I-beam
section is produced by pultrusion and subsequently tested in bending. The predicted response with FRPBEAM correlates well with the experimental results. As illustrated by design analysis and optimization examples presented in this study, the experimentally and numerically verified computer program can be used to analyze existing FRP shapes and develop new optimized shapes for the civil structural market.

ABSTRACT: An analytical study of local buckling of discrete laminated plates or panels of fiber-reinforced plastic (FRP) structural shapes is presented. Flanges of pultruded FRP shapes are modeled as discrete panels subjected to uniform axial in-plane loads. Two cases of composite plate analyses with different boundary
conditions and elastic restraints on the unloaded edges are presented. By solving two transcendental equations simultaneously, the critical buckling stress resultant and the critical value of the number of buckled waves over the plate aspect ratio are obtained. Using this new solution technique and regression analysis, simplified expressions for predictions of plate buckling stress resultants are efficiently formulated in terms of coefficients of boundary elastic restraints. The effects of restraint at the flange-web connection are considered, and explicit expressions for the coefficients of restraint for I- and box-sections are given; it is shown that actual cases lie between simply supported and fully restrained (clamped) conditions. The theoretical predictions show good agreement with experimental data and finite-element eigenvalue analyses for local buckling of FRP columns. In a similar manner, web plate elements of FRP shapes under in-plane shear loads are modeled with and without elastic restraints provided by the flange panels. The present formulation can be applied to several cases to determine local buckling capacities of laminated plates with elastic restraints along the unloaded edges and can be further used to predict the local buckling strength of FRP shapes, such as columns and beams.

ABSTRACT: Finite element method (FEM) is applied to analyze the buckling performance of alloy aluminum stiffened panel subjected to uniform axial compression. With the skin thickness and stiffener pitch unchanged, the influence of flange thickness, flange length, stiffener thickness and stiffener height on compress buckling critical loads are studied by FEM. Important parameters influencing the buckling performance are identified and the results offer a referenced measure for the optimization design and engineering application of the structure.

DOI: 10.4028/www.scientific.net/AMM.184-185.1189

ABSTRACT: Finite element method is applied to analyze the buckling performance of composite stiffened panel. Compress buckling critical loads of six types panels with T or Z-section stiffeners are calculated by FEM. The emulational calculation results show that with same cross section area, critical buckling load of panel with T-section stiffeners increases with the reduction of stiffener pitch and the increase of stiffener numbers, while the buckling load of panel with Z-section stiffeners increases to a certain level and then keep almost changeless. To T-section stiffener panels, the relation between thickness of skin and buckling load is approximately quadratic trinomial. Conclusions obtained can offer a referenced measure for the optimization design and engineering application of the structure.
ABSTRACT: An experimental investigation of the local compression flange buckling and failure of commercially produced pultruded fiber-reinforced plastic (FRP) I-shaped beams is described in this paper. Results of tests on pultruded E-glass/polyester and E-glass/vinylester composite material beams are described. The test configuration was designed to cause local buckling and ultimate failure of the compression flange of the beams and to prevent global lateral-torsional buckling. The beams were stiffened to prevent crippling and warping at the supports, and local tensile failure at the load points. All beams were monitored with strain gages and LVDT’s. Buckling loads, failure loads, buckling stresses, deflections, and failure modes are reported. Effective mechanical properties of the beams, obtained from overall flexural and shear strain data, are presented. A discussion of the different failure characteristics of the polyester and the vinylester beams is provided.

ABSTRACT: Fiber-reinforced plastic (FRP) composite decks have been increasingly used in highway bridge applications, both in new construction and rehabilitation and replacement of existing bridge decks. Recent applications have demonstrated that FRP honeycomb panels can be effectively and economically used for highway bridge deck systems. This paper is concerned with design modeling and experimental characterization of a FRP honeycomb panel with sinusoidal core geometry in the plane and extending vertically between face laminates. The analyses of the honeycomb structure and components include: (1) constituent materials and ply properties, (2) face laminates and core wall engineering properties, (3) equivalent core material properties, and (4) apparent stiffness properties for the honeycomb panel and its equivalent orthotropic material properties. A homogenization process is used to obtain the equivalent core material properties for the honeycomb geometry with sinusoidal waves. To verify the accuracy of the analytical solution, several honeycomb sandwich beams with sinusoidal core waves either in the longitudinal or transverse directions are tested in bending. Also, a deck panel is tested under both symmetric and asymmetric patch loading. Finite element (FE) models of the test samples using layered shell elements are further used to correlate results with analytical predictions and experimental values. A brief summary is given of the present and future use of the FRP honeycomb panel for bridge decks. The present simplified analysis procedure can be used in design applications and optimization of efficient honeycomb structures.

ABSTRACT: Designing an optimized composite laminate requires finding the minimum number of layers, and the best fiber orientation and thickness for each layer. To date, several optimization methods have been introduced to solve this challenging problem, which is often non-linear, non-convex, multimodal, and multidimensional, and might be expressed by both discrete and continuous variables. These optimization techniques can be studied in two parts: constant stiffness design and variable stiffness designs. This paper concentrates on the first part, which deals with composite laminates with uniform stacking sequence through their entire structure. The main optimization methods in this class are described, their characteristic features are contrasted, and the potential areas requiring more investigation are highlighted.

ABSTRACT: This paper deals with an innovative integrated hollow space core sandwich composite construction that possesses several multi-functional benefits in addition to the providing lightweight and bending stiffness advantages. In comparison with traditional foam and honeycomb cores, the integrated space core provides a means to route wires/rods, embed electronic assemblies, and store fuel and fire-retardant foam, among other conceivable benefits. In the current work, the low-velocity impact (LVI) response of innovative integrated sandwich core composites was investigated. Three thicknesses of integrated and functionality-embedded E-glass/epoxy sandwich cores were considered in this study—including 6, 9 and 17 mm. The low-velocity impact results indicated that the hollow and functionality-embedded integrated core suffered a localized damage state limited to a system of core members in the vicinity of the impact. The peak forces attained under static compression and LVI were in accordance with Euler's column buckling equation. Stacking of the core was an effective way of improving functionality and limiting the LVI damage in the sandwich plate. The functionality-embedded cores provided enhanced LVI resistance due to energy additional
energy absorption mechanisms.

ABSTRACT: The search for lightweight and highly efficient structural components is a continuing process. Reducing the structural weight and improving the load carrying capabilities of these structures will allow designers to add additional capabilities while reducing cost. The basic functions of aerospace structures are to transmit and sustain the applied loads, provide a basic shape and to protect the payload. Shell stiffened structures have been used for many years to fulfill these applications. Most of the airframe components are normally plate or shell type structures. Efficiency dictates that they are stiffened or semi-monocoque in construction. The usual means of stiffening is to use longitudinal stringers and frames or ribs. An alternate approach to stiffening is the concept of isogrid, which employs a repetitive equilateral triangular pattern of ribs. The isotropic property and effective Poisson's ratio around 0.3 enables the isogrid to be mathematically transformed to an equivalent homogeneous material layer 1-2. Isogrids, in general, offer a unique set of advantages: (1) they possess a high stiffness to weight ratio; (2) stiffening results in high effective bending stiffness for circumventing local flutter, vibration and buckling problems; (3) stiffening members are useful for attachment of secondary structures and non-structural items and for the introduction of concentrated or localized loads; and (4) cutouts for access doors and windows are easily incorporated into the design.

ABSTRACT: A procedure for simplifying the derivation of stiffness matrices used in the finite element analysis of instability and nonlinear structural problems is presented. The displacement functions assumed to derive the nonlinear components of element stiffness matrices provide inter-element continuity of displacement derivatives of order one less than appear in the energy functional and therefore comply with established convergence criteria for finite element analysis. For the class of problems discussed, this implies the use of linear polynomial displacement functions, which simplifies the derivation considerably and avoids the need for complex numerical integration. A number of practical examples are discussed to illustrate the effectiveness of this procedure.

ABSTRACT: Theoretical analyses are presented for the buckling of circular cylindrical shells partially subjected to external liquid pressure. The shells are assumed to stand vertically with the lower end clamped, and the upper end clamped or free. In the analyses, the Donnell equations are used for the basic equation, and prebuckling deformation as well as the membrane state of stress of the shell are taken into account. The
The Galerkin method is used, and the critical pressures at various liquid heights as well as the wave numbers, are obtained for a wide range of the geometrical parameters of the shell $Z$. A convenient chart which indicates the buckling liquid height for a given shell and liquid are presented. Experimental studies are also conducted by using test cylinders made of polyester film, and water. The theoretical and experimental results for the buckling liquid height, are in excellent agreement.

ABSTRACT: Theoretical analysis has been presented for the effect of internal liquid pressure on the buckling of circular cylindrical shells subjected to external liquid pressure. The shell is assumed to stand vertically with the lower end clamped, and the upper end clamped or free. In the analysis, the Donnell equation was used for the basic equation, and the prebuckling deformation of the shell was taken into account. The Galerkin method was used, and the critical pressures at various internal liquid heights as well as the buckling wave numbers, were obtained for a wide range of the geometrical parameters $Z$ a given shell. The effect of internal liquid on the buckling mode was also clarified. To confirm the validity of the analysis, experimental studies were also conducted by using test cylinders made of polyester film and water. Theoretical and experimental results were in good agreement.

ABSTRACT: Theoretical analyses are presented for the dynamic stability of a clamped-free cylindrical shell partially filled with liquid, under vertical excitation. In the analyses, the dynamic version of the Donnell equations and the velocity potential theory were used for the motions of the shell and the liquid, respectively. The problem was solved by using the modified Galerkin method so as to satisfy the boundary conditions. The equations of motion coupling the shell and the liquid were derived from a type of coupled Mathieu's equation. It is found that the parametric principal resonance could occur, as well as the parametric combination resonance of the sum type, involving two natural vibrations with the same circumferential wave number but with different axial mode number. The latter type of parametric resonance apparently has not been previously studied. The instability regions where parametric resonance occurs were determined by using Hsu's method. To compare with the experimental results which had been stated in a companion paper, detailed numerical calculations were carried out for the two test cylinders partially filled with water. Excellent agreement between theory and experiment was demonstrated for the instability regions.

ABSTRACT: The aim of the present paper is to present numerical procedures, using two types of FE methods, for the secondary and higher order bifurcations (tertiary and quarternary bifurcations) which appear after the
first buckling of thin shell structures. With a limitation to a cylindrical shell under axial compression, the post-bifurcation behavior after the first bifurcation is analyzed precisely by considering modal coupling between several deformation modes of higher order harmonic wave numbers, and on all the way of post-bifurcation path the positive definiteness of incremental stiffness matrix of uncoupled modes is examined step by step to find if any higher order bifurcation or transcritical bifurcation appears. Based on the step-by-step examination, the higher order bifurcation points and the corresponding bifurcation modes are traced.

**Papers by Professor Peter von Buelow (Bülow) relating to shell-type parts of architectural creations:**

ABSTRACT: A mathematical model is constructed to study the buckling of rectilinearly orthotropic, truncated conical shells. The model consists of three coupled variable coefficient partial differential equations for the shell displacements; the formulation presented takes into account the action of locally supported applied forces normal to the lateral surface of the shell and contains two fundamental novelties: the introduction of special combinations of constitutive parameters to gauge the deviation from isotropy and a transformation of both coordinates and displacements on the developed cone surface to render the problem tractable.

ABSTRACT: In this paper, the axisymmetric and non-axisymmetric buckling of finite elastic cylindrical shell, which is impacted on the end by axial step loads, is discussed with the aid of the stress wave propagating and reflecting. By solving the disturbed equations, the bifurcation condition of the dynamic buckling, critical buckling load and buckling mode are obtained. The results show that when the thickness is not very small, non-axisymmetric critical buckling load is higher than axisymmetric one; that when the thickness is very small, non-axisymmetric buckling can occur first and that since the wave is reflected on the other end of the shell, the critical buckling load decreases further. The results are in agreement with the physical phenomenon in experiments.
ABSTRACT: Over the last few decades, storage tanks have become bigger and thinner. Because of this, the buckling capacity of these cylindrical shells may well be the determining factor of shell thickness. In this paper, the critical buckling load of isotropic and orthotropic cylinders subjected to different types of wind load distributions is investigated. The prebuckling displacements are obtained by using the membrane theory of shell analysis. The principle of minimum potential energy in conjunction with Ritz's approach is used to obtain the stability matrix. The size of the stability matrix in this analysis is $(81 \times 81)$. By solving the stability matrix as an eigenvalue problem, the critical pressures are obtained as eigenvalues and the deflection shapes as eigenvectors.

In the present study cylindrical shells of various dimensions, which are fixed at the base and free at the top, are investigated. The buckling load curves for isotropic and orthotropic cylinders of various dimensions are given for practical use.

ABSTRACT: The influence of concrete creep on the response of shallow reinforced concrete shells is analyzed in this contribution in the context of time-dependent shell buckling. The classical time-invariant stability analysis is extended to account for the long-term creep buckling, which is characterized by a continuous increase of deformation and time-dependent stability failure, if a certain critical load factor is exceeded. For a systematic study of these phenomena on a cylindrical roof shell, a recently proposed time-invariant and a time-dependent material model for concrete are combined in the framework of the long-term multi-level simulation concept, taking into account elasto-plastic deformation, crack damage and nonlinear basic creep of concrete. The performed numerical analyses provide an insight into the mechanisms of creep buckling of reinforced concrete shells as well as its sensitivity with respect to main influence factors and emphasize the relevance of interaction mechanisms between short- and long-term loadings.

ABSTRACT: The initiation of cracking and its location are of vital importance in the analysis and the design of concrete shell structures. Openings are common design requirement in shell roofs for light and ventilation. However, analysis and design procedures are lacking for such cases. Close-form elasticity solutions for concrete
shells with openings are unavailable. Therefore, FE modeling for such structures is required. The objective is to create a finite element model capable of predicting the nonlinear cracking loads of reinforced concrete shells. A rigorous evaluation of the role of openings and their dimensions are studied and design recommendations for shells with different opening dimensions and cracking loads are suggested. The FE model consists of a total of 17550 solid brick concrete elements with six layers across the shell thickness. Each element has 8 nodes with three translational degrees of freedom. The model predicts the nonlinear cracking load, and the crushing mechanism for thin concrete shells with varying thickness with and without openings. Results of the finite element predictions are validated with the finite strip theory for thin concrete shells. Good agreement between FE results and theory is observed for deflections and stresses. The failure model of concrete material used in this analysis proved to be accurate in predicting the nonlinear behavior of reinforced concrete thin shells. When the dimension of the opening increases along the mid-span axis of the shell, the cracking stress required increases because the increase in the opening dimension is directed away from the high stress levels in the shell center. On the other hand, if the opening dimension is increased in the longitudinal direction of the shell, the required load to initiate cracking will decrease because of the high level of stress concentration present in the vicinity.

Shawomir Koczubiej and Czeslaw Cichon (Kielce University of Technology, Poland), “Shell-beam model of thin-walled space structures for geometrically nonlinear analysis”, Computer Methods in Mechanics (CMM-2011, 9-12 May 2011, Warsaw, Poland)
ABSTRACT: In the paper, the finite shell-beam model for geometrically nonlinear analysis of thin-walled space structures with open cross-section has been proposed. The standard discretization using beam thin-walled elements is connected with the space discretization of the frame joints. The case of special construction of joints, where complete warping transmission is ensured, has also been considered. Examples confirmed the effectiveness of the proposed FEM analysis.

ABSTRACT: An analysis of four-noded C0-shell elements is presented that assesses their ability to represent the membrane-bending coupling phenomena in the governing shell equations by facet approximations. It is shown that four-noded shell elements can capture the predominant coupling phenomena consistent with the classical assumptions invoked in the first-order linear shell theories. Encouraged by this ability, a new four-noded C0-shell element is presented that employs only one-point spatial integration rule. The inevitable spurious mechanisms resulting from reduced integration are compensated for by a systematic rank-correction technique that was previously developed for a plate-bending element. The element is applied to classical cylindrical buckling problems with encouraging results.

ABSTRACT: This paper presents the effects of elastic supports on the buckling of circular cylindrical shells under bending. Stability was investigated using Donnell’s equation and the Galerkin method, including the spring constant of the elastic support. The results of this investigation indicate that the effects are similar in the cases of bending and axial compression.

ABSTRACT: Thin walled tubes of circular cross-section are efficient structural elements and thus, as would be expected, are not uncommon in plants, especially those which belong to the Monocotyledonae. Traditional analyses of the strength of these tubular members utilize formulae which were developed for isotropic materials. The present paper deals with the great influence of the high elastic anisotropy of the plant tissue on the mechanical behavior of such tubular stems and leaves in bending. It will be seen that under these circumstances the propensity of the tube to fail due to non-linear effects (deformation of the cross-section) is greatly increased.

ABSTRACT: The aim of this paper is to describe buckling deformations of hollow cylinders whose buckled configurations consist of inextensional deformations of their original middle surface, through minimization of two competing energy forms: a bulk elastic energy and an interface bending energy. These minimal energy configurations are obtained through descent minimization within the class of folding deformations. The non-
standard problem of minimization over variable triangulations is considered.

ABSTRACT: The general instability of thin-walled orthotropic circular cylindrical shells under external pressure is investigated. The buckling pressure can be predicted with the use of simple analytical formulae derived from an asymptotic analysis of the corresponding eigenvalue problems. The results predicted by these formulae are compared with finite element solutions and the four types of experimental models investigated by Ross (Thin Walled Structures 1996;26(3):179–93). The comparison proved to be accurate enough for practical purpose except for experimental model 1.

ABSTRACT: In creep buckling analysis, small deflexion approximations generally influence the calculated displacement-time relations and may also result in the prediction of different phenomena from those indicated by exact analyses. Part II examines the nature of these approximations and the effects of using them. As in Part I, much significance is attached to the link between a structure's creep buckling behaviour at constant load and its instantaneous buckling and post-buckling behaviour under varying load. Analyses of simple single degree of freedom models are used for illustration. Some general conclusions are drawn which permit a better understanding of the relationships between the different types of analysis that have been used in previous creep buckling studies.

ABSTRACT: This paper has developed an efficient nonlinear finite element method that covers both initial deformations and initial stresses of general distribution in calculating the ultimate strength of ring-stiffened cylinders. The developed method and two world-widely used commercial codes(NASTRAN and ABAQUS) were simultaneously applied to the same analysis model within the extent those commercial codes can cover, to check the validity of the present method. After the validity check, it was used for parametric studies for more general case of initial stress distribution, which drew some useful information about the imperfection sensitivity of the ultimate strength of ring-stiffened cylinders.

ABSTRACT: Two new variational functionals are introduced for buckling analysis of cylindrical shells. In the first, admissible functions satisfy all the equilibrium equations and the Euler-Lagrange equations emerge as a set of compatibility equations. In this sense this procedure complements the well known minimum potential energy method. In the second, the transverse equilibrium and membrane compatibility requirements are satisfied by the admissible functions and the system equations emerge as a set of membrane equilibrium and transverse compatibility equations. This formulation can be considered as complementary to Von Karman's well known method. The new functionals are used to obtain solutions for 2 classic examples.

ABSTRACT: The Semi-Loof Shell element originally developed by Irons [2] for linear elastic analysis of thin shell structures is formulated to include large deflection and plastic deformation effects. In this paper the details of the finite element formulation of the problem using total Lagrangian coordinate systems are presented and different element matrices are given. For plastic materials following the Prandtl-Reuss flow rule with isotropic strain hardening a multi-layer approach using a subincremental technique is employed. Numerical results on the performance of the element for a variety of applications are presented. These computer studies include complete load-deflection curves into the post-buckling range and comparisons are made with other existing results. Current experience with the element indicates that it is a reliable and competitive element for nonlinear analysis of shells of general geometry.

ABSTRACT: Results are presented and some modifications made to problems posed in an earlier paper by the authors on the extension of the semi-loof element to the analysis of shell structures involving instabilities, snap-through and material nonlinearities. In this paper, by adopting a more refined method for solving problems of plasticity, in conjunction with a subincremental technique, more accurate results are obtained. The second-order Runge-Kutta method employed in this study shows significant improvement in the accuracy of the stresses in the shell as compared to the case when only the simple point-slope method of Euler is used. The detailed computational procedure for elastoplastic analysis of shell problems is presented in a way that can readily be incorporated into standard computer packages. Results obtained for large deflection analysis of plastic shells of different geometries and boundary conditions are compared with the available solutions and show very good agreement.

ABSTRACT: Aspects and theories of nonlinear analysis of structures, with special emphasis on structures that are discretized by the finite element method, are discussed. The updated Lagrangian formulation and the incremental Hellinger-Reissner variational principle are adopted. The independently assumed fields employed are the incremental displacements and incremental strains. Accordingly, the incremental second Piola-Kirchhoff stress and the incremental Washizu strain are selected as the incremental stress and strain measures. Various schemes for the transformation of the second Piola-Kirchhoff stress to Cauchy stress are included. Two versions of linear and nonlinear element stiffness and mass matrices are considered. These are the director and simplified versions. Variable thickness of the shell is considered so as to account for the ‘thinning effect’ due to large strain. Material nonlinearity studied in this paper is of elasto-plastic type with isotropic strain hardening. Cases in which small elastic but large plastic strain condition applies are considered and the J2 flow theory of plasticity, in conjunction with Ilyushin's yield criterion, is employed. To simplify the derivation of (small displacement) stiffness matrix and to facilitate the derivation of explicit expressions for the element matrices, the non-layered approach has been applied.

ABSTRACT: In a companion paper [M. L. Liu and C. W. S. To, Comput. Struct. 54, 1031–1056 (1995)] theories and incremental formulation of nonlinear shell structures discretized by the finite element method are discussed. The updated Lagrangian formulation and the incremental Hellinger-Reissner variational principle are adopted. The independently assumed fields employed are the incremental displacements and incremental strains. Based on the theory and incremental formulation explicit element stiffness and mass matrices of three node flat triangular shell finite elements are derived. In the present paper the derived element matrices are applied to nine examples. The latter include static and dynamic response analysis of shell structures with geometrical, material, and geometrical and material nonlinearities. The formulation adopted and element matrices derived are found to be accurate, flexible and applicable to various types of shell structures with geometrical and material nonlinearities.

ABSTRACT: The thick shell element of Ahmad, Irons and Zienkiewicz has been used in the study of plate and shell buckling and vibration problems. A concise tensor based theory for finite elements, in general, and the shell element, above, in particular is developed in this study. Using this theory, expressions for the geometric stiffness and mass matrix of the above element are developed. The computer implementation of the theory centred on two aspects. Firstly, the programming of the geometric stiffness and mass matrix expressions. Secondly a general review has been carried out to establish as efficient a program as possible. This efficiency is both in terms of user data preparation and computational effort within the program. In this regard, it should be noted that the numerical integration procedure used in creation of the element stiffness matrices involves many repetitive operations. Therefore any extraneous operations, for example, multiplication of zero terms, leads to
large inefficiencies. The subspace iteration method of Bathe and Wilson has been used for determining buckling loads and natural frequencies of vibration. A modified iteration method is developed, which allows use of the method for certain examples which previously were not solvable using the standard method. These examples are characterized by having as a solution set, pairs of eigenvalues, equal in magnitude, but opposite in sign. This modified method has been incorporated in the program with the basic standard method. Examples in the buckling field which exhibit this behaviour include the shear buckling of flat plates and the lateral buckling of beams. Both these cases have been investigated in this study.

ABSTRACT: The purpose of this study has been to explore the use of super-parametric finite elements for the determination of buckling loads for plates and shells. For this, it was necessary to develop the geometric stiffness matrix for the shell element. In addition to this, it was necessary to choose a numerical method for the solution of the large scale eigenvalue problem that arises from the formulation. The subspace iteration method was chosen for its versatility in handling large scale problems, but it was found that the standard technique broke down because of the presence of positive and negative eigenvalues. The paper describes how the method was modified to overcome this problem. Results are given for comparative studies on the buckling loads of both plates and shells.

ABSTRACT: The faceted representation is employed in the paper to derive a 24-dof triangular shell element for the instability analysis of shell structures. This element, without the deficiencies of displacement incompatibility, singularity with coplanar elements, inability to model intersections, and low-order membrane strain representation, which are normally associated with existing flat elements, has previously been found by the authors to perform well in linear static shell analyses. The total Lagrangian approach is used in the nonlinear formulation, and the results of the various numerical examples indicate that its performance is comparable to existing nonlinear shell elements. An extrapolation stiffness procedure, which will improve the convergence characteristics of the constant arc length solution algorithm used here, is also presented.

ABSTRACT: The large displacement analysis of flat faceted shell element, previously developed by Meek and Tan [15] is further developed. This element, has been already tested in the nonlinear range via the use of the total Lagrangian formulation and a somewhat cumbersome procedure for the calculation of the joint orientation matrices at each step of the calculations [25]. However, this approach is quite complex and by taking advantage of the positions of the rotational degrees of freedom, being located at the Loof nodes along the edges and normal to the edges, a simple and elegant formulation is obtained. The theory is developed in incremental form and the updated Lagrangian approach with the co-rotational formulation is employed. Numerical examples are
presented and compared with other published results to verify the proposed formulation.

ABSTRACT: A plane circular ring is modeled by various elements, some straight and others curved. All formulations have two translations and one rotation as nodal df. We consider static deflection, under point loading, and bifurcation buckling, under constant-direction loading and fluid pressure loading. Matrices that account for fluid pressure loading are derived. Numerical examples show that excellent results are given by a standard straight beam element whose length is that of the arc it subtends.

ABSTRACT: The similitude invariant and the scaling laws of the symmetric cross-ply laminated circular cylindrical shells for buckling and free vibration problems are derived by applying the similitude transformation to the governing differential equations directly. The scaling laws obtained by this approach are unique because they are forced by the governing differential equations. In the absence of the experimental data, the validity of the scaling laws is verified by numerical experiments. This is done by calculating theoretically the buckling loads and fundamental frequencies for free vibration of the model and substituting into the scaling laws. The predicted values of the prototype from the scaling laws are then compared with those values from the closed-form solution. Examples for the complete similitude cases with various stacking sequences, number of plies, and radius ratios show exact agreement. The presented relationships between the model and prototype will greatly facilitate and reduce the costly experiment. In reality, it may not be feasible to construct the model to fulfill the similarity requirements completely. Several cases of partial similitude are investigated and verified numerically. Modeling with distortion in stacking sequences is recommended, but model with distortion in material properties yields moderately high percent of discrepancy.

ABSTRACT: Structural buckling failure due to high external hydrostatic pressure is a major consideration in designing rings and long cylindrical shell-type structures. This paper presents a direct approach for enhancing buckling stability limits of thin-walled rings/long cylinders that are fabricated from multangle fibrous laminated composite lay-ups. The mathematical formulation employs the classical lamination theory for calculating the critical buckling pressure, where an analytical solution that accounts for the effective axial and flexural stiffness separately as well as the inclusion of the coupling stiffness terms is presented. The associated
design optimization problem of maximizing the critical buckling pressure has been formulated in a standard nonlinear mathematical programming problem with the design variables encompassing the fiber orientation angles and the ply thicknesses as well. The physical and mechanical properties of the composite material are taken as preassigned parameters. The proposed model deals with dimensionless quantities in order to be valid for thin shells having different thickness-to-radius ratios. Useful design charts are given for several types of anisotropic rings/long cylinders showing the functional dependence of the buckling pressure on the selected design variables. Excellent results have been obtained for cases of filament wound rings/long cylinders fabricated from three different types of materials: E-glass/vinyl-ester, graphite/epoxy and S-glass/epoxy. It was shown that significant improvement in the overall stability level can be attained as compared with a baseline shell design. In fact, the developed methodology has been proved to be a useful design tool for selecting an optimal staging sequence of a thin-walled anisotropic ring/long cylinder having arbitrary thickness-to-radius ratio.

ABSTRACT: This paper presents a generalized formulation for the problem of buckling optimization of anisotropic, radially graded, thin-walled, long cylinders subject to external hydrostatic pressure. The main structure to be analyzed is built of multi-angle fibrous laminated composite lay-ups having different volume fractions of the constituent materials within the individual plies. This yield to a piecewise grading of the material in the radial direction; that is the physical and mechanical properties of the composite material are allowed to vary radially. The objective function is measured by maximizing the critical buckling pressure while preserving the total structural mass at a constant value equals to that of a baseline reference design. In the selection of the significant optimization variables, the fiber volume fractions adjoin the standard design variables including fiber orientation angles and ply thicknesses. The mathematical formulation employs the classical lamination theory, where an analytical solution that accounts for the effective axial and flexural stiffness separately as well as the inclusion of the coupling stiffness terms is presented. The proposed model deals with dimensionless quantities in order to be valid for thin shells having arbitrary thickness-to-radius ratios. The critical buckling pressure level curves augmented with the mass equality constraint are given for several types of cylinders showing the functional dependence of the constrained objective function on the selected design variables. It was shown that material grading can have significant contribution to the whole optimization process in achieving the required structural designs with enhanced stability limits.

ABSTRACT: This paper presents a mathematical model for enhancing the buckling stability of composite, thin-walled rings/long cylinders under external pressure using radial material grading concept. The main structure to be analyzed is built of multi-angle fibrous laminated lay-ups having different volume fractions of the constituent materials within the individual plies. This leads to a piecewise grading of the material in the radial direction. The objective is to maximize the critical buckling pressure while preserving the total structural mass at a constant value equal to that of a baseline design. The fiber volume fractions are included among the standard design variables such as fiber orientation angles and ply thicknesses, which are used by many investigators in the field. The model employs the classical lamination theory, where an analytical solution that accounts for the effective axial and flexural stiffness separately is given. The critical buckling pressure contours subject to the mass equality constraint are given for several types of anisotropic rings/long cylinders showing the functional dependence of the constrained objective function on the selected design variables. It is shown that material grading can have significant contribution to the whole optimization process in achieving the required structural designs with enhanced stability limits.

PARTIAL INTRODUCTION: The theory of thin shells investigates the properties of rigid deformable bodies of extremely small thickness. It has become intuitively obvious for many researchers, therefore, that the mechanical properties of a thin-walled shell depend heavily on the geometric properties of its median surface. As early as 1908, therefore, Mallock [160], investigating postcritical deformations of long cylindrical tubes under axial compression, which may be accompanied by significant changes in the shape of the shell and small tension-compression deformations in the median surface…. 

ABSTRACT: A.V. Pogorelov developed a little-known theory of thin elastic shells. He considered a class of piecewise inextensional deformations, in which relatively sharp creases separate areas of inextensional deformation. Within a crease the deformation is inextensional in the plane perpendicular to the crease. The local form of the crease minimises the strain energy, which has bending and stretching components. The paper outlines the theory, applies it to radially loaded open-topped cylindrical shells, and compares it with measurements by Holst and Lukasiewicz.

ABSTRACT: The aim of this contribution is to propose a new averaged nonasymptotic model of stationary stability problems for thin linear-elastic cylindrical shells reinforced by stiffeners which are periodically, densely spaced along one direction tangent to the shell midsurface. As a tool of modeling we shall apply the tolerance averaging technique. The resulting equations have constant coefficients in the periodicity direction. Moreover, in contrast with models obtained by the asymptotic homogenization technique, the proposed one makes it possible to describe the effect of the periodicity cell size on the global shell stability (a length-scale effect). It will be shown that this effect plays an important role in the shell stability analysis and cannot be neglected.

ABSTRACT: A new averaged non-asymptotic model of stationary stability problems for thin elastic cylindrical shells reinforced by a dense system of stiffeners periodically spaced along one direction tangent to the shell midsurface has been proposed by Tomczyk (2005). The aim of this contribution is to apply this model to investigate the effect of a period length on the axially symmetric buckling of the shells under consideration.

DOI: 10.1155/DENM/2006/79853

ABSTRACT: The object of considerations is a thin linear-elastic cylindrical shell having a periodic structure along one direction tangent to the shell midsurface. The aim of this paper is to propose a new averaged nonasymptotic model of such shells, which makes it possible to investigate free and forced vibrations, parametric vibrations, and dynamical stability of the shells under consideration. As a tool of modeling we will
apply the tolerance averaging technique. The resulting equations have constant coefficients in the periodicity direction. Moreover, in contrast with models obtained by the known asymptotic homogenization technique, the proposed one makes it possible to describe the effect of the period length on the overall shell behavior, called a length-scale effect.

ABSTRACT: Stability analysis of noncircular shells is performed with allowance for nonlinear subcritical deformation. Explicit expressions for the rigid displacements of elements of noncircular cylindrical shells are obtained and used to construct shape functions of an effective quadrilateral finite element of natural curvature. A finite element algorithm for solving problems of nonlinear deformation and stability of shells is developed.
Stability problem of an elliptic cylindrical shell is considered. The effect of the ellipticity and subcritical nonlinear deformation of the shell on the critical load is studied. Results obtained are compared with available experimental data.

ABSTRACT: A study is made of the stability of cylindrical shells of oval cross section loaded by a shear force combined with torsional and bending moments. The variational method of finite elements in displacements is used. The subcritical stress-strain state of the shells is considered momental and nonlinear. The effects of the nonlinearity of shell deformation and shell ovalization on the critical load and buckling mode are determined.

ABSTRACT: A finite element statement of solving problems on stability of reinforced elliptic cylindrical shells taking into account momentness and nonlinearity of their subcritical stress strain state is presented. The explicit expressions for displacements of noncircular cylindrical shell elements as rigid bodies are determined by integrating the equations obtained by equating the components of linear strains to zero. These expressions were used to construct the form functions for an efficient quadrilateral finite element of natural curvature. An efficient numerical algorithm of nonlinear deformation and stability of shells was developed. The stability of reinforced elliptic cylindrical shells under combined loading by bending moment, transverse boundary force and internal pressure is analyzed. We also examine how the critical loads are affected by the strain nonlinearity and ellipticity of shell deformation at the subcritical stage.

ABSTRACT: A boundary layer analysis is carried out to determine the possible form of large axisymmetrical deflection states for thin elastic spherical shells subjected to uniform external pressure. For the case of complete spheres it is shown that the governing equations admit boundary layer solutions corresponding to large deflections provided the pressure is sufficiently small. However, such solutions are found to exist for nonshallow clamped spherical caps for a much wider range of pressure. Numerical results are presented for the latter case.

ABSTRACT: This paper examines the post-buckling deformations of cylindrical shells conveying viscous fluid. The wall deformation is modelled using geometrically nonlinear shell theory, and lubrication theory is used to model the fluid flow. The coupled fluid–solid problem is solved using a parallelized FEM technique. It is found that the fluid–solid interaction leads to a violent collapse of the tube such that immediate opposite-wall contact occurs after the buckling if the volume flux is kept constant during buckling. If the pressure drop through the tube is kept constant during the buckling, the fluid–solid coupling slows down the collapse (compared to buckling under a dead load). The effects of various parameters (upstream pressure, axial pre-stretch and the geometry of the tube) on the post-buckling behaviour are examined and the exact geometrically nonlinear shell theory is compared to Sanders’ (1963) moderate rotation theory. Finally, the implications of the results for previous models which described the wall deformation using so called “tube laws” are discussed.

ABSTRACT: This paper is concerned with the problem of viscous flow in an elastic tube. Elastic tubes collapse (buckle non-axisymmetrically) when the transmural pressure (internal minus external pressure) falls below a critical value. The tube's large deformation during the buckling leads to a strong interaction between the fluid and solid mechanics. In this study, the steady three-dimensional Stokes equations are used to analyse the slow viscous flow in such a tube whose deformation is described by geometrically nonlinear shell theory. Finite element methods are used to solve the large-displacement fluid-structure interaction problem. Typical wall deformations and flow fields in the strongly collapsed tube are shown. Extensive parameter studies illustrate the tube's flow characteristics (e.g. volume flux as a function of the applied pressure drop through the tube) for boundary conditions corresponding to the four fundamental experimental setups. It is shown that lubrication theory provides an excellent approximation of the fluid traction while being computationally much less expensive than the solution of the full Stokes equations. Finally, the computational predictions for the flow characteristics and the wall deformation are compared to the results obtained from an experiment.

ABSTRACT: This research deals with several novel aspects of the nonlinear behaviour of thick-walled cylindrical hyperelastic tubes under external pressure. Initially, we consider bifurcation from a circular cylindrical deformed configuration of a thick-walled circular cylindrical tube of incompressible isotropic elastic material subject to combined axial loading and external pressure. In particular, we examine both axisymmetric and asymmetric modes of bifurcation. The analysis is based on the three-dimensional incremental equilibrium equations, which are derived and then solved numerically for a specific material model using the Adams-Moulton method. We assess the effects of wall thickness and the ratio of length to (external) radius on the bifurcation behaviour. The problem of the finite axisymmetric deformation of a thick-walled circular cylindrical elastic tube subject to pressure on its external lateral boundaries and zero displacement on its ends is formulated for an incompressible isotropic neo-Hookean material. The formulation is fully nonlinear and can accommodate large strains and large displacements. The governing system of nonlinear partial differential equations is derived and then solved numerically using the C++ based object-oriented finite element library Libmesh. The weighted residual-Galerkin method and the Newton-Krylov nonlinear solver are adopted for solving the governing equations. Since the nonlinear problem is highly sensitive to small changes in the numerical scheme,
convergence was obtained only when the analytical Jacobian matrix was used. A Lagrangian mesh is used to discretize the governing partial differential equations. Results are presented for different parameters, such as wall thickness and aspect ratio, and comparison is made with the corresponding linear elasticity formulation of the problem, the results of which agree with those of the nonlinear formulation only for small external pressure. Not surprisingly, the nonlinear results depart significantly from the linear ones for larger values of the pressure and when the strains in the tube wall become large. Typical nonlinear characteristics exhibited are the “corner bulging” of short tubes, and multiple modes of deformation for longer tubes. Finally the general fully nonlinear governing equations in Lagrangian form for the three dimensional large deformations of an elastic tube under external pressure are developed.

ABSTRACT: Recent advancements in computational methods has led to improvements in the compu- tational modeling of tensile failure of composite laminates. Models for compressive failure however, have not yet
reached the same level of maturity. Particularly in the case of fiber kinking there is a need for improved modeling techniques. Fiber kinking occurs when fiber imperfection combined with matrix failure lead to localized deformation in a band of finite width (kink bands). Current computational models have focused on micro-level, where matrix and fibers are modeled independently. The various experimental and analytical research on fiber kinking has led to numerous failure criteria and analytical models for kink bands. The collapse response of kink bands however, has yet to be incorporated in a meso-level computational model. A step is required to translate these micro-mechanical and analytical models to a meso-level framework and improve the state of the art of compressive failure modeling of composite laminates.

In this thesis an attempt is made at transitioning from a micro to a meso-level failure model for fiber kinking. A discontinuous approach is proposed for modeling kink bands. The kink bands are represented as strong discontinuities in the displacement field using the phantom node method. With this method the angle of failure propagation can be easily controlled. The discontinuities are introduced after violation of a stress-based failure criterion and therefore necessitates the use of an initially rigid cohesive law to incorporate the kink band response. To construct such a law a shifted formulation is used, meaning, the law is derived with a finite initial stiffness and shifted to achieve the initially rigid behavior. Strong discontinuity analysis and a discrete micromechanical model are used to derive two separate cohesive models in the local kink band coordinate frame, while a simplified approach is also applied to derive a third model in the discontinuity coordinate frame.

The nonlinear characteristics and bifurcation of the models necessitate the use of a capable solution algorithm that will follow the true equilibrium path. Therefore the crack opening displacement arclength method is used to; indirectly control direction of crack growth, pass the bifurcation point and capture possible snap-back behavior. Additionally an adaptive time stepping strategy is applied to increase efficiency and robustness. The model and algorithm have been implemented in a one dimensional framework using Timoshenko beam elements and verified against an analytical solution. The local models have shown to capture the trends derived using the analytical solution well, with the strong discontinuity model being the most accurate. The simplified approach however fails to properly account for these trends.

The current work has resulted in an initial step towards a meso-level computational model of fiber kinking. It is shown that the discontinuous approach provides a good representation of kink bands provided that a proper cohesive model is used that incorporates both material and geometrical parameters influencing kink bands.

This paper addresses the question of strength and mechanical failure in exoskeletons and endoskeletons: a biomechanics analysis”, Journal of the Royal Society Interface, 12 September 2012, DOI: 10.1098/rsif.2012.0567

ABSTRACT: This paper addresses the question of strength and mechanical failure in exoskeletons and endoskeletons. We developed a new, more sophisticated model to predict failure in bones and other limb segments, modeled as hollow tubes of radius $r$ and thickness $t$. Five failure modes were considered: transverse fracture; buckling (of three different kinds) and longitudinal splitting. We also considered interactions between...
failure modes. We tested the hypothesis that evolutionary adaptation tends towards an optimum value of \( r/t \), this being the value which gives the highest strength (i.e. load-carrying capacity) for a given weight. We analysed two examples of arthropod exoskeletons: the crab merus and the locust tibia, using data from the literature and estimating the stresses during typical activities. In both cases, the optimum \( r/t \) value for bending was found to be different from that for axial compression. We found that the crab merus experiences similar levels of bending and compression \textit{in vivo} and that its \( r/t \) value represents an ideal compromise to resist these two types of loading. The locust tibia, however, is loaded almost exclusively in bending and was found to be optimized for this loading mode. Vertebrate long bones were found to be far from optimal, having much lower \( r/t \) values than predicted, and in this respect our conclusions differ from those of previous workers. We conclude that our theoretical model, though it has some limitations, is useful for investigating evolutionary development of skeletal form in exoskeletons and endoskeletons.

ABSTRACT: The main goal of this work is to prove the equivalence of various formulations existing in the current literature which give the governing equations of small displacements superimposed over initial static deformations of thin cylindrical shells. It is shown that the main difference comes from the definition of incremental stress resultants and the dependence of elastic coefficients on initial deformation. When the functional dependence of elastic coefficients on initial deformation is taken into consideration, it is shown that all the derivations are equivalent to each other.

ABSTRACT: To model the competition between capillary and elastic forces in controlling the shape of a small lung airway and its interior liquid lining, we compute the equilibrium configurations of a liquid-lined, externally pressurized, buckled elastic tube. We impose axial uniformity and assume that the liquid wets the tube wall with
zero contact angle. Non-zero surface tension has a profound effect on the tube's quasi-steady inflation-deflation characteristics. At low liquid volumes, hysteresis arises through two distinct mechanisms, depending on the buckling wavenumber. Sufficient compression always leads to abrupt and irreversible collapse and flooding of the tube; flooding is promoted by increasing liquid volumes or surface tension. The model captures mechanisms whereby capillary-elastic instabilities can lead to airway closure.

ABSTRACT: The combined load case of bending and torsion of a cantilever inflated beam is a load case that has not been studied extensively. When a series of inflated beams is placed parallel to each other as can be the case for an inflatable wing, each beam experiences a combination of torque and bending. A theoretical model already exist for such a load case but it is limited to membrane like materials. This paper deals with beams made of materials that need to be treated like a shell. It requires a modification for the wrinkling load due to solely bending and solely torsion. Semi-empirical expressions for both cases are presented for both cylindrical and conical shaped beams.

ABSTRACT: Static and dynamic analysis of fully clamped shallow spherical shells, subjected to uniform normal pressure on concave side and continuously supported on Pasternak foundation on the convex side, is made using Berger's and modified Berger's techniques. Expressions for large static deflections are obtained and results compared with those of Nash and Modeer. The preceding techniques are employed to get the approximate expressions for natural frequency. Values of nondimensional natural frequency obtained by various methods are compared with results of Reissner, Nowacki, Bucco, and others. While a modified Berger's approach gives very good results for static analysis of fully clamped shells, the original Berger's approach is found to be more suitable for free vibration analysis, as results tally with those obtained by Réissner, using Rayleigh's method, even for higher ratios of (H/h). The modified Berger's technique gives sufficiently accurate values of natural frequencies only for smaller values of (H/h).

ABSTRACT: In this paper, energy method and finite difference method are used to compute the instability behavior of multilayered fiber reinforced composite cylindrical shells under axial compression, hydrostatic pressure and torsion. The influences of initial imperfections, geometrical nonlinearities of shells and physical nonlinearities of the materials to the buckling and postbuckling behavior of the shells are considered. The effect of transverse shear is also discussed. The computational results of this paper are well agreed with the experimental data.

References listed at the end of the paper:

ABSTRACT: This paper proposes a theoretical method to analyze the buckling and postbuckling behavior of multi-layered fiber reinforced composite cylindrical shells under uniform axial or hydrostatic compression. The influences of shear nonlinearity of the composite material and the initial imperfection of the shell geometry are taken into account. For the computation of the critical form potential energy method is used. Numerical results are given for boron epoxy composite cylindrical shells with various fiber orientation and different layer
numbers. Results show that the shear nonlinearity of the composite materials and the initial imperfections of the shells are both important for the composite and postbuckling behavior of the composite cylindrical shells.

Yang Yang and William W. Liou (Department of Aeronautical and Mechanical Engineering, Western Michigan University, Kalamazoo, USA)
ABSTRACT: A reduced-order general continuum method is used to examine the mechanical behavior of single-walled carbon nanotubes (CNTs) under compressive loading and unloading conditions. Quasi-static solutions are sought where the total energy of the system is minimized with respect to the spatial degree of freedom. We provide detailed buckled configurations for four different types of CNTs and show that, among the cases studied, the armchair CNT has the strongest resistance to the compressive loading. It is also shown that the buckled CNT will significantly lose its structural strength with the zigzag lattice structure. The unloading post-buckling of CNT demonstrates that even after the occurrence of buckling the CNT can still return to its original state making its use desirable in fields such as synthetic biomaterials, electromagnetic devices, or polymer composites.

ABSTRACT: Thin-walled cylindrical shells are widely used in many industrial sectors as light structural elements. Determination of their buckling strength under various types of loading conditions is a crucial work for engineering design. Due to the needs of research of crashworthiness, dynamic buckling of cylindrical shells subjected to the strong axial impact becomes a frontier issue in recent years. The axial impact is a very complex dynamic process because of the coupling of multiple effects. In this paper, the buckling mechanism of cylindrical shells subjected to axial impact and the influences of boundary conditions, and energy absorption properties have been investigated by experiments.

ABSTRACT: The dynamic buckling of circular cylindrical shells subjected to axial impact by a rigid body is discussed in this paper in accordance with the energy law. Accounting for the propagation of stress wave, the power series solution of this problem has been obtained by the power series approach. The critical buckling criterion of this problem is proposed by analyzing the characteristics of solution. The relationship between critical velocity and impacting mass, as well as other conclusions, are obtained by using theoretical analysis and numerical computation.

ABSTRACT: This research examines the effect of the tube-bending process on subsequent crashworthiness of aluminum alloy s-rail structures. Through experiments, the effects of bending process parameters, tube initial thickness, thickness changes, work hardening and bend radius on the energy absorption characteristics of s-rail impact structures are assessed. Finite element simulations of the manufacturing and impact testing of s-rail structures are developed to provide additional insight. The deformation history, including strains, thickness changes and residual stresses are transferred from the tube-bending models into the crash models. Through simulation, effects of thickness changes and work hardening on the energy absorption of s-rails are examined. The change in geometrical features of the s-rail due to a different bend radius, on crashworthiness of the s-rail structure was found to play a significant role in offsetting any potential increases in force and energy absorption due to work hardening and thickness changes in the material due to pre-bending. By not accounting for work hardening and thickness changes in the material due to the bending process during the modeling of the crash event, the predicted peak force as well as the energy absorption at the point of tearing was reduced by 25–30% and 18%, respectively.

Ashokanand Chathbai (Wichita State University, College of Engineering, Department of Mechanical Engineering, Wichita, Kansas, USA), “Parametric study of energy absorption characteristics of a rectangular aluminum tube wrapped with e-glass/epoxy”, Master’s Thesis, May 2007, URI: http://hdl.handle.net/10057/1119

ABSTRACT: Analysis of crashworthy structures has been a primary area of interest for many researchers for quite a few years now. The quest for a better energy absorbing structure or a better crashworthy structure has led researchers to carry out various analysis procedures experimentally and also by simulating the characteristics. E-glass fiber reinforced epoxy wrapped over aluminum tube has proven to possess better energy absorbing capabilities. This study attempts to analyze certain characteristics of such hybrid structures. This thesis examines the properties with respect to energy absorption of the abovementioned tubes when certain parameters such as ply orientation, angle of impact, speed of impact for different aspect ratios, are varied. The axial crushing behavior and the energy absorption capability of aluminum composite hybrid tube under quasi-static loading is studied using LS-Dyna finite element solver. A aluminum tube, externally wrapped with E-glass epoxy composite material with two layers and ply orientation of +/- 30deg., +/- 45deg. and 0/90deg., are used for finite element analysis. The speeds considered are 8mph, 15mph and 30mph. The angles of impact considered are 0deg., 15deg., and 30deg. The analysis is carried out for various permutations and combinations of the above mentioned Parameters, and the results obtained are studied and aims at optimum set of parameters for making the energy absorption of such hybrid structures.

ABSTRACT: Using a generalized quasi-continuum method, we characterize the post-buckling morphologies and energetics of thick multi-walled carbon nanotubes (MWCNTs) under uniaxial compression. Our simulations identify for the first time evolving post-buckling morphologies, ranging from asymmetric periodic rippling to a helical diamond pattern. We attribute the evolving morphologies to the coordinated buckling of the constituent shells. The post-buckling morphologies result in significantly reduced effective moduli that are strongly dependent on the aspect ratio. Our simulation results provide fundamental principles to guide the future design of high-performance, MWCNT-based nanodevices.

ABSTRACT: This paper presents the second of a series of solutions to the buckling of imperfect cylindrical shells subjected to an axial compressive load. In particular, the current problem reviewed is the case of a homogeneous cylindrical shell with random axisymmetric imperfections. The problem solution for the determination of the critical buckling load utilizes a statistical approach to define the random imperfections as opposed to the deterministic methods most often employed in the pressure vessel industry. The imperfections are treated as a random function of the axial (i.e., longitudinal) position on the shell. The Monte Carlo technique is utilized to create a large sample of random shell geometries from which to eventually calculate a critical buckling load for each randomly generated shell geometry. Having matched or predefined the statistical parameters (including the co-variance) of interest as determined from actual manufacturing statistics to the Monte Carlo simulation of shell geometries, the reliability of the critical buckling load is then calculated for the set of cylindrical shells with the random axisymmetric imperfections. The ASME Boiler and Pressure Vessel Code Section VIII fabrication tolerances as supplemented by ASME Code Case 2286-1 are reviewed and addressed in light of the findings of the current study and resulting solutions with respect to the critical buckling loads. The method and results described herein are in stark contrast to the “knockdown factor” approach currently utilized in ASME Code Case 2286-1. Recommendations for further study of the imperfect cylindrical shell are also outlined in an effort to improve on the current design rules regarding column buckling of large diameter shells designed in accordance with ASME Section VIII, Divisions 1 and 2 and ASME STS-1 in combination with the suggestions contained within Code Case 2286-1.

**ABSTRACT:** This paper presents the third of a series of solutions to the buckling of imperfect cylindrical shells subjected to an axial compressive load. In particular, the initial problem reviewed is the case of a homogeneous cylindrical shell of variable thickness that is of an axisymmetric nature. The equilibrium equations as first introduced by Donnell over seventy years ago are discussed and reviewed in establishing a basis for embarking upon a solution that utilizes finite difference methods to solve the resulting equilibrium and compatibility equations. The ultimate objective of these calculations is to achieve a quantitative assessment of the critical buckling load considering the small axisymmetric deviations from the nominal cylindrical shell wall thickness. Clearly in practice, large diameter, thin wall shells of revolution that form stacks are never fabricated with constant diameters and thicknesses over the entire length of the assembly. The method and results described herein are in stark contrast to the “knockdown factor” approach currently utilized in ASME Code Case 2286-1. The results obtained by finite difference method agree well with those published by Elishakoff and Williams for the prediction of buckling load.

**ABSTRACT:** This paper presents the comparison of reliability technique that employ Fourier series representations of random axisymmetric imperfections in axially compressed cylindrical shells with evaluations prescribed by ASME Section VIII, Division 2. The ultimate goal of the reliability type technique is to predict the buckling load associated with the axially compressed cylindrical shell. The representation of initial geometrical imperfections in the cylindrical shell requires the determination of appropriate Fourier coefficients. The buckling of cylindrical shells in any type of loading is sensitive to the form and amplitude of geometric imperfections present in the structure. Initial geometric imperfections have significant effect on the load carrying capacity of axisymmetrical cylindrical shells. Many deterministic and probabilistic techniques are there to predict shell behavior during buckling. Fourier decomposition is used to interpret imperfections as structural features can be easily related to the different components of imperfections. The mean vector and the variance-covariance matrix of Fourier coefficients are calculated from the simulated shell profiles. Recommendations for further use of Fourier coefficients through simulation by Monte Carlo Method are laid down. Large number of shells thus created can be used to calculate buckling stress for each shell. The probability of the ultimate buckling stress exceeding a predefined threshold stress can be calculated.

“Fourier Series Analysis of Cylindrical Pressure Vessel Subjected to External Pressure”, ASME 2009 Pressure
ABSTRACT: This paper presents the comparison of a reliability technique that employs a Fourier series representation of random asymmetric imperfections in a cylindrical pressure vessel subjected to external pressure. Comparison with evaluations prescribed by the ASME Boiler and Pressure Vessel Code, Section VIII, Division 2 Rules for the same shell geometries are also conducted. The ultimate goal of the reliability type technique is to predict the critical buckling load associated with the chosen cylindrical pressure vessel. Initial geometric imperfections are shown to have a significant effect on the load carrying capacity of the example cylindrical pressure vessel. Fourier decomposition is employed to interpret imperfections as structural features that can be easily related to various other types of defined imperfections. The initial functional description of the imperfections consists of an axisymmetric portion and a deviant portion, which are availed in the form of a double Fourier series. Fifty simulated shells generated by the Monte Carlo technique are employed in the final prediction of the critical buckling load. The representation of initial geometrical imperfections in the cylindrical pressure vessel requires the determination of appropriate Fourier coefficients. Multi-mode analyses are expanded to evaluate a large number of potential buckling modes for both predefined geometries and associated asymmetric imperfections as a function of position within a given cylindrical shell. The probability of the ultimate buckling stress that may exceed a predefined threshold stress is also calculated. The method and results described herein are in stark contrast to the “knockdown factor” approach as applied to compressive stress evaluations currently utilized in industry. Recommendations for further study of imperfect cylindrical pressure vessels are also outlined in an effort to improve on the current design rules regarding column buckling of large diameter pressure vessels designed in accordance with ASME Boiler and Pressure Vessel Code, Section VIII, Division 2 and ASME STS-1.

ABSTRACT: This paper presents the first of a series of solutions to the buckling of imperfect cylindrical shells subjected to an axial compressive load. The initial problem is the case of a homogeneous cylindrical shell of variable thickness that is of an axisymmetric nature. The equilibrium equations as first introduced by Donnell over 70 years ago are thoroughly presented as basis for a solution employing perturbation methods. The ultimate objective of these calculations is to achieve a quantitative assessment of the critical buckling load considering the small axisymmetric deviations from the nominal shell wall thickness. Clearly in practice, large diameter thin wall shells of revolution that form stacks (as found in flue gas desulphurization absorber assemblies) are never fabricated with constant diameters and thicknesses over the entire length of the assembly. As such, ASME Boiler and Pressure Vessel Code Section VIII shell thickness tolerances as supplemented by ASME Code Case 2286-1 are reviewed and addressed in comparison to the resulting solutions with respect to the critical buckling loads. The method and results described herein are in stark contrast to the “knockdown factor” approach currently utilized in ASME Code Case 2286-1. Recommendations for further study of the imperfect cylindrical shell are also outlined in an effort to improve on the current rules regarding column buckling of large diameter shells designed in accordance with ASME Section VIII, Divisions 1 and 2 and ASME STS-1 in combination with the suggestions contained within Code Case 2286-1.

“Optimum design of cylindrical shell under buckling pressure”, Journal of Lanzhou University, 2003-01,
doi: CNKI:SUN:LDZK.0.2003-01-005
ABSTRACT: The mechanism of bifurcation instability of shells is the instant course for shell-structure design. On the basis of energy criterion, the buckling lateral pressures of cylindrical shell with variable thickness and arbitrary axisymmetrical boundary conditions have been derived. The optimum model involves the maximum buckling pressure of the cylindrical shell subjected to constraints of the volume that is constant and to strength condition. Numerical results show the effectiveness of the method reported.

ABSTRACT: This paper investigates the combined torsional buckling of multi-walled carbon nanotubes (MWNTs) coupling with radial pressures. The analysis is based on the continuum mechanics model, and the effect of the van der Waals interaction between adjacent tubes is taken into account. A buckling condition is derived for determining the critical shear membrane force under combined torsional buckling, which clearly indicates the role of radial pressures. The critical shear membrane force and the buckling mode are worked out for three typical MWNTs subjected to various internal pressure or external pressure. It is shown that the effect of internal pressure or external pressure on the critical shear membrane force for combined torsional buckling of MWNTs is related to the types of MWNTs. This effect is strong for thin MWNTs, moderate for thick MWNTs and small for solid MWNTs. Numerical results also indicate that the buckling mode corresponding to the critical shear membrane force of MWNTs is unique and only dependent on the structure of MWNTs. In particular, for combined torsional buckling of MWNTs with very small internal pressure or external pressure, the buckling mode is just that for the corresponding pure torsional buckling.

doi:10.1016/j.ijsolstr.2007.11.00
ABSTRACT: This paper reports the results of an investigation on combined torsional buckling of multi-walled carbon nanotubes (MWNTs) under combined torque, axial loading and radial pressures based on the continuum mechanics model, which takes into account the effect of the van der Waals interaction between adjacent tubes. A buckling condition is derived for determining the critical buckling torque and associated buckling mode. In particular, for combined torsional buckling of double-walled carbon nanotubes, an explicit expression is
obtained and some detailed results are demonstrated. According to the innermost radius-to-thickness ratio, MWNTs are classified into three types: thin, thick, and (almost) solid. Numerical results are worked out for the critical buckling torque and associated buckling mode for all the three types of MWNTs subjected to various axial stresses (axial tensile stresses or axial compressive stresses), internal pressures, and external pressures. It is shown that, the axial tensile stress or the internal pressure will make the MWNTs resist higher critical buckling torque, while the axial compressive stress or external pressure will lead to a lower critical buckling torque. The effect of axial stress (axial tensile stress or axial compressive stress) on the critical buckling torque of MWNTs is very small for all the three types of MWNTs, while the effect of the internal pressure or external pressure is related to the types of MWNTs, which is strong for the thin MWNTs, moderate for the thick MWNTs, and small for the solid MWNTs. Numerical results also indicate that, the associated buckling mode is unique and dependent on the structure of MWNTs. Especially, for combined torsional buckling of MWNTs with very small axial stress and radial pressures, the buckling mode is just the one for the corresponding pure torsional buckling.

ABSTRACT: This paper investigates the torsional buckling of multi-walled carbon nanotubes under combined axial and radial loadings based on the continuum mechanics model. In particular, an explicit expression is obtained for the torsional buckling of double-walled carbon nanotubes (DWNTs) under combined loadings. Numerical results show that axial tensile stress or internal pressure will make DWNTs resist higher critical shear membrane force, while axial compressive stress or external pressure will lead to a lower critical shear membrane force. Further, for torsional buckling of DWNTs coupling with small axial stress and internal pressure or external pressure, the effect of the axial stress, internal pressure or external pressure on the critical shear membrane force is linear, and the associated buckling wave numbers are unique and the same as that under corresponding pure torque.

Chao Guozhong Zhao Huilin (Department of Civil Engineering, Southeast University, China?), “The theoretical and experimental studies of elastic buckling of single layer sphere grids shell”, Journal of Southeast University (Natural Science Edition), 1988-01, doi: cnki:ISSN:1001-0505.0.1988-01-004, ABSTRACT: This paper presents the theoretical and model experimental studies of elastic buckling of single layer sphere grids shell. A finite element method program of elastic buckling of the structure was finished with consideration of large displacement behaviour. The analysis of the model structure was made by use of the program. The analysis results show that the analysis theory is reliable and the program is resultful. This paper has discussed this analysis theory and showed the further research direction.

ABSTRACT: A linear analysis method is offered to predict the theoretical elastoplastic buckling of stringer
stiffened cylindrical shells subjected to longitudinal loading. Welding residual stresses are taken into account in the calculation, but effects of geometrical imperfections and pre-buckling displacements are ignored. The examples analysed show a good correlation between the analytical results and those obtained experimentally with stocky models of moderate geometrical imperfections.

ABSTRACT: Based on fundamental assumptions, an analysis of the constitutive relations between the internal forces and deformations of discrete rectangular reticulated structures is given. On the basis of this, an equivalent continuum model is adopted and the application of the principle of virtual work leads to non-linear governing equations and corresponding boundary conditions.

ABSTRACT: This paper deals with non-linear vibration of rectangular reticulated shallow shells by applying non-linear elastic theory of such structures established by the author. Using the assumed (generalized) Fourier series solutions for transverse deflection (lattice joint transverse displacement) and force function, weighted means of the trial functions lead to the relations among the coefficients related to the solutions and vibration equation which determines the unknown time function, and then the amplitude-frequency relations for free vibration and forced vibration due to harmonic force are derived with the aid of the regular perturbation method and Galerkin procedure, respectively. Numerical examples are given as well.

ABSTRACT: An asymptotic solution is formulated for non-linear buckling of elastically restrained imperfect shallow spherical shells continuously supported on a non-linear elastic foundation. The asymptotic iteration method is introduced to result in a cubic non-linear analytical relation between the external load and central transverse displacement (deflection) of the structures incorporating the effects of geometrical imperfection, edge-restraint coefficients, moduli of foundation and characteristic geometrical parameter. The resulting expression can be used easily to evaluate the effects of these factors on buckling behaviors. Numerical examples are given, and comparisons of the available results show validity of the method suggested in the present work.

ABSTRACT: Non-linear buckling behaviors of single-layer squarely-reticulated shallow spherical shells with geometrical imperfections and continuously supported on springs have been studied in this paper. The shell structure is subjected to uniform vertical load and the imperfection has been assumed to have the same mode as that of transverse displacement of the shell, but the specific form of mode has not been presumed. Using the asymptotic iteration method, an analytical solution is obtained on the basis of a theoretical model proposed by the author. The resulting nondimensional expression between the external load and central transverse displacement (deflection) can be conveniently adopted to analyze non-linear behaviors of the structures and evaluate the effects of various parameters (e.g., stiffness of spring, imperfect factor and boundary conditions, etc.) on buckling behaviors. Numerical examples are given and compared with available results. Effects of several factors are also demonstrated.

ABSTRACT: The paper describes a combined analytical, numerical and experimental analysis on the compressive strength of hexagonal chiral honeycombs due to elastic buckling of the unit cells under flatwise compressive loading. Hexagonal chiral honeycombs are cellular structures composed noncentresymmetric unit cells, with an in-plane negative Poisson _s ratio (NPR) with a value of "_1. Cylinders connected by tangent ligaments at 60∞ degrees compose the unit cells. Approximated analytical models are proposed for the purpose of initial design assuming the main contribution to the elastic collapse stress being given by the nodes, and considering also the superposition of the critical elastic loads of each component of the unit cell. The models are expressed in terms of nondimensional geometric unit cell parameters (ligament to cylinder radius aspect ratio and relative density), and core material properties. Finite element calculations using shell and brick elements are also performed on unit cell models with periodic boundary conditions using linear bifurcation buckling analysis. The analytical and numerical results are compared with the outcome of a series of experimental flatwise compressive tests carried out on chiral honeycomb samples manufactured using rapid prototyping technique in PA sintered powder and ABS plastics. The comparison shows good convergence between the sets of results, and highlights the specific deformation mechanisms of the hexagonal chiral honeycomb cell.

ABSTRACT: The torsion of carbon nanotubes is studied by molecular dynamics simulations. The torsional behavior of a chiral single-walled carbon nanotube (SWCNT) is dependent on the loading directions due to its structural asymmetry. The critical buckling shear strain of a SWCNT in one direction may be 1.8 times higher than that in the opposite direction. This means that one can choose the most appropriate SWCNT for his special purpose in designing a torsional component (e.g., oscillators and springs) of nanomechanical devices using carbon nanotubes. Meanwhile, the finding indicates that a simple thin shell model is not suitable for predicting
torsional behavior of small SWCNTs at large strains.

ABSTRACT: The impact behaviour of tubular hydroformed axial crush tubes is examined. The results of dynamic axial crush tests performed with both non-hydroformed and hydroformed AA5754 aluminum alloy tubes were compared to predictions from finite element models. Explicit dynamic finite element simulations of the hydroforming and crash events were carried out with particular attention to the transfer of forming history from the hydroforming simulations to the crash models. The values of tube thickness, work hardening, and residual stresses at the end of the hydroforming simulations were used as the initial state for the crash models. In general, simulations performed using the von Mises yield criterion with isotropic material behaviour gave reasonable predictions when compared to experimental data. It was found that it was important to account for the forming history of the hydroforming operation in the axial crush models. The results showed that work hardening resulting from hydroforming is beneficial to increasing the energy absorption during crash, whereas thickness reduction decreased the energy absorption. Residual stresses had little effect on the energy absorption characteristics. It was also shown that the energy absorption characteristics of tubes with the same mass could vary greatly by adjusting the geometry of the tube and the amount of work hardening experienced by the tube during hydroforming.

ABSTRACT: The mechanism of atherosclerotic plaque rupture is not fully understood. Mechanical stress may be one of the factors contributing to the instability of the fibrous plaque cap. The existence of a severe stenosis may lower the transmural pressure enough to cause the collapse of arteries leading to high concentrated compressive and tensile stresses. This study presents quantitative estimates of the stresses and deformations in the collapsed thick-walled artery. The results of large deformation finite element calculations identify the locations of the high stress concentrations and their magnitudes which cannot be precisely predicted under a thin-wall assumption. The maximum compressive stress calculated reached 80% of the Young's modulus for fairly small negative transmural pressures. Results are useful to predict likely locations of the plaque cap rupture due to compressive stresses. The tube law of area as a function of transmural pressure showed a large discrepancy from a thin-wall calculation. The buckling pressure calculated for the outer-to-inner wall surface radius ratio of 1.60 was nearly 30% lower than that of the elastic thin-wall buckling theory. An increase in eccentricity further reduced this buckling pressure. The results indicate that a thick plaque which is eccentric increases the likelihood of collapse of stenotic arteries.

Riaz, M., Fulati, A., Amin, G., Alvi, N. H., Nur, O., Willander, M. (Department of Science and Technology,
ABSTRACT: Buckling and elastic stability study of vertical well aligned ZnO nanorods grown on Si substrate and ZnO nanotubes etched from the same nanorods was done quantitatively by nanoindentation technique. The critical load, modulus of elasticity, and flexibility of the ZnO nanorods and nanotubes were observed and we compared these properties for the two nanostructures. It was observed that critical load of nanorods (2890 microN) was approximately five times larger than the critical load of the nanotubes (687 microN). It was also observed that ZnO nanotubes were approximately five times more flexible (0.32 nm/microN) than the nanorods (0.064 nm/microN). We also calculated the buckling energies of the ZnO nanotubes and nanorods from the force displacement curves. The ratio of the buckling energies was also close to unity due to the increase/decrease of five times for one parameter (critical load) and increase/decrease of five times for the other parameter (displacement) of the two samples. We calculated critical load, critical stress, strain, and Young modulus of elasticity of single ZnO nanorod and nanotube. The high flexibility of the nanotubes and high elasticity of the ZnO nanorods can be used to enhance the efficiency of piezoelectric nanodevices. We used the Euler buckling model and shell cylindrical model for the analysis of the mechanical properties of ZnO nanotubes and nanorods.

Todd O. Williams and Frank L. Addessio (Los Alamos National Laboratory, Theoretical Division, Fluid Dynamics T-3, MSB216, Los Alamos, NM 87545, U.S.A.), “A general theory for laminated plates with delaminations”, International Journal of Solids and Structures, Vol. 34, No. 16, June 1997, pp. 2003-2024, ABSTRACT: An approximate analytical model for the behavior of a laminated composite plate in the presence of delaminations and other local effects is presented. The model is based on a generalized displacement formulation implemented at the layer level. The governing equations for a layer are obtained using the principle of virtual work. These governing equations for a layer are used in conjunction with the explicit satisfaction of both the interfacial traction continuity and the interfacial displacement jump conditions between layers to develop the governing equations for a laminated composite plate, including delaminations. The fundamental unknowns in the theory are the displacements in the layers and the interfacial tractions. The theory is sufficiently general that any constitutive model for the interfacial fracture (i.e. delamination) as well as for the layer behavior can be incorporated in a consistent fashion into the theory. The interfacial displacement jumps are expressed in an internally consistent fashion in terms of the fundamental unknown interfacial tractions. The current theory imposes no restrictions on the size, location, distribution, or direction of growth of the delaminations. Therefore, the theory can predict the initiation and growth of delaminations at any location as well as interactive effects between delaminations at different locations within the laminate. Pagano's exact solution for the cylindrical bending of a laminated plate has been modified to include the effects of delamination. An interface model, which expressed the displacement jump as a linear function of the surface tractions, was implemented into this modification of the exact solution. This extension was used to validate the approximate plate theory. The correlation between the approximate approach and the exact solution is seen to be excellent. The approximate plate theory is seen to give very accurate predictions for the interfacial tractions in a direct and consistent fashion, i.e. without the need to use integration of the pointwise equilibrium equations. This allows the interfacial displacement jumps in the presence of delaminations to be modeled accurately. It is seen that these displacement jumps have a significant effect on both the macroscopic and microscopic behavior of a laminated plate.
ABSTRACT: A generalized theory for laminated plates, including delamination, is developed. The laminate model is based on a generalized displacement formulation implemented at the layer level. The equations of motion for a layer, which are explicitly coupled with both the interfacial traction continuity and the interfacial displacement jump conditions between layers, are used to develop the governing equations for a laminated composite plate. The delamination behavior can be modeled using any general constitutive fracture law. The interfacial displacement jumps are expressed in an internally consistent fashion in terms of the fundamental unknown interfacial tractions. The current theory imposes no restrictions on the size, location, distribution, or direction of growth of the delaminations. Therefore, the theory can predict the initiation and growth of delaminations at any location as well as interactive effects between delaminations at different locations within the laminate. The proposed theory is used to consider the dynamic response of laminated plates in cylindrical bending. First it is shown that the dynamic implementation agrees well with the exact predictions of a plate under static loading conditions. Static, cylindrical bending is considered to validate the numerical implementation. Next, different dynamic loading cases are considered. First, the required level of discretization through the thickness of the laminate necessary to accurately capture the wave propagation characteristics for monotonic tensile loading transverse to the plate is determined. Next, the influence of the delamination on the free vibration behavior of a plate is considered. It is shown that the presence of delaminations can result in significant deviations from the perfectly bonded free vibration behavior. Finally, the plate is subjected to dynamic loading conditions that demonstrate the influence of internal wave interactions on the overall behavior of the plate.

ABSTRACT: A new type of plate theory for the nonlinear analysis of laminated plates in the presence of delaminations and other history-dependent effects is presented. The formulation is based on a generalized two length scale displacement field obtained from a superposition of global and local displacement effects. The functional forms of global and local displacement fields are arbitrary. The theoretical framework introduces a unique coupling between the length scales and represents a novel two length scale or local-global approach to plate analysis. Appropriate specialization of the displacement field can be used to reduce the theory to any currently available, variationally derived, displacement based (discrete layer, smeared, or zig-zag) plate theory. The theory incorporates delamination and/or nonlinear elastic or inelastic interfacial behavior in a unified fashion through the use of interfacial constitutive (cohesive) relations. Arbitrary interfacial constitutive relations can be incorporated into the theory without the need for reformulation of the governing equations. The theory is sufficiently general that any material constitutive model can be implemented within the theoretical framework. The theory accounts for geometric nonlinearities to allow for the analysis of buckling behavior. The theory represents a comprehensive framework for developing any order and type of displacement based plate theory in the presence of delamination, buckling, and/or nonlinear material behavior as well as the interactions between these effects. The linear form of the theory is validated by comparison with exact solutions for the behavior of perfectly bonded and delaminated laminates in cylindrical bending. The theory shows excellent correlation with the exact solutions for both the inplane and out-of-plane effects and the displacement jumps due to delamination. The theory can accurately predict the through-the-thickness distributions of the transverse stresses.

without the need to integrate the pointwise equilibrium equations. The use of a low order of the general theory, i.e. use of both global and local displacement fields, reduces the computational expense compared to a purely discrete layer approach to the analysis of laminated plates without loss of accuracy. The increased efficiency, compared to a solely discrete layer theory, is due to the coupling introduced in the theory between the global and local displacement fields.

ABSTRACT: The bifurcation buckling problem of laminated composite plates is formulated within the framework of a multilength scale plate theory. This theory is a combination of single-layer and layer-wise theories. It is generated by representing the displacement as the sum of global and local effects that introduce a coupling between the two length scales. Comparisons between the presently predicted buckling loads of homogeneous and orthotropic laminated plates and the exact solutions show a very good correlation. Furthermore, the theory accurately predicts the buckling load of symmetric cross-ply plates as compared with the results of a layer-wise approach. This accuracy is achieved with reduced computation expense. The global–local plate theory is general enough to incorporate delamination effects. As a result of the inclusion of these effects, the buckling loads of plates with imperfect interlaminar bonding are predicted.

INTRODUCTION: The present paper summarizes a series of recent investigations that were conducted by the authors which address the analysis of bifurcation buckling, parametric stability, dynamic buckling and thermally induced dynamic buckling of composite plates and shells. Various types of material behavior are assumed including linearly elastic, nonlinearly elastic and thermo-inelastic.

References listed at the end of the paper:

ABSTRACT: A new type of general, theoretical framework for the development of comprehensive, nonlinear, multiscale plate theories for laminated structures is presented. The theoretical framework utilizes a generalized two scale description of the displacement field based on a superposition of global and local effects where the functional forms for the global and local displacement fields are arbitrary. The two scale nature of theory allows it to explicitly consider the layered nature of the structure. The subsequent development of the governing equations for the theory is carried out using the general nonlinear equations of continuum mechanics referenced to the initial configuration. The equations of motion and the lateral surface boundary conditions for the theory...
are derived using the method of moments over the different scales subject to an orthogonality constraint. The theory satisfies the interfacial constraints and the top and bottom surface boundary conditions in a strong sense. Delamination effects are incorporated into the theory through the use of cohesive zone models (CZMs). Arbitary CZMs can be incorporated into the theory without the need for reformulation of the governing equations. The theory is formulated in a sufficiently general fashion that any type of history-dependent material can be used to describe the inelastic response of the materials composing the layers. Furthermore, as a result of the multiscale nature of the theory it can be specialized to single scale theories of the equivalent single layer (ESL) or discrete layer (DL) types in a unified fashion and without the need for any reformulation. While the starting point for the proposed theory is the same as used by Williams [Williams, T.O., 1999. A generalized multilength scale nonlinear composite plate theory with delamination. Int. J. Solid Struct. 36, (20) 3015–3050; Williams, T.O., 2001. Efficiency and accuracy considerations in a unified plate theory with delaminations. Comp. Struct. 52, (1) 27–40; Williams, T.O., 2005. A generalized, multilength scale framework for thermo-diffusionally-mechanically coupled, nonlinear, laminated plate theories with delaminations. IJSS 42, (5–6) 1465–1490] the subsequent formulation is significantly different. The differences in the two theories allow the currently proposed theory to improve on the capabilities of the previous theory; particularly in the satisfaction of the traction continuity constraints at the interfaces. It is shown that the theory is capable of providing accurate predictions for all of the fields in perfectly bonded and delaminated plates even for relatively low orders of displacement approximations. In particular, the theory is shown to provide accurate predictions for the transverse stresses that are continuous across the interfaces directly from the constitutive relations.

ABSTRACT: The initial imperfections criteria is used in the nonlinear finite element analysis, and the initial minute imperfect method is put forward to research the disturbance strategy of nonlinear bifurcation buckling. The basic thought, the step and the merits, and demerits of the method are analyzed. The method is used to research the behaviors of a truss dome, a Williams toggle frame and a K6 single-layer latticed dome. The model of the Williams toggle frame is experimented. Results indicate that the initial minute imperfect method is feasible and right. And it is disclosed that the reason of nonlinear bifurcation buckling is the initial minute imperfects of the actual structures.

Daniel King, “Collapse dynamics of ultrasound contrast agent microbubbles”, Ph.D dissertation, Mechanical Engineering, University of Illinois at Urbana-Champaign, February 2013

ABSTRACT: Ultrasound contrast agents (UCAs) are micron-sized gas bubbles encapsulated with thin shells on the order of nanometers thick. The damping effects of these viscoelastic coatings are widely known to significantly alter the bubble dynamics for linear and low-amplitude behavior; however, their effects on strongly nonlinear and destruction responses are much less studied. This dissertation examines the behaviors of single collapsing shelled microbubbles using experimental and theoretical methods. The study of their dynamics is particularly relevant for emerging experimental uses of UCAs which seek to leverage localized mechanical forces to create or avoid specialized biomedical effects. The central component in this work is the study of postexcitation rebound and collapse, observed acoustically to identify shell rupture and transient inertial
cavitation of single UCA microbubbles. This time-domain analysis of the acoustic response provides a unique method for characterization of UCA destruction dynamics. The research contains a systematic documentation of single bubble postexcitation collapse through experimental measurement with the double passive cavitation detection (PCD) system at frequencies ranging from 0.9 to 7.1 MHz and peak rarefactional pressure amplitudes (PRPA) ranging from 230 kPa to 6.37 MPa. The double PCD setup is shown to improve the quality of collected data over previous setups by allowing symmetric responses from a localized confocal region to be identified. Postexcitation signal percentages are shown to generally follow trends consistent with other similar cavitation metrics such as inertial cavitation, with greater destruction observed at both increased PRPA and lower frequency over the tested ranges. Two different types of commercially available UCAs are characterized and found to have very different collapse thresholds; lipid-shelled Definity exhibits greater postexcitation at lower PRPAs than albumin-shelled Optison. Furthermore, by altering the size distributions of these UCAs, it is shown that the shell material has a large influence on the occurrence of postexcitation rebound at all tested frequencies while moderate alteration of the size distribution may only play a significant role within certain frequency ranges. Finally, the conditions which generate the experimental postexcitation signal are examined theoretically using several forms of single bubble models. Evidence is provided for the usefulness of modeling this large amplitude UCA behavior with a size-varying surface tension as described in the Marmottant model; better agreement for lipid-shelled Definity UCAs is obtained by considering the dynamic response with a rupturing shell rather than either a non-rupturing or nonexistent shell. Moreover, the modeling indicates that maximum radial expansion from the initial UCA size is a suitable metric to predict postexcitation collapse, and that both shell rupture and inertial cavitation are necessary conditions to generate this behavior. Postexcitation analysis is found to be a beneficial characterization metric for studying the destruction behaviors of single UCAs when measured with the double PCD setup. This work provides quantitative documentation of UCA collapse, exploration into UCA material properties which affect this collapse, and comparison of existing single bubble models with experimentally measured postexcitation signals.

ABSTRACT: This dissertation reports the results of an analytical, numerical and experimental investigation dealing with hot-rolled I-section steel members acted by a combination of major-axis bending and axial tension (“beams subjected to tension”), which is relatively rare in practice and, therefore, has received little attention from researchers in the past. In particular, there are no guidelines for the design against buckling ultimate limit states of such members (only their cross-section resistance is checked). This means that the axial tension favourable effect on lateral-torsional buckling/failure is neglected, thus leading to over-conservative designs – indeed, a beam subjected to axial tension is currently designed against lateral-torsional failure as a “pure beam”.

In order to acquire scientific knowledge and provide design guidance on this topic, the lateral-torsional stability, failure and design of hot-rolled steel I-beams with fork-type end supports and acted by simple transverse loadings (mostly applied end moments) and various axial tension values are addressed in this work. After developing and validating an analytical expression to calculate critical buckling moments of beams under uniform bending and axial tension, numerical (beam finite element) buckling results are presented for the non-uniform bending cases. Then, two full-scale tests involving a narrow and a wide flange beams under eccentric tension are described and their results are used to develop shell and beam finite element models – the latter are subsequently employed to perform a parametric study aimed at gathering a fairly extensive ultimate strength/moment data bank. Finally, this data bank is used to assess the merits of a design approach proposed in this work for beams subjected to tension and collapsing in lateral-torsional modes – this design approach, which consists of slightly modifying the current procedure prescribed in Eurocode 3 to design beams against lateral-
torsional failure, is shown to provide ultimate moment estimates that correlate very well with the values obtained from the numerical simulations. The predictions of the proposed design approach are also compared with those of the design procedure included in the ENV version of Eurocode 3 (but later removed).

ABSTRACT: This thesis investigates the behavior of small diameter composite tubes that are exposed to external pressure. Composite tubes have a superior strength to weight ratio compared to steel tubes. The oil industry is facing new challenges and the demand for more robust materials is increasing. Prior to substituting steel material with composites in tubes, it is important to gain knowledge about the behavior of composite tubes and develop reliable analytical methods.

An experimental and analytical study of small diameter carbon fiber tubes was carried out in this thesis. The tubes were made using filament winding with a layup of [+75] and a wall thickness of 1.5 mm. The tubes were tested under external pressure with optical fibers attached to measure the strain during the tests. A linear buckling analysis and Riks analysis was done using the Abaqus solver to predict buckling and compare strain results to the experimental tests. The transverse and longitudinal Young’s modulus were experimentally found and implemented into the finite element analysis.

The predicted buckling value deviated significantly from the experimental tests. In the experimental tests, the tubes buckled at 52.5% lower pressure than what was expected from the finite element analysis. The strain readings from the optical fibers gave higher values than the strains from the finite element analysis at equal
pressures. However, strain at equal pressure might not be comparable because the tube from the analysis could withstand higher pressure before it started showing tendencies of buckling.

In conclusion, the analytical model in this thesis has its weaknesses and can be further improved to capture the imperfections of the tube more accurately.

ABSTRACT: The finite element method has been employed to study the effects of different boundary conditions on the axial buckling of multiwall carbon nanotubes (MWCNTs). Unlike previous works, both homogeneous and heterogeneous end constraints are considered for the constituent tubes of various MWCNTs comprising shell-type (i.e., the length-to-diameter ratio L/D'<10), beam-type (i.e., L/D'>10), and the two different types of constituent tubes. The results show that clamping the individual tubes of simply supported or free MWCNTs exerts a variety of influences on their buckling behaviors depending on the type of the MWCNTs, the position, and the number of the clamped tubes. Clamping the outermost tube can enhance the critical buckling strain up to four times of its original value and can shift the buckling modes of those MWCNTs consisting both shell- and beam-type tubes. In contrast, little difference can be observed when simply supported ends of MWCNTs are replaced by free ends or vice versa. Explicit buckling mode shapes obtained using the finite element method for various physically realistic cases have been shown in the paper.

M. Elgaaly (Civil and Architectural Engineering Department, Drexel University, 32nd and Chestnut Streets, Philadelphia, PA, USA), “Post-buckling behavior of thin steel plates using computational models”, Advances in Engineering Software, Vol. 31, Nos. 8-9, August 2000, pp. 511-517, doi:10.1016/S0965-9978(00)00037-5

ABSTRACT: Thin plates loaded in plane will buckle at very small loads, and due to unavoidable out-of-plane imperfections, the theoretical buckling load cannot be observed experimentally. If the plate is adequately supported along its boundaries, it will be able to carry a much higher load than the theoretical buckling load. Computational models can be used to study the post buckling behaviour of thin plate structures up to failure. Failure of such structures is usually due to large out-of-plane deflections, yielding, and rupture. Therefore, the computational model should include the effects of geometric and material nonlinearities. In this paper, the nonlinear finite element analysis program NONSAP and ANSR-III were modified and used in the analysis. Since these programs did not include the suitable elements and material properties to conduct the subject study, new elements and new material properties were added to the programs. In particular, a thin shell element was added and the solution routines were modified to improve its accuracy and efficiency. The modified programs were used on a Super Computer to calculate the post buckling strength of stiffened and un stiffened plates subjected to uniaxial compression, and plates subjected to in plane bending or shear. Crippling of plates subjected to in-plane or eccentric edge compressive loads was also examined. The results from the computational models were compared with test results and reasonable agreements were obtained. A computational model was developed for a multi-story thin steel plate shear wall subjected to cyclic loading and the results from the model were compared with experimental results, and again agreement was achieved.

Zhi-Min Li (School of Ocean and Civil Engineering, Shanghai Jiao Tong University, Shanghai, 200030, People’s Republic of China), “Postbuckling of a shear-deformable anisotropic laminated cylindrical shell under

ABSTRACT: A postbuckling analysis is presented for a shear-deformable anisotropic laminated cylindrical shell of finite length subjected to external pressure in thermal environments. The material properties are expressed as linear functions of temperature. The governing equations are based on Reddy’s higher-order shear-deformation shell theory with the von Karman-Donnell-type kinematic nonlinearity. The nonlinear prebuckling deformations and initial geometric imperfections of the shell are both taken into account. The boundary-layer theory of shell buckling, which includes the effects of nonlinear prebuckling deformations, large deflections in the postbuckling region, and the initial geometric imperfections of the shell, is extended to the case of shear-deformable anisotropic laminated cylindrical shells under lateral or hydrostatic pressure in thermal environments. The singular perturbation technique is employed to determine the interactive buckling loads and postbuckling equilibrium paths. The results obtained show that the variation in temperature, layer setting, and the geometric parameters of such shells have a significant influence on their buckling load and postbuckling behavior.

ABSTRACT: The nonlinear buckling and postbuckling of a shear-deformable anisotropic laminated cylindrical panel of finite length is investigated based on a boundary-layer theory for buckling. The layers of the panel are assumed to be linearly elastic. The governing equations are based on Reddy’s higher-order shear deformation theory of shells and include the von Karman-type kinematic nonlinearity and extension/twist, extension/flexure, and flexure/twist couplings. The nonlinear prebuckling deformations and the initial geometric imperfections of the panel are both taken into account. The postbuckling behavior of the panel under axial compression is analyzed. A singular perturbation technique is employed to determine its buckling loads and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling behavior of perfect and imperfect moderately thick anisotropic laminated cylindrical panels with different geometric parameters and stacking sequences. The new finding reveals that there arises a compressive stress along with an associate shear stress and twisting when a moderately thick anisotropic laminated cylindrical panel is subjected to axial compression.

Zhi-Min Li, Zhong-Qin Lin and Guan-Long Chen (School of Mechanical Engineering and State Key Laboratory of Mechanical System and Vibration, Shanghai Jiao Tong University, Shanghai 200240, China), “Postbuckling of shear deformable geodesically stiffened anisotropic laminated cylindrical shell under external pressure”, J. Pressure Vessel Technology, Vol. 133, No. 2, February 2011, DOI: 10.1115/1.4001742

ABSTRACT: A boundary layer theory for buckling and postbuckling of anisotropic laminated thin shells is extended to shear deformable stiffened anisotropic laminated shells. A postbuckling behavior is investigated for a shear deformable anisotropic laminated cylindrical shell with geodesical stiffener of finite length subjected to lateral or hydrostatic pressure. The material of each layer of the shell is assumed to be linearly elastic, anisotropic, and fiber-reinforced. The governing equations are based on a higher-order shear deformation shell theory with von Kármán–Donnell-type of kinematic nonlinearity and including the extension/twist, extension/flexural, and flexural/twist couplings. The nonlinear prebuckling deformations and initial geometric imperfections of the shell are both taken into account. A singular perturbation technique is employed to determine the buckling pressure and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling response of perfect and imperfect, moderately thick, geodesically stiffened shells, axial and ring stiffened shells, and unstiffened shells with different values of shell parameters and stacking sequence. The results confirm that there exists a circumferential stress along with an associate shear stress when the shell is subjected to lateral pressure. The postbuckling equilibrium path is stable for the moderately long shell under external pressure and the shell structure is virtually imperfection-insensitive.

ABSTRACT: A mixed finite-element algorithm is proposed to study the dynamic behavior of loaded shells of revolution containing a stationary or moving compressible fluid. The behavior of the fluid is described by
potential theory, whose equations are reduced to integral form using the Galerkin method. The dynamics of the shell is analyzed with the use of the variational principle of possible displacements, which includes the linearized Bernoulli equation for calculating the hydrodynamic pressure exerted on the shell by the fluid. The solution of the problem reduces to the calculation and analysis of the eigenvalues of the coupled system of equations. As an example, the effect of hydrostatic pressure on the dynamic behavior of shells of revolution containing a moving fluid is studied under various boundary conditions.

ABSTRACT: We consider a finite element algorithm intended to study the dynamic behavior of an elastic cylindrical shell filled with an immovable or flowing fluid. To describe the fluid, we use the perturbed velocity potential whose equations with the corresponding boundary conditions are solved by the Bubnov-Galerkin method. To describe the shell, we use the variation principle, which includes the linearized Bernoulli equation for calculating the hydrodynamic pressure acting on the shell on the side of the fluid. Solving the problem is reduced to calculating and analyzing the eigenvalues of the coupled system of equations obtained as a result of combining the equations for the perturbed velocity potential and the shell displacements. We consider several test problems in which, along with the comparison of the computational results with the earlier published experimental, analytic, and numerical data, we also study the dynamic behavior of the “shell-fluid” system for various boundary conditions for the perturbed velocity potential.

ABSTRACT: A finite-element algorithm is proposed to investigate the dynamic behavior of elastic shells of revolution containing a quiescent or a flowing inviscid fluid in the framework of linear theory. The fluid behavior is described using the perturbed velocity potential. The shell behavior is treated in the framework of the classical shell theory and variational principle of virtual displacements incorporating a linearized Bernoulli equation for calculation of hydrodynamic pressure acting on the shell. The problem reduces to evaluation and analysis of the eigenvalues in the connected system of equations obtained by coupling the equations for velocity perturbations with the equations for shell displacements. For cylindrical shells, the results of numerical simulations are compared with recently published experimental, analytical and numerical data. The paper also reports the results of studying the dynamic behavior of shells under various boundary conditions for the perturbed velocity potential. The investigation made for conical shells has shown that under certain conditions an increase in the cone angle can change a divergent type of instability to a flutter type.

ABSTRACT: The finite element method is applied to analyze a stationary or rotating cylindrical shell containing a co-rotating compressible fluid. The motion of the rotating fluid is described in the framework of
the potential theory. The behavior of shells is analyzed using the classical shell theory. It has been found that the loss of stability in the stationary shells occurs in the form of a flutter. It has been shown that in the case of rotating shells the loss of stability is prevented by taking into account the initial circumferential tension caused by the centrifugal forces.

Oñate, J. Oliver and A. Huerta (Eds), Barcelona, Spain, 2014

PARTIAL INTRODUCTION: The plastic collapse limit and the shakedown limit which define the load-carrying capacity of structures are important in assessing the structural integrity. Due to the high expenses of experimental setups and the time consuming full elastic-plastic cyclic loading analysis, the determination of these limits by means of direct plasticity methods has been of great interest to many designers. Moreover, a certain evaluation of structural performance can be conducted only if the uncertainty of the actual load-carrying capacity of the structure is taken into consideration since all resistance and loading variables are random in nature. To ensure the safety of the structures to be designed, two approaches are normally used [1]. The classical approach fixes the values of the safety factors and chooses the values of the design variables to satisfy the safety conditions. All the variables involved are then assumed to be deterministic and fixed to particular quantiles, i.e. mean value or characteristic values [2]. The probability-based approach deals directly with realistic random variables to find the global probability of failure as the basic design criterion. Obviously, the later problem is more difficult since the evaluation of the probability of failure is not an easy task, especially when the structure has more than one failure mode (multimode failure or multiple design points). In this case, analysis of the structural system is required to evaluate the safety of the structure as a whole [1]. To handle problems of this kind, the real structure is sometimes modelled by an equivalent system in such a way that all relevant failure modes can be treated [2].

ABSTRACT: We present a simplified numerical method which can be used to predict efficiently the response of long thin plates under effects of residual stresses induced by production process such as rolling or continuous annealing. The principle consists in assuming harmonic buckling mode along the sheet length, and we consider Koiter-Budiansky post-buckling theory to compute the stress-deflection curve. In this way, only the width of the sheet has to be discretized by 1D finite elements. The size and shape of the flatness defects can be predicted efficiently and for a large number of cases. Various types of residual stresses and loadings can be accounted for. In particular, we will see the influence of the global traction on the buckling and post-buckling behavior. The numerical results are compared with experimental data and full numerical computations.

ABSTRACT: The paper summarizes a part of the activity currently carried out by the CEN/TC250 SC9 Committee, which is presently engaged in setting up the “Second Generation” of EC9 on aluminium structures. In particular, new expressions of imperfection reductions factors $\alpha$ for unstiffened shells are proposed. The new formulation, which is calibrated on the basis of simulation buckling data available in literature, corrects a small issue of the previous one, giving at the same time more reliable and consistent results.

ABSTRACT: A generalization of the Euler–Plateau problem to account for the energy contribution due to twisting of the bounding loop is proposed. Euler–Lagrange equations are derived in a parametrized setting and a buckling analysis is performed. A pair of dimensionless parameters govern buckling from a flat, circular ground state. While one of these is familiar from the Euler–Plateau problem, the other encompasses information about the ratio of the torsional rigidity to the bending rigidity, the twist density and the size of the loop. For sufficiently small values of the latter parameter, two separate groups of buckling modes are identified. However, for values of that parameter exceeding the critical twist density arising in Michell's study of the stability of a twisted elastic ring, only one group of buckling modes exists. Buckling diagrams indicate that a loop with greater torsional rigidity shows more resistance to transverse buckling. Additionally, a twisted flexible loop spanned by a soap film buckles at a value of the twist density less that the value at which buckling would occur if the soap film were absent.

ABSTRACT: A variety of technical applications, which use functionally graded materials (FGM) generates a need for stability analysis of structures made of these materials. Generally, these investigations have focused on natural vibrations and stability of empty shells and only a small number of research papers are devoted to functionally graded shells containing fluid. To our knowledge there is only one paper in the literature [1], which analyzes the shells filled with incompressible fluid. However, fluid conveying structures with slightly non-circular or non-circular cross-sections are extensively used in modern technologies. This is a strong reason for the development of advanced numerical algorithms allowing us to simulate their behavior. This paper presents a 3D formulation of the spectral problem and finite element algorithm (FEM) for its numerical implementation, designed to investigate natural vibrations and stability of prestressed functionally graded shells with arbitrary cross-section interacting with a quiescent or flowing compressible fluid. The motion of non-viscous fluid is described by the wave equation, which together with the impermeability condition and appropriate boundary conditions are transformed using the Bubnov–Galerkin method. Simulation of the shell with arbitrary cross-section is carried out on the assumption that its curvilinear surface is approximated to sufficient accuracy by a set of plane rectangular elements [2]. The strains are calculated using the relations of the Kirchhoff–Love’s thin shells theory. A mathematical formulation of the dynamic shell
problem has been developed by applying the variational principle of virtual displacements.

ABSTRACT: This paper is concerned with the numerical investigation of hydroelastic stability of stationary or rotating coaxial cylindrical shells, interacting with compressible fluid flows having the axial and tangential velocity components. The behavior of a flowing and rotating compressible fluid is considered in the framework of the potential theory. Elastic shells are described using the model of the classical shell theory. Numerical implementation was accomplished based on the semi-analytical variant of the finite element method. The paper presents the results of numerical experiments on the stability of shells interacting with different flow patterns for a variety of boundary conditions, geometrical dimensions, width of the annular gap between the outer and inner shell under the constraint of the outer shell rigidity. It has been shown that the elasticity of the outer shells has the greatest effect on the dynamic behavior of coaxial shells interacting with fluid flows having different combinations of velocity components.

ABSTRACT: A method aimed at the optimization of locally varying laminates is investigated. The structure is partitioned into geometrical sections. These sections are covered by global plies. A variable-length representation scheme for an evolutionary algorithm is developed. This scheme encodes the number of global plies, their thickness, material, and orientation. A set of genetic variation operators tailored to this particular representation is introduced. Sensitivity information assists the genetic search in the placement of reinforcements and optimization of ply angles. The method is investigated on two benchmark applications. There it is able to find significant improvements. A case study of an airplane’s side rudder illustrates the applicability of the method to typical engineering problems.

ABSTRACT: Interaction curves for vibration and buckling of thin-walled composite box beams with arbitrary lay-ups under constant axial loads and equal end moments are presented. This model is based on the classical lamination theory, and accounts for all the structural coupling coming from material anisotropy. The governing differential equations are derived from the Hamilton’s principle. The resulting coupling is referred to as triply flexural–torsional coupled vibration and buckling. A displacement-based one-dimensional finite element model with seven degrees of freedoms per node is developed to solve the problem. Numerical results are obtained for
thin-walled composite box beams to investigate the effects of axial force, bending moment, fiber orientation on the buckling loads, buckling moments, natural frequencies and corresponding vibration mode shapes as well as axial-moment–frequency interaction curves.

ABSTRACT: This report describes a systems approach to the nonlinear finite element analysis of shell structures. The research objective is to understand the structure a small language and computational environment should take so that matrix and nonlinear finite element computations can interact in a seamless manner. One four-node-thick shell finite element and one eight-node-thick shell finite element is formulated and implemented in ALADDIN [1]. The finite elements are based on a three-dimensional continuum formulation, and are simplified by assuming a flat element geometry. Numerical experiments are presented for in-plane displacements of a flat plate, and out-of-plane bending of a cantilever structure. In each case, material nonlinearities are modeled with bi-linear and Ramberg-Osgood stress-strain curves. The report concludes with recommendations for further work in the areas of nonlinear finite element solution procedures and enhancements to ALADDIN's problem-solving infrastructure.

ABSTRACT: By analysing the possible failure modes at each level, we propose a hierarchical design for highly efficient mechanical structures to withstand hydrostatic crush pressure, which becomes fractal in the limit of zero pressure. We deduce the Hausdorff dimension of these designs (over the range of length scales where this applies), and show that through changing the number of hierarchical levels, the power law scaling relation between applied external pressure and volume of material required can be altered in a systematic way. The design can be applied to arbitrary shapes, but for clarity we present two examples (cylinder and sphere).

ABSTRACT: A multi-level analysis of skin/stiffener debonding is used for the fuselage design of future aircraft during postbuckling. The specimens composed of a laminate (the skin) to which an over-thickness (the flange) had been added were subjected to four-point bending, which led to interface failure between the flange and the skin. These tests were performed with several configurations and parameters, such as the orientation of the plies located at the interface, temperature (-50, 20 and 70 deg.C), ageing and manufacturing mode: co-cured or co-
bonded. The flange shape (tapered or not) and thickness were also considered. Test data are presented and analyzed and critical configurations are identified. Finite element models were developed and the flange debonding loads computed, firstly by use of cohesive models and then through a fracture mechanics approach (Virtual Crack Closure Technique). In both cases, the Benzeggagh-Kenane criterion was selected and proved its efficiency but the fracture mechanics approach was an order of magnitude less time consuming, which will enable future modelling to include larger sizes.

ABSTRACT: In the framework of test analysis pyramid, large specimens were studied. To represent the bending behaviour during postbuckling, specimens composed of a plate with a stiffener were supported on five points and loaded transversely by two points, thus being subjected to “seven point” bending. By modifying the positions of the two loading points, symmetrical and antisymmetrical buckles that led to interface failure between the flange and the skin could be simulated. First a global numerical model of the test was made in order to assess the efficiency of the approach developed in the first part of this study. Predictions were in accordance with experiments despite strong scatter. Then, a global/local test method was considered. In this method, the global model considered shell elements although the local model used volume elements. The onset of delamination was correctly predicted at local level. Finally, the method was applied to two large stiffened panels subjected to compression and shear.

ABSTRACT: This paper is devoted to the optimal design of laminated composite structures. The goal of the study is to assess the quality and the performance of an algorithm based on the directional derivative method. Particular attention is paid to the one-dimensional search, a critical step of the process, performed by cubic splines approximation. The optimization problem is formulated as weight minimization, under constraints on the mechanical behavior of the structure. The assumed design variables are the ply thicknesses, treated as continuous design variables, constrained by technological requirements. The structural analysis is performed making use of quadrilateral four-node composite elements, based on the first order shear deformation theory. The algorithm is applied to the optimization of a rectangular laminated plate. The results obtained are compared with those obtained by other similar studies and show the effectiveness and accuracy of the proposed approach.

ABSTRACT: This work determines the maximal possible deformations of a corrugated sheet where the
corrugation pattern consists of two circular segments. The influence of the lay-up of cross-ply laminates and the influence of the geometry is investigated. The calculations are based on considerations of layerwise strains that are calculated with the help of an analytical singly-curved shell model. For the evaluation of the influence of geometric nonlinearities according finite element simulations are performed and compared to the linear strain limit calculations. The influence of scalable geometry parameters is also investigated.

ABSTRACT: This paper describes and applies a theory for practical second-order analysis and design of steel frames. The practicality, convenience and high precision of the method of ‘Non-linear Integrated Analysis and Design (NIDA)’ that allows for the second-order effects for design of steel frames and trusses is demonstrated. The need for using two or more elements per member to accurately simulate the axial load effect on the element stiffness and to locate the maximum moment along an element is eliminated. Unlike previous work for ‘Advanced Analysis' which is difficult to use in practice as it ignores many important practical features such as element imperfection, the proposed method meets the current design code requirements and is based on the first-plastic-hinge concept which is currently adopted by engineers. Furthermore, the element by itself can predict the beam-column load carrying capacity using a single element per member to model the P-Δ effect and, therefore, it can be used for simultaneous analysis and design. The use of several elements per member still possesses an error of idealising a physically smoothly curved member by a series of segments of straight elements. Conceptually, the suggested method designs a structure by modelling accurately its true behaviour, instead of making use of empirical formulae for individual member checks. It is readily available for design application of realistic structures and it is envisaged that the NIDA will initiate a revolution in the practical design of steel structures.

ABSTRACT: Ultra-lightweight thermoformed stiffened structures are emerging as a viable option for spacecraft applications due to their advantage over inflatable structures. Although pressurization may be used for deployment, constant pressure is not required to maintain stiffness. However, thermoformed stiffening features are often locally nonlinear in their behavior under loading. This thesis has three aspects: 1) to understand stiffness properties of a thermoformed stiffened ultra-lightweight panel, 2) to develop finite element models using a phased-verification approach and 3) to verify panel response to dynamic loading. This thesis demonstrates that conventional static and dynamic testing principles can be applied to test ultra-lightweight thermoformed stiffened structures. Another contribution of this thesis is by evaluating the stiffness properties of different stiffener configurations. Finally, the procedure used in this thesis could be adapted in the study of similar ultra-lightweight thermoformed stiffened spacecraft structures.

ABSTRACT: The ability of modulating the dynamic response of structural elements may play a fundamental role in terms of noise and vibration propagation and reduction levels. Specifically, controlling some dynamic features, like stiffness and damping, may remarkably extend the working range of a specific component, with consequent integration and efficiency benefits. Smart Materials, combined with innovative design philosophies (i.e., ‘Self-Adaptive Structures’, ‘Self-Repairing Structures’)... gave rise to real possibilities for the implementation of non-conventional solutions. Within the noise and vibration field, a family of strategies, focused on damping (active constrained layer dampers, rheological layers) and stiffness (embedded Shape Memory Alloys, SMA, acting on the stress field) control, is developing, by giving birth to original and efficient
solutions. SMA, due to their capability of transmitting large forces and deformations, and producing remarkable stiffness variations, represent good candidates for actuation problems and stiffness control solutions. The idea of using embedded SMA components to affect the structural dynamic response was already considered by several authors; among the others, Diodati and others focused their attention on the prediction of the effects due to the heat activation of SMA wires, embedded within a fiber-glass laminate. SMA induced stress originated significant FRF peaks shift, encouraging the authors to develop an optimization procedure to find out the most efficient placement and orientation of the active elements within the panel, aimed at maximizing the achievable frequency peak shift. In this article, a numerical model already introduced was examined and upgraded to suit the logic of a generic optimization process. The specific connections between the structure and the wires (sliding wires) was realized by proper constraint architecture, able to catch the best the physical nature of the mutual interaction. Then, due to the large amount of the parameters to be identified (in plane angle and location of each wire) and the non-continuous nature of some of them, a genetic optimization approach was picked up and implemented, assuming the peak shifts as the fitness function. The activated is then compared with the non-activated response, in order to estimate the attained performance.

ABSTRACT: For the numerical analysis of shells undergoing finite rotations doubly curved finite shell elements are developed via the displacement formulation. The derivation starts from a consistent finite-rotation shell theory which is transformed by a variational procedure into an incremental formulation. Thus, the non-linearity can be treated by an incremental-iterative technique. The non-linear element matrices are obtained by a tensor-oriented procedure permitting a direct transformation of the initial equations into efficient numerical models. Unlike in the usual procedure, the KIRCHHOFF-LOVE assumption is treated as a subsidiary condition at the element level. This computer-oriented approach permits the elimination of the dependent rotational degrees of freedom without loss of accuracy. Finally, some examples are presented to demonstrate the ability of the resulting finite elements to deal with finite-rotation problems.

ABSTRACT: For composite laminates consisting of an arbitrary number of orthotropic laminae first a finite-rotation theory is presented as basis of isoparametric finite-element formulations. The derivation is achieved by a Reissner-Mindlin type kinematic assumption which allows a constant shear deformation distribution across the thickness. The constitutive equations are presented in a general form such that orthotropic material behaviour with material axes varying arbitrarily across the thickness may easily be considered in numerical implementation, also when using curvilinear coordinates. Special attention is taken to predict the force distribution in the deformed shell structure. This theory is then transformed into a four-node isoparametric assumed-strain finite element. Unlike in the degeneration approach, interpolation polynomials are introduced directly for rotation variables determining the deformed position of the unit normal vector. The capability of the finite element developed to deal with strongly nonlinear situations is demonstrated by many examples. Also numerical results are presented permitting a systematical comparison of classical and isoparametric approaches concerning the numerical efficiency.

ABSTRACT: For arbitrary multilayered shell structures made particularly of composite material layers a refined finite-rotation theory with seven independent displacement variables is developed, approximating the displacement field by a cubic series expansion of thickness coordinates. This model allows a quadratic shear deformation distribution across the thickness. Procedures are given permitting a unique determination of the first order displacement term in the case of finite rotations. Kinematic relations are formulated in two alternative forms suitable for both classical and isoparametric finite element formulations. The constitutive relations presented model orthotropic material properties varying arbitrarily across the thickness. This third order single-layer theory is then transformed, by introducing further constraints, into three simplified models: a third order theory with five independent displacement variables, a Mindlin-Reissner type theory and a Kirchhoff-Love type theory. These four models differ, however, from each other essentially in the constraints imposed on the first and third order displacement variables: a significant advantage for a unified finite element development. Finally, the Mindlin-Reissner type theory is generalized to a layer-wise model being the most predictive one in dealing with local interlaminar effects. The theoretical models are transformed into adequate finite shell elements and then compared by means of appropriate examples concerning their prediction capability. Also examples are given demonstrating their applicability to finite-rotation phenomena.

ABSTRACT: The objective of this contribution is the development of theoretical and numerical models applicable to large strain analysis of hyperelastic shells confining particular attention to incompressible materials. The theoretical model is developed on the basis of a quadratic displacement approximation in thickness coordinate by neglecting transverse shear strains. In the case of incompressible materials this leads to a three-parametric theory governed solely by mid-surface displacements. The material incompressibility is expressed by two equivalent equation sets considered at the element level as subsidiary conditions. For the simulation of nonlinear material behaviour the Mooney-Rivlin model is adopted including neo-Hookean materials as a special case. After transformation of nonlinear relations into incremental formulation doubly curved triangular and quadrilateral elements are developed via the displacement method. Finally, examples are given to demonstrate the ability of these models in dealing with large strain as well as finite rotation shell problems.

ABSTRACT: The objective is the theoretical and numerical simulation of large-strain phenomena of rubber-like shells by means of shear deformation models. The development starts with a general applicable shell model constructed on the basis of quadratic displacement approximation which involves two thickness stretching parameters. This model is then coupled with incompressible material models of Mooney-Rivlin and neo-Hookean types. Material incompressibility is described by two-dimensional constraints considered at the
element level as subsidiary conditions. A special care is given to the stress prediction in the presence of large-strains. After transformation of the theoretical model into an incremental formulation a four-node isoparametric finite element is derived. Examples are finally given to demonstrate the ability of this model to deal with very strong deformations and to predict the related stresses.

ABSTRACT: This paper considers the crushing which occurs in a spherical shell made of ductile material on striking a rigid wall. A static analysis is developed which allows for strain hardening, while for relatively low impact velocities, such as to permit the effect of inertia to be neglected, strain rate sensitivity is allowed for in an empirical manner. The analysis presented is applicable to spherical shells with a mean radius to thickness ratio exceeding seven, constructed in ductile material obeying a simple power law work hardening relationship. The deformation is assumed to occur in two phases. In the first phase a local flattening of the shell in contact with the rigid wall occurs, while in the second, an axisymmetric dimpling of the previously flattened portion takes place. Other workers have discovered that at radius to thickness ratios exceeding one hundred, a third mode of behaviour takes place when a number of non-axisymmetric nodes can be formed. The analysis in this paper, however, is only applicable to lower ratios when the crushing deformation, although reaching a value of half the radius, remains axisymmetric, as is borne out in all the experimental results examined for correlation. A number of assumptions and simplifications are made, all of which are clearly stated below. Reference is made to earlier papers on this subject and a comparison is made of correlations by such earlier work and by the present analysis in respect of a group of quasi-static tests carried out by the Civil Engineering Department of the Queen's University of Belfast under a Leverhulme Trust fellowship funding: this is described in detail in Appendix 1. The result of a moderate velocity impact test on a spherical shell of 625 mm diameter is utilized to examine the correlation given by the present analysis taking strain rate effect into account. Note: the first author was mainly concerned with the analysis, while the co-authors carried out the experimental work detailed in Appendix 1.

ABSTRACT: Traditionally assessment of ship's longitudinal strength has been made by comparing the elastic stresses at the deck or bottom shell to fractions of the material yield strength. This results in high reserve capacity due to inherent redundancies in ship structures. Residual strength, which is defined as the strength of the structure after damage, has rarely been considered either during design or at the time of repair. In this report, key elements required to undertake an engineering analysis to evaluate the residual strength have been identified. Emphasis has been placed on assessing the residual strength of marine structures damaged due to normal operating loads. Methods available to industry for evaluation of damage such as, fracture and ultimate strength have been summarized. An example problem, illustrating the application of an integrated approach to residual strength assessment on a particular ship type, is presented.

ABSTRACT: Current ship structural design criteria for stiffened plate panels is based upon a strength of materials approach using either linear plate or beam theory. This approach neglects the effects of vertical shear (normal to the plate surface), membrane and torsional stress components induced by the flexibility of the panel's supporting structure. Recent trends towards the use of higher strength materials have resulted in the design of grillage structures which are more flexible and therefore increase the vertical shear, membrane and torsional stress components in the plate panel. This report presents the results of a study undertaken to determine the effect of the stiffness characteristics of the supporting members of the grillage structure on the plate panel stress. Grillage scantlings were developed using first principals based approach and then analyzed using finite element techniques to take into account the flexibility of the grillage stiffeners and to quantify the effects of vertical shear, membrane and torsional stress components.

PARTIAL INTRODUCTION: The finite element method is conceptually straightforward in that complex structures are idealized, in a representation, by a network or mesh of simpler interlocking structures, the simpler structures or finite elements being amenable to mathematical analysis…

ABSTRACT: A Multidisciplinary-Design-Optimization (MDO) approach for the initial design of wing structures based on the integrated modeling of structures, aerodynamics, flight dynamics, and aeroelasticity, has been developed. The procedure is based on the use of a standard numerical optimizer which employs structural, aeroelastic, and aerodynamic analyzers (a finite-element analyzer for structures, panel method analyzer for aerodynamics, and a longitudinal trim analyzer for flight mechanics) in the MDO process. The space discretizations of the numerical models – namely, the structural and aerodynamic meshes – are dynamically updated as function of wing-structure geometry variables during the optimization process. The geometric-updating procedure has been validated using available analytical solutions for a structural optimization problem. The obtained MDO solutions are essentially based on a first-principle formulation but, in the meanwhile, they do not result to be computationally expansive. Moreover, in order to make the implemented MDO algorithm more computationally efficient and effective, an analytical method based on Matched-Filter Theory (MFT) has been used to evaluate the worst aeroelastic-response case due to a gust input having an assigned energy level with the purpose of obtaining a final design also optimizing the gust-response performance. The optimization capabilities of using geometry design variables vs the standard structural design variables in the MDO process have been highlighted. Moreover, the use of a composite objective function, combining structure and aerodynamic issues, has been shown further capabilities of the presented MDO procedure. Finally, some results are also presented for a benchmark regional aircraft wing to show the potentiality of the approach.
ABSTRACT: A nonlinear aeroelastic analysis method using computational fluid dynamics/computational structure dynamics (CFD/CSD) is presented and applied to the nonlinear flutter and limit-cycle-oscillation (LCO) research of a cropped delta wing. This computational method couples a nonlinear finite element method (FEM) model with a CFD solver by using a high-fidelity interface interpolation, and is capable of investigating aeroelastic problems with both structural and aerodynamic nonlinearities. The structural analysis is based on a quadrilateral flat-shell element and an updated Lagrange (UL) formulation, which can be employed to model geometric nonlinearities arising from large deflections. With the Navier-Stokes (N-S) equations as the control equations, a finite volume CFD solver is formulated to calculate transonic aerodynamics. The nonlinear flutter calculation demonstrates the validity of the presented method. Finally the cropped-delta-wing LCO is computed, and the calculation precision is obviously better than the existing results.

ABSTRACT: A simple nonlinear analysis is presented to evaluate the displacements and stresses which arise from an axi-symmetric band of geometric imperfection in a pressurised sphere. The displacements and stresses solutions are derived in terms of Fourier series. Different shapes of initial geometric imperfections can be readily analysed by representing the shapes by Fourier series. It is concluded that the peak meridional stress is greater than the peak circumferential stress. Furthermore, the magnitude of the peak stress is scarcely influenced by the location of the imperfection shape. Generally, the stress distribution at the distorted region of the sphere can be characterised by the shape of imperfection and the membrane stress value; it is not so much affected by the different ‘radius to thickness’ ratio. The simple analysis highlights some important results which are not apparent in the other solution approaches.

ABSTRACT: A procedure to analyze axisymmetric solids undergoing large nonaxisymmetric deformation is presented. The plane of axisymmetry is modeled by isoparametric quadrilateral finite elements with dependence in the circumferential direction determined by a continuous Fourier series. Although the Fourier harmonics are coupled for such analyses, the size of the resulting model can be much smaller than it would be if brick elements were to be used. This model reduction can significantly decrease the amount of computational effort needed for analyzing this class of problems. Different schemes for solving the coupled nonlinear equations are evaluated by analyzing two structures subjected to different loadings and exhibiting various amounts of geometric nonlinearity. The coupled systems of linear simultaneous equations occurring at each Newton-Raphson iteration are solved by both direct and indirect solution schemes. Several types of Gauss-Seidel and conjugate gradient iterations are shown to be quite efficient and robust. The effectiveness of these indirect solution techniques are a result of using the uncoupled stiffness matrices to precondition the coupled systems of
linear simultaneous equations. The continuous Fourier series approach also provides a very simple, efficient, and reliable way to conduct adaptive refinement in the circumferential direction.

SUMMARY: Deformation of the outermost parts of single-plate planetary bodies is often modelled in terms of the response of a spherical elastic shell to surface or basal loading. As the thickness of such elastic lithosphere is usually much smaller than the radius of the body, the deformation is commonly approximated by that obtained for a thin elastic shell of uniform thickness. The main advantage of the thin shell approximation is its simplicity—the solution can be expressed analytically if the thickness of the shell is uniform, but even in the case of a thin shell of variable thickness, when the problem must be solved numerically, the computational costs are much lower than in a fully 3-D case. Here we analyse the error of the thin shell approximation by comparing it with the solution obtained for a shell of finite thickness using finite element methods. Special attention is paid to a shell of variable thickness and, in general, to the effect of elastic thickness variations on local deformation. For a shell of uniform thickness with the outer radius corresponding to Mars, we find that the error in radial displacement at low harmonic degrees ($l \leq 20$) does not exceed 5 per cent for small shell thicknesses ($d \leq 50$km) and 10 per cent for thick shells ($d \sim 250$km). Similar accuracy is also found for a shell of variable thickness if the thin shell approximation is used. Our numerical tests indicate that local deformation of a shell is mostly sensitive to the average thickness of the shell in the near zone while the effect of thickness variations in the far zone can be neglected in the first approximation. Consequently, the extremely simple thin shell method, designed for shells of uniform thickness, can be effectively used to obtain a reasonably accurate estimate of deflection even in the case of a shell with varying thickness. Finally, we investigate the deformation of an elastic lithosphere due to viscous flow beneath the shell, and we propose an extension of the concept, recently developed to correct dynamic topography for the effect of an elastic lithosphere, to the case of a shell of variable thickness.

ABSTRACT: A C0 continuous finite element formulation of a higher order shear deformation theory is presented for predicting the linear and geometrically non-linear, in the sense of von Karman, transient responses of composite and sandwich laminated shells. The displacement model accounts for the non-linear cubic variation of the tangential displacement components through the thickness of the shell and the theory requires no shear correction coefficients. In the time domain, the explicit central difference integrator is used in conjunction with the special mass matrix diagonalization scheme which conserves the total mass of the element and includes effects due to rotary inertia terms. Numerical results for central transverse deflection and stresses are presented for composite and sandwich laminated shells with various boundary conditions subjected to different types of loads and are compared with the results from other sources. Some new results are also included for future reference.

ABSTRACT: A C0 continuous displacement based finite element formulation of a higher order theory for linear and geometrically non-linear analysis which accounts for large displacements in the sense of von Karman of symmetrically laminated composite and sandwich shells under transverse loads is presented. The displacement model accounts for non-linear and constant variation of tangential and transverse displacement components, respectively, through the shell thickness. The assumed displacement model eliminates the use of shear correction coefficients. The discrete element chosen is a nine-node quadrilateral element with nine degrees of freedom per node. The accuracy of the present formulation is then established by comparing the present results with the available analytical, closed-form two-dimensional solutions, three-dimensional elasticity solutions and other finite element solutions. Some new results are generated for future comparisons to and evaluations of sandwich shells.

ABSTRACT: (none given)

ABSTRACT: A simple and effective method is developed in this paper for free vibration analysis of shells of revolution with either internal or external fluids. The fluid region is treated analytically by the use of eigenfunction expansions, and the collocation method using the roots of the orthogonal polynomial as collocation points is used to solve the integro-differential equations which describe the motion of the shell. The proposed approach is formulated in some detail. The versatility and accuracy are illustrated through several numerical examples. The method appears to be relatively easy to set up and gives satisfactory results.

ABSTRACT: Free vibration characteristics of filament wound anisotropic shells of revolution are investigated by using multisegment numerical integration technique in combination with a modified frequency trial method. The applicability of multisegment numerical integration technique is extended to the solution of free vibration problem of anisotropic composite shells of revolution through the use of finite exponential Fourier transform of the fundamental shell equations. The governing shell equations comprise the full anisotropic form of the constitutive relations, including first-order transverse shear deformation, and all components of translatory and rotary inertia. The variation of the stiffness coefficients along the axis of the shell is also incorporated into the solution method. Filaments are assumed to be placed along the geodesic fiber path on the shell of revolution resulting in the variation of the stiffness coefficients along the axis of the composite shell of revolution with general meridional curvature. Sample solutions have been performed on the effect of the variation of the stiffness coefficients on the free vibration behavior of filament wound truncated conical and spherical shells of revolution.

ABSTRACT: An analytical solution procedure is presented for the free vibrations of shells of revolution having two bonded elastic layers and circular meridional curvature. A set of governing equations of motion are obtained by applying Hamilton's principle to the Lagrangian function of the shell vibration. These equations of motion are higher order partial differential equations having variable coefficients, and analytical solutions are obtained by expanding these variable coefficients into infinite power series. Effects of various parameters, such as material properties of the shell layers, upon natural frequencies and mode shapes are investigated.

ABSTRACT: In the present paper, experimental studies on dynamic plastic buckling of circular cylindrical shells under axial impact are carried out. Hopkinson bar and drop hammer apparatus are used for dynamic loading. Three groups of circular cylindrical shells made of copper are tested under axial impact. From the experiments, the first critical velocity corresponding to the axi-symmetric buckling mode and the second critical velocity corresponding to the non-axisymmetric buckling mode are determined. The present results come close to those of second critical velocity given by Wang Ren[4–6]. Two different kinds of non-axisymmetric buckling modes oval-shaped and triangle shaped are founded. The buckling modes under two loading cases, viz. with small mass but high velocity and with large mass and low velocity using Hopkinson bar and drop hammer, are different. Their critical energies are also discussed.

ABSTRACT: Shell triangular finite elements are examined which are parametrically represented by quadratic polynomials of the surface coordinates. It is shown that isoparametric representation of the rectangular components of displacement does not provide an acceptable description of inextensional bending of a curved surface—its bending is accompanied with middle surface strains which are too large to be ignored.
Considerable improvement is made in the approximation to inextensional bending when the displacements are parametrically represented by cubic polynomials. The approximate inextensional bending modes are determined by examining eigenvalues of the positive semi-definite matrix of the integrated sums of squares of the principal middle surface strains taken over the element surface. Numerical results are listed for specimen finite elements which have positive, zero or negative Gaussian curvature. The Fortran computer program written for this investigation is described elsewhere.

ABSTRACT: The role of bending in the finite element analysis of problems in the linear theory of thin shells is examined through an in-depth study of the behavior of a vehicle finite element. The chosen element is the very simple combined constant strain and constant bending moment flat triangle. It emerges that this vehicle element is a superb performer and the examination of its behaviour reveals that there are two quite different roles for the bending freedoms. One role concerns inextensional bending movements which extend over the whole model. The other role concerns local rotational movements which accompany the curvature changes of inextensional bending and of edge effect. Extensive numerical comparisons of demonstration inextensional bending movements are made against solutions obtained from the classical theory for shells which are very deep and which have strongly negative Gaussian curvature. Comparison of edge effect concerns a circular cylindrical thin shell. The paper concludes by giving details of a rudimentary matrix procedure which is currently under development and which is intended for use in the preliminary assessment of thin shell finite element models.

ABSTRACT: An expression for the strain energy of a shell of negative Gaussian curvature, including thickness shear deformations and without neglecting z/R in comparison with unity, is derived. Then a curved trapezoidal finite element formulation based on the principle of minimum potential energy is obtained. The shell element has eight nodes with 40 degrees of freedom and at each node there are three displacements and two rotations. The formulation is applicable for both thin and moderately thick shell analysis. The performance of this finite element is verified by applying it to some problems existing in the literature.

ABSTRACT: Based on a total Lagrangian approach, the shell element formulation developed by two of the
authors is extended to non-linear field. The proposed shell element belongs to the degenerated 3D type, with a Mindlin–Reissner approach and five effective degrees of freedom per node. A detailed description of the geometry and kinematics characterisation of the element, as well as of the stress–strain relationship is presented. Numerical testing of the non-linear model indicates excellent performance of the proposed finite element shell, both in simulating large displacement and rotations, and in the buckling analysis of some classical test examples, e.g., cylinder and sphere.

ABSTRACT: The present investigation deals with the nonlinear analysis of the dynamic buckling response and global stability aspects of two 3-DOF spring-mass, initially imperfect dissipative simplified structural models under step loading, simulating elastic shell panels of revolution and in particular a spherical cap and a conical panel. It is found that snapping, which is the main characteristic of the actual continuous structures, is successfully captured by the proposed simulations, which following a straightforward nonlinear approach are found to exhibit dynamic snap-through buckling, associated with a point attractor response in the large, implying global stability. Furthermore, the presence of physically not accepted complementary equilibrium configurations does not affect the long term response of the autonomous systems dealt with, but only complicates the motion and elongates the time before the final steady state. Finally, the criterion of zero total potential energy yields excellent lower bounds of the exact dynamic buckling loads, very important for structural design purposes.

ABSTRACT: The buckling of a finite section of a cylindrical shell resembling a two-dimensional contact lens, and the collapse of a tubular shell of infinite extent are considered. The deformation is due, respectively, to the application of an edge force or to a negative transmural pressure. In both cases, the shell develops elastic bending moments due to the deformation from a specified resting shape according to a linear constitutive equation, accompanied by in-plane and transverse shear tensions. In the case of a section of a shell with a flat resting shape, classical results due to Euler and Love show that, as the applied edge force is increased beyond a sequence of thresholds, an infinite family of deformed shapes becomes possible corresponding to buckled states that bifurcate from the zero-curvature resting configuration. It is shown here that a corresponding infinite family of shapes is also possible for a finite shell whose resting shape is a section of circle. These shapes, however, no longer arise from bifurcations, but rather constitute disconnected solution branches of a nonlinear boundary-value problem. A closed cylindrical shell whose cross-section has a circular resting shape exhibits similar bifurcations when the difference between the exterior and interior pressure exceeds a sequence of thresholds, but a shell with a non-circular resting shape deforms into a multitude of shapes described by isolated solution branches. The computed two-dimensional buckled shapes are used to reconstruct the three-dimensional shape of a slowly collapsing fluid-conveying vessel. The reconstruction procedure involves stacking together cross-sections at axial positions that are found by integrating the differential equation determining the axial pressure distribution in unidirectional pressure-driven flow, subject to a constant flow rate. The dimensionless coefficient
relating the local pressure gradient to the flow rate is computed by solving the Poisson equation governing unidirectional viscous flow using a boundary-element method, and expressing the flow rate as a boundary integral involving the shear stress which is available from the solution of the boundary-integral equation. In an appendix, the energy of the bending state is discussed with reference to specific choices made by previous authors in various branches of science and engineering.

ABSTRACT: The buckling and collapse of empty and liquid-filled thin-wall cylindrical tubes resting on a horizontal or inclined plane is considered. The deflection is due to the action of gravity causing the tube to deform under the influence of its own weight, or due to a negative transmural pressure pushing the tube inward on the outside. Classical thin-membrane theory is used to formulate a boundary-value problem describing the shell deformation, and the results illustrate families of deformed shapes of inextensible shells with point or segment contact occurring between the shell and the supporting surface or between two collapsed sections of the shell. The computed two-dimensional deformed shapes are used to reconstruct the three-dimensional shape of a slowly collapsing fluid-conveying vessel in the absence of significant hydrostatic pressure variations over the cross section.

ABSTRACT: The flow-induced deformation of a two-dimensional membrane with a circular unstressed shape clamped at the two ends on a plane wall at an arbitrary contact angle is considered. Working under the auspices of generalized shell theory, the membrane is allowed to develop in-plane tensions, transverse tensions, and bending moments determined by the curvature of the resting and deformed shapes. A system of ordinary differential equations governing the membrane shape is formulated, and the associated boundary-value problem is solved by numerical methods. Numerical results are presented to illustrate the deformation of a clamped membrane due to gravity or a negative transmural pressure. The shell formulation is coupled with a boundary-integral formulation for Stokes flow, and an efficient iterative scheme is developed to describe deformed equilibrium shapes of a membrane attached to a plane wall in the presence of an overpassing shear flow. Computations for different contact angles and shear rates reveal a wide variety of profiles and illustrate the distribution of the membrane tension developing due to the flow-induced deformation.

ABSTRACT: There is a need for reliable methods to determine approximate solutions of nonlinear continuous systems. Recently, it has been proved that finite–degree–of–freedom Galerkin–type discretization procedures applied to some distributed–parameter systems may fail to predict the correct dynamics. By contrast, direct procedures yield reliable approximate solutions. Starting from these results and extending some of these concepts and procedures, we compare the outcomes of these two approaches (the Galerkin discretization and the direct application of a reduction method to the original governing equations) with experimental results. The nonlinear planar vibrations of a buckled beam around its first buckling mode shape are investigated. Frequency–response curves characterizing single-mode responses of the beam under a primary resonance are generated using both approaches and contrasted with experimentally obtained frequency–response curves. It is shown that discretization leads to erroneous quantitative as well as qualitative results in certain ranges of the buckling level, whereas the direct approach predicts the correct dynamics of the system.

“Parametric instabilities of nonlinearily viscoelastic cylindrical shells and rings subject to periodic hydrostatic excitations”, (date & publisher not given in the pdf file; most recent reference is 2005)

ABSTRACT: Refined theories for accurate predictions of the onset of the parametric instabilities and the ensuing post-critical solutions are employed to investigate on how these instabilities are influenced by commonly neglected effects in shells and rods such as inertia terms, shear deformations, and material nonlinearities (Antman, 2005; Antman and Calderer, 1987; Antman, 2001).

Parametrically excited systems are pervasive in mechanics (e.g., dynamic buckling of columns, rings and shells, water waves in vertically forced containers, stability of general motions). In particular, parametrically forced rings and cylindrical shells are of significant interest in engineering applications such as aircraft fuselages or turbo machineries where the forcing is represented by the gradient between the inner and outer pressures. Although the theory of parametrically excited linear discrete systems governed by linear ordinary differential equations is well established (Yukubovich and Starzhinskii, 1975; Nayfeh and Mook, 1979), a comprehensive theory of parametrically excited nonlinear systems is far from being achieved. Moreover, only a few works have treated parametrically excited structural systems taking into account inertia, geometric and material nonlinearities.

Among others, Bolotin (1964) studied the Mathieu equation with cubic nonlinearities while, more recently, Rand and co-workers (2004) have investigated nonlinear Mathieu equations with either quadratic damping or cubic springs. In the quadratically-damped Mathieu equation, they showed the existence of a secondary bifurcation in which a pair of limit cycles come together and disappear (a saddle-node of limit cycles). In parameter space, this secondary bifurcation appears as a curve which emanates from one of the transition curves of the linear Mathieu equation. Further, Rand (1996) studied a two-term truncation of a parametrically excited PDE, and showed, using averaging, that the normal form of the system exhibits a rich diversity of dynamical behaviors.

When dealing with parametric excitations in spatially continuous structural systems, to overcome discretization errors, that can be also qualitative in the worst scenario, there is a need to rigorously treat, e.g. via asymptotics, the governing parametrically forced PDE’s instead of dealing with their reduced-order counterparts (Lacarbonara, 1999). In the present work, an asymptotic multiple-scale treatment of parametrically forced nonlinear PDE’s, representative of cylindrical shells and rods suffering bending, extension and shear deformations, is presented. Considering nonlinearly visco-elastic cylindrical shells and rings under hydrostatic pressure, general results about the leading classes of motions are discussed; namely, breathing motions, shearless motions and general motions of shells and rings undergoing extension, bending and shear deformations.

It is shown that when the shell or ring are subject to uniform pulsating pressure with frequency being nearly twice the frequency…

“...and transverse shear strains”, Composite Structures, Vol. 92, No. 12, November 2010, pp. 3011-3019, doi:10.1016/j.compstruct.2010.05.017
ABSTRACT: The onset of buckling in square laminated multi-layered composite plates, subject to unidirectional in-plane loads, is investigated within the framework of a generalized higher-order shear deformation theory suitable to capture significant transverse shear and thickness-wise deformation effects. The displacement field is expanded in a Taylor series of the thickness coordinate with arbitrary polynomial degree; in turn, the series coefficients, expressed as a superposition of admissible functions, are determined according to the Rayleigh–Ritz method. Truly higher-order polynomial terms, along with a sufficient number of in-plane admissible functions, are shown to be necessary for convergence towards the fundamental buckling load multiplier. As a by-product, reduced-order models are identified for various plate geometries and lamination schemes. The sensitivity of the lowest buckling load with respect to the nondimensional parameters (the thickness ratio, the ratio between the elastic moduli, the ply angle) is investigated. In particular, the attention is focused on the cross-over phenomenon between the lowest two buckling eigenvalues in multi-layered composite square plates with different lamination schemes. The presented results shed light onto the buckling behavior of thick shear-deformable multi-layered plates.

ABSTRACT: The general, statically and kinematically exact, six-field theory of branched shell structures, extended to nonlinear problems of shell dynamics involving also large overall motion, is discussed. The generalized Newmark algorithm on the proper orthogonal group SO(3) with Newton iterations is proposed. Numerical simulations of the behavior of an elastically twisted T-shaped shell structure in forced and free rotations with large overall motion are presented.

ABSTRACT: We propose a new four-node C0 finite element for shell structures undergoing unlimited translations and rotations. The considerations concern the general six-field theory of shells with asymmetric strain measures in geometrically nonlinear static problems. The shell kinematics is of the two-dimensional Cosserat continuum type and is described by two independent fields: the vector field for translations and the proper orthogonal tensor field for rotations. All three rotational parameters are treated here as independent. Hence, as a consequence of the shell theory, the proposed element has naturally six engineering degrees of freedom at each node, with the so-called drilling rotation. This property makes the element suitable for analysis of shell structures containing folds, branches or intersections. To avoid locking phenomena we use the enhanced assumed strain (EAS) concept. We derive and linearize the modified Hu–Washizu principle for six-field theory of shells. What makes the present approach original is the combination of EAS method with asymmetric membrane strain measures. Based on literature, we propose new enhancing field and specify the transformation matrix that accounts for the lack of symmetry. To gain knowledge about the suitability of this field for asymmetric strain measures and to assess the performance of the element, we solve typical benchmark examples with smooth geometry and examples involving orthogonal intersections of shell branches.

ABSTRACT: The paper summarises some findings on torsional buckling of thin-walled I-beam columns. The study is divided into two parts. Firstly, the effect of initial deflection on torsional buckling load of thin-walled I-beam column is discussed. Starting from the description of kinematics, strain and stress, the governing differential equations of torsional buckling are derived from the principle of stationary potential energy. The critical load of torsional buckling is determined with the aid of the perturbation approach. The numerical example concerning simply supported I-beam column is presented and discussed on the grounds of the theory of thin-walled members and compared with the result obtained from non-linear 6-parameter theory of shells. Secondly, the localisation of local buckling modes is studied. This effect, observed during the modelling by shell theory, strongly affects the I-beam columns behaviour with relatively wide flanges.
ABSTRACT: A 4-node C0 shell element with drilling degrees of freedom is presented in this paper. The element is developed within the nonlinear 6-field shell theory. Kinematics of the shell is described by two independent fields: the vector field for translations and the proper orthogonal tensor field for rotations. Within the theoretical formulation no restriction is applied on magnitudes of displacements and rotations. To avoid locking phenomena the proposed element combines two interpolation schemes: the assumed natural strain (ANS) for transverse shear strains and the enhanced assumed strain (EAS). The latter interpolation is used with asymmetric (in-plane) membrane strains. The performance of the element is evaluated by example of benchmark problems with special emphasis on shell structures containing orthogonal intersections.

ABSTRACT: The whole process of dynamic elastic-plastic analysis was carried out for Schwedler elliptical shell structure by using the theory of elastic-plastic finite element, and in combination with the force characteristics of reticulated shell. Its elastic-plastic aseismatic performance was explored. Emphasis is laid on the dynamic performance and failure modes of the shell structure when helped by BRB under strong earthquakes. The results show that BRB has a valid effect on the shell's elastic-plastic performance.

ABSTRACT: Stability analysis of the radial pulsations of a gas microbubble that is encapsulated by a thin viscoelastic shell and surrounded by an ideal incompressible liquid is carried out. Small axisymmetric disturbances in the microbubble shape are imposed and their long and short term stability is examined depending on the initial bubble radius, the shell properties, and the parameters, i.e., frequency and amplitude, of the external acoustic excitation. Owing to the anisotropy of the membrane that is forming the encapsulating shell, two different types of elastic energy are accounted for, namely, the membrane and bending energy per unit of initial area. They are used to describe the tensions that develop on the shell due to shell stretching and bending, respectively. In addition, two different constitutive laws are used in order to relate the tensions that develop on the membrane as a result of stretching, i.e., the Mooney-Rivlin law describing materials that soften as deformation increases and the Skalak law describing materials that harden as deformation increases. The limit for static buckling is obtained when the external overpressure exerted upon the membrane surpasses a critical value that depends on the membrane bending resistance. The stability equations describing the evolution of axisymmetric disturbances, in the presence of an external acoustic field, reveal that static buckling becomes relevant when the forcing frequency is much smaller than the resonance frequency of the microbubble, corresponding to the case of slow compression. The resonance frequencies for shape oscillations of the microbubble are also obtained as a function of the shell parameters. Floquet analysis shows that parametric instability, similar to the case of an oscillating free bubble, is possible for the case of a pulsating encapsulated microbubble leading to shape oscillations as a result of subharmonic or harmonic resonance. These effects take place for acoustic amplitude values that lie above a certain threshold but below those required for static buckling to occur. They are quite useful in providing estimates for the shell elasticity and bending resistance based on a frequency/amplitude sweep that monitors the onset of shape oscillations when the forcing frequency resonates with the radial pulsation, $\omega_f = \omega_0$, or with a certain shape mode, $\omega_f = 2\omega_n$. An acceleration based instability, identified herein as dynamic buckling, is observed during the compression phase of the pulsation, evolving over a small number of periods of the forcing, when the amplitude of the acoustic excitation is further increased. It corresponds to the Rayleigh-Taylor instability observed for free bubbles, and has been observed with contrast agents as well, e.g., BR-14. Finally, phase diagrams for contrast agent BR-14 are constructed and juxtaposed with available experimental data, illustrating the relevance and range of the above instabilities.
ABSTRACT: Two new finitely deformed dynamical beam models are established for serious study on non-linear vibrations of thick beams subjected to arbitrarily given external loads. The total potentials of these beam models are non-convex with double-well structures, which can be used in post-buckling analysis and frictional contact problems. Dual extremum principles in unstable dynamic systems are developed. A pure complementary energy principle (in terms of the second Piola-Kirchhoff type stress only) in finite deformation mechanics is actually constructed. An interesting triality theory in post-buckling analysis is proved. This theory shows that if the gap function introduced by Gao and Strang in 1989 in positive, the generalized pure complementary energy has only one saddle point, which gives a global stable buckling state. However, if the gap function is negative, the generalized complementary energy may have two so-called super-critical points: the one which minimizes the pure complementary energy gives another relatively stable buckling state; and the other one which maximizes the complementary energy is an unstable buckling state. Application in unilateral buckling problem is illustrated, and an analytic solution for non-linear complementarity problem is obtained. Moreover, the general duality theory proposed recently is generalized into the non-linear dynamical systems. A pair of dual Duffing equations are obtained.

ABSTRACT: This paper treats the finite axisymmetric deflection and snapping of spherical caps which are point loaded at the apex and simply supported at the boundary. The problem is formulated using a stationary potential energy principle and solved numerically. The response of caps up to critical loads and into the postbuckling regime to eversion and beyond is studied and detailed. Phenomena such as snapthrough, snapback, multiple load free equilibria, aversion and irreversibility, are found to occur.

ABSTRACT: A theory for the axisymmetric deformation of isotropic, hyperelastic circular plates which is valid for arbitrarily large strains and rotations is developed. The theory is implemented numerically and used to perform an extensive analysis of uniformly-loaded circular plates with hinged and clamped edges. Particular
attention is paid to large-strain and large-rotation effects.

ABSTRACT: This paper presents a study on the use of the tension field theory for efficient representation of textiles. A highly buckled membrane model provides the simplest approach for visualization of vertical fabrics. The differential equation of tension lines gives the outline of the wrinkles. An equation system is presented, which, when iteratively solved supplies the basic variables of realistic fabric displacements: the number and positions of wrinkles, and the wrinkle depth. The model can also represent important physical characteristics of textiles, as malleability, elasticity and weight. However the tension field theory does not attempt to describe the field of displacements normal to the membrane surface, which are the main point of the work here presented. Experimental measures have been developed as a way to verify the adequacy of the equations and to subsidize empirical propositions for improvement of the model. How to use this approach for textile visualization is the objective of this work. Although the original theory is complex, the resulting algorithm is simpler and faster than many numerical treatments already used for prediction of the cloth aspect. The idea is to nd a simple realistic model that turns possible the addition in the displacement field of other important necessities of the fashion industry like animations and textures.

ABSTRACT: True membranes are no-compression structures which exhibit the unique response of wrinkling. Prediction of the associated wrinkle parameters is of practical importance. Accurate measurement of membrane wrinkling has heretofore not been presented in the literature; among other requirements, noncontact methods must be used. First, some background information on membrane wrinkling prediction and measurement is given. Then, an experimental apparatus is discussed within which a membrane was subject to planar loading. The measurement system consisted of a capacitance-based noncontact displacement sensor mounted in an XYZ frame. A computer controlled the forces applied to the membrane, as well as the motion of the XYZ frame during data acquisition. Results are presented and conclusions are drawn regarding the wrinkle parameters.

ABSTRACT: We investigated solvent induced transition of surface instability from wrinkles to creases in poly(2-hydroxyethyl methacrylate) (PHEMA) gels with depth-wise crosslinking gradients. The mode of surface instability and morphology of surface patterns was found to be dependent on the equilibrium linear expansion, which was a function of crosslinker concentration and the solvent–polymer interaction. The maximum linear expansion was obtained when the PHEMA film was swollen in a good solvent, which had the Hildebrand solubility parameter ($\delta_s$) close to that of PHEMA gels, 26.6 to 29.6 MPa$^{1/2}$. In a relatively poor solvent (e.g. water), wrinkling patterns were obtained and the morphology was determined by the concentration of the crosslinker, ethylene glycol dimethacrylate (EGDMA). In a good solvent, such as alcohol and alcohol/water mixture, the equilibrium linear expansion ratio increased significantly, leading to the transition from wrinkling to creasing instability. In an ethanol/water mixture, we systematically varied the ratio between ethanol and water and observed the transition from wrinkling to creasing when gradually adding ethanol to water, and the reverse transition when adding water in ethanol. The onset of the linear expansion ratio for creasing ($\alpha_{cw}$) was again found dependent on EGDMA concentration: $\alpha_{cw} \approx 2.00$ and 1.3, respectively, for gels with 1 and 3 wt% EGDMA. Finally, we demonstrated confinement of the creases by combining swelling and photopatterning.

ABSTRACT: Approximate closed-form solutions are obtained for the static stress and deformation as well as
the stability of an orthotropic layered shell of revolution with properties which vary along the meridian and through the wall thickness. The shell is subjected to axisymmetrical load and temperature distributions. The nonlinear “prestress” or “pressurization” effect is taken into consideration. It is of interest that due to the nonhomogeneity of the shell wall significant bending stresses can occur far from support points. The asymptotic results agree with numerical values obtained from two computer programs using direct numerical methods, even for shells that are relatively shallow.

INTRODUCTION: Extensive plans are in progress for large structures in space applications, as discussed in the 2nd National Space Inflatables Workshop (1998). The consensus is that much of this will be possible only with inflatable structural elements. There are considerable challenges in the development of such devices as reliable tools. Analytical simulation can play a significant role in speeding the development and increasing the reliability. However, the analysis of an inflated tube undergoing large displacements is prohibitive for a direct calculation using thin shell theory. An evaluation of the approximate techniques in use for inflatables is given by Jenkins (1991). A comprehensive study of nonlinear shell theory is given by Libai and Simmonds (1998). However, a convenient method, both sufficiently accurate and numerically efficient, for dealing with the deployment of membranes and complex structures has not seemed to be available.

ABSTRACT: Two experiments quantified the forces necessary for large deformation of an inflated cylindrical tube made of a material with a high elastic modulus. In the first experiment, the end force required to maintain a buckled cylinder at a given kink angle was determined. In the second experiment, the lateral force required to pinch the membrane symmetrically between two flat blades was measured. An approximate theory is used, based on the observation that during deformation the membrane conserves its initial zero Gaussian curvature in regions free of wrinkling. The novel feature is a simple approximation for the cross-sectional shape. This permits the volume of the deformed cylinder to be quickly calculated. For walls that have negligible extensional and bending energy, the potential energy consists of only the pressure multiplied by the volume and the work of the prescribed load. Minimization of this potential energy yields results for the indentation and buckling problems that are in reasonable agreement with the experimental measurements. For small displacements in the blade pinching experiment, the volume approximation overestimates the force. It is found that a local solution analogous to the Hertzian contact problem provides a better approximation. For the kinked tube with end loading, an interesting feature is a decrease in the load when the fold from one side contacts the opposite side of the tube. The calculations indicate that a minimum potential energy exists with the fold straight. For slightly larger kink angles, however, the fold buckles out of the plane of symmetry. The moment at the single kink, due to the end loads, remains between bounds from the analysis of a pressurized elastic tube with nonpositive stresses.
ABSTRACT: The motivation for this work is the need for efficient means of computing the deployment of large, inflatable, space structures. Recent work has been on the load-deformation properties of folded and rolled pressurized tubes. The approach is to use basic properties of thin shells to determine appropriate approximations for the deformed shape. This is then used in an energy formulation in which the work of the pressure and the external loads dominates. For some problems, the stretching of the tube wall is also significant. In the present work the behavior of a tube with symmetric rigid blade loading is considered. Previous results are inadequate for the moderate values of the blade displacement. A satisfactory solution is obtained with a modified shape function for the tube cross section and with elastic stretching of the wall.

ABSTRACT: With respect to an arbitrary configuration of a deformed structure, two sets of incremental equations are proposed for the deformation analysis of revolution shells and diaphragms loaded by both lateral pressures and the initial stresses produced in manufacturing. These general equations can be reduced to the simplified Koiter's Reissner-Meissner-Reissner (RMR) equations and the simplified Reissner's equations, when the initial stresses are set to zero. They can also be deduced to the total Lagrange form or the updated Lagrange form, respectively, as the structure is specified as the undeformed or the former-deformed configurations. These incremental equations can be easily transformed into finite difference forms and solved by common numerical solvers of ordinary differential equations. Some numerical examples are presented to show the applications of the incremental equations to the deep shell of revolution and the corrugated diaphragms used in microelectro-mechanical system (MEMS). The results are in good agreement with those from finite element method (FEM).

ABSTRACT: In this paper, we consider bifurcation from a circular cylindrical deformed configuration of a thick-walled circular cylindrical tube of incompressible isotropic elastic material subject to combined axial loading and external pressure. In particular, we examine both axisymmetric and asymmetric modes of bifurcation. The analysis is based on the three-dimensional incremental equilibrium equations, which are derived and then solved numerically for a specific material model using the Adams–Moulton method. We assess the effects of wall thickness and the ratio of length to (external) radius on the bifurcation behaviour. References listed at the end of the paper:

ABSTRACT: The problem of the finite axisymmetric deformation of a thick-walled circular cylindrical elastic tube subject to pressure on its external lateral boundaries and zero displacement on its ends is formulated for an incompressible isotropic neo-Hookean material. The formulation is fully nonlinear and can accommodate large strains and large displacements. The governing system of nonlinear partial differential equations is derived and then solved numerically using the C++ based object-oriented finite element library Libmesh. The weighted residual-Galerkin method and the Newton-Krylov nonlinear solver are adopted for solving the governing equations. Since the nonlinear problem is highly sensitive to small changes in the numerical scheme, convergence was obtained only when the analytical Jacobian matrix was used. A Lagrangian mesh is used to discretize the governing partial differential equations. Results are presented for different parameters, such as wall thickness and aspect ratio, and comparison is made with the corresponding linear elasticity formulation of the problem, the results of which agree with those of the nonlinear formulation only for small external pressure. Not surprisingly, the nonlinear results depart significantly from the linear ones for larger values of the pressure and when the strains in the tube wall become large. Typical nonlinear characteristics exhibited are the “corner bulging” of short tubes, and multiple modes of deformation for longer tubes.

ABSTRACT: A model describing oscillations of nonlinear thin plates excited by patches made of a piezoelectric ceramic is considered. The specific of the model is that the mutual coupling between elastic deformations and electric fields is assumed. Partial differential equations describing the model are stated and their solvability is proved. The question of homogenization when the number of the piezoelectric patches goes to infinity whereas their dimension goes to zero is discussed.

ABSTRACT: An optimised structure is one which uses the smallest quantity of the best material to perform its function, with adequate safety factor or margin for error. Structural optimisation occurs not only in mechanical engineering, but also in nature: plants with hollow stems or stalks gain a height advantage, and are thus more efficient, by approaching the optimum shape. Here we consider the optimisation of orthotropic tubes, typifying, in a mechanical sense, stalk and stem. The stiffness and strength of orthotropic tubes of initially circular section are reviewed, and diagrams are proposed which allow the optimum section shape to be selected.

ABSTRACT: Eight variations of higher-order transverse shear deformation (HTSD) theory were developed for composite shells. Three attributes were varied to produce the eight variations. These attributes include the order of the thickness expansions used to approximate the shell shape factors and the assumed linear displacement field and the nonlinearity of transverse shear strain. Several cylindrical shell problems were investigated using SHELL, a finite-element code with a 36 degree of freedom cylindrical shell element. MACSYMA, a symbolic manipulation code, was used to formulate the element independent stiffness arrays for each variation of the theory. When all nonlinear strain-displacement terms for transverse shear were included for thin shallow isotropic cylindrical shells, the theory predicted a more flexible response during collapse. Higher-order thickness expansions had negligible effect upon results for shallow shell problems investigated. For deeper shells, the linear displacement assumption prohibited the use of nonlinear strain-displacement relations for transverse shear strains. Thus, for deep shells nonlinearity was limited to in-plane strain-displacement relations.

Landon M. Kanner (Department of Civil Engineering, University of Virginia), “Inflation of strain-stiffening rubber-like thin spherical shells”, publisher and date not given in the pdf file. This is probably a thesis.)

ABSTRACT: In this paper, we investigate the predictions of several widely used strain-stiffening phenomenological constitutive models for the classical limit point instability that is well-known to occur in the inflation of internally pressurized rubber-like spherical thin shells (balloons). The shells are composed of incompressible isotropic nonlinearly elastic materials. For a variety of specific strain-energy densities that give rise to strain-stiffening in the stress-stretch response, the inflation pressure versus stretch relations are given explicitly and the monotonicity, or lack thereof, of the inflation curves is examined. While such results are known for constitutive models that exhibit a gradual stiffening (e.g. exponential and power-law models), our primary focus is on materials that undergo severe strain-stiffening in the stress-stretch response. In particular, we consider two recently developed constitutive models that reflect limiting chain extensibility at the molecular level. Results for classical models are also presented for comparison. It is shown that for materials with sufficiently low extensibility no limit point instability occurs and so stable inflation is then predicted for such materials. The results have a variety of aerospace applications, e.g. to deployable space structures and NASA Weather Balloons.

ABSTRACT: In this study, the effect of compressibility on the nonlinear buckling of the simply supported polyurethane spherical shells subjected to an apical concentrated load is presented. The problem is strongly nonlinear both physically and geometrically. Since the closed form solution of the corresponding algebraical and differential equations is not possible, numerical methods are used unavoidably. The governing equations of the problem are converted to algebraical difference equations via the finite difference method and the obtained algebraical equations are solved numerically by using the Newton—Raphson method. Several numerical experiments corresponding to the various values of a thickness parameter, a depth parameter and a material constant related with the compressibility of polyurethane are performed and the force—apex deflection curves are drawn. Concluding remarks pertaining to the effect of the variation of the material constant related with the compressibility on the buckling loads and buckling deflections of the simply supported polyurethane spherical shells, subjected to an apical load, with various thicknesses and depths are presented.

ABSTRACT: Previously, the effect of compressibility on the nonlinear buckling behaviour of thin, polyurethane, simply-supported spherical shells subjected to apical loads has been presented without
considering the orders of the thickness and height of the spherical shells. In the meantime; it has been observed that although the variations of the thickness and height of the spherical shells do not affect the comments made for the effect of the compressibility on the buckling loads, they do affect the comments made for the effect of the compressibility on the buckling deflections considerably. In this study; combined effect of the compressibility, height and thickness on the buckling loads, buckling deflections and the apical load-apical deflection diagrams of polyurethane, thin, simply-supported spherical shells subjected to apical loads is investigated. Comparing the force-deflection diagrams corresponding to various values of the parameters pertaining to the compressibility of the material used, the height and the thickness of the shell; the variations of the buckling loads, buckling deflections and forms of the force-deflection diagrams corresponding to the various combinations of the mentioned parameters are discussed.

ABSTRACT: (not available)

SUMMARY: The great interest of mixed, hybrid, or complementary energy principles lies in the search of more refined stress-fields than by use of the primal method, in particular in zones of high stress-gradients. Moreover the accuracy of the stresses is of primary importance in buckling and post-buckling problems.
After having recalled the author’s extension of the buckling criterion to various mixed principles by means of a very general method, one applies these criteria to the case of thin elastic or elastoplastic shells without shear strain, and in particular in the case of a surface principle of complementary energy with finite rotation. It is also provided post-buckling formulae for mixed principles in the classical cases of limit points or symmetric and asymmetric bifurcation point with or without imperfections. The criteria can be applied through a partitioning primal-mixed strategy.

47. Marcal P.V. Finite element analysis with material non-linearities. Theory and Practice. MARC CDC Background papers.

ABSTRACT: The computational problem of shell structures in large displacements and large rotations has prompted numerous theories and approximations. The introduction of the finite rotation was successfully realized in 1972 by Fraeijs de Veubeke in three-dimension, and led to the creation of a dual nonlinear variational principle where the stresses as new unknowns were statically admissible. Following this line, its extension to shells, though not so easy, allows to provide statically admissible surface stresses. Now stability problems are directly governed by accurate stresses, and particularly in case of shells. After a recall of the dual variational principle for shells with large displacements, finite rotations and transverse shear deformations, a dual theory of stability is developed, namely the stability criterion and the post-buckling in the dual theory.

ABSTRACT: Dual nonlinear stability of a new kind of thin concrete shell-spherical steel-concrete ribbed shell-is analyzed, and critical loads are determined by all course tracing, considering double nonlinear geometrical and material nonlinear. A comprehensive parametric stability analysis of composite ribbed shell with various geometric parameters has been carried out. The critical loads and the unstable areas distribution are discussed thoroughly. Based on these results, the behaviors of nonlinear stability are concluded, the change trend of critical loads and instability mode under different situation are obtained, and at last the degree of critical loads decreasing is defined under initial imperfection.

Kevin J. Silva (School of Engineering, Air Force Institute of Technology, Wright-Patterson AFB, Ohio), “Finite
Element Investigation of a Composite Cylindrical Shell Under Transverse Load with through Thickness Shear and Snapping”, Master’s Thesis, December 1989

ABSTRACT: The static response of a circular cylindrical open shell (curved panel) constructed of an orthotropic graphite/epoxy laminate is numerically investigated in this thesis. The shell is subjected to an inward point load, centered on and normal to the shell surface, which maintains its original orientation through deformation (i.e. dead load). The shell displacement response is seen to vary widely with shell geometry and boundary conditions, not only in magnitude of deformation but also in the nature and progression of the collapse under critical load. The finite element analysis is conducted with a quasi-two dimensional thin shell element which incorporates parabolic transverse shear stress through the thickness. The element can be formulated with either large displacement/rotation kinematics or the simpler Donnell relations. To enable tracking through critical load and displacement points and investigation of the post-critical regime, a solution algorithm other than the popular Newton-Raphson technique with displacement control or load control is required. The algorithm employed here uses a modified Riks/Wempner technique. It allows continuous tracing of the load-deflection response through critical load and critical displacement points. Step size is automatically scaled to follow the solution path closely in the areas of large load or displacement changes which surround critical points.

ABSTRACT: Guided by the three-dimensional theory of coupled thermoelasticity with second sound, a system of shear-deformable shell equations is consistently derived in invariant, differential and variational forms for the high-frequency vibrations of temperature-dependent materials. The first part of the paper is concerned with a unified variational principle describing the fundamental equations of thermoelasticity. The differential type of variational principle is presented by expressing Hamilton's principle for the thermal part of a thermoelastic region and then combining it with its mechanical part. In the second part, the hierarchic system of non-isothermal shell equations is systematically established by use of the variational principle together with
Mindlin's kinematic hypothesis for shells. The system of two-dimensional approximate equations which may take account of all the significant mechanical and thermal effects, including the temperature dependency of material, governs the extensional, thickness-shear, flexural and torsional as well as coupled vibrations of shells of uniform thickness. Lastly, in the third part, emphasis is placed on certain cases involving special material, geometry and kinematics. Besides, a theorem is devised so as to enumerate the initial and boundary conditions sufficient for the uniqueness in solutions of the system of non-isothermal shell equations.

ABSTRACT: This note derives an analytical relationship for an inextensible network when it buckles. According to the relationship, the applied compressive force can be determined according to the maximum absolute values of deflection and angle of deflection in the network's wrinkles.

ABSTRACT: The existence of stable solutions for geometrically nonlinear theory of shells has been widely discussed by mechanicians during the last century. But, certainly because of the difficulty met in the classical three dimensional nonlinear elasticity, few mathematical results have been obtained. A possibility is to apply the polyconvexity introduced in nonlinear elasticity by J. Ball [1] to ad'hoc shell theories. But unfortunately the positive results are restricted to a special class of materials. Another approach consists in using the so-called G-convergence. This theory has been suggested by the italian school (E. De Giorgi and G. Dal Maso, [9]), and an application to shell models has been given by H. Ledret and A. Raoult [19]. But the main drawback, in our opinion, is that the solution transgresses the equilibrium equations and the difficulty is to make sense to the model obtained. Therefore, it is not yet possible to use these results for the physical problem to be solved. In this paper, we suggest another theory based on some nonlinear mathematical tools which have already been used for particular shell models in [12]. The first part gives a formulation of a general geometrically nonlinear shell model based on a full description of the large kinematical movement induced by a Kirchhoff-Love field. The objectivity property is checked for a class of materials (energy invariance under the only effect of a nonlinear rigid body motion). Then the existence of stable solutions is proved using minimizing sequences and some mathematical tricks based on compactness of few nonlinear terms.

ABSTRACT: The paper presents some results from a study being undertaken at Liverpool into the application of laser welding technology to the design and fabrication of blast and impact resistant structures in the transportation industries. A novel facility has been developed at Liverpool for analysis of dynamic pressure loading of structures, such as aircraft fuselage panels. In the initial work to compare riveted and laser welded panels, the study has included experiments to lap weld AA2024-T3 sheet with both CO2 and YAG lasers, initial
dynamic loading tests on a riveted panel, quasi-static and uniaxial tensile tests on laser welded and riveted AA2024-T3 specimens and FE modelling of the trial riveted structures under loading. In conclusion, more consistent weld penetration on lap joints of 1.6mm thick alloy were obtained with a 3.5kW Nd:YAG laser, than a CO2 laser of equivalent power. Initial tests on a riveted panel identified some boundary conditions and failure loads for future tests. Uniaxial tests on laser welded and riveted specimens of AA2024-T3 indicated that the laser-welded joints have higher strength per unit joint length than the riveted ones, but exhibit more brittle failure. For the initial test panel, failure under dynamic loading occurred at a peak pressure of only 0.6 bar. The FE models of the preliminary tests compare well with experiment, based on mid-panel displacement measurements, but need further development to account for weak points in the frames where the test panel eventually failed.

ABSTRACT: The main aim of the work reported in this paper was to assess the response of panels representative of aircraft structures, to pulse pressure loading by means of experimental and finite element (FE) techniques. A series of experiments were conducted to compare the responses and failure modes of stiffened, aluminium alloy panels, joined using conventional riveting techniques and laser welding. The failure pressures of the riveted panels ranged from 29 to 36 kPa and a number of principal modes of failure were identified, namely (1) rivet shear/tensile failure, (2) frame buckling, (3) stringer buckling and (4) frame rupture. In the case of the laser-welded panels, failure pressures were between 28 and 33 kPa and failure was dominated by significant tearing along the weld heat affected zone at the frame–skin interface. The FE models correctly modelled most of the principal modes of failure observed experimentally and central panel displacement was also predicted well up until the time at which failure initiated.

ABSTRACT: Results from experiments on partially restrained corrugated panels exposed to uniformly distributed quasi-static pressure loading are presented. The corrugated panels were 910 mm long and 880 mm wide, with semi-rigid connections top and bottom, and free sides. The corrugated profile was asymmetric with a pitch of 220 mm. Three types of boundary connections were investigated which offered varying levels of support flexibility, and all failed due to localised buckling at the centre of the corrugations. The results are compared to finite element modelling predictions.

ABSTRACT: Applying the uniform-approximation technique, consistent plate theories of different orders are derived from the basic equations of the three-dimensional linear theory of elasticity. The zeroth-order approximation allows only for rigid-body motions of the plate. The first-order approximation is identical to the classical Poisson-Kirchhoff plate theory, whereas the second-order approximation leads to a Reissner-type
theory. The proposed analysis does not require any a priori assumptions regarding the distribution of either
displacements or stresses in thickness direction.

ABSTRACT: This writing is meant to restitute — a year later, to the best of my recollection — the contents of a series of six lectures I gave in Udine, at the Centro Internazionale di Scienze Meccaniche, within the framework of the Course on Classical and Advanced Theories of Thin Structures: Mechanical and Mathematical Aspects (June 5–9 2006). For this reason, I have made an effort to keep my presentation style informal and colloquial, even when, here and there, I have added some complementing material. There are three parts. In the Premiss, I try and explain why and how, to my taste, the mechanics of thin structures should be presented; in particular, I introduce the direct and deductive approaches and I collect a few bits of history of the latter, in its two main variants, the asymptotic method and the method of internal constraints. Section 2 is devoted to an exposition of the method of formal scaling, a unified approach to classic rod and plate theories that is an outgrowth of the method of internal constraints. Finally, in Section 3, I discuss how to best approximate the stress field in a linearly elastic structure-like body, by exploiting the freedom in the choice of reactive stress fields that maintain the constraints.

ABSTRACT: Structural design is a mature field of engineering. The relatively recent efforts for lightweight structures have motivated increasing use of formal mathematical optimization techniques for selecting the shape and sizes of structural members. How to obtain rigorous optimal topologies has been an elusive goal until the very recent introduction of the homogenization method. The present article describes a system for designing complete structures from only an initial space and loading specifications. A three-phase design process is followed: generate an approxiamate topological image with homogenization, process the image to obtain a practical realistic structure, and refine the final topology by detailed shape and size optimization. An overview of the system at its present state of development is given together with some examples.

ABSTRACT: Out-of-plane deformations of paper, such as fluting, significantly deteriorate the quality of a printed product. There are several explanations of fluting presented in the literature but there is no unanimously accepted theory regarding fluting formation and retention which is consistent with all field observations. This paper first reviews the existing theories and proposes a mechanism that might give an answer to most of the questions regarding fluting. The fluting formation has been considered as a post-buckling phenomenon which has been analysed with the help of the finite element method. Fluting retention has been modelled by introducing an ink layer over the paper surface with the ink stiffness estimated from experimental results. The impact of fast drying on fluting has been assessed numerically and experimentally. The result of the study suggests that fluting occurs due to small-scale hygro-strain variations, which in turn are caused by the moisture variations created during fast convection (through-air) drying. The result also showed that ink stiffening alone
cannot explain the fluting amplitudes observed in practice, but that high drying temperatures promote inelastic (irreversible) deformations in paper and this may itself preserve fluting.

ABSTRACT: A tensegrity structure is a special truss structure in a stable equilibrium, with selected members designated for only tension loading, and the members in tension form a continuous network of cables separated by a set of compressive members. This paper develops an explicit analytical model of the nonlinear dynamics of a large class of tensegrity structures, constructed of rigid rods connected by a continuous network of elastic cables. The kinematics are described by positions and velocities of the ends of the rigid rods, hence, the use of angular velocities of each rod is avoided. The model yields an analytical expression for accelerations of all rods, making the model efficient for simulation, since the update and inversion of a nonlinear mass matrix is not required. The model is intended for shape control and design of deployable structures. Indeed, the explicit analytical expressions are provided herein for the study of stable equilibria and controllability, but the control issues are not treated in this paper.

ABSTRACT: Tensegrity structures consist of strings (in tension) and bars (in compression). Strings are strong, light, and foldable, so tensegrity structures have the potential to be light but strong and deployable. Pulleys, NiTi wire, or other actuators to selectively tighten some strings on a tensegrity structure can be used to control its shape. The article describes some principles we have found to be true in a detailed study of mathematical models of several tensegrity structures. We describe properties of these structures which hold quite generally. We describe how pretensing all strings of a tensegrity makes its shape robust to various loading forces. Another property asserts that the shape of a tensegrity structure can be changed substantially with little change in the potential energy of the structure. Thus shape control should be inexpensive. This is in contrast to the control of classical structures which require substantial energy to change their shape.

ABSTRACT: This paper summarizes the literature on reconciliation of finite element analyses with in-plane bending experiments on piping elbows. It then describes in detail two four-point-bending tests on straight pipes and two in-plane bending tests on elbows and the corresponding nonlinear finite element analyses. Using a new procedure for obtaining a stress-strain curve for stainless steel using only values for E, Sy, and Su and a representative stress-strain curve from a test on a similar material specimen, the nonlinear responses of the piping components tested are shown to be simulated more accurately than previously published results.

ABSTRACT: Most design codes for circular shell structures include a limit on out-of-round imperfections. However, commonly used measures of out-of-roundness fail to identify shapes that have constant diameter but are not circular. It is shown that out-of-roundness imperfections that take these forms can significantly affect the strength of nominally circular shell structures. An alternative measure of out-of-roundness is proposed that captures all out-of-round shapes, gives the same measure of out-of-roundness for elliptical structures as currently used measures and is easy to apply.

ABSTRACT: To get in touch with mesh refinement techniques a program is developed to perform such a mesh refinement for the STAGS-A computer code. After consulting some articles on this subject I decided to use the so-called strain energy density method. To illustrate the working of the program a few examples are dealt with. These examples prove the mesh refinement program to yield excellent results for values of N (rows x columns) small compared to the ones found in the traditional way of calculating. Finally in Appendix 1 the input and output files for this program are described and explained.
ABSTRACT: In the first stage of sheet metal stamping, a binder ring, an annular surface surrounding the die cavity, clamps down on the flat blank, bending it to a developable binder wrap surface which may be smooth or buckled. Buckles generally appear in the binder wrap when the binder ring does not lie on a smooth developable surface that spans the die cavity. However, sometimes buckles can improve the formability of the stamped part, so the ability to design buckled developable surfaces becomes desirable. Designing buckled developable surfaces requires geometric modeling of creases and other singularities in the interior a flat sheet. In this paper we review the properties of such surfaces, show how to approximate buckled binder wrap surfaces by developable three-dimensional triangulations and discuss the insights gained from specific examples.

ABSTRACT: Cardboard honeycomb energy dissipating material (EDM) is used extensively for protection of cargo that is air dropped. Whilst air dropped containers are deployed with parachutes, a significant amount of energy still requires dissipating on impact with the ground. The specification of cardboard EDM in dynamic applications has tended to be ad-hoc with no thorough understanding of the energy absorbing characteristics of the material. This paper seeks to address this gap in knowledge.

ABSTRACT: In this paper, based on the theory of Donnell-type shallow shell, a new displacement-type stability equations is first developed for laminated composite circular conical shells with triangular grid stiffeners by using the variational calculus and generalized smeared stiffener theory. The most general bending stretching couplings, the effect of eccentricity of stiffeners are considered. Then, for general stability of composite triangular grid stiffened conical shells without twist coupling terms, the approximate formulas are obtained for critical external pressure by using Galerkin's procedure. Numerical examples for a certain C/E composite conical shells with inside triangular grid stiffeners are calculated and the results are in good agreement with the experimental data. Finally, the influence of some parameters on critical external pressure is studied. The stability equations developed and the formulas for critical external pressure obtained in this paper should be very useful in the astronautical engineering design.

doi:10.1016/j.tafmec.2010.06.014
ABSTRACT: Thin-walled members are commonly used as energy absorbers in engineering structures and often contain cutouts. This study performed numerical simulations of high strength steel cylindrical shells with elliptical cutouts subjected to dynamic axial impact. The LS-DYNA code was the primary analytical tool used to analyze the influence of cutout locations, cutout shapes and symmetry of cutout on the energy absorption capabilities and the crush characteristics of tubes with a cutout. For high strength steel tubes made from a rate sensitive material, the stress–strain curves of different strain rates were used to elucidate the effect of dynamic impact on the strain rate. Our results show that collapse crushing behavior is strongly influenced by the location and symmetry of cutouts and the variation of major axis influences the peak crush load.

ABSTRACT: Composite tubes can be reinforced with continuous fibers. When such tubes are subjected to crushing loads, the response is complex and depends on interaction between the different mechanisms that control the crushing process. The modes of crushing and their controlling mechanisms are described. Also, the resulting crushing process and its efficiency are addressed.

ABSTRACT: This paper is an investigation into the design of an energy absorbing street pole, concerning the frontal impact of a vehicle. With design engineers now are looking at other ways to improve vehicle occupant safety by focusing on the advantages that can be achieved by improving the crashworthiness of street furniture. The study of axial crush behaviour of metal materials are investigated along with a number of variables such as cross-sectional shape, shell thickness, materials, as well as the velocity affects on tubes. Different simulations are carried out on the effects of bedded crumple initiators placed a various heights from the top of the tube, in determining the desired value of peak load reduction, along with the effect in energy absorption of the tube. With the conclusion of the desired variables for the design of an energy absorbing tube, the tubes are placed 90 degrees to that of the base of the model street pole to modify the pole design. Simulation of frontal impact of a vehicle and street pole are analysed and compared to that of the energy absorbing street pole concept. Studies are carried out by numerical simulation via the explicit finite element code LS-DYNA. Results compare the absorbed energy and the deflection of each variable, and recommend optimum design for the pole structure which improved vehicle crashworthiness.

ABSTRACT: The high thickness of heads used in pressure vessels is always one of the main concerns of designers and manufacturers. A comprehensive analytical and experimental study has been conducted by the authors on all types of heads including torispherical heads (under external and internal pressure) to come up
with a procedure to reduce their thicknesses using stiffening-rings. The result of the experiments and Finite Element Analysis (FEA) on torispherical heads with pressure on their concave side are presented in this paper. A method for determining the dimensions of the most suitable ring and its location on heads as well as its effect on the reduction of head thickness is addressed. The experimental results show good agreement with the analytical calculations and confirm that suitable stiffening-rings, in most cases, could considerably reduce head thicknesses.

INTRODUCTION: All around us, in natural forms, art, architecture, engineering, and consumer products, we
find surfaces whose geometry is vastly richer than the Euclidean geometry we learn in high school. To treat surface geometry analytically requires rather advanced tools, but it is possible to gain much insight into the subject by performing measurements on the surfaces of physical objects. Beem [1] suggested some activities along these lines, and Henderson [6] has made ample use of physical models. Casey [3,4] has described a series of experiments that are designed to bring modern geometrical concepts within the reach of students who might no yet be in a position to study differential geometry formally. In the present paper, as an illustration, a method of estimating the Gaussian curvature of surfaces from surface measurements is described.

INTRODUCTION: This chapter is concerned with basic assumptions and equations of plates and basic concepts of elastic stability. Herein, we shall illustrate the concepts and the applications of these equations by means of relatively simple examples; more complex applications will be taken up in the following chapters.

ABSTRACT: The design and analysis of the large span steel latticed shell structure in site of Yuyao Tianluoshan is introduced, and some key problems are dwelled on in this paper. By the geometrical nonlinear finite element method, the nonlinear stability analysis is carried out. The buckling modal and the whole course of instability are shown by two analysis method, the eigen-buckling analysis and the geometrical nonlinear finite element method. The influence of spring support to the stability of the structure is analyzed. It is shown that the structure has good wind-resisting capacity, which is fit to the circumstance near sea with lots of typhoon. Large compressive membrane stresses arise in the structure under the condition of temperature rise, leading to a significant reduction in the stability load-carrying capacity of the structure.

ABSTRACT: In modern engineering there is a considerable interest in predicting the behavior of post-buckled structures. With current lightweight, aerospace, and high performance applications, structural elements frequently operate beyond their buckled load. This is especially true of plates, which are capable of maintaining stability at loads several times their critical buckling load. Additionally, even structures such as cylindrical shells may be pushed into a post-buckled range in these extreme applications. Because of the nature of these problems, continuation methods are particularly well suited as a solution method. Continuation methods have been extensively applied to a range of problems in mathematics and physics but have been used to a lesser extent in engineering problems. In the present work, continuation methods are used to solve a variety of buckling and stability problems of discrete dynamical systems, plates and cylinders. The continuation methods, when applied to dynamic mechanical systems, also provide very useful information regarding the modal behavior of the structure, including linearized natural frequencies and mode shapes as a by-product of the solution method. To verify the results of the continuation calculations, the commercial finite element code ANSYS is used as an independent check. To confirm stable equilibrium shapes for square plates, a set of experiments on polycarbonate plates is also presented.

ABSTRACT: To serve the common needs of the society, structural engineers should achieve impressive gains over high strength, light weighted, safe and economical structures. As rapid advances in the construction materials, in many situations, fibre reinforced polymer (FRP) composites provide opportunities for enhanced efficiency, primarily because of their high strength to weight ratio. They can also be combined with steels to form composites enabling them to be used as structural members and have become an attractive option which may produce a confident retrofitting of steel structures, attracting a great deal of attention in these recent years. Carbon fibre reinforced polymer (CFRP) is a comparatively new and revolutionary class of composite material manufactured from fibres and resins and has proven effect for the development of new as well as repairing of deteriorated material. The strength properties of CFRPs jointly make up one of the ultimate reasons for which civil engineers prefer them in the design of structures. However, like most structural materials, CFRPs have a few drawbacks that would create some doubts to civil engineers to apply it in practical field: brittle behaviour, susceptibility to deformation under long-term loading, UV degradation and temperature and moisture effects. Also, another downside to the age of these advanced composites is the relatively lower stiffness exhibited by CFRPs. As a consequence, serviceability rather than strength limit tends to provide the controlling influence on design. In the context of thin-walled shell structures, the relatively low stiffness to strength ratio of CFRP makes that buckling driven largely by elastic buckling behaviour and becomes the dominant design constraint. At this time, it becomes difficult to achieve the required levels of load carrying capacity by using shells constructed from just CFRP. For this reason too, the high stiffness of steel contributes to make it an attractive material for the design of shells in which buckling is likely to be an important issue. On the other hand, steel cylindrical shells when exposed to the hostile chemical on marine environments show their vulnerability to corrosion. That’s why a novel way to protect steel shells from corrosion and to make CFRP shells strengthened is to coat them with these veneers of suitable amount of CFRP. In this context CFRP, if collectively used with thin steel shells, the mechanical properties of the new composite material will be tremendously increased. Since the mechanical properties of CFRP make them ideal for widespread applications in construction of civil engineering field, buckling behaviour determines the relationship between strength, life span and economy of any structures. Also, it is necessary to introduce the fibres’ position, direction and volume in the matrix material at highly stressed regions in certain positions, direction and volume in order to obtain the maximum efficiency from the reinforcement to a minimal amount at a region of low stressed value. For this reason too, buckling mechanism is likely to be an important issue. Similarly, CFRP composite materials exhibit collapse modes that are significantly different from the collapse modes of steel materials. That’s why, investigation over strengthening of thin-walled steel shells with the application of small amount of CFRP could become an important issue. To lower down the downside of the lower stiffness exhibited by CFRP shells and to diminish the major problem associated with steel shells, a new composite sandwich structure has been introduced in this research and the effect of CFRP reinforcements under axial as well as lateral compression has been studied through three kinds of analytical procedures; the linear eigen value analysis, the modified RS (reduced stiffness) analysis and the fully non-linear numerical experiment, presenting a novel way of strengthening thin-walled steel cylindrical shells against buckling. With these multiple treatments, valuable information for the design of CFRP-based hybrid structural elements has been predicted and suggested the influence of CFRP to increase the load-carrying capacity of the thin-walled steel structures having complex buckling collapse behaviour. The research thesis has total 10 chapters. Firstly, a survey of recent FRP applications, objective of research and preliminary numerical equations has been derived. Secondly, the analytical model has been proposed and the analytical procedure related to the proposed model has been discussed. Thirdly, investigation as well as results has been predicted for nonlinear buckling behaviour, effects of reinforcement thickness and effects of angle of fibre orientation for both the lateral and axial loading conditions. Finally, these results are summarized in the conclusion part along with the suggestions for the better prediction of the result.

http://www.graduate.technion.ac.il/theses/Abstracts.asp?Id=22501
ABSTRACT: ElectroMechanical Buckling (EMB) is the bifurcation response which results from the coupling of electromechanical bifurcation and mechanical buckling. The work presented here is seemingly the first time ever this coupling is considered and analyzed. This work also includes a first ever experimental validation of EMB. Mechanical buckling occurs in slender structures that are subjected to an axial compressive load which is larger than a critical value. In this dissertation it is shown that an electrostatic field can instigate buckling even when the compressive load is below the critical value. The EMB voltage is a monotonically increasing function of the axial load. Motivated by this, a novel method for measuring residual stress in micro-structures is presented. This method enables to measure compressive as well as tensile stresses, in a continuous wide range. The EMB response of a pre-stressed slender microbeam that is bonded to a linear elastic foundation and is subjected to electrostatic forces is also investigated. In this dissertation it is shown that the EMB of such a microbeam can be used to achieve reversible, electrostatic on/off switching of surface flexures. In this work, the electromechanical buckling and postbuckling of a circular cylindrical micro shell that is subjected to a radial axi-symmetric electrostatic force is also investigated. It is found that the initial electromechanical postbuckling of such a micro shell is unstable for the range of parameters considered.

ABSTRACT: Fibre reinforced composite plates and shells are increasingly replacing traditional metallic ones. The manufacturing process and service of the composite laminates frequently lead to delamination. Delamination reduces the stiffness and strength of composite laminates because they allow out of plane displacement of plies to occur more easily. Dynamic stability analysis is an integral part of most engineering structures. The present work deals with the study of the effects of free vibration, buckling and dynamic stability of delaminated cross ply composite plates and shells. A first order shear deformation theory based on finite element model is developed for studying the instability region of mid plane delaminated composite plate and shell. The basic understanding of the influence of the delamination on the natural frequencies, non-dimensional buckling load and non-dimensional excitation frequency of composite plates and shells is presented. In addition, other factors affecting the vibration, buckling and dynamic instability region of delaminated composite plates and shells are discussed. The numerical results for the free vibration, buckling and dynamic stability of laminated cross-ply plates and shells with delamination are presented. As expected, the natural frequencies and
the critical buckling load of the plates and shells decrease with increase in delamination. Increase in delamination also causes dynamic instability regions to be shifted to lower excitation frequencies.

ABSTRACT: In several industries such as civil, mechanical, and aerospace, thin-walled structures are often used due to the high strength and effective use of the materials. Because of the increased consumption there has been increasing focus on optimizing and more detailed calculations. However, finely detailed calculations will be very time consuming, if not impossible, due to the large amount of degrees of freedom needed. The present thesis deals with a novel mode-based approach concerning more detailed calculation in the context of distortion of the cross section which model distortion by a limited number of degrees of freedom. This means that the classical Vlasov thin-walled beam theory for open and closed cross sections is generalized as part of a semi-discretization process by including distortional displacement fields. A novel finite-element-based displacement approach is used in combination with a weak formulation of the shear constraints and constrained wall widths. The weak formulation of the shear constraints enables analysis of both open and closed cell cross-sections by allowing constant shear flow. Variational analysis is used to establish and identify the uncoupled set of homogeneous and non-homogeneous differential equations and the related solutions. The developed semi-discretization approach to Generalized Beam Theory (GBT) is furthermore extended to include the geometrical stiffness terms for column buckling analysis based on an initial stress approach. Through variations in the potential energy a modified set of coupled homogeneous differential equations of GBT including initial stress is establish and solved. In this context instability solutions are found for simply supported columns and by solving the reduced order differential equations the cross-section displacement mode shapes and buckling load factor are given. In order to handle arbitrary boundary conditions as well as the possibility to add concentrated loads as nodal loads the formulation of a generalized one-dimensional semi-discretized thin-walled beam element including distortional contributions is developed. From the full assembled homogenous solution as well as the full assembled non-homogeneous solution the generalized displacements of the exact full solution along the beam are found. This new approach is a considerable theoretical development since the obtained GBT equations including distributed loading found by discretization of the cross section are now solved analytically and the formulation is valid without special attention and approximation also for closed single or multi-cell cross sections. Furthermore, the found eigenvalues have clear mechanical meaning, since they represent the attenuation of the distortional eigenmodes and may be used in the automatic meshing of approximate distortional beam elements. The magnitude of the eigenvalues thus also gives the natural ordering of the modes. The results are compared to results found using other computational methods taking distortion of the cross section into account. Thus, the results are compared to results found using the commercial FE program Abaqus as well as the free available software GBTUL and CUFSM concerning conventional GBT and the finite strip method, respectively. Reasonable matches are obtained in all cases which confirm that this new approach to GBT provides reasonable results with a very small computational cost making it a good alternative to the classical FE calculations and other available methods.

ABSTRACT: The nonlinear vibrations of a thin, elastic, laminated composite circular cylindrical shell, moving in axial direction and having an internal resonance, are investigated in this study. Nonlinearities due to large-amplitude shell motion are considered by using Donnell's nonlinear shallow-shell theory, with consideration of the effect of viscous structure damping. Differently from conventional Donnell's nonlinear shallow-shell equations, an improved nonlinear model without employing Airy stress function is developed to study the nonlinear dynamics of thin shells. The system is discretized by Galerkin's method while a model involving four degrees of freedom, allowing for the traveling wave response of the shell, is adopted. The method of harmonic balance is applied to study the nonlinear dynamic responses of the multi-degrees-of-freedom system. When the structure is excited close to a resonant frequency, very intricate frequency-response curves are obtained, which show strong modal interactions and one-to-one-to-one-to-one internal resonance phenomenon. The effects of different parameters on the complex dynamic response are investigated in this study. The stability of steady-state solutions is also analyzed in detail.

ABSTRACT: This thesis studies the possibilities of determination of the critical buckling force of laminated composite cylindrical shells through analytical as well as through FEM approach. The analytical solution is presented in detail and a Matlab program is made to allow its calculation. FEM solutions are done using two different solvers of the MSC.Nastran software, the effects of different settings of the solvers are explored as well as the general behaviour of the solvers. All of the approaches are in the end compared and a several conclusions are proposed.

“Experimental investigation on buckling of GFRP cylindrical shells subjected to axial compression”, Journal of Mechanical and Civil Engineering (IOSR-JMCE), Vol. 9, No. 5, pp 20-25, November-December 2013
ABSTRACT: Composite cylindrical shells are being used in submarine, underground mines, aerospace applications and other civil engineering applications. Thin cylindrical shells are more prone to fail in buckling rather than material failure. An experimental study on buckling of glass fiber reinforced plastics layered composite cylindrical shells under displacement and load controlled static axial compression are reported. The experimental results are compared with general purpose finite element program (ANSYS). Limit point loads evaluated for geometric imperfection magnitudes shows an excellent agreement with experimental results which clearly indicates the confidence gained on the numerical results presented. Present study finds direct application to qualitatively investigate the influence of geometric imperfection on other advanced grid-stiffened structures.

ABSTRACT: The main key performance factors of honeycombs are represented by the ability to withstand through-thickness compression and to absorb energy by plastic deformation of the cell walls. The knowledge of the constituent material properties, including the sensitivity of these structures to material defects, and of the folding mechanism occurring during the crushing mode represents a basic step to perform reliable finite element analyses able to accurately reproduce the behavior of such structures. The present paper reports a comprehensive study of the compressive response of hexagonal honeycomb structures made of phenolic resin-impregnated aramid paper (Nomex); the compressive response is numerically investigated and compared with experimental results. A shell model of a representative single cell made of expanded Nomex has been created using the implicit ABAQUS finite element solver. Imperfections due to the manufacturing process are taken into account including material imperfections (elastic modulus variability) and geometrical defects (thickness variability). Imperfections are included in the model by defining different material and thickness properties for each element according to a pre-defined statistical distribution. The effects of imperfections on the honeycomb structure behavior are investigated. The predicted structural response, numerically obtained using different sets of imperfections, shows a good correlation with experimental results.

ABSTRACT: The increasing number of successful applications of fibre reinforced polymer (FRP) laminates in realizing civil structures as well as their subsequent technological development have attracted the attention of the international scientific community, a special interest being given to understand in greater detail all aspects connected to the use of new materials. This paper deals to manufacture composite laminate by using glass fiber as reinforcing material and unsaturated polyester as matrix material. Here the investigation of critical buckling load has been done with changing the fiber orientation at succeeding lamina by 45°.

ABSTRACT: Wind turbine towers are belonging to towering cylinder shell structures, which are easy to appear buckling instability under wind or other complicated loads, and on which integral elastic-plastic buckling analyses have great theoretical and practical significances. This paper used large deflection nonlinear pre-buckling and Koiter initial post-buckling theories, and adopted the finite element scheme of updated integration algorithm and LDC nonlinear solution method, then analyzed the linear buckling, elastic-plastic static buckling, and post-buckling response of the towers with initial imperfections in different location and size. It has obtained that: 1) the critical load of towers with elastic-plastic buckling is much smaller than it with elastic buckling; 2) gravity has certain influence on the critical buckling load; 3) the critical buckling load is insensitive to initial imperfections, meanwhile the imperfections which located on the top or the bottom of the tower are inferior for the stability of tower.

“Mechanical behavior of glass/epoxy tubes under combined static loading. Part I: Experimental”, Composites Science and Technology, Vol. 69, No. 13, October 2009, pp. 2241-2247, Special Issue: Smart Composites and Nanocomposites, doi:10.1016/j.compscitech.2009.06.009
ABSTRACT: A series of biaxial static tests of E-glass/epoxy tubular specimens [±45]2, subjected to combined torsion and tension/compression were performed to simulate complex stress states encountered in a wind turbine rotor blade. The failure locus in the effective axial-shear stress plane was derived experimentally while in-plane strain tensor components were measured in the tube outer surface. By means of shell theory and strain measurements in the surface of the specimen, the in-plane shear response of the outer ply was obtained, revealing dependence each time to the combined tube loading. The correlation established between the ratio of transverse normal and in-plane shear stress in the principal coordinate ply system and the elastic shear modulus, suggested a strong dependence, warning on the implications for design and certification procedures.

ABSTRACT: Experimental results from a series of biaxial static tests of E-Glass/Epoxy tubular specimens [±45]2, were compared successfully with numerical predictions from thick shell FE calculations. Stress analysis was performed in a progressive damage sense consisting of layer piece-wise linear elastic behavior, simulating lamina anisotropic non-linear constitutive equations, failure mode-dependent criteria and property degradation strategies. The effect of accurate modeling of non-linear shear stress–strain response, dependent on the plane stress field developed, was proved of great importance for the numerical FEA predictions, concerning macroscopic stress–strain response. Ultimate load prediction was influenced more decisively when degradation strategies for the compressive strength along the fiber direction were considered.

INTRODUCTION: Many papers have been published and they have demonstrated that the finite strip method has higher efficiency than the finite element method as a smaller number of degrees of freedom are involved in the solution. The increase in the popularity and the number of potential applications of the finite strip method has created a demand for a definitive text/reference on the subject. Fulfilling this demand, The Finite Strip Method provides practicing engineers, researchers, and students with a comprehensive introduction and theoretical development, and a complete treatment of current practical applications of the method. This paper takes the review of some of the important paper finds conclusion that semi-energy FSM formulation is more economical compared to the full-energy FSM and FEM analyses.

ABSTRACT: It has been previously demonstrated that increasing structural complexity can lead to lighter weight structures. However, it is not clear that structural complexity or hierarchy enables lighter weight structures for all architectures and load cases. In this paper, the performance trends in linear truss structures are investigated as a function of self-similar hierarchy order and of loading conditions. The investigations show the order of structural hierarchy resulting in a lightest weight self-similar four longeron solid element truss-column is 2nd (a truss made from trusses) for requirements representative of space structures. The resulting truss-column is typically an order of magnitude lighter than the corresponding 1st order truss-column and two to four times larger in diameter. Long and lightly loaded columns are shown to have the greatest potential for mass reduction with increasing hierarchy. Optimization results for 1st and 2nd order self-similar triangular single-laced double-bay trusses subject to bending strength and stiffness requirements are also presented. A comparison of 1st and 2nd order results show a factor of 30 reduction in truss mass and a simultaneous factor of nine increase in truss diameter.

ABSTRACT: A new approach to the study of the effects of randomly distributed imperfections on grid-shell structures is presented. The simulation of randomly distributed out-of-scheme imperfections has been performed, introducing a kind of spatial correlation in order to avoid events that even if statistically possible, has to be considered not achievable from a pragmatic point of view. The fields of imperfections take into account the initial stress state of the imperfect structure that may appear as a consequence of the geometric perturbation. Some computational tests have been finally carried out on a sample structure.

ABSTRACT: The paper concerns the design of a new sports arena and in particular of a aluminium roof structure for the Mandela Forum, which is the major sports arena of Florence. The project key-element is the aluminium geodesic dome, chosen in order to set up a covering with optimal and functional structure and shape. The key topic discussed in this paper concerns the geometrical issue of the structural optimization, in fact comparing several types of iron framework domes, the geodesic one seemed to be the best choice, as proved
through mathematical and computational models. The numerical analyses showed that the geodesic framework is stiffer than other configurations, moreover it minimizes the material used: indeed the overall beam length is optimized. Furthermore, due to the framework regularity, the stress state is almost uniform in the whole structure beams.

ABSTRACT: The energy absorption characteristics of E-glass/Polypropylene (PP) isogrid composite panels under quasi-static transverse load conditions have been investigated. Experimental tests and finite element simulations were performed for isogrid composite panels in three-point bending boundary condition. Results of tests and simulations show that loading the panels on rib side results in greater specific energy absorption along with larger displacements compared to skin side loading which is more abrupt. These results can be used to advantage in weight-critical automotive side impact crashworthy applications. Vibration response measurements which were used as a non-destructive tool for evaluating the quality of as-manufactured isogrid plates and monitoring induced damage in one of the plates are also presented.

ABSTRACT: This paper presents a numerical method of analysing the elastic stability of thin laminated and longitudinally stiffened shells of revolution. The anisotropic elastic properties of composite materials are taken into account. The discrete longitudinal stiffener is dealt with as a beam-column, and its eccentricity effect is also considered. The basic elastic and geometric stiffness properties of the stiffeners are synthesized into a stiffness matrix compatible with an axisymmetric shell element by a series of transformations to be used in conjunction with a finite element representation of a thin axisymmetric shell, where the displacements are decomposed into Fourier harmonics. Thus, the effect of the stiffeners can be rigorously accounted for in stability analysis. Examples are given to show that the results agree well with existing solutions by other analytical methods and by experiments.

ABSTRACT: The stability of arch and shell structures with random imperfections subjected to random loading is investigated. Arches are analyzed under different types of transverse loads while axial and/or pressure loading are considered for cylindrical shells. A probabilistic analysis of the randomness in the geometric imperfections along with the uncertainty in both loading and material properties is presented. The study investigates the effect of spatial variability of the different random parameters in the problem on the buckling load and the associated displacements. The imperfection sensitivity is studied for several geometrical configurations of the arches and shells and for various values of the statistical parameters for the random shape imperfections. One- and two-dimensional random fields are introduced with different types of autocorrelation functions to characterize the structures and the imperfections. A sufficient number of terms is considered using two series expansion methods to express the field in terms of its spectral decomposition. The first employs the Karhunen-Loeve theorem where the autocorrelation coefficient function is expanded in terms of its eigenvalues and eigenfunctions, while the second method utilizes any complete set of orthogonal functions. These techniques are compared with both the midpoint and local averaging methods for random field discretization and prove to be more computationally efficient within a given level of accuracy. Both first- and second-order reliability methods (FORM/SORM) along with Monte Carlo simulation are used to evaluate different modes of instability based on the buckling load or the associated displacements. The probability density and the cumulative distribution functions of the buckling load are presented for various distributions of the imperfections. The sensitivity of the buckling load and the postbuckling displacements to different parameters is also presented. An extensive parametric study through many numerical examples is performed to establish a better understanding of the effects of the spatially variable imperfections on the buckling of arches and shells.

ABSTRACT: The article presents the results of the experimental investigation of the process of deformation of cylindrical shells with circular nonreinforced notches. It is shown that the dependences of the load bearing capacity of shells on the parameters determining the notches (radius and their number) have sections each of which is characterized by wave formation determining the mechanism of failure.

ABSTRACT: Tests of cross-ply composite tubes were performed under combined axial and torsional loading up to failure. Strength properties and failure mechanisms were evaluated with reference to the biaxiality ratio of the loading. The scattering of the biaxial strength data was analyzed using the Weibull distribution. The axial contraction of carbon fiber-reinforced plastic (CFRP) tubes under biaxial loading was investigated theoretically and experimentally. Artificial neural networks were introduced to predict the failure strength using the algorithm of the error back-propagation. The prediction was also made by the Tsai-Wu theory using the experimental data and by the combined optimized tensor-polynomial theory. A comparison shows that the artificial neural network has the smallest root-mean-square (RMS) error of the three prediction methods. The prediction of the axial contraction of the tubes correlates well with the results of a linear variable differential transformer (LVDT) of the testing machine. From the phenomenological analysis of the failure and the fractographic observations of the fracture surface, three types of failure modes and microscopic failure were investigated, depending on the biaxiality ratio, and the corresponding failure mechanisms are suggested.

ABSTRACT: Biaxial tests have been conducted on cross-ply carbon/epoxy composite tube under combined torsion and axial tension/compression up to failure. Strength properties and distributions were evaluated with reference to the biaxial loading ratio. The scatter of the biaxial strength data was analyzed by using a Weibull distribution function. Artificial neural networks were introduced to predict failure strength by means of the error back-propagation algorithm for learning, providing a different and new approach to the representation of complicated behavior of composite materials. Further prediction is made from experimental data by the use of Tsai–Wu theory and a combined optimized tensor polynomial theory. Comparison shows that the artificial neural network has the smallest root-mean-square error of the three prediction methods.

ABSTRACT: This paper presents a hybrid meta-heuristic algorithm called multiple start guided neighbourhood search (MSGNS) algorithm for combinatorial optimisation which combines the good features of popular guided local search algorithms like simulated annealing and tabu search. It has been organized as a multiple start algorithm to maintain a good balance between intensification and diversification. The proposed hybrid meta-heuristic algorithm has been employed to solve optimal stacking sequence design problem of laminate composite structures. First, the algorithm has been employed to solve the problem of optimal stacking sequence of a composite plate for which the results of various algorithms are available in the literature. This study is basically to validate and also to demonstrate the effectiveness of the proposed algorithm over several existing
meta-heuristic algorithms. Later, a practical design example of fiber-reinforced composite cylindrical skirt of solid rocket motor of aerospace vehicle is investigated. A skirt is a potential element for weight reduction in rocket motors as it leads to reduction of the total weight of solid rocket motor. Due to its significance for solid rocket motors, it is proposed to optimise the weight as well as cost of the fiber-reinforced composite cylindrical skirt subjected to a buckling strength constraint and an overstressing strength constraint under aerodynamic torque and axial thrust. This is achieved by arriving at an optimal stacking sequence for the cylinder satisfying all the design constraints and also by employing multiple composite materials. Classical laminate theory combining with elastic stability theory of thin shells is used to arrive at buckling strength and overstressing strength of the fiber-reinforced composite cylindrical skirt. The Tsai-Wu failure criterion is employed to assess the first ply failure. Buckling strength and failure strength of the cylindrical skirt is described by using buckling load factor and overstressing load level factor. Numerical simulations carried out in this paper clearly demonstrate the superiority of the proposed MSGNS algorithm over the popularly used combinatorial algorithms like genetic algorithm and simulated annealing.

CONCLUSIONS: 1. Analysis of the results obtained for the example of boron-plastic and hybrid three-layer shells leads us to conclude that the kinematically uniform model cannot be used to calculate the PRDS of three-layer shells with bearing layers having a stiffness three to four times greater and a density roughly one order greater than the stiffness and density of the filler material. 2. The replacement of the rigid fiber-reinforced material of the middle layer of the shell by a “soft” and light material such as foam plastic leads to a situation whereby the initial sections of the RDI connected with vibrations of the shell as a whole in the x, y, and z directions are shifted toward smaller frequencies θ. Here, the number of regions ηθ(ℓ, n)/ρ=1, 3, ..., 10 forming the RDI is greater, at least on the initial sections, due to the fact that regions corresponding to different modes of parametric vibration are brought closer together. The width of these regions of dynamic instability is decreased by several factors compared to the width of the corresponding ηθ of the RDI spectrum of a shell having all of its layers made of a stiff material. 3. Calculated results obtained in the present study but not reported in this article show that the RDI's connected with vibration of the middle layer in the transverse shear planes and in the direction of the z axis change in a manner similar to that described in Part 2 (compressive vibrations). The remaining six RDL's connected with the same vibrations of the bearing layers of the shell are shifted toward larger θ. The width of all of the regions of the nine RDI's indicated here is negligibly small.

ABSTRACT: To account for plastic deformation in plate and shell structures an elasto-viscoplastic solution algorithm is considered based on Perzyna's model for material behaviour. This algorithm can be employed to solve for time-dependent elasto-viscoplastic situations and by allowing steady-state conditions to be reached, elasto-plastic problems can also be considered. For the large displacement elasto-viscoplastic analysis of thin shells, an incremental stiffness procedure is employed together with a Lagrangian description of the stress and strain vectors. The Šemiloof plate and shell elements are used for finite element space discretization. The procedures developed are applied to the solution of several numerical examples and the solutions compared with results from other sources where available.

ABSTRACT: This paper presents the application of a refined finite element model to the elastic and elastic-plastic dynamic analysis of anisotropic laminated plates. Dynamic analysis is based on Newmark's algorithm used in conjunction with the Hughes and Liu predictor-corrector scheme resulting in an ‘effective static problem’ which is solved using a Newton-Raphson-type process. Flow theory is used in the inelastic range and the Huber-Mises yielding surface extended by Hill for anisotropic materials is adopted. Numerical results obtained for two categories of anisotropic structures, namely cross-ply laminated plates and angle-ply laminated plates, are presented and the effects of anisotropy and bending/stretching coupling on the dynamic elastic and elastic-plastic responses are discussed. The effects of lamina stack sequences and lamina angle sequences on the dynamic responses are also considered.

ABSTRACT: The New Zealand Society for Earthquake Engineering (NZSEE) has a study group working on the seismic design of storage tanks. The study group is preparing a revision of the widely acknowledged NZSEE 1986 document “Seismic Design of Storage Tanks”. Draft amendments of the loading procedures in the 1986 document have been prepared. This paper presents a summary of the proposed approach. …

ABSTRACT: This paper focuses on the localized nonlinear buckling of pressure vessel under internal pres-sure caused by initial geometric imperfection. The localized plastic buckling occurred in the transition region in the torispherical end closure of a pressure vessel has been analyzed by FEM. By introducing two types of initial geometrical imperfections, the arc-length method of modified-Riks/Ramm procedure is employed to simulate the deformation process during loading. The first type of imperfection is determined from the elasto-static displacements, into the zone where it is circumferentially compressed. The second type of imperfection is the irregular thickness of the vessel, also into the zone where it is circumferentially com-pressed. The buckling point is captured from the load-deflection curve of a typical point within the buckled zone, and the corresponding buckling load is calculated. The results show that after the first buckling initiated, the succeeding loading will lead to more wrinkles within the compressive transition region, which agree well with the results of experiments.

ABSTRACT: The paper presents theoretical and numerical studies of the buckling of steel shells subjected simultaneously to axial and pressure loading. The type of combined non-uniform loading used for this analysis (horizontal pressure and wall frictional pressure which occurs in the silos) is given in the Eurocode 1 part 4. An Abaqus program was used to study the influence of the parameters affecting the strength of the shell. The results of this parametric study were used to develop a new semi-analytical method for the prediction of the critical stress of the stiffened and isotro-pic shells. The corresponding formulae are compared, in different examples of geometrical shells, with the results obtained by finite element simulation and by the formulae for buckling design given in recommendation EC3.

ABSTRACT: A solid shell element model with six degrees of freedom per node is applied to buckling and postbuckling analysis of geometrically nonlinear shell structures. The present model allows changes in the thickness direction and does not require rotational angles or parameters for the description of the kinematics of deformation. The finite element model is constructed based on the assumed strain formulation in which an assumed strain field is chosen to prevent locking while maintaining kinematic stability. Numerical results show that the present model allows large increments in the iterative solution scheme for pre- and postbuckling analysis. In particular, it appears that the model provides a means to pinpoint a bifurcation point on the
geometrically nonlinear deformation path.

Daniel Trybula (Institute of Applied Mechanics, Faculty of Mechanical Engineering, Cracow University of Technology, Poland), “Stabilization of Post-Buckling Path By Axial Loading Controlled By Displacements for Cylindrical Shells under Torsion”, Mechanics, Technical Transactions, Politechniki Krakowskiej, Issue 8, Year (Vol.?)107

ABSTRACT: A post-buckling path for a cylindrical shell under torsional moment is unstable one. It means that the loss of stability of a shell can be associated with a snap-through, which can lead to very large displacements and, finally, to destruction of the structure. The effect of modification of the post-buckling behavior in most cases has been obtained by changing of geometry of a structure. In this paper an alternative concept is applied, namely stabilization of the post-buckling path is obtained by application of an additional loading acting to the structure without changing its geometry. This additional loading is applied to a structure by imposing a certain axial displacement to the ends of the shell. It causes an axial tensional force, which can stabilize the post-buckling path. The problem was formulated as a problem of optimization, namely the minimum value of the axial load - the initial pretension u, which leads, together with the passive force, to stabilization of the post-buckling path is looked for. Calculations were performed using ANSYS code.

References listed at the end of the paper:

ABSTRACT: The post-buckling path for a cylindrical shell under compressive radial pressure is unstable. The effect of modification of the post-buckling behaviour is in most cases obtained by changing sizing variables, which are usually dimensions of the design element. In this article an alternative concept is applied, namely stabilization of the post-buckling path for a simply supported cylindrical shell under radial compressive pressure is obtained by application of additional loadings acting on the structure without changing the shape or sizes of the optimized element. These loadings can be either active forces applied to the structure or passive ones (reactions of the additional supports) or both active and passive forces acting simultaneously. All three types of stabilizing forces were investigated. Calculations were performed using the ANSYS 11.0 Academic Research code for elastic and elastic–plastic deformations of shells of different length and thickness.

ABSTRACT: The effect of stabilization of unstable post-buckling behavior of a structure usually is obtained by changing its geometry. In this paper, a possibility of stabilization of the initially unstable post-buckling path for a cylindrical shell under torsion by application of additional independent loadings acting on the structure without changing the shape and size of the shell is investigated. It occurred that axial tension improves the resistance against buckling for the cylindrical shell under torsion and can stabilize the unstable post-buckling path. On the other hand, internal pressure does not stabilize the post-buckling path but it improves the resistance of such a structure against instability.

Methods in Engineering, 42, 7, 1231-1262

ABSTRACT: Shell structures are widely used in many industries thanks to their high efficiency in terms of load carrying capacity vs. weight optimal ratio. However, it is well known that these structures are also characterized by a high sensitivity to buckling instabilities, triggered by ineluctable initial shape imperfections, space-varying material properties and/or boundary conditions, unknown to some extent. These imperfections or rather unknown properties, inherent to the manufacturing process, are highly unpredictable and thus hard to take into account at the design stage. In this paper, the authors propose a stochastic approach to model those initial shape imperfections, considered as random, and accounting for uncertain spatially varying material properties and thicknesses, based on the random field theory. The assessment of the failure probability is addressed by means of subset simulations, which outperform crude Monte Carlo performance when estimating small probabilities. Critical buckling loads of the shell structure are determined using an original Finite Element-based method known as the Asymptotic Numerical Method (ANM), which accounts both for geometric and material nonlinearities. The ANM was proved to be less computationally demanding and robust than classical incremental-iterative methods offered in general purpose FE codes. Finally, for illustration purposes, the whole approach is applied to an example derived from the well-known Scordelis-Lo shell roof.

ABSTRACT: We present a new 6-node triangular bending element (called DKTP) based on a discrete Kirchhoff model. A corresponding new flat-shell element, DLTP, having quadratic variation of in-plane displacement is also presented. This element has 6 degrees-of-freedom (u, v, w, thetax, thetay, thetaz) at each corner node and 3 degrees-of-freedom (u, v, w) at each mid-side node. Detailed numerical experimentation is presented to demonstrate the efficiency and reliability of these elements.

ABSTRACT: The comparative efficiency of three flat triangular shell elements is being assessed for analysing non-linear behaviour of general shell structures. The bending formulation of the three elements is based on a discrete Kirchhoff model (namely the well-known 3-node DKT element and a new 6-node DKTP element). The in-plane behaviour is defined by constant (CST), linear (LST) and quadratic (QST) strain approximations. The super-position of bending and membrane elements leads to the 3-node DCT element (DKT plus CST), the 3-node DQT element (DKT plus QST) and the 6-node DLT element (DKTP plus LST). The geometrically non-linear formulation is based on an approximate updated Lagrangian formulation (AULF) and the solution is obtained by using the Newton-Raphson method with an automatic arc-length control method. Illustrative examples include pre- and post-buckling of different shell structures showing, in particular, some bifurcation points, large rotations and displacements and very important membrane-bending coupling.

ABSTRACT: In the paper the linear and non-linear stability analysis of columns and beams made of steel coldformed thin-walled sigma profiles is presented. Both single (asymmetric) and double (symmetric) sigma sections are considered. Local and global buckling phenomena are studied for a wide range of lengths from short columns and beams to long ones. Particular attention is paid to coupled instability, when local buckling occurs close to global one. Coupled modes can take flexural, torsional or combined flexural-torsional forms.
Usually this kind of instability strongly influences the overall post-buckling behaviour. It is well known that these structures are sensitive to initial geometric imperfections [3]. Simplified theories proposed by Timoshenko and developed by Vlasov provide good results only in the case of global buckling. Therefore, in the paper FEM employing shell elements is used to capture the interactive buckling effects. The influence of initial imperfections on buckling and post-buckling behaviour is studied using nonlinear stability analysis with Riks method. The results are compared with results provided by simplified theories. Buckling and nonlinear post-buckling analyses in compression, in simple and skew bending are performed. These issues were also studied in [2]. Imperfections are usually introduced by perturbations in the geometry as a linear superposition of buckling modes, obtained from the linear eigenvalue problem. We follow this approach, however, the patterns and amplitudes of imperfections refer to our own measurements performed “in situ” and processed statistically. These measured imperfections are transferred to FEM model, using discrete Galerkin method for error minimization. Special attention is focused on modelling the double sigma members, which cross-sections are composed of two sigma members connected in discrete points distributed along the webs. It was found that buckling loads may strongly differ with those obtained from analysis for continuous web connection [1]. The influence of head plates, stiffness and spacing of connectors and slenderness coefficients on buckling behavior is studied by the way of examples. The examples are solved using the general purpose finite element program, ABAQUS.

N. Hosseinzadeh (Dept. of Structural Engineering, International Institute of Earthquake Engineering and Seismology (IIEES), Tehran, Iran), “Seismic Vulnerability Analyses of Steel Storage Tanks in an Oil Refinery Complex Using Dynamic Analyses”, The 14th World Conference on Earthquake Engineering October 12-17, 2008, Beijing, China

ABSTRACT: Cylindrical steel above ground tanks extensively used in oil refinery complexes and oil depots in Iran. Average capacity of this kind of tanks is about 20,000 kl with diameter of about 40 m and height of about 14 meter. Past earthquake experiences in Japan, U.S. and Turkey show that these tanks are very vulnerable to strong ground motions. Failure modes such as settlement, shell buckling, Roof Damage and overturning are the main causes of extensive material leakage and fire immediately after an earthquake. In this paper 181 tanks in an oil refinery complex are categorized into 30 types in order to seismic vulnerability evaluation and retrofit design. International documented references such as new revisions of API650 and ASCE standards and Finite Element Method is used in this study. Important parameters such as Liquid sloshing, tank bottom uplift and liquid-shell interaction considered in dynamic analyses. Site-specific spectrum, as well as site compatible earthquake records considered as input motions. The results show that about 60 percent of the existing tanks are vulnerable and require retrofitting or strengthening.

Zhang, Chonghou (Dept. of Civil Engineering, Tsinghua University, Beijing, China), “Plastic buckling of cylindrical shells under transverse loading”, Tsinghua Science and Technology, Vol. 13, No. 2, pp. 202-210,
ABSTRACT: Thick cylindrical shells under transverse loading exhibit an elephant foot buckling mode, whereas moderately thick cylindrical shells show a diamond buckling mode. There exists some intermediate geometry at which the transition between buckling modes can take place. This behavior is significantly influenced by the radius-to-thickness ratio and the material yield strength, rather than the length-to-radius ratio and the axial force. This paper presents a critical value at which the transition of buckling modes occurs as a function of the radius-to-thickness ratio and the material yield strength. The result shows that the circumferential wave number of the diamond buckling mode increases with decreasing wall thickness. The strain concentration is also intensified for the diamond buckling modes compared with the elephant foot buckling modes.

Hong Pu Liu, Xiao Jing Li, Di Wang, Jian Sheng Tang, Xue Ling Yang, Cheng Jun Zhu (Non-traditional Machining Center, Henan Polytechnic Institute, Nanyang 473009, China), “The Structural Dynamical Buckling Analysis for a Novel Vacuum Autoclave under the Extreme Operating Conditions”, Advanced Materials Research (Volumes 143 - 144), October 2010, pp. 888-893, doi: 10.4028/www.scientific.net/AMR.143-144.888

ABSTRACT: The elastic buckling load is physically important in design of the pressure vessel with shell framework because it is actually the critical step in a thin-walled shell configuration that will eventually lead to complete failure. An finite element model of vacuum autoclave was established and the buckling load calculations under the extreme operating conditions have been carried out to obtain the modal deformation condition and the safety factor. The results showed that the structure has a higher safety factor, which indicated that the vacuum autoclave design can meet the working condition requirements.

ABSTRACT: Stability is one of the serious problems associated with slender structural elements. Column is an important member of such elements that the study of its complex behavior is necessary due to their significant use in the structural applications. In this paper, the influence of initial imperfection on the stability of a compressible column with load-dependant support is studied. The column model is introduced, considering compressibility and load-dependant behavior of the support. The effect of initial imperfection is considered in the equilibrium equation of the column and the equilibrium paths are plotted in each state of reference support stiffness functions for specific imperfection magnitudes. In each state, the change of critical load of the column versus the values of the imperfection is extracted and the effect of initial imperfection on the stability of the column is discussed.

ABSTRACT: The rocking dynamics of the tank is discussed through introduction of the rock–translation interaction. Firstly, the discussion on the ideal rigid bottom plate tank ensures the necessity of the rock–translation interaction for evaluating rocking responses of the tank. Secondly, to trace rocking behaviors of the actual tank, the proposed method is expanded by employing an assumption of the effective moment inertia of
liquid for rocking motion. The comparison of analytical results with the experimental ones corroborates its applicability. Finally, the sufficient friction on the pivoting edge to enter and sustain the rocking motion of the tank is examined.

Iunio Iervolino, Giovanni Fabbrocino and Gaetano Manfredi (Dept. of Structural Analysis and Design, University of Naples Federico II, Italy), “Seismic Vulnerability of Standardised Industrial Components: Application to Oil Storage Tanks”, Paper No. 552, 13th World Conference on Earthquake Engineering Vancouver, B.C., Canada August 1-6, 2004

ABSTRACT: Industrial risk requires taking into account natural hazards including earthquakes. In the Quantitative Risk Analysis (QRA) perspective seismic failure may be added to system faulty events. Fragility analysis of industrial components presents some aspects that requires the development of specific reliability tools. The present paper discusses the definition of a rational procedure for seismic vulnerability assessment of standardized industrial constructions in a probabilistic framework.

The coverage of a category of components by a single analysis process and the independence on the assumptions on the structural model, even if dynamic analyses are performed, can be addressed as the main advantages of the proposed method. Both seismic capacity and demand are considered as probabilistic. The application example is focused on the elephant foot buckling of unanchored sliding tanks. A regression-based method is applied to relate fragility curves to parameters varying in the domain of variables for structural design.

ABSTRACT: Large regions in many countries are exposed to earthquakes, thus seismic risk evaluation is a relevant issue and requires specific knowledge development and integration between different skills. Failure of critical constructions can have direct and indirect influence on public safety; in fact, pollution or damages due to explosions can be related to collapse of industrial facilities. In the present paper, after a review of available data concerning industrial plants in Italy with specific reference to their exposure to earthquake actions, the main aspects related to structural design and seismic evaluation of existing facilities for oil storage are discussed and the main features of probabilistic procedures able to give fragility curves of structures and components to be used in seismic risk assessment are outlined.

ABSTRACT: FPSOs have a risk profile different from fixed platforms and commercial trading tankers. Being stationed in one location and routinely visited by supply boats and shuttle tankers. FPSOs can be collided by these ships. In addition, passing ships also pose a collision risk if an FPSO is close to a sailing route. This paper presents a systematic approach to address the risk of collision and contact damage. It is aimed to propose a framework that can be applied in structural designs and risk assessment schemes. The focus is placed on accident scenarios, evaluation approaches and acceptance criteria, the three major issues for a risk assessment and also for a relevant design standard. Accident scenarios and the associated occurrence frequency may be determined through statistics from historical data, expert opinions, and risk analysis, depending on different situations. A spectrum of tools has been developed in recent years that predicts the structural damage of collisions, including simple formulae, simplified analytical methods, simplified FEM, and non-linear FEM simulations. Those based on the advanced structural crashworthiness theory provide powerful and practical tools, and are well suited for design evaluations and risk analysis. Contact damage is more likely to occur than accidents resulting in rupture of shell plating. However, this type of accident has received very limited attention. An analytical approach is presented for analyzing contact damage that can be used during earlier design stage. Acceptance criteria for collision and contact accidents are discussed. The emphasis is on structural integrity including local strength and hull performance.

ABSTRACT: The static stability of thin-walled composite beams, considering shear deformation and geometrical non-linear coupling, subjected to transverse external force has been investigated in this paper. The theory is formulated in the context of large displacements and rotations, through the adoption of a shear deformable displacement field (accounting for bending and warping shear) considering moderate bending rotations and large twist. This non-linear formulation is used for analyzing the prebuckling and postbuckling behavior of simply supported, cantilever and fixed-end beams subjected to different load condition. Ritz's method is applied in order to discretize the non-linear differential system and the resultant algebraic equations are solved by means of an incremental Newton–Rapshon method. The numerical results show that the beam loses its stability through a stable symmetric bifurcation point and the postbuckling strength is in relation with the buckling load value. Classical predictions of lateral buckling are conservative when the prebuckling displacements are not negligible and the non-linear buckling analysis is required for reliable solutions. The analysis is supplemented by investigating the effects of the variation of load height parameter. In addition, the critical load values and postbuckling response obtained with the present beam model are compared with the results obtained with a shell finite element model (Abaqus).

ABSTRACT: Based on a seven-degree-of-freedom shear deformable beam model, analytical solutions are derived for the lateral stability analysis of cross-ply laminated thin-walled beams subjected to combined axial and bending loads. The model includes shear deformability in a full form, i.e., shear flexibility due to both bending and nonuniform warping is considered. The theory is formulated in the context of large displacements and rotations, considering moderate bending rotations and large twist. Composite is assumed to be made of symmetric balanced laminates and especially orthotropic laminates. The closed-form analytic expressions obtained in this paper are valid for simply supported bisymmetric beams. These fundamental solutions explicitly identify the influence of geometric nonlinear effects due to the prebuckling deformation. The numerical results are compared with the bifurcation loads of the postbuckling response. In addition, the effects of the variation of load height parameter and fiber angle orientation are investigated.

“Post Buckling Analysis of the Ariane 5 Front Skirt (Rosetta-Mission)”, EUROPEAN CONFERENCE FOR AEROSPACE SCIENCES (EUCASS), (no publisher or date given in the pdf file; latest reference is dated PARTIAL INTRODUCTION: This contribution addresses the analysis of the behaviour of the ARIANE 5 front skirt concerning the nonlinear structural stability in the launching phase of the Rosetta-Mission. The front skirt consists of a stiffened shell structure and is part of the main stage of the ARIANE 5 … transmitting the booster loads into the actual launcher. The main load carrying elements are load introduction structures, circumferential frames and axial stiffened cylindrical shells. Within the framework of the flight worthiness assessment for the Rosetta mission, a nonlinear analysis of the front skirt for two critical flight cases was performed. The contracting body for this job was MAN-Technologie AG in Augsburg, Germany. The crucial points of the analysis strategy itself, which had to be considered for the flight worthiness assessment, were: (1) Load case selection, (2) Boundary conditions, (3) Post buckling behavior and (4) Imperfection sensitivity. The computations described in the following were carried out by means of the general purpose program ABAQUS [7], Version 6.4.1.

References listed at the end of the paper:
ABSTRACT: In the design of a modern lightweight structure, it is of technical importance to assure its safety against the buckling under the applied loading conditions. For this issue, the determination of the critical load in an ideal condition is not sufficient, but it is further required to clarify the post-buckling behavior, that is, the behavior of the structure after passing through the critical load. One of the reasons is to estimate the effect of practically unavoidable imperfections on the critical load and the second is to evaluate the ultimate strength to exploit the load-carrying capacity of the structure. For the buckling problem of circular cylindrical shells under axial compression, a number of experimental and theoretical studies have been made by many researchers. In the case of the very thin shell that exhibits elastic buckling, experimental results show that after the primary buckling, secondary buckling takes place accompanying successive reductions in the number of the circumferential waves in each mode change on one-by-one step. In this paper we traced this successive buckling of circular cylindrical shells using some of the general purpose implicit FEM codes currently available. For geometrically nonlinear static problems including buckling and post-buckling, we carried out our studies with two approaches; one is to use the arc length method (the modified Riks method), and the other is stabilizing with the aid of (artificial) damping especially for the local instability. Our analysis procedure consists of the following 2 steps. Before reaching the point exhibiting the comparatively stable state after the primary buckling, the arc length method is applied. After that point, the artificial damping is applied. The results simulate unstable successive buckling and show good agreement with experiments.

“Corotational formulation for nonlinear dynamics of beams with arbitrary thin-walled open cross-sections”,
ABSTRACT: A new consistent corotational formulation for nonlinear dynamics of beams with arbitrary thin-walled cross-section is presented. The novelty is that the warping deformations and the eccentricity of the shear center are fully taken into account. Therefore, additional terms are introduced in the expressions of the inertia force vector and the tangent dynamic matrix. Their contribution is then investigated considering several numerical examples. Besides, the element has seven degrees of freedom at each node and cubic shape functions are used to interpolate local transverse displacements and axial rotations. The formulation’s accuracy is assessed considering five examples with comparisons against 3D-solid solutions.

ABSTRACT: In the framework of the direct approach shells are considered as deformable surfaces consisting of particles, and the relations of the theory are obtained with the methods of analytical mechanics. In the present work we assign to each particle five degrees of freedom, namely three translations and two in-plane rotations. The principle of virtual work produces all the relations of the theory of shells: equations of equilibrium,
boundary conditions, definition of the force factors and the general form of constitutive equations. Remarkable consistency and clarity is achieved both in the relations of the theory and in the derivation process. A new formulation of the Piola tensors for a shell is suggested in order to transform the equations to the reference configuration. To analyze the effects of buckling or geometric stiffening, we linearize these equations in the vicinity of a pre-deformed configuration. Some new semi-analytical results on buckling and supercritical behavior of an axially compressed cylindrical shell are presented. The correspondence between the equations and the variational formulation is discussed in view of development of efficient numerical procedures for modeling nonlinear deformations of shells. Results of finite element modeling of the nonlinear deformation of a shell structure are discussed in comparison with the fully three-dimensional solution of the problem.

DOI: 10.1007/978-3-7091-1777-4_4
ABSTRACT: We begin with the asymptotic splitting of the equations of the three-dimensional theory of elasticity for a thin plate into a problem over the thickness and the equations of the classical plate model. All groups of the three-dimensional equations (equilibrium, compatibility, etc.) are processed separately. Both the material anisotropy and inhomogeneity in the thickness direction are included in the analysis along with the electromechanical coupling in the form of piezoelectric effects. The classical nonlinear theory of curved shells follows with the direct approach to a material surface with five degrees of freedom of particles: three translations and two rotations. Equations of equilibrium, boundary conditions and general constitutive relations are the consequences of the principle of virtual work. Further we transform the equations to the differential operator of the reference configuration with the Piola tensors, which allows linearizing the equations in the vicinity of a pre-stressed and pre-deformed state. Several example problems for a cylindrical shell are considered. A novel finite element scheme with a smooth approximation of the surface of the shell concludes the chapter. The method is presented in Mathematica environment for linear plate problems, and then a general implementation for large deformations of curved shells is discussed. We demonstrate the convergence properties of the numerical scheme on several examples, some of which have been considered in the literature before. “Thin shells with piezoelectric transducers: Theory, numerical modelling and verification”, 7th ECCOMAS
Thematic Conference on Smart Structures and Materials (SMART), 2015
ABSTRACT: For the modelling of thin elastic shells with attached piezoelectric transducers, we consider a material surface with certain mechanical degrees of freedom in each point. Additionally, electrical unknowns are present within the domain, where the piezoelectric transducers are attached, such that the sensing and actuating behavior can be properly accounted for. The modelling is done in the geometrically nonlinear regime, but the electromechanically coupled constitutive relations are treated within the framework of Voigt’s linear theory of piezoelectricity. Owing to the assumed thinness of the shell the influence of shear is neglected in the modeling. A Finite Element scheme for the solution of the resulting model is implemented and the solutions computed with the present theory are compared to results computed with the commercially available FE code Abaqus. Different examples are presented ranging from large deformations, to snap through instability and to a linear analysis. A very good agreement between the results is obtained, from which the accuracy of the thin shell formulation as a material surface is concluded. Next, an existing physical shell is modeled within the linearized version of the present theory and the computational results are compared to measurement results from the physical experiment. The agreement is reasonably good; natural frequencies as well as eigenmodes are considered for the comparison. Concerning the eigenmodes the MAC criterion is used. Finally, the resulting linear time invariant dynamical system for the simulation of the physical shell is imported into Mathematica and different strategies for passive and active control are tested and compared to each other. Concerning passive control methods classical single mode shunt-damping using an optimized RL-network is studied.

Shunqi Zhang, “Nonlinear FE Simulation and Active Vibration Control of Piezoelectric Laminated Thin-Walled Smart Structures”, Ph.D. dissertation, Dept. of Machine Knowledge, Technical University of Aachen, 2014
ABSTRACT: This dissertation deals with nonlinear finite element modeling and active vibration control for piezoelectric integrated smart structures, and is presented in two parts. In the first part, an electro-mechanically coupled large rotation finite element model is developed for static and dynamic analysis of thin-walled structures with piezoelectric sensor and actuator layers. The present large rotation theory is based on the first-
order shear deformation hypothesis, which has six independent kinematic parameters but expressed by five
nodal degrees of freedom. Unrestricted finite rotations are described by two rotations using the Euler angle
representation method. Due to the assumption of small strains and weak electric potential, linear piezoelectric
coupled constitutive equations and a linearly distributed electric potential through the thickness are considered.
In order to show the necessity of the large rotation theory in the application of thin-walled composite or smart
structures undergoing large rotations, several simplified nonlinear shell theories are implemented into finite
elements for thin-walled structures as well. The second part develops a disturbance rejection control with a
Proportional-Integral (PI) observer which uses step functions to construct a fictitious model of disturbances for
active vibration control of smart structures. To improve the dynamic behavior of the existing PI observer, a
Generalized PI (GPI) observer is proposed and developed. Therefore, any unknown disturbances can be
estimated and compensated by the present disturbance rejection control with either a PI or GPI observer.
Additionally, PID, LQR and LQG control strategies are implemented to show the advantages of the proposed
disturbance rejection control.

ABSTRACT: Composite materials have been extensively used in engineering thanks to their lightweight,
superior mechanical performances and possibility to tailor the structural behavior, increasing the available design space. Variable Angle Tow (VAT) structures exploits this advantage by adopting a curvilinear patterns for the fibers constituting the lamina. This work, for the first time, extends the Generalized Unified Formulation (GUF) to the case of fourth-order triangular shell elements and VAT composites. Functionally graded material properties in both the thickness and in-plane directions are also possible. The finite element has been formulated with layers of variable thickness with respect to the in-plane coordinates.

GUF is a very versatile tool for the analysis of Variable Stiffness Composite Laminates (VSCLs); it is possible to select generic element coordinate systems and define different types of axiomatic descriptions (Equivalent Single Layer, Layer Wise, and Zig-Zag enhanced formulations) and orders of the thickness expansions. Each displacement is independently treated from the others. All the infinite number of theories that can be generated with GUF are obtained by expanding six theory-invariant kernels (formally identical for all the elements), allowing a very general implementation. Finally, the possibility of tailoring the theory/order to increase the accuracy in desired directions makes the GUF VAT capability a very powerful tool for the design of aerospace structures.

ABSTRACT: The concept of snap divergence and post-critical states are theoretically formulated for Joined Wings with the arc length technique. The true critical condition is compared with the divergence speed evaluated by solving an eigenvalue problem about a steady state equilibrium, showing how in some cases this last approach is not reliable and even nonconservative.

The work assesses the difference of the nonlinear responses relative to mechanical loads (both conservative and follower ones) used to mimic the real loading condition and the aerodynamic forces. Two joined-wing configurations, characterized by a different location of the joint, are investigated. It is demonstrated that the lift/displacement response may hide the physical snap divergence occurrence, leading to non-physical interpretation of the stability properties of the system. Thus, as a consequence, use mechanical loading to mimic aerodynamic effects should be meditated since they may not give a reliable picture.

Aeroelastic stiffening and softening effects are observed for the different cases, and it is discussed how practical instability situation may not be encompassed by the formal mathematical criterion (singularity of the system tangent matrix).

Finally, physical interpretation of the static aeroelastic deformation is provided with particular emphasis on the conditions that lead to the snap divergence. The bending/torsion coupling at geometric (sweep angle of the wings) and material (composite materials) level for each wing can not be thought as an isolate property, since, due to the overconstrained nature of the system, the actions are transferred between different parts of the system. In other words, an intuitive approach that tries to fine tune the design of a part as an isolate entity may
not lead to meaningful results.

ABSTRACT: This paper analyses the free vibration response of sandwich curved and flat panels by introducing the zig-zag function $(-1)^k$ in the displacement models of classical and higher order two-dimensional shell theories. The main advantage of ZZF is the introduction of a discontinuity in the first derivative, zig-zag effect, of the displacements distribution with correspondence to the core/faces interfaces. Results including and discarding ZZF are compared. Several values of face-to-core stiffness ratio (FCSR) and geometrical plate/shell parameters have been analyzed. Both fundamental vibration modes and those corresponding to high wave numbers are considered in the analysis. It is concluded that: (1) ZZF is highly recommended in the free vibration analysis of sandwich plates and shells; (2) the use of ZZF makes the error almost independent by
FCSR parameter; (3) ZZF is easy to implement and its use should be preferred with respect to other ‘more cumbersome’ refined theories.

ABSTRACT:
The linear equivalent plate approach developed and used for the aeroelastic optimization of composite wings at the conceptual design stage is a Ritz approach based on simple polynomial functions as generalized coordinates.
Generalization to the case of geometrically nonlinear structural behavior is presented here in an effort to assess accuracy and performance of the method in the nonlinear static and dynamic cases. Using the von-Karman plate formulation for moderately large deformations, 3-dimensional assemblies of thin-plate segments are modeled using a penalty function approach to impose boundary conditions and compatibility of motion between adjacent segments. Closed form expressions for mass and stiffness terms (linear and nonlinear) make numerical integration unnecessary. Numerical results obtained by the present method for a variety of plate structures, in both static and dynamic cases, show good correlation with published results and results by other computer codes. The present formulation is also compared with large-deformation Updated Lagrangian formulation results. Limits of applicability, in terms of the range of deformations still captured accurately by the equivalent plate method, are studied in all test cases.

ABSTRACT: Two-dimensional theories and finite elements are assessed to analyze displacement and stress fields in sandwich, composites plates. Two benchmarks are used to conduct the assessment. The first benchmark is a sandwich plate loaded by harmonic distribution of transverse pressure for which a three-dimensional closed-form solution exists in the literature. The second benchmark is a rectangular sandwich plate loaded by a transverse pressure located at the center. More than 20 plate theories and finite elements were implemented in a unified formulation recently proposed by the authors. Classical theories based on displacement assumptions are compared to advanced mixed models formulated on the basis of Reissner’s mixed variational theorem. Both equivalent single-layer models as well as layerwise models are considered. Analytical closed-form solutions and finite elements are given. The considered benchmarks highlight both the performance and limitations of the considered two-dimensional theories. The convenience of layerwise description and advanced mixed theories has been demonstrated. The second benchmark especially proved the need for layerwise models to capture the local effects.

ABSTRACT: In the first part of this paper we have deduced a classification of asymptotic shallow shell models with respect to the level of applied forces, from the non-linear threedimensional elasticity. We have used a constructive approach based on a dimensional analysis of the non-linear three-dimensional equilibrium equations, which naturally makes appear dimensionless numbers characterizing the applied forces (F and G) and the geometry of the shell (ε and C). To limit our study to one-scale problems, these dimensionless numbers are expressed in terms of the relative thickness ε of the shell, considered as the perturbation parameter. In the first part, we have studied the case of shallow shells corresponding to C = ε². In the second part of this paper, we will study the case of strongly curved shells for which C = ε. The classification that we obtain is then more complex. It depends not only on the force levels, but also on the existence of inextensional displacements which keep invariant the metric of the middle surface of the shell.

Brief description of the contents of this special issue (written by the Guest Editors):
The topics of the papers included in this volume are diverse enough, tackling stability problems of steel structures with thin and thick walled bar members, open and hollow sections, plated structures and curved
sandwich panels. There are theoretical, numerical and experimental approaches and combinations of them used in solving stability problems. The 12 papers have been framed into two parts: 
Part I: Theoretical background, numerical and experimental advanced studies – 7 papers; 
Part II: Design codification oriented studies – 5 papers.

“Erosion of interactive buckling load of thin-walled steel bar members: Contribution of ‘Timisoara School’”
ABSTRACT: The paper presents a summary of the activity and research achievements of the Romanian researchers of Timisoara School in the field of stability of cold-formed steel members. Both, fundamental theory and applied instability contributions are focussed. Post-critical theory of elastic structures, the analysis of stable and unstable components of bifurcation load, coupling of bifurcations modes (e.g. mod interaction), erosion of critical load are the topics in which the theoretical contributions of Timisoara School are significant. Present paper focuses the mode interaction problems of thin-walled steel bar members only, integrating some relevant results obtained by the authors through a state-of-art review.

ABSTRACT: The analysis of slender structures, characterized by complex buckling and postbuckling phenomena and by a strong imperfection sensitivity, is heavily penalized by the lack of adequate computational tools. Standard incremental iterative approaches are computationally expensive and unaffordable, while FEM implementation of the Koiter method is a convenient alternative. The analysis is very fast, its computational burden is of the same order as a linearized buckling load evaluation and the simulation of different imperfections costs only a fraction of that needed to characterize the perfect structure. The main objective of the present work is to show that finite element implementations of the Koiter method can be both accurate and reliable and to highlight the aspects that require further investigation.

“Effect of distortion on the structural behavior of thin-walled steel regular polygonal tubes”

ABSTRACT: This paper addresses the effect of cross-section distortion on the structural behaviour of thin-walled tubes with single-cell regular convex polygonal cross-sections (RCPS) and provides an in-depth view on the underlying mechanical aspects. In particular, the first-order, buckling (bifurcation) under uniform compression and undamped free vibration behaviours are characterised using the modal decomposition features and computational efficiency of a GBT (Generalised Beam Theory) specialization for RCPS recently developed by the authors [1]. Several analytical and illustrative numerical results are presented and discussed within the paper.

“Axial impact of open-section TWCF columns – experimental study”

ABSTRACT: The paper is devoted to the results of experimental study into the crushing behaviour of TWCF open section columns subjected to axial impact. Steel channel and top-hat section was under investigation. The paper contains a results summary of quasi-dynamic and dynamic impact tests performed on about 100 of those sections of different dimensions subjected to axial load of different velocities. Experimental quasi-dynamic tests were conducted on the testing machine with different loading velocities up to 600 mm/min. The impact tests were performed on the drop hammer rig with the impact energy up to 5 kJ and impact velocity up to 10 m/s. An influence of the column initial length and impact velocity on the crushing behaviour (failure mode) was investigated. Particularly, the critical length of the transition from progressive buckling to global bending failure mode and its dependence on section dimensions and the impact velocity was under investigation. Experimental results were compared with the results of the analytical calculations of critical (transition) buckling length based on the simplified analytical theoretical models. The results are presented in load-time and load-shortening diagrams and failure patterns. Some conclusions concerning the determination of critical buckling length, applicability of the theoretical models applied and an influence of the impact velocity upon the critical buckling length and final mode of failure related to the energy absorption capability of columns are derived.

ABSTRACT: An energy formulation of a simply supported cylindrically curved sandwich panel loaded in compression is introduced and the corresponding potential energy function is evaluated. The mechanical model
of a cylindrically curved sandwich panel comprises three interacting buckling modes, corresponding to nine degrees of freedom comprising $q_s$, $q_x$ and $q_y$ components of local snake $(m, n)$ and overall $(k, l)$ modes, the related local hourglass $(m, n)$ mode. Finally, closed-form solutions are presented for the global and local buckling modes.

“Imperfection sensitivity of thin plates loaded in shear”

ABSTRACT: The paper deals with imperfection sensitivity analysis of longitudinally stiffened thin plates loaded in shear. The aim of this paper is to demonstrate the use of optimization method for direct determination of the worst imperfection shape. New linear constraints are considered in optimization method in order to find not only the worst but also realistic imperfection shape. Further on, different solutions of arbitrary shapes that are used to estimate the worst imperfection are introduced and compared. Finally, a parametric analysis seeking the worst imperfection shape is performed and discussed.

INTRODUCTION: Elastic buckling of cylindrical shells under axial compression is regarded as one of the most difficult tasks involved in the buckling phenomenon. Buckling of a thin-walled shell is typically a local phenomenon that may be triggered by a small, local disturbance. In the case of a very thin shell that exhibits elastic buckling, experimental results show that the first single buckle is initiated at the local portion of the cylinder, the number of buckles sharply increases, and thus the cylinder loses its overall structural stability. In this paper, we trace this successive buckling process using the latest in finite element analysis technology. This paper also describes the generation of singularities in a large-deformed viscoelastic cylindrical shell.

PARTIAL INTRODUCTION: Corrugated steel buried structures (CSBS) have been in use in the United Kingdom in various forms for many decades. The smaller structures are largely circular or near circular in form and are usually enclosed by the corrugated steel sheeting. Arch forms known as super-span structures have been introduced in recent years to span wider crossings…The aims of this project were to:
1. evaluate the comparative reliability of long span structures designed in terms of the draft standard and short span structures designed in terms of the existing standard.
2. evaluate the nature and degree of possible undue conservatism in the proposed draft standard.
3. evaluate the relative reliability of CSBS compared to other bridge types...

ABSTRACT: The newly developed p-M diagram provides a means for readily evaluating the collapse and/or buckling load of pressure equipment with external flaws simultaneously subjected to internal pressure, p and external bending moment, M due to earthquake, etc. In this paper, some FEAs for large diameter vessels with an external flaw were conducted under (1) pure external bending moment, and (2) subjected simultaneously to both internal pressure and external bending moment, in order to determine the plastic collapse load by applying the twice-elastic slope (TES) as recommended by the ASME and to determine the buckling load. The p-M line adopted in the Ibaraki FFS rule based on the measured yield stress indicates that the safety margin for the TES loads at the LTA is about 1.2–1.8, and 1.5–2.0 for the buckling loads. The Ibaraki FFS rule that prevents buckling by applying Donnell's equation of FS = 2 can assure adequate levels of integrity and safety.

ABSTRACT: Damage generally refers to the more or less gradual development of micro-voids and micro-cracks. Damage mechanics is the modelling of these phenomena on a structural analysis scale. In this paper we first recall the non-linear behaviour models we have developed to model composite laminates. Then we present two examples of implementations of such models in a structural analysis code in order to simulate the inner-failure of a structure, or to study delamination initiation.

ABSTRACT: The problem of multilayered degenerated 3-D shell elements for which the numerical integration is performed for each ply is that of the high generation time in non-linear analysis when the number of plies is important. But these elements give accurate results for thin and moderately thick shells, so in order to reduce the generation time explicit thickness integration is investigated. We first write an expansion of the strain-displacement matrix in power series of the thickness variable in order to obtain explicit expressions of the tangent stiffness matrix and internal force vector, appearing in the non-linear formulation. Explicit expressions
of non-linear stiffness matrices are presented, using the explicit integration-first approximation. Simple expressions of several matrices, sub-matrices and vectors appearing in the formulation are given here in order to obtain an important computing-time gain. Next, some numerical validation tests comparing the classical element with numerical thickness integration and this one are discussed to prove validity of this formulation.

ABSTRACT: A nomograph is introduced, which is based on the stability equations for an orthotropic cylindrical shell. The equations are derived from the assumption of the exact displacement versus strain relationship and of linear-elastic material behaviour. The displacement versus strain relationship is the same as Flügge indicated for the isotropic cylindrical shell. The nomograph can be used to determine in a fast and direct way the ideal local and global buckling pressure and the critical buckling form of a ring-stiffened circular cylindrical shell under external pressure. The determining values are useful for the preliminary design. They can serve as input values for an idealization concept that describes the method for obtaining a representative substructure for a finite element calculation. The subsequent geometrically and physically non-linear stability analysis of the subsystem is performed using two ring-reinforced cylinders as an example, and then compared with experimental results.

ABSTRACT: In this paper, a review of past and recent developments in the dynamics of flexible multibody systems is presented. The objective is to review some of the basic approaches used in the computer aided kinematic and dynamic analysis of flexible mechanical systems, and to identify future directions in this research area. Among the formulations reviewed in this paper are the floating frame of reference formulation, the finite element incremental methods, large rotation vector formulations, the finite segment method, and the linear theory of elastodynamics. Linearization of the flexible multibody equations that results from the use of the incremental finite element formulations is discussed. Because of space limitations, it is impossible to list all the contributions made in this important area. The reader, however, can find more references by consulting the list of articles and books cited at the end of the paper. Furthermore, the numerical procedures used for solving the differential and algebraic equations of flexible multibody systems are not discussed in this paper since these procedures are similar to the techniques used in rigid body dynamics. More details about these numerical procedures as well as the roots and perspectives of multibody system dynamics are discussed in a companion review by Schiehlen [79]. Future research areas in flexible multibody dynamics are identified as establishing the relationship between different formulations, contact and impact dynamics, control-structure interaction, use of modal identification and experimental methods in flexible multibody simulations, application of flexible multibody techniques to computer graphics, numerical issues, and large deformation problem. Establishing the relationship between different flexible multibody formulations is an important issue since there is a need to clearly define the assumptions and approximations underlying each formulation. This will allow us to establish guidelines and criteria that define the limitations of each approach used in flexible multibody dynamics. This task can now be accomplished by using the “absolute nodal coordinate formulation” which was recently introduced for the large deformation analysis of flexible multibody systems.
ABSTRACT: Many flexible multibody applications are characterized by high inertia forces and motion discontinuities. Because of these characteristics, problems can be encountered when large displacement finite element formulations are used in the simulation of flexible multibody systems. In this investigation, the performance of two different large displacement finite element formulations in the analysis of flexible multibody systems is investigated. These are the incremental corotational procedure proposed by Rankin and Brogan and the nonincremental absolute nodal coordinate formulation recently proposed. It is demonstrated in this investigation that the limitation resulting from the use of the nodal rotations in the incremental corotational procedure can lead to simulation problems even when very simple flexible multibody applications are considered. The absolute nodal coordinate formulation, on the other hand, does not employ infinitesimal or finite rotation coordinates and leads to a constant mass matrix. Despite the fact that the absolute nodal coordinate formulation leads to a complex expression for the elastic forces, the results presented in this study, surprisingly, demonstrate that such a formulation is efficient in static problems as compared to the incremental corotational procedure. The excellent performance of the absolute nodal coordinate formulation in static and dynamic problems can be attributed to the fact that such a formulation does not employ rotations and leads to exact representation of the rigid body motion of the finite element.

ABSTRACT: The objective of this study is to develop simple and accurate elastic force models that can be used in the absolute nodal co-ordinate formulation for the analysis of two-dimensional beams. These force models which account for the coupling between bending and axial deformations are derived using a continuum mechanics approach, without the need for introducing a local element co-ordinate system. Four new different force models that include different degrees of complexity are presented. It is shown that the vector of the elastic forces can be significantly simplified as compared to the elastic force model developed for the absolute nodal co-ordinate formulation using a local element frame [1]. Despite the simplicity of the new models, they account for elastic non-linearity in the strain–displacement relationship. Therefore, they lead to more accurate results as compared to the more complex models developed using the local frame method which does not account for the non-linearities in the strain–displacement relationships. Numerical results are presented in order to demonstrate the use of the new models and test their performances in the analysis of large deformations of flexible multibody systems.

ABSTRACT: In this investigation, a non-incremental solution procedure for the finite rotation and large deformation analysis of plates is presented. The method, which is based on the absolute nodal coordinate formulation, leads to plate elements capable of representing exact rigid body motion. In this method, continuity conditions on all the displacement gradients are imposed. Therefore, non-smoothness of the plate mid-surface at the nodal points is avoided. Unlike other existing finite element formulations that lead to a highly nonlinear inertial forces for three-dimensional elements, the proposed formulation leads to a constant mass matrix, and as a result, the centrifugal and Coriolis inertia forces are identically equal to zero. Furthermore, the method relaxes some of the assumptions used in the classical and Mindlin plate models and automatically satisfies the objectivity requirements. By using a general continuum mechanics approach, a relatively simple expression for the elastic forces is obtained. Generalization of the formulation to the case of shell elements is discussed. As examples of the implementation of the proposed method, two different plate elements are presented; one plate element does not guarantee the continuity of the displacement gradients between the nodal points, while the other plate element guarantees this continuity. Numerical results are presented in order to demonstrate the use of the proposed method in the large rotation and deformation analysis of plates and shells. The numerical results, which are compared with the results obtained using existing incremental procedures, show that the solution obtained using the proposed method satisfies the principle of work and energy. These results are obtained using explicit numerical integration method. Potential applications of the proposed method include high-speed metal forming, vehicle crashworthiness, rotor blades, and tires.
Per Hyldahl, “Rectangular shell elements based on the absolute nodal coordinate formulation”, PhD dissertation, Dept. of Engineering, Aarhus University, Aalborg, Denmark, July 2015

ABSTRACT: This thesis concerns the development of tools that are useful for designing machine systems and components in an virtual environment using flexible multibody dynamics. Initially, flexible multibody dynamics is briefly reviewed to explain available formalisms and possible applications of this method. Subsequently, attention is turned towards the analysis of structures that undergo large deformations and rotations using shell finite elements based on the absolute nodal coordinate formulation, ANCF. This topic is the focus for the remainder of the thesis. The thesis is divided into three main parts. The first part acts as a general introduction to ANCF based shell finite elements and sums up available elements found in the research literature. In the end, a new ANCF element developed during this PhD project is presented which gives enhanced modeling capabilities of problems including e.g. moving boundary conditions. The second part concerns the performance and behavior of a certain class of ANCF shell elements that are developed for analysis of thin shell structures. This includes discussions on differences concerning their kinematic descriptions and disclosure of certain issues regarding their performance. Those being sensitivity to irregular mesh, poor representation of curved structures and load dependent convergence when analyzing curved structures. The final part concerns the development of a new versatile ANCF shell element. This element is distinguished by being able to describe both thin and thick curved structures. This part contains a thorough derivation of its kinematics and stiffness description, as well as numerical examples to demonstrate its performance. However, this part of the study is not yet complete. Finally, the findings of this PhD project are summed up in a conclusion and possibilities for further studies and perspectives are outlined.

ABSTRACT: In this study, the governing equations for large deflection of elastic thin shallow shells are deduced into an algebraic cubic equation to determine the unknown coefficient of the assumed deflection by applying Galerkin’s method in combination with the algebraic polynomial and Fourier series. For the dynamic problem, the coefficient is replaced by an unknown function of time; after the same process is applied, the governing equations are deduced to be a nonlinear ODE of order two called the Duffing equation, and its analytical solution is known. The combination of the algebraic polynomial and Fourier series gives very rapid convergence in the asymptotic solutions.

ABSTRACT: We are presenting a simple low-order solid-shell element formulation—having only displacement degrees of freedom (dofs), i.e., without rotational dofs—that has an optimal number of parameters to pass the patch tests, and thus allows for efficient and accurate analyses of large deformable multilayer shell structures using elements at extremely high aspect ratio. With the dynamics referred to a fixed inertial frame, the elements
can be used to analyze multilayer shell structures undergoing large overall motion. The formulation of this element is based on the mixed Hu-Washizu variational principle leading to a novel enhancing strain tensor (enhanced assumed strain (EAS) method) that renders the computation particularly efficient, with improved in-plane and out-of-plane bending behavior (Poisson thickness locking), especially in refined analyses of composite structures involving a large number of high aspect-ratio layers. The energy–momentum conserving algorithm in the context of current solid shell element is presented. We discuss the EAS formulation based on the displacement gradient and its complexity compared to formulation on the Green–Lagrange strain. Shear locking and curvature thickness locking are treated using the assumed natural strain (ANS) method. The element has an optimal combination of the ANS method and the minimal number of EAS parameters required to pass the plate bending patch test. Numerical examples involving dynamic analyses (with conservation of energy and momentum) of multilayer shell structures having a large range of element aspect ratios are presented. Several implicit direct integration methods with/without numerical dissipation are used and compared in terms of the accuracy, stability and cost in multilayer shell structure. Finally, we note that the topic in this paper is a fitting dedication to Professor Ekkehard Ramm, who has made important pioneering contributions in this research direction.

ABSTRACT: Multigrid finite-element solvers using the corotational formulation of finite elements provide an attractive means for the simulation of deformable bodies exhibiting linear elastic response. The separation of rigid body motions from the total element motions using purely geometric methods or polar decomposition of the deformation gradient, however, can introduce instabilities for large element rotations and deformations. Furthermore, the integration of the corotational formulation into dynamic multigrid elasticity simulations requires to continually rebuild consistent system matrices at different resolution levels. The computational load imposed by these updates prohibits the use of large numbers of finite elements at rates comparable to the small-strain finite element formulation. To overcome the first problem, we present a new method to extract the rigid body motion from total finite element displacements based on energy minimization. This results in a very stable corotational formulation that only slightly increases the computational overhead. We address the second problem by introducing a novel algorithm for computing sparse products of the form RKR(transpose), as they have to be evaluated to update the multigrid hierarchy. By reformulating the problem into the simultaneous processing of a sequential data and control stream, cache miss penalties are significantly reduced. Even though the algorithm increases memory requirements, it accelerates the multigrid FE simulation by a factor of up to 4 compared to previous multigrid approaches. Due to the proposed improvements, finite element deformable body simulations using the corotational formulation can be performed at rates of 17 tps for up to 12k elements.

Chao-Chieh Lan (Department of Mechanical Engineering, National Cheng Kung University, No. 1 University Road, Tainan 701, Taiwan), “Analysis of large-displacement compliant mechanisms using an incremental linearization approach”, Mechanism and Machine Theory, Vol. 43, No. 5, May 2008, pp. 641-658, doi:10.1016/j.mechmachtheory.2007.03.010
ABSTRACT: Compliant mechanisms transmit motion and force by deflection of their flexible members. They are usually made of a monolithic piece of material and thus involve no wear, backlash, noise, and lubrication. To predict more accurately their deflected shape in larger working range, the analysis of compliant mechanisms has usually based on nonlinear numerical techniques such as the finite element method. However, the problems
of nonlinear analyses are their numerical instability and extensive computation time. These have limited further applications of compliant mechanisms. In this paper, the global coordinate model (GCM) with an incremental linearization approach is presented to turn the nonlinear problem into a sequence of linear problems. Both geometric and material nonlinearities are considered. As a result, numerous linear analysis techniques can be applied to facilitate design and prototyping of compliant mechanisms. Systematic procedures are developed to analyze generic compliant mechanisms that may include non-uniform or initially curved segments. Illustrations are shown with results validated experimentally and by comparing with the nonlinear finite element method. It is expected that the proposed approach can serve as a basis for broader applications of compliant mechanisms.

ABSTRACT: The nonlinear vibrations of a composite panel subjected to uniform edge compression and a high-supersonic coplanar flow is analysed. Third-order piston theory aerodynamics is used and the effects of in-plane edge restraints, small initial geometric imperfections, transverse shear deformation, and transverse normal stress are considered in the structural model. Periodic solutions and their bifurcations are determined using a predictor-corrector type Shooting Technique, in conjunction with the Arclength Continuation Method for the static state. It is demonstrated that third-order aerodynamic nonlinearities are destabilizing, and hard flutter oscillations (both periodic and quasiperiodic) of the buckled panel are obtained. Furthermore, chaotic motions of an uncompressed panel, as well as a buckled-chaotic transition, and chaos via period-doubling are possible, and the associated Lyapunov exponents are computed. A coexistence of the buckled state with flutter motion may also occur. Results indicate that edge restraints parallel to the flow do not significantly affect the immediate post-critical response, and that a higher-order shear deformation theory is required for a moderately thick/flexible-in-transverse-shear composite panel.

ABSTRACT: The non-linear dynamic behavior of a uniformly compressed, composite panel subjected to non-linear aerodynamic loading due to a high-supersonic co-planar flow is analyzed. The effects of in-plane edge restraints, small initial geometric imperfections, transverse shear deformation, and transverse normal stress are considered in the structural model which satisfies the traction-free condition on the panel faces. The panel flutter equations, derived via Galerkin's Method, are solved using Arclength Continuation for the static solution and a predictor-corrector type Shooting Technique to obtain periodic solutions and their bifurcations. The possibility of hard flutter is demonstrated when considering non-linear aerodynamics. Furthermore, edge compression could yield multiple buckled states or coexistence of multiple periodic solutions with the stable static solution, that is, the panel could either remain buckled or flutter. Edge restraints normal to the flow appear to stabilize the panel, whereas those parallel to the flow may result in a buckled-flutter-buckled transition. Quasi-periodic and chaotic motions and associated Lyapunov exponents are also obtained. For perfect panels, results obtained by the Shooting Technique and the Method of Multiple Scales are in agreement only within the immediate post-flutter regime. Results indicate that a shear deformation theory is required for moderately thick composite panels.
ABSTRACT: A flexible material, such as a woven or braided fabric, may be tailored to form an arch when inflated. Such arches have been used as the framework for transportable shelters and are analyzed in this paper. It is assumed that the cross section of the pressurized arch is circular and that only in-plane (membrane) stresses are present. An analytical solution for these initial stresses is given for an arbitrary arch centerline shape. Then external loads are applied, and the additional stress resultants include bending and twisting moments. The linear thin-shell theory of Sanders is used to formulate the governing equations, including the effect of the initial membrane stresses. The material is linearly elastic, nonhomogeneous, and orthotropic. Approximate solutions are obtained using the Rayleigh–Ritz method. In the examples, the centerline of the arch is a semi-circle, the ends are fixed, and the material is homogeneous and isotropic. Four loads are treated: a symmetric (‘full’) snow load, an asymmetric (‘half’) snow load, a wind load symmetric with respect to the plane of the arch centerline, and a distributed load acting sideways. The resulting deflections are computed and plotted.

DOI: 10.4028/www.scientific.net/AMR.594-597.2753
ABSTRACT: Cylindrical shells are widely used in civil engineering. Examples include cooling towers, nuclear containment vessels, metal silos and tanks for storage of bulk solids and liquids, and pressure vessels. Cylindrical shells subjected to non-uniform wind pressure display different buckling behaviours from those of cylinders under uniform external pressure. At different aspect ratios, quite complex buckling modes occur. The geometric nonlinearity may have a significant effect on the buckling behavior. This paper presents a widely study of the nonlinear buckling behavior of cylindrical shells of uniform thickness under wind loading. The finite element analyses indicate that for stocky cylinders, the nonlinear buckling modes are the circumferential compression buckling mode, which is similar to cylinders under uniform external pressure, while for cylinders in mediate length, pre-buckling ovalization of the cross-section has an important influence on the buckling strength.

ABSTRACT: This is the last of three companion papers which examine the elastic buckling and collapse of laser-welded sandwich panels with an adhesively bonded core and unidirectional vertical webs. By evaluation of the buckling stress in the first two papers it has been found that the buckling stress in compression parallel and normal to the webs typically reaches the proportional limit of the face plate and web material well before elastic buckling occurs. Hence, this paper presents an extension of the buckling model into the elastoplastic regime, with the aim of determining the ultimate (local) strength of the sandwich and of allowing experimental verification of the results. Using tangent modulus theory to 'plasticize' the elastic buckling model, the ultimate
strength is evaluated for a sandwich configuration with high-strength steel face plates and a broad range of core moduli. The critical load predicted by the inelastic buckling model agrees well with non-linear finite element results and experimental values obtained from compression testing.

Gin Boay Chai and Chun Wee Yap (School of Mechanical and Aerospace Engineering, Nanyang Technological University, 50 Nanyang Avenue, Singapore 639798, Singapore), “Coupling effects in bending, buckling and free vibration of generally laminated composite beams”, Composites Science and Technology, Vol. 68, Nos. 7-8, June 2008, pp. 1664-1670, doi:10.1016/j.compscitech.2008.02.014

ABSTRACT: A closed form expression to determine the effective flexural modulus of a laminated composite beam is developed and presented in this contribution. This effective flexural modulus is applied to the bending, buckling and free vibration response of generally laminated composite beams with various boundary supports. The expression was developed using the combination of the Euler-Bernoulli beam and classical lamination theory. In addition the results of an extensive finite element analysis are used to validate the analytical model. The comparison of the analytical results, the finite element results and the experimental results showed good correlation. It is also observed that coupling response is an important variable that must be included in the computation of the effective flexural stiffness of generally laminated beam.

Chun Wee Yap and Gin Boay Chai (School of Mechanical and Aerospace Engineering, Nanyang Technological University, 50 Nanyang Avenue, Singapore 639798, Singapore), “Analytical and numerical studies on the buckling of delaminated composite beams”, Composite Structures, Vol. 80, No. 2, September 2007, pp. 307-319, doi:10.1016/j.compstruct.2006.05.010

ABSTRACT: In this article, an innovative approach is proposed using the Euler-Bernoulli beam and classical lamination theory (CLT) to create an analytical model that can be used to obtain the buckling load of a delaminated composite beam. Furthermore, the finite element method is used as a tool to validate the analytical model. An 8-noded shell element and a contact pair are used in the numerical simulation. Studies are carried out on ply orientation, stacking sequence, through-the-width location of the delamination, delamination length and effect of total number of plies. It is found that application of R2 to the analytical model will always yield a more accurate answer than use of R1. It is also observed that $B16^2/A66$ is an important expression that must be included to compute the flexural stiffness of the individual sub-laminates of the anti-symmetric laminated beam considered more accurately. Moreover, it is noted that the length of the delamination will affect the accuracy and difference between the analytical predictions. Nevertheless, the analytical results and simulation values are in good agreement.

ABSTRACT: This paper is concerned with the theoretical analysis and correlation with the numerical results of the displacement time histories of the cylindrically curved laminated composite shells exposed to normal blast shock waves. The laminated composite shell is clamped at its all edges. The dynamic equation of the cylindrical shell used in this study is valid under the assumptions made in Love's theory of thin elastic shells. The constitutive equations of laminated composite shells are given in the frame of effective modulus theory. The governing equation of the cylindrical shell is solved by the Runge-Kutta method. In addition, a finite element
modeling and analysis are presented and compared with the theoretical results. The peak deflections and response frequencies obtained from theoretical and numerical analyses are in agreement. The effects of material properties and geometrical properties are examined on the dynamic behaviour.

ABSTRACT: Locking phenomena in C0 curved finite elements are studied for displacement, hybrid-stress and mixed formulations. It is shown that for a curved beam element, shear and membrane locking are interrelated and either shear or membrane underintegration can alleviate it. However, reduced shear integration tends to diminish the membrane-flexural coupling which characterizes curved elements. Locking can also be expected in certain types of mixed formulations, the hybrid-stress formulations avoids locking for beams (but not for shells). Methods for avoiding locking are explored and alternatives evaluated.

ABSTRACT: A finite element formulation and algorithm for the nonlinear analysis of the large deflection, materially nonlinear response of impulsively loaded shells is presented. A unique feature of this algorithm is the use of a bilinear four-node quadrilateral element with single-point quadrature and a simple hourglass control which is orthogonal to rigid body modes on an element level and does not compromise the consistency of the equations. The geometric nonlinearities are treated by using a corotational description wherein a coordinate system that rotates with the material is embedded at the integration point; thus the algorithm is directly applicable to anisotropic materials without any corrections for frame invariance of material property tensors. This algorithm can treat about 200 element-time-steps per CPU second on a CYBER 170/730 computer in the explicit time integration mode. Numerous results are presented for both elastic and elastic-plastic problems with large strains that show that the method in most cases is comparable in accuracy with an earlier version of this algorithm employing a cubic triangular plate-shelf element, but substantially faster.

ABSTRACT: A simple triangular shell element which incorporates the effects of coupling between membrane and flexural behaviour and avoids membrane locking is described. The element uses a discrete Kirchhoff bending formulation and a constant strain membrane element. For the purpose of permitting inextensional modes and thus avoiding membrane locking, a decomposition technique, which can also be viewed as a strain projection method, is used. The method is illustrated first for a beam element and then for a triangular shell element. Results are presented for a variety of linear static problems to illustrate its accuracy and some highly non-linear problems to indicate its applicability to collapse analysis.

ABSTRACT: The numerical quadrature of the stiffness matrices and force vectors is a major factor in the accuracy and efficiency of the finite element methods. Even in the analysis of linear problems, the use of too many quadrature points results in a phenomenon called locking whereas the use of insufficient quadrature points results in a phenomenon called spurious singular mode. Therefore, efficient numerical quadrature schemes for structural dynamics are developed. It is expected that these improved finite elements can be used more reliably in many structural applications. The proposed developed quadrature schemes for the continuum and shell elements are straightforward and are modularized so that many existing finite element computer codes can be easily modified to accommodate the proposed capabilities. This should prove of great benefit to many computer codes which are currently used in structural engineering applications.

ABSTRACT: In the safety analysis of components of nuclear reactors, it is important to be able to analyze the postbuckling response. For shell structures of complicated shapes, triangular finite elements possess the most versatility in that they can easily be used to represent complicated geometries with openings, cutouts, and other features, whereas quadrilateral elements encounter difficulties in these situations. Therefore, they have added a triangular element to the SAFE/RAS code. The element was specifically designed to eliminate membrane locking. A finite element program with explicit time integration, SAFE/RAS treats both material and geometric nonlinearities. The purpose of this study was to test the performance of this element in postbuckling problems. In these highly nonlinear situations, the triangular element does not perform as well and is substantially stiffer than the quadrilateral. This is illustrated in the comparison of the response of the above-core support columns for the triangular and quadrilateral element models, respectively.

ABSTRACT: In this paper, a resultant-stress degenerated-shell element is described and a variety of numerical examples, including the post-buckling analysis of an axially loaded perfect cylinder, are presented. The general degenerated nonlinear shell theory of Hughes and Liu is employed in deriving this resultant-stress degenerated-shell element. Contrary to the traditional integration through the thickness approach, which assumes no coupling between the in-plane and transverse material and structural response matrices, the present approach can permit use of arbitrary, three-dimensional (3-D) nonlinear constitutive equations. Furthermore, explicit expressions of the element matrices for a 4-node shell element are developed. This rank-sufficient 4-node shell element, termed the resultant-stress degenerated-shell (RSDS) element, avoids the need for the costly numerical quadrature function evaluations of the element matrices and force vectors. And thus there are large increases in
computational efficiency with this method. The comparisons of this RSDS element with six other shell elements are also given in this paper.

ABSTRACT: A triangular element which requires only one quadrature point per element is described along with its implementation in the nonlinear, explicit time integration program SAFE/RAS. The implementation of an Ilyushin flow law which eliminates the need for integration through the thickness and simple formulas for stable time steps is also described. The performance of the triangular and quadrilateral elements is compared in large deflection, elastic-plastic problems. Applications to the analysis of above-core structures in breeder reactors are also described.

ABSTRACT: An adaptive finite element procedure is developed for the transient analysis of nonlinear shells. The scheme is an h-method which employs fission and fusion. Criteria based on incremental work and deviation of the bilinear finite element approximation to the shell from a Kirchhoff-Love surface are used as criteria for adaptivity. The example problems show that the adaptive schemes are capable of achieving substantial improvements in accuracy for a given computational effort. They include both material and geometric nonlinearities and local and global buckling. In order to formulate an r-adaptive method, the conservation laws, the constitutive equations, and the equation of state for path-dependent materials are formulated for an arbitrary Lagrangian-Eulerian description. Both geometrical and material nonlinearities are included in this setting.

ABSTRACT: The effect of follower forces and initial stresses on the stability of the central difference method is studied. As a model, bar and beam elements are considered by means of the element eigenvalue inequality. It is shown that both follower-force pressure loads and tensile initial stresses decrease the stable timestep but the decrease becomes significant only when the pressure or stress is greater than about a tenth of the tangent modulus.

ABSTRACT: An adaptive finite element procedure is developed for the transient analysis of nonlinear shells. The scheme is an h-method which employs fission and fusion of elements to adaptively refine and coarsen the mesh. Incremental work and deviation of the bilinear finite element approximation to the shell from a Kirchhoff-Love surface are used as error criteria for adaptivity. The example problems show that the adaptive schemes are capable of achieving substantial improvements in accuracy for a given computational effort. They include both material and geometric nonlinearities and local and global buckling.

ABSTRACT: The evolution of computational methods for crashworthiness and related fields is described and linked with the decreasing cost of computational resources and with improvements in computational methodologies. The latter includes more effective time integration procedures and more efficient elements. Some recent developments in methodologies and future trends are also summarized. These include multi-time step integration (or subcycling), further improvements in elements, adaptive meshes, and the exploitation of parallel computers.

ABSTRACT: A rank-sufficient flat triangular shell element with drilling degrees-of-freedom is described. A variational basis for this element has been provided by a three-field variational principle with relaxed interelement compatibility and traction continuity conditions. A generalized spurious mode control procedure has been developed in order to stabilize zero energy kinematical modes. Excellent performance has been found in an obstacle course and buckling problems.

T. Belytschko and I.S. Yeh (Department of Civil Engineering, Robert R. McCormick School of Engineering and Applied Science, The Technological Institute, Northwestern University, Evanston, IL 60208-3109, USA),

ABSTRACT: In the pinball contact-impact algorithm, the interpenetration check is simplified by enforcing it only on a set of spheres embedded within the elements. In the splitting pinball adaptation of this algorithm, the parent pinball is split into a hierarchy of descendent pinballs whenever interpenetration of the parent pinballs is detected. The interpenetration check is then applied to the descendent pinballs and contact forces are generated. This provides a better representation of the contact surface for thin shell elements. The implementation of the method with a penalty contact method is described and examples are given. It is also shown that the method easily and automatically handles edge-to-edge, edge-to-surface, and self-surface contact without any user specification.

ABSTRACT: A new four-node shell element for nonlinear analysis which is useful for explicit time integration with single point quadrature is presented. An assumed strain method is used to stabilize the zero-energy modes of the element. The stabilization procedure is based on the Hu-Washizu variational principle and does not require the input of any stabilization parameters. Example problems show good accuracy and rate of convergence compared with fully integrated 4-node elements, however the physically stabilized element is substantially faster than the fully integrated element.

ABSTRACT: A meshless approach to the analysis of arbitrary Kirchhoff shells by the Element-Free Galerkin (EFG) method is presented. The shell theory used is geometrically exact and can be applied to deep shells. The method is based on moving least squares approximant. The method is meshless, which means that the discretization is independent of the geometric subdivision into “finite elements”. The satisfaction of the C1 continuity requirements is easily met by EFG since it requires only C1 weights; therefore, it is not necessary to resort to Mindlin-Reissner theory or to devices such as discrete Kirchhoff theory. The requirements of consistency are met by the use of a polynomial basis of quadratic or higher order. A subdivision similar to finite elements is used to provide a background mesh for numerical integration. The essential boundary conditions are enforced by Lagrange multipliers. Membrane locking, which is due to different approximation order for transverse and membrane displacements, is removed by using larger domains of influence with the quadratic basis, and by using quartic polynomial basis, which can prevent membrane locking completely. It is shown on the obstacle course for shells that the present technique performs well.

ABSTRACT: Meshless approximations based on moving least-squares, kernels, and partitions of unity are examined. It is shown that the three methods are in most cases identical except for the important fact that partitions of unity enable p-adaptivity to be achieved. Methods for constructing discontinuous approximations and approximations with discontinuous derivatives are also described. Next, several issues in implementation are reviewed: discretization (collocation and Galerkin), quadrature in Galerkin and fast ways of constructing consistent moving least-square approximations. The paper concludes with some sample calculations. (cited by 1303 people as of August 2011!)

ABSTRACT: The computability of non-linear problems in solid and structural mechanics problems is examined. Several factors which contribute to the level of difficulty of a simulation are discussed: the smoothness and stability of the response, the required resolution, the uncertainties in the load, boundary conditions and initial conditions and inadequacies and uncertainties in the constitutive equation. An abstract measure of the level of difficulty is proposed, and some examples of typical engineering simulations are
classified by this measure. We have put particular emphasis on engineering calculations, where many of the factors that diminish computability play a prominent role.

ABSTRACT: A general methodology to develop hyper-elastic membrane models applicable to crystalline films one-atom thick is presented. In this method, an extension of the Born rule based on the exponential map is proposed. The exponential map accounts for the fact that the lattice vectors of the crystal lie along the chords of the curved membrane, and consequently a tangent map like the standard Born rule is inadequate. In order to obtain practical methods, the exponential map is locally approximated. The effectiveness of our approach is demonstrated by numerical studies of carbon nanotubes. Deformed configurations as well as equilibrium energies of atomistic simulations are compared with those provided by the continuum membrane resulting from this method discretized by finite elements.
References listed at the end of the paper:

ABSTRACT: The formulation and finite element implementation of a finite deformation continuum theory for the mechanics of crystalline sheets is described. This theory generalizes standard crystal elasticity to curved monolayer lattices by means of the exponential Cauchy–Born rule. The constitutive model for a two-dimensional continuum deforming in three dimensions (a surface) is written explicitly in terms of the underlying atomistic model. The resulting hyper-elastic potential depends on the stretch and the curvature of the surface, as well as on internal elastic variables describing the rearrangements of the crystal within the unit cell. Coarse grained calculations of carbon nanotubes (CNTs) are performed by discretizing this continuum mechanics theory by finite elements. A smooth discrete representation of the surface is required, and subdivision finite elements, proposed for thin-shell analysis, are used. A detailed set of numerical experiments, in which the continuum/finite element solutions are compared to the corresponding full atomistic calculations of CNTs, involving very large deformations and geometric instabilities, demonstrates the accuracy of the proposed approach. Simulations for large multi-million systems illustrate the computational savings which can be achieved.

ABSTRACT: In the design of a modern lightweight structure, it is of technical importance to assure its safety against the buckling under the applied loading conditions. For this issue, the determination of the critical load in an ideal condition is not sufficient, but it is further required to clarify the postbuckling behavior, that is, the behavior of the structure after passing through the critical load. One of the reasons is to estimate the effect of practically unavoidable imperfections on the critical load and the second is to evaluate the ultimate strength to exploit the load-carrying capacity of the structure. For the buckling problem of circular cylindrical shells under axial compression, a number of experimental and theoretical studies have been made by many researchers. In the case of the very thin shell that exhibits elastic buckling, experimental results show that after the primary buckling, secondary buckling takes place accompanying successive reductions in the number of the circumferential waves at every mode shift on one-by-one step. In this paper we traced this successive buckling of circular cylindrical shells using the latest in general-purpose FEM technology. We carried out our studies with three approaches; one is to use the arc-length method (the modified Riks method), the second is static stabilizing with the aid of (artificial) damping especially for the local instability and the third is to use the explicit dynamic procedure. The studies accomplished the simulation of the successive buckling following unstable paths, and show good agreement with the experimental results.

“Tracing nonlinear equilibrium paths of structures subjected to thermal loading”, Computational Mechanics, Vol. 38, No. 6, pp 505-520, November 2006

ABSTRACT: This work presents numerical methods for path tracing and nonlinear stability analysis, including critical point computation and branch-switching, of structures subjected to thermal loading. The differences between the thermal loading case and the standard case of mechanical loading are addressed from both conceptual and computational standpoints. The implementation of the presented methods in a nonlinear finite element system originally designed to deal with mechanical loading is discussed in detail. The techniques presented here are validated by numerical examples.

ABSTRACT: A finite deformation continuum theory is derived from interatomic potentials for the analysis of the mechanics of carbon nanotubes. This nonlinear elastic theory is based on an extension of the Cauchy-Born rule called the exponential Cauchy-Born rule. The continuum object replacing the graphene sheet is a surface without thickness. The method systematically addresses both the characterization of the small strain elasticity of nanotubes and the simulation at large strains. Elastic moduli are explicitly expressed in terms of the functional form of the interatomic potential. The expression for the flexural stiffness of graphene sheets, which cannot be obtained from standard crystal elasticity, is derived. We also show that simulations with the continuum model combined with the finite element method agree very well with zero temperature atomistic calculations involving severe deformations.

Marino Arroyo (1) and Ted Belytschko (2)
ABSTRACT: The understanding of the mechanics of atomistic systems greatly benefits from continuum mechanics. One appealing approach aims at deductively constructing continuum theories starting from models of the interatomic interactions. This viewpoint has become extremely popular with the quasicontinuum method. The application of these ideas to carbon nanotubes presents a peculiarity with respect to usual crystalline materials: their structure relies on a two-dimensional curved lattice. This renders the cornerstone of crystal elasticity, the Cauchy–Born rule, insufficient to describe the effect of curvature. We discuss the application of a theory which corrects this deficiency to the mechanics of carbon nanotubes (CNTs). We review recent developments of this theory, which include the study of the convergence characteristics of the proposed continuum models to the parent atomistic models, as well as large scale simulations based on this theory. The latter have unveiled the complex nonlinear elastic response of thick multiwalled carbon nanotubes (MWCNTs), with an anomalous elastic regime following an almost absent harmonic range.

ABSTRACT: This paper improves the 16 degrees-of-freedom quadrilateral shell element based on pointwise Kirchhoff–Love constraints and introduces a consistent large strain formulation for this element. The model is based on classical shell kinematics combined with continuum constitutive laws. The resulting element is valid for large rotations and displacements. The degrees-of-freedom are the displacements at the corner nodes and one rotation at each mid-side node. The formulation is free of enhancements, it is almost fully integrated and is found to be immune to locking or unstable modes. The patch test is satisfied. In addition, the formulation is simple and amenable to efficient incorporation in large-scale codes as no internal degrees-of-freedom are employed, and the overall calculations are very efficient. Results are presented for linear and non-linear problems.

ABSTRACT: Carbon nanotubes (CNTs) can undergo collapse from their customary cylindrical configurations to ribbons. The energy minima corresponding to these two states are identified using either atomistic molecular
mechanics or the theory of finite crystal elasticity with reduced dimensionality. The minimum energy path between these two minima is found using the nudged elastic band reaction-pathway sampling scheme. The energetics of CNT collapse is explored for both single- and multi-walled CNTs as well as small bundles. The process has a strong diameter dependence, with collapse being more favorable for the larger diameter tubes, but is nearly independent of chirality. The saddle point always lies close to the collapsed state, and the absolute barrier energies—even for fairly short tube lengths—are sufficiently high, even when the reaction is highly exothermic, that thermal activation cannot initiate collapse via this pathway. The hydrostatic pressure required to buckle and collapse CNTs of various diameters is discussed.

**ABSTRACT:** A meshfree method for thin shells with finite strains and arbitrary evolving cracks is described. The C1 displacement continuity requirement is met by the approximation, so no special treatments for fulfilling the Kirchhoff condition are necessary. Membrane locking is eliminated by the use of a cubic or quartic polynomial basis. The shell is tested for several elastic and elasto-plastic examples and shows good results. The shell is subsequently extended to modelling cracks. Since no discretization of the director field is needed, the incorporation of discontinuities is easy to implement and straightforward.

**INTRODUCTION:**

This paper describes a meshfree method for treating the dynamic fracture of shells. It includes both geometric and material nonlinearities and also includes a meshfree fluid model, so that complex fluid-structure interaction problems are feasible. Here we illustrate this capability with the fracture of a fluid-filled cylinder that is impacted by a penetrating projectile. The shell formulation is based on the Kirchhoff-Love (KL) theory. A meshfree thin shell based on the imposition of the KL constraints was first proposed by Krysl and Belytschko [1]. However, the shell was developed for small deformations, small strains and elasticity. Three dimensional modelling of shear deformable shells and degenerated shells in a meshfree context was studied by Noguchi et al. [2], Li et al. [3] and Kim et al. [4]. Usually, a low order polynomial basis was used, e.g. in [3], a trilinear polynomial basis was applied and the method was applied to several non-linear problems. However, for thin structures, three dimensional modelling of shell structures is computationally expensive. Garcia et al. [5] developed meshfree methods for plates and beams; the higher continuity of meshfree shape functions was exploited for Mindlin-Reissner plates in combination with a p-enrichment. Wang and Chen [6] proposed a meshfree method for Mindlin-Reissner plates. Locking is treated using second order polynomials for the approximation of the translational and rotational motion in combination with a curvature smoothing stabilization. Kanok-Nuukchai et al. [7] addressed shear locking for plates and beams in the element-free Galerkin method.

We develop a meshfree thin shell that combines classical shell theory with a continuum based shell. The kinematic assumptions of classical KL shell theory is adopted. We make use of the generality provided by the continuum description, so that constitutive models developed for continua are easily applicable to shells. The formulation is valid for finite strains.

We include in the shell the capability to model cracks, which are modeled either by cracked particles as in Rabczuk and Belytschko [8] or by a local partition of unity [9, 10, 11]. Due to the higher order continuity of meshfree methods, which enables the use of Kirchhoff-Love shell theories in pristine form, the incorporation of discontinuities is very simple and straightforward. The director field is not discretized, which simplifies the incorporation of discontinuities. In our meshfree model, the concepts for modelling cracks in continua can be adopted directly to shells.

The paper is arranged as follows: First, the kinematics of the shell is described. Then, the meshfree method, the element-free Galerkin (EFG) method, is reviewed and the concept how to incorporate continuum constitutive models is described. The extensions to modelling cracks is described in section 5. Finally, we test the meshfree shell for different elastic linear and nonlinear problems, plastic problems and cracking problems.

ABSTRACT: This paper presents a formulation for a new family of thin shell finite elements. The element is formulated by using a convected material frame notion which offers an interesting framework to take into
account large transformations. Bending behaviour is calculated from the Love-Kirchhoff assumptions and from a finite difference technique between adjacent elements. We therefore called this element SFE for semi-finite element. This method allows us to keep C0 continuity without introducing other variables than the 3 classical displacements, which reduces computational time. In this paper, a full formulation of this element is described more precisely. It takes into account the coupling effect between both membrane and bending behaviour. Various sample solutions that illustrate the effectiveness of the element in linear and nonlinear analysis are presented, with some sheet metal forming examples.

ABSTRACT: This first of two companion papers develops a new variational principle for the buckling analysis of thin-walled members based on the principle of stationary complementary energy. Some of the aspects of the Vlasov thin-walled beam theory (the rigid cross section assumption, and the stress expressions) are postulated to describe the behavior of members while other aspects of the theory (i.e., the zero shear strain assumption at mid-surface) are discarded. Koiter's formulation based on polar decomposition theory in finite elasticity is adopted to formulate expressions for statically admissible stress resultant fields. The stationarity conditions of the complementary energy expression are then evoked to yield the conditions of neutral stability and associated boundary conditions in which the rotation fields appear explicitly. The formulation seamlessly incorporates shear deformation effects and load position effects. Also, the Wagner effect and the mono-symmetry property which arise in displacement based formulations arise in the present formulation in a natural way.

ABSTRACT: This paper presents an application of the spline strip method based on the first-order shear deformation Sanders shell theory to analyze vibration of antisymmetric angle-ply laminated cylindrical panels with two opposite circumferential edges simply supported and varying boundary conditions on the remaining two straight edges. To demonstrate the accuracy and convergence of the semi-numerical method, the results are compared with those obtained by the classical shell theory and by the first-order shear deformation shell theory. Stable convergence and good accuracy are obtained. The effects of the geometric parameters and material parameters on the frequencies of graphite-epoxy laminated cylindrical panels with some boundary conditions are analyzed.

ABSTRACT: This paper presents an application of the spline strip method based on the first-order shear deformation Sanders' shell theory to analyze vibration of symmetric and antisymmetric cross-ply laminated cylindrical panels with two opposite circumferential edges simply supported and some boundary conditions on the remaining two straight edges. To demonstrate the accuracy and convergence of the semi-numerical method,
the results are compared with those obtained by the classical shell theory and by the refined shear deformation shell theory. Stable convergence and good accuracy are obtained. The effects of the geometric parameters and material parameters on the frequencies of graphite-epoxy laminated cylindrical panels with some boundary conditions are analyzed.

ABSTRACT: This paper presents an application of the spline strip method based on the high-order shear deformation Donnell's shell theory to analyse vibration of thick laminated cylindrical panels with two opposite circumferential edges simply-supported and some boundary conditions on the remaining two straight edges. To demonstrate the accuracy and convergence of the semi-numerical method, the results are compared with those obtained by the first-order shear deformation shell theory. Stable convergence and good accuracy are obtained. The comprehensive comparison of both the high-order shear deformation Donnell's shell theory and the first-order shear deformation Donnell's shell theory is studied for graphite-epoxy laminated cylindrical panels with some boundary conditions.

ABSTRACT: This paper examines the post-buckling deformations of cylindrical shells conveying viscous fluid. The wall deformation is modelled using geometrically nonlinear shell theory, and lubrication theory is used to model the fluid flow. The coupled fluid-solid problem is solved using a parallelized FEM technique. It is found that the fluid-solid interaction leads to a violent collapse of the tube such that immediate opposite-wall contact occurs after the buckling if the volume flux is kept constant during buckling. If the pressure drop through the tube is kept constant during the buckling, the fluid-solid coupling slows down the collapse (compared to buckling under a dead load). The effects of various parameters (upstream pressure, axial pre-stretch and the geometry of the tube) on the post-buckling behaviour are examined and the exact geometrically nonlinear shell theory is compared to Sanders’ (1963) moderate rotation theory. Finally, the implications of the results for previous models which described the wall deformation using so called “tube laws” are discussed.

ABSTRACT: In this paper, a geometrically nonlinear hybrid/mixed curved quadrilateral shell element (HMSHEL4N) with four nodes is developed based on the modified Hellinger/Reissner variational principles. The performance of element is investigated and tested using some benchmark problems. A number of numerical examples of plate and shell nonlinear deflection problems are included. The results are compared with theoretical solutions and other numerical results. It is shown that HMSHEL4N does not possess spurious zero energy modes and any locking phenomenon, and is convergent and insensitive to the distorted mesh. A good agreement of the results with theoretical solutions, and better performance compared with displacement finite
element method, are observed. It is seen that an efficient shell element based on stress and displacement field assumptions in solution and time is obtained.

Chen Fangqi, Wu Zhiqiang and Chen Yushu (Department of Mathematics, Department of Mechanics, Tianjin University, Tianjin 300072, China), “The high codimensional bifurcations and universal unfolding problems of a viscoelastic circular cylindrical shell”, Acta Mechanica Sinica, 2001-05

doi: cnki:ISSN:0459-1879.0.2001-05-008

ABSTRACT: The nonlinear dynamical behavior of a viscoelastic circular cylindrical shell under a harmonic excitation applied at both ends is discussed. Using singularity theory and choosing nondegenerate germ, the universal unfolding problem of the bifurcation equation is studied. The results indicate that the universal unfolding is a high codimensional bifurcation problem with codimension 5 (contains a modal parameter). Additionally, all possible forms of the universal unfoldings are given, and the transition sets in parameter plane and the bifurcation diagrams are plotted under some conditions for unfolding parameters. It is well know that the dynamical behavior of nonlinear Mathieu equation in some special forms has been studied by many authors, such as, Bogoliubov N.N., Mitropolisky Y.A., Nayfeh A.H. and Mock D.T. Especially, by introduction of symmetry group action technique, Chen Yushu and Langford W.F. established the bifurcation classification results for stable responses of non-linear Mathieu equation in general form. A sense of theoretical and experimental results with Z2-symmetric bifurcations were obtained for a parametric excitation system with one degree of freedom. One knows that a symmetric unfolding of a bifurcation equation may describe possible dynamical behavior when original system is subjected to a small perturbation with the symmetry. However, when original system is subjected to a small perturbation which does not possess the symmetry's symmetric unfolding cann't present completely the dynamical behavior of original system. In this case, one should investigate the universal unfoldings of bifurcation equation including symmetry-breaking bifurcations. For a thin viscoelastic circular cylindrical shell with Flugge-type nonlinearity under a periodic excitation applied at axis. The present paper studies the symmetry-breaking bifurcation problem. The results obtained here indicate that, under symmetry-breaking cases, there exist richer dynamic buckling patterns than those obtained under symmetry case. Clearly, the new results provide some inspirations for the analysis and design of dynamic bulking experiments of this class of system, and improve the singularity analysis method proposed by Chen Yushu and Langford W.F.

ABSTRACT: The nonlinear vibration fundamental equation of circular sandwich plate under uniformed load and circumjacent load and the loosely clamped boundary condition was established by von Karman plate theory, and then accordingly exact solution of static load and its numerical results were given. Based on time mode hypothesis and the variational method, the control equation of the space mode was derived, and then the amplitude frequency-load character relation of circular sandwich plate was obtained by the modified iteration method. Consequently the rule of the effect of the two kinds of load on the vibration character of the circular sandwich plate was investigated. When circumjacent load makes the lowest natural frequency zero, critical load is obtained.

ABSTRACT: The paper deals with the stability and some aspects of optimal design with respect to stability of geometrically nonlinear, elastic toroidal shells with open profiles. Shells rotationally symmetric in the narrower sense (toroidal segments) as well as in the broader sense (toroidal shell-arches), subjected to external pressure or to a combined loading (pressure and overall bending), are considered. The influence of the pressure distribution on its critical value as well as the post-buckling behaviour are discussed for the toroidal segments with various boundary conditions. The instability modes of the shell-arches for linear trajectories of the combined loading are also analysed. A double step parametrical optimization consisting of a midsurface design (1st step) and a design with respect to the thickness of the wall (2nd step) is performed for a toroidal segment. Constant distance between the supports and constant area of the meridional cross-section are applied as the constraints, respectively.

ABSTRACT: The bounce of a hollow spherical ball from a hard flat surface results in large deformations of the thin-walled shell; these deformations increase the internal stresses in the shell near a knuckle of bending and also increase the internal gas pressure inside the shell. This paper calculates the deformation and consequent contact forces that repel the ball from the surface, and compares the results with both a finite element analysis and experimental data. A table tennis ball is considered as an example of a thin-walled elastic shell. Since for an elastic ball there are no energy losses due to inelastic material behaviour, the analysis assumes that all energy losses are due to either friction in the contact area or impulsive forces arising from the instantaneous rate-of-change of momentum in the knuckle. In practice, the table tennis ball shows energy losses that increase with increasing impact speed; these losses substantially exceed the losses taken into account by the elastic shell analysis.

ABSTRACT: The dynamic collapse behavior of thin, composite cylindrical shells subjected to transverse point loads is considered. The dynamic behavior of the undamped cylindrical shells of varying radii is analyzed with a finite element formulation that incorporates all nonlinear Green's strain terms in the in-plane directions; transverse strains are linear and vary parabolically through the shell thickness. This formulation is denoted as the simplified large displacement/rotation (SLR) theory. Graphical representations are used extensively to examine dynamic behaviors not noted in similar research that utilized the DSHELL finite element code. Composite plate behavior is also explored. Comparison of the higher-order formulations to Donnell and von Karman models, modified with transverse shear flexibility, is also made. Several deep shell configurations, using the SLR and Donnell models, are analyzed in an effort to determine the maximum displacement and rotational limits of these formulations. The nonlinear features of the plates and shells imply the potential for
chaotic behavior. Various techniques are used to characterize the chaotic behavior of these undamped shells in pre- and post-collapsed states. Nonlinear analysis, Nonlinear dynamics, Chaos, Finite element analysis, Collapse, Buckling, Composites, Structural mechanics, Cylindrical shells, Plates.

ABSTRACT: There has been much debate on the choice for the representative wall thickness for the thin-shell model, although this model has demonstrated remarkable success in capturing many types of behavior of single-walled carbon nanotubes (SWNTs), in determining the buckling strains under compression, torsion, and bending, in particular. This analysis, using the Tersoff-Brenner potential and ab initio calculations, shows that the elasticity of the model thin shell evolves from isotropic to square symmetric with the decreasing tube diameter, leading to significant diameter dependence for all the elastic moduli and the representative wall thickness. Furthermore, the elastic moduli of multiwalled carbon nanotubes of diameters up to 10 nm are also size dependent.

ABSTRACT: Pre-stressed multi-walled carbon nanotube (PS-MWCNT), of which the interwall distance is less than 0.34 nm, holds for the highest Young's modulus while its interlayer shear strength is several orders higher than normal MWCNT. The buckling behaviors of PS-MWCNTs with two to six layers are studied using both molecular mechanics simulation and continuum mechanics models in this paper. Considering the interlayer distance as the key factor, we reveal three features of the buckling behavior of PS-MWCNTs subjected to axial loading: 1) the buckling membrane force is not a monotonic function of interlayer distance, depending on the nanotube index (i.e. diameter); 2) the buckling membrane force increases as the interlayer distance decreases for PS-MWCNTs with a fixed intertube chirality, which is a combined effect of interlayer distance and tube diameter; 3) for PS-MWCNTs with the same innermost tube, the buckling membrane force increases as the number of walls increases. Furthermore, molecular mechanics simulation and multi-shell continuum model show an agreement on the trend of the buckling membrane force as a function of interlayer distance, tube chirality index, and number of layers. These results can serve as a bridge between the molecular simulation and the continuum model for the buckling behaviors of PS-MWCNT.

ABSTRACT: Koiter’s shell model is derived systematically from nonlinear elasticity theory, and shown to furnish the leading-order model for small thickness when the bending and stretching energies are of the same order of magnitude. An extension of Koiter’s model to finite midsurface strain emerges when stretching effects are dominant.

ABSTRACT: Atomic simulations of the structures and stability of defect-free multiwalled carbon toroidal rings were performed using the second-generation empirical bond-order potential and a Morse-type van der Waals potential. It was found that a multiwalled toroidal ring improves the structural stability over its outermost single-walled counterpart, implying a stabilizing effect from the inner rings. This can be explained by the superlinear relation between the critical ring diameter and its tube diameter existing in single-walled rings. However, the findings that the critical diameter of an armchair ring is larger than that of a zigzag ring with the same tube diameters, and that the inclusion of torsion exhibits a negative effect on the stability of a multiwalled ring, are in contrast to that of a single-walled nanoring. In addition, the instability of a multiwalled nanoring always starts with the formation of many short-wavelength ripples on the compressed side of the outermost
tube. Subsequently, some of the ripples develop into buckles, resulting in buckling failures.

ABSTRACT: The article investigates the bifurcation phenomenon in plate welding. The evolution of the buckling phenomenon starts during the weld cooling cycle caused by an onset inelastic strain incompatibility condition. In this study, the researchers attempt to elucidate a numerical procedure to determine the peak temperature-based buckling criterion for welding thin steel plates.

ABSTRACT: The buckling in stability of a long multilayer linearly viscoelastic shell, composed of different materials and loaded with a uniformly distributed external pressure of given intensity, is investigated. By neglecting the influence of fastening of its end faces, the initial problem is reduced to an analysis of the loss of load-carrying capacity of a ring of unit width separated from the shell. The new problem is solved by using a mixed-type variational method, allowing for the geometric nonlinearity, together with the Rayleigh-Ritz method. The creep kernels are taken exponential with equal indices of creep. As an example, a three-layer ring with a structure symmetric about its midsurface is considered, and the effect of its physimechanical and geometrical parameters, as well as of wave formation, on the critical time of buckling in stability of the ring is determined. It is found that, by selecting appropriate materials, more efficient multilayer shell-type structural members can be created.

ABSTRACT: Membranes enclosing capsules and biological cells undergo periodic compression and stretching due to an imparted hydrodynamic traction as they rotate in a shear flow. Compression may cause transient or permanent buckling manifested by the onset of wrinkled shapes. To study the effect of pre-compression and pre-stretching on the critical conditions for buckling, the response of an elastic circular plate flush mounted on a plane wall and deforming under the action of a uniform tangential load due to an over-passing simple shear flow is considered. Working under the auspices of the theory of elastic instability of plates governed by the linear von Karman equation, an eigenvalue problem is formulated resulting in a fourth-order partial differential equation with position-dependent coefficients parametrized by the Poisson ratio. Solutions are computed by applying Fourier series expansions to derive an infinite system of coupled ordinary differential equations, and then implementing orthogonal collocation. The solution space is illustrated, critical values for buckling are identified, the associated eigenfunctions representing possible modes of deformation are displayed, and the effect of the Poisson ratio is discussed.

ABSTRACT: Single-wall carbon nanotubes (SWCNT) have been frequently modeled as thin shells, but the shell thickness and Young's modulus reported in literatures display large scattering. The order of error to approximate SWCNTs as thin shells is studied in this paper via an atomistic-based finite-deformation shell theory, which avoids the shell thickness and Young's modulus, but links the tension and bending rigidities directly to the interatomic potential. The ratio of atomic spacing (Delta approximately equal to 0.14 nm) to the radius of SWCNT, Delta/R, which ranges from zero (for graphene) to 40% [for a small (5,5) armchair SWCNT (R=0.35 nm)], is used to estimate the order of error. For the order of error O((Delta/R)^3), SWCNTs cannot be represented by a conventional thin shell because their constitutive relation involves the coupling between tension and curvature and between bending and strain. For the order of error O((Delta/R)^2), the tension and bending (shear and torsion) rigidities of SWCNTs can be represented by an elastic orthotropic thin shell, but the thickness and elastic modulus cannot. Only for the order of error O(Delta/R), a universal constant shell thickness can be defined and SWCNTs can be modeled as an elastic isotropic thin shell.

“Efficient handling of stability problems in shell optimization by asymmetric ‘worst-case’ shape imperfection”,
doi: 10.1002/nme.2113

ABSTRACT: The paper presents an approach to shape optimization of proportionally loaded elastic shell
structures under stability constraints. To reduce the stability-related problems, a special technique is utilized, by
which the response analysis is always terminated before the first critical point is reached. In this way, the
optimization is always related to a precritical structural state. The necessary load-carrying capability of the
optimal structure is assured by extending the usual formulation of the optimization problem by a constraint on
an estimated critical load factor. Since limit points are easier to handle, the possible presence of bifurcation
points is avoided by introducing imperfection parameters. They are related to an asymmetric shape perturbation
of the structure. During the optimization, the imperfection parameters are updated to get automatically the
‘worst-case’ pattern and amplitude of the imperfection. Both, the imperfection parameters and the design
variables are related to the structural shape via the design element technique. A gradient-based optimizer is
employed to solve the optimization problem. Three examples illustrate the proposed approach.

Novgorod, Russia), “Numerical modeling of nonlinear deformation and buckling of composite plate-shell
structures under pulsed loading”, Mechanics of Composite Materials, Vol. 35, No. 6, 1999, pp. 495-506,
doi: 10.1007/BF02259471

ABSTRACT: Nonlinear three-dimensional problems of dynamic deformation, buckling, and posteritical
behavior of composite shell structures under pulsed loads are analyzed. The structure is assumed to be made of
rigidly joined plates and shells of revolution along the lines coinciding with the coordinate directions of the
joined elements. Individual structural elements can be made of both composite and conventional isotropic
materials. The kinematic model of deformation of the structural elements is based on Timoshenko-type
hypotheses. This approach is oriented to the calculation of nonstationary deformation processes in composite
structures under small deformations but large displacements and rotation angles, and is implemented in the
context of a simplified version of the geometrically nonlinear theory of shells. The physical relations in the composite structural elements are based on the theory of effective moduli for individual layers or for the package as a whole, whereas in the metallic elements this is done in the framework of the theory of plastic flow. The equations of motion of a composite shell structure are derived based on the principle of virtual displacements with some additional conditions allowing for the joint operation of structural elements. To solve the initial boundary-value problem formulated, an efficient numerical method is developed based on the finite-difference discretization of variational equations of motion in space variables and an explicit second-order time-integration scheme. The permissible time-integration step is determined using Neumann's spectral criterion. The above method is especially efficient in calculating thin-walled shells, as well as in the case of local loads acting on the structural element, when the discretization grid has to be condensed in the zones of rapidly changing solutions in space variables. The results of analyzing the nonstationary deformation processes and critical loads are presented for composite and isotropic cylindrical shells reinforced with a set of discrete ribs in the case of pulsed axial compression and external pressure.

ABSTRACT: The purpose of doing probabilistic structural analysis is to provide the designer with a more realistic ability to assess the importance of uncertainty in the response of a high performance structure. The objective of this five-year contract effort (NASA Contrast NAS3-24389) on Probabilistic Structural Analysis Methods (PSAM) is the development of several modular structural analysis packages capable of predicting the probabilistic response distribution for key structural variables such as stress, displacement, natural frequencies, buckling loads, transient responses, etc. The structural analysis packages include stochastic modeling of loads, material properties, geometry (e.g. tolerances), and boundary conditions. The structural analysis solution is in terms of the cumulative distribution function (CDF) and confidence bounds. Two methods of probability modeling are included in the analysis packages. One of these is the well established Monte Carlo simulation method; the other is a fast probability integration (FPI) algorithm which will be discussed in the paper. PSAM tools can be used to estimate structural safety and reliability, while providing the engineer with information on the confidence that should be given to the predicted behavior. Perhaps most critically, the PSAM results provide information to the designer on those variables for which the design is most sensitive.

ABSTRACT: The buckling and fracture modes of thick (diameter >20 nm) multiwall carbon nanotubes (MWCNTs) under compressive stress were examined using in situ transmission electron microscopy. The overall dynamic deformation processes of the MWCNTs as well as the force/distance curves can be obtained. The buckling behavior of MWCNTs under compression falls into two categories, the first is non-axial buckling and subsequently complex Yoshimura patterns can be induced on the compressive side of the MWCNTs. The second is axial buckling followed by catastrophic failure. We find the buckling mode of thick MWCNTs is highly dependent on the diameter and length of the MWCNTs. A continuum mechanics model is employed to determine the buckling mode criterion for the MWCNTs. Moreover, the shell by shell fracture mode and planar fracture mode of MWCNTs are directly observed in our experiments.

Zhejiang University, Hangzhou 310027, China), “Effect of weld reinforcement on axial plastic buckling of welded steel cylindrical shells”, Journal of Zhejiang University-SCIENCE A (Applied Physics & Engineering) ISSN 1673-565X (Print); ISSN 1862-1775

ABSTRACT: The effect of weld reinforcement on axial plastic buckling of welded steel cylindrical shells is investigated through experimental and numerical buckling analysis using six welded steel cylindrical shell specimens. The relationship between the amplitude of weld reinforcement and the axial plastic buckling critical load is explored. The effect of the material yield strength and the number of circumferential welds on the axial plastic buckling is studied. Results show that circumferential weld reinforcement represents a severe imperfect form of axially compressed welded steel cylindrical shells and the axial plastic buckling critical load decreases with the increase of the mean amplitude of circumferential weld reinforcement. The material yield strength and the number of circumferential welds are found to have no significant effect on buckling waveforms; however, the axial plastic buckling critical load can be decreased to some extent with the increase of the number of circumferential welds.

ABSTRACT: The buckling behaviour and collapse mechanism of elastic-plastic cylindrical shells subjected to longitudinal impact were studied by impact experiments and computer simulations. Attention was focused on the influence of the geometry and material property of the shell and loading condition on dynamic buckling response. Varieties of bucking models and the switching between the modes in buckling process were observed. Particularly, the phenomenon of so called dynamic plastic buckling in relatively low impact velocity was captured by high speed photograph in impact test of cooper specimen. This experimentally confirms that the dynamic plastic buckling does not necessarily require high impact velocity. The whole process of impact buckling was simulated by LS-DYNA code. The effects of the stress wave and the transverse inertia and plastic hardening modulus, etc. on initiation of wrinkle in earlier phase of buckling are analysed.

ABSTRACT: The generality and simplicity has made the shell element employed in a wide rage of finite element analysis for mechanics problems. The demand of shell models are rapidly growing to perform large-
scale computations in important industrial applications to structural problems, sheet forming processes and composite shell structures. Since the general shell element has no stiffness associated with the drilling direction, any slight disturbance to the drilling rotation in the generalized load vector tends to amplify the rotation to an unrealistic large amount, which results in an unreliable solution. In addition, most shell elements fail in the analysis of non-smooth shell structures or shell structures with stiffener connections where three rotation components have to be considered. For remedy of that, many recent efforts have been done to include the sixth degree-of-freedom of the drilling rotation compatible to the physical meaning. In this paper, a four-node degenerated shell element with the implicit numerical scheme is developed to calculate non-linear problems based on the Belytschko-Leviathan's linear one-point quadrature shell element with the drilling degree of freedom. In formulating for the shell element, the physical stabilization scheme is used to control the zero-energy mode of the element for one-point quadrature shell elements. The element is then extended for the nonlinear elasto-plastic analysis of shell structures undergoing large deformation in conjunction with the updated Lagrangian formulation. Many numerical problems including patch tests and benchmark tests are solved to investigate the performance of the element in comparison with conventional ones. Typical problems are the shell structure subjected to drilling moments, warped shells, and structures with sharp edges within the shell. The performance tests have been carried out focusing on the accuracy of the deformed shape and the convergence as well as the computing time. In order to demonstrate the versatility and applicability of the present shell element, the static buckling analysis of a thin-walled S-beam structure has been solved and compared with commercial codes.

ABSTRACT: Under the effect of an inner pressure, a thick hyperelastic shell cylinder is susceptible to developing mechanical instabilities, leading to a bifurcated shape that no longer has the initial cylindrical symmetry. The considered problem has a strong resonance in a biomedical context, considering pathologies encountered for arteries, such as aneurysm. In this contribution, the mechanical behavior of thick elastic shells has been analyzed, considering a thick-walled cylindrical hyperelastic model material obeying a transversely isotropic behavior, first in a large-displacement situation and then in a large-deformation case. The response of the material is assumed to be instantaneous, so that time-dependent effects shall not be considered in this paper. The case of a Saint-Venant–Kirchhoff material is considered with special emphasis to exemplify a large-displacement small-strain situation; the neo-Hookean behavior is next considered to enlarge the constitutive law toward consideration of large strains. The stability conditions of the shell are studied and bifurcation conditions formulated in terms of the applied pressure and of the geometrical and mechanical parameters that characterize the shell. Analytical solutions of some bifurcation points are evidenced and calculated when the direction of the fibers coincide with the cylinder axis.
M. Sanjarani Pour (Mathematics College, Sistan and Balochestan University, Zahedan, Iran), “WKB Analysis Of The Buckling Of A Neo-Hookean Cylindrical Shell Of Arbitrary Thickness Subject To An External Pressure”, International Journal of Applied Mechanics, Vol. 02, No. 04, December 2010, DOI: 10.1142/S1758825110000792

ABSTRACT: By using the WKB method to solve the eigenvalue problem that results from a linear bifurcation analysis, we show that for a cylindrical shell of arbitrary thickness made of a neo-Hookean material which is subjected to an external hydrostatic pressure, the circular cross-section buckles into a non-circular shape at a value of \( \mu_1 \) which depends on \( A_1/A_2 \) and the mode number, where \( A_1 \) and \( A_2 \) are the undeformed inner and outer radii, and \( \mu_1 \) is the ratio of the deformed inner radius to \( A_1 \). We show that this problem is amenable to the WKB method based on the largeness of the mode number. Similar to the case of a Varga cylindrical tube [Sanjarani Pour, 2005], the dependence of \( \mu_1 \) on \( A_1/A_2 \) has a boundary layer structure. Simple asymptotic expressions for the bifurcation condition are obtained. It has been shown that the asymptotic results obtained in the outer and inner regions agree with the numerical results. The two sets of results obtained for the eigenfunction with the aid of WKB and determinant methods are almost indistinguishable.

M. Sanjarani Pour (Mathematics College, Sistan and Balochestan University, Zahedan, Iran), “A WKB analysis of the buckling condition for a cylindrical shell of arbitrary thickness subjected to an external pressure”, IMA Journal of Applied Mathematics, Vol. 70, No. 1, pp. 147-161, April 2013

ABSTRACT: We consider the plane-strain buckling of a cylindrical shell of arbitrary thickness which is made of a Varga material and is subjected to an external hydrostatic pressure on its outer surface. The WKB method is used to solve the eigenvalue problem that results from the linear bifurcation analysis. We show that the circular cross-section buckles into a non-circular shape at a value of \( \mu_1 \) which depends on \( A_1/A_2 \) and a mode number, where \( A_1 \) and \( A_2 \) are the undeformed inner and outer radii, and \( \mu_1 \) is the ratio of the deformed inner radius to \( A_1 \). In the large mode number limit, we find that the dependence of \( \mu_1 \) on \( A_1/A_2 \) has a boundary layer structure: it is constant over almost the entire region of \( 0 < A_1/A_2 < 1 \) and decreases sharply from this constant value to unity as \( A_1/A_2 \) tends to unity. Our asymptotic results for \( A_1 - 1 = O(1) \) and \( A_1 - 1 = O(1/n) \) are shown to agree with the numerical results obtained by using the compound matrix method.

Reddy (Advanced Computational Mechanics Laboratory, Department of Mechanical Engineering, Texas A & M University, College Station, TX 77843-3123, USA), “Analytical solutions for bending, vibration, and buckling of FGM plates using a couple stress-based third-order theory”, Composite Structures, Vol. 103, pp 86-98, 2013, DOI: 10.1016/j.compstruct.2013.03.007

ABSTRACT: Analytical solutions of a general third-order plate theory that accounts for the power-law distribution of two materials through thickness and microstructure-dependent size effects are presented. The Navier solution technique is adopted to derive analytical solutions to simply supported rectangular plates. The modulus of elasticity and the mass density are assumed to vary only through thickness of plate and a single material length scale parameter of a modified couple stress theory captures the microstructure-dependent size effects. Examples of bending, buckling, and vibration problems are presented to show effects of the power-law distribution of two materials and the microstructure-dependent size parameter.

ABSTRACT: This paper presents a cylindrical strain based shallow shell finite element which is developed for
linear and geometrically non-linear analysis of cylindrical shells. The developed element is rectangular in plan and has the only five essential degrees of freedom at each corner node. The displacement fields of the element satisfy the exact requirement of rigid body modes. The efficiency of the element is demonstrated by applying it to the linear and geometrically nonlinear analysis of shell structures. The suitability of the element is also tested for natural frequencies’ calculations of cylindrical shells. Results obtained by the present element are compared with those available in the literature. These comparisons show that efficient convergence characteristics and accurate results can be obtained by using the present element.

“Buckling of multicomponent elastic shells with line tension”, Soft Matter, 2012, 8, 636-644
DOI: 10.1039/C1SM06325A
ABSTRACT: We explore the effects of line tension on the shape of two component elastic shells. Segregation between components with different elastic properties combined with the subtleties related to the spherical topology leads to a rich variety of shapes. They range from irregular polyhedra at weak segregation to Janus-like morphologies with spherical and buckled regions coexisting on the same shell for large values of the line tension. We use Monte Carlo simulations to map a detailed phase diagram as a function of the relative fraction of the two components, the ratio of their bending rigidities, and the strength of the line tension.

ABSTRACT: We study how the stability of spherical crystalline shells under external pressure is influenced by the defect structure. In particular, we compare stability for shells with a minimal set of topologically-required defects to shells with extended defect arrays (grain boundary "scars" with non-vanishing net disclination charge). We perform Monte Carlo simulations to compare how shells with and without scars deform quasi-statically under external hydrostatic pressure. We find that the critical pressure at which shells collapse is lowered for scarred configurations that break icosahedral symmetry and raised for scars that preserve icosahedral symmetry. The particular shapes which arise from breaking of an initial icosahedrally-symmetric shell depend on the Foppl-von Karman number

ABSTRACT: Thin elastic spherical shells are known to exhibit a buckling instability at a finite external pressure. We study how this buckling is influenced by a weak region in an otherwise uniform shell, focusing on the case of a single small circular soft spot that is thinner than the rest of the shell. Using numerical simulations and theoretical arguments, we show that the soft region fundamentally alters the buckling behavior of the shell. The soft spot influences both the pressure at which the shell buckles, and the postbuckling shape of the shell.
Depending on the properties of the soft spot, we find either a single buckling transition or two separate transitions as the external pressure is increased. We analyze the dependence of these buckling transitions on the size and thickness of the soft region. Besides contributing to our fundamental understanding of buckling transitions in inhomogeneous shells, our results can be applied to designing capsules with tunable shapes.

ABSTRACT: Thermal fluctuations strongly modify the large length-scale elastic behavior of cross-linked membranes, giving rise to scale-dependent elastic moduli. Whereas thermal effects in flat membranes are well understood, many natural and artificial microstructures are modeled as thin elastic shells. Shells are distinguished from flat membranes by their nonzero curvature, which provides a size-dependent coupling between the in-plane stretching modes and the out-of-plane undulations. In addition, a shell can support a pressure difference between its interior and its exterior. Little is known about the effect of thermal fluctuations on the elastic properties of shells. Here, we study the statistical mechanics of shape fluctuations in a pressurized spherical shell, using perturbation theory and Monte Carlo computer simulations, explicitly including the effects of curvature and an inward pressure. We predict novel properties of fluctuating thin shells under point indentations and pressure-induced deformations. The contribution due to thermal fluctuations increases with increasing ratio of shell radius to thickness and dominates the response when the product of this ratio and the thermal energy becomes large compared with the bending rigidity of the shell. Thermal effects are enhanced when a large uniform inward pressure acts on the shell and diverge as this pressure approaches the classical buckling transition of the shell. Our results are relevant for the elasticity and osmotic collapse of microcapsules.

ABSTRACT: The crumpling of spherical crystalline lattices where the topological defects are frozen is studied. The geometry of the crumpled membrane is found to depend on the set of topological defects and more exotic defect sets can result in crumpled shapes resembling that of the Platonic and Archimedean solids. The phase diagram of the crumpled spheres can be categorized by two dimensionless numbers h/R (aspect ratio) and R/a (lattice ratio), where h is the thickness of the shell, R is the radius of the initial sphere and a is the average bond length of the triangulation. The shapes of the crumpled membrane can be understood using rotationally invariant quantities formed from spherical harmonics coefficients and a Landau free energy can be written, involving quadratic and cubic rotational invariants. Shells with different topological defects have qualitatively different hysteresis behaviors and the transitions appear to be first order in general.

ABSTRACT: Colloidal capsules can sustain an external osmotic pressure; however, for a sufficiently large pressure, they will ultimately buckle. This process can be strongly influenced by structural inhomogeneities in the capsule shells. We explore how the time delay before the onset of buckling decreases as the shells are made more inhomogeneous; this behavior can be quantitatively understood by coupling shell theory with Darcy’s law. In addition, we show that the shell inhomogeneity can dramatically change the folding pathway taken by a capsule after it buckles.

PARTIAL INTRODUCTION: Many important natural or technological situations require understanding thin, spherical shells; examples include colloidal capsules for chemical encapsulation and release [1–3], biological cells [4,5], pollen grains [6], submersibles [7], chemical storage tanks [8], nuclear containment shells [8], and even the Earth’s crust [9]. In many cases, the utility of such a shell critically depends on its response to an externally imposed pressure. For small pressures, a homogeneous, spherical shell, characterized by a uniform thickness, supports a compressive stress, and it shrinks isotropically. Above a threshold pressure, however, this shrinkage becomes energetically prohibitive; instead, the shell buckles, reducing its volume by forming a localized indentation at a random position on its surface. For the case of a homogeneous shell, this threshold pressure can be calculated using a linearized analysis of shell theory [10,11], while the exact morphology of the shell after it buckles requires a full nonlinear analysis [12–14]. However, many shells are inhomogeneous, characterized by spatially varying thicknesses and elastic constants [6,15–18]. Such inhomogeneities can strongly influence how a shell buckles [6,10,19–23]. Unfortunately, despite its common occurrence in real shells, exactly how inhomogeneity influences the onset of buckling, as well as the shell morphology after buckling, remains to be elucidated. A deeper understanding requires careful investigation of the buckling of spherical shells with tunable, well-defined, inhomogeneities. In this Letter, we use a combination of experiments, theory, and simulation to study the buckling of spherical colloidal capsules with inhomogeneous shells of non-uniform thicknesses. We show that the onset of buckling, above a threshold external osmotic pressure, is well described by shell theory; however, even above this threshold, the capsules do not buckle immediately. We find that the time delay before the onset of buckling decreases as the shells are made more inhomogeneous; these dynamics can be quantitatively understood by coupling shell theory with…

We study the behavior of thin elastic sheets that are bent and strained under the influence of weak, smooth confinement. We show that the emerging shapes exhibit the coexistence of two types of domains that differ in their characteristic stress distributions and energies, and reflect different constraints. A focused-stress patch is subject to a geometric, piecewise-inextensibility constraint, whereas a diffuse-stress region is characterized by a mechanical constraint - the dominance of a single component of the stress tensor. We discuss the implications of our findings for the analysis of elastic sheets that are subject to various types of forcing.

ABSTRACT: The dynamic analysis of laminated composite shell structures is performed using a simple displacement-based 18-degree-of-freedom triangular flat shell element, obtained by the superposition of a membrane element and a plate element. The membrane element is based on the assumed natural deviatoric strain formulation (ANDES), having corner drilling degrees of freedom and optimal in-plane bending response. The plate element employs the Timoshenko’s laminated composite beam function to define the deflections and rotations on the element boundaries. This formulation provides first-order shear flexibility to the element and naturally avoids shear-locking problems as thin shells are analyzed. The geometrically nonlinear behavior of the structures is achieved by the element independent corotational formulation (EICR) together with a consistent treatment of finite rotations. An energy conserving procedure for the time-integration of the nonlinear dynamic equations is also included. Finally, two examples are presented to show that the algorithm is able to solve highly nonlinear dynamic problems.

ABSTRACT: A new formulation for corotational nonlinear dynamic analysis of thin-shell structures involving large displacements and finite rotations has been presented in this paper. By introducing the kinematic description of the geometrically exact quasi-static shell model to describe the motion of an arbitrary material point in a triangular shell element, the new expressions for the inertial force vector and tangent inertia matrix were derived systematically. The elastic deformation was handled by using the consistent symmetrizable equilibrated corotational formulation, which is independent with respect to the local finite element modeling. An energy-momentum-conserving algorithm and an energy-decaying/momentum-conserving algorithm were developed for nonlinear dynamic analysis by applying the generalized energy-momentum method in the corotational formulation. Three classic numerical examples, including the dynamic response, free motion, and dynamic buckling of thin-shell structures, were computed to verify the accuracy and capability of the presented formulation for solving the nonlinear dynamic problems of thin-shell structures with finite rotations. In the relevant numerical example, the conservations of linear momentum and angular momentum of a shell structure due to the time-integration algorithms in the corotational formulation were investigated.

ABSTRACT: This work deals with the evaluation of the different modeling options based on the FEM to reproduce the structural performance of a composite stiffened panel in postbuckling regime under uniform pressure. Two fundamental modeling options are used for this purpose: monolithic and multi-part approaches. These strategies are based respectively on standard and 7-parameter finite element shell formulations as underlying mechanical theories. The numerical results obtained by means of these alternatives are compared with the experimental response of the panel with special emphasis in the postbuckling evolution of the behavior of the structure, and incorporating the initial geometric imperfections of the panel in the simulations.

ABSTRACT: Carbon nanotubes (CNTs) are capable to absorb and encapsulate some molecules to create new hybrid nano-structures providing a variety of functionally useful properties. CNTs functionalized by encapsulating single-stranded deoxy-ribonucleic acid (ssDNA) promise great potentials for applications in nanotechnology and nano-biotechnology. In this paper, buckling instability of ssDNA-CNT i.e. hybrid nano-structure composed of ssDNA encapsulated inside CNT has been investigated using the nonlocal elasticity theory. The nonlocal elasticity theory is capable to capture the small scale effects due to the discontinuity of nano-structures at atomic scales. The nonlocal elastic rod and shell equations are derived for modeling ssDNA and CNT respectively. Providing numerical examples, it is predicted that, ssDNA-(10,10) CNT is more resistant than the pristine (10,10) CNT against the buckling instability under radial pressure due to the inter-atomic van der Waals interactions between DNA and CNT. Furthermore, nonlocal elasticity theory predicts lower critical buckling pressure than does the local elasticity theory.

ABSTRACT: This article reviews recent applications of controlled wrinkling for creating structured and/or patterned interfaces, and its use in metrology. We discuss how wrinkles develop as a result of in-plane compression of thin sheets. As the wavelength of wrinkles is only dependent on elastic properties and thickness of the sheets, the phenomenon can be used in metrology for determination of elastic properties. The second aspect is its use for patterning and topographical structuring of surfaces. If mechanical properties and thickness are well controlled, wrinkle orientation and geometry can be tailored. Wavelengths between fractions of a micron and many micrometers are feasible. This process is based on a macroscopic deformation and upscaling to larger areas is possible which provides an attractive alternative to bottom-up or top-down approaches for surface patterning. We describe the formation of stable surface wrinkles in thin sheets of different materials having different surface chemistries, report on applications, and discuss the usefulness of wrinkles for building hierarchical structures.

ABSTRACT: In humans and many other mammals, the cortex (the outer layer of the brain) folds during development. The mechanics of folding are not well understood; leading explanations are either incomplete or at odds with physical measurements. We propose a mathematical model in which (i) folding is driven by tangential expansion of the cortex and (ii) deeper layers grow in response to the resulting stress. In this model the wavelength of cortical folds depends predictably on the rate of cortical growth relative to the rate of stress-induced growth. We show analytically and in simulations that faster cortical expansion leads to shorter gyral wavelengths; slower cortical expansion leads to long wavelengths or even smooth (lissencephalic) surfaces. No
inner or outer (skull) constraint is needed to produce folding, but initial shape and mechanical heterogeneity influence the final shape. The proposed model predicts patterns of stress in the tissue that are consistent with experimental observations.

ABSTRACT: A methodology is introduced for calculating the allowable buckling stress in equipment operating in the time-dependent (creep) range. Norton’s equation coupled with various procedures such as the stationary stress method, classical creep buckling equations, and the isochronous stress–strain diagrams are utilized to obtain a practical design approach for equipment operating in the time-dependent range. Various components are investigated such as slender columns, cylindrical shells, spherical components, and conical transition sections.

ABSTRACT: This paper studies the collapse of a void in an elastomer caused by osmosis. The void is filled with liquid water, while the elastomer is surrounded by unsaturated air. The difference in humidity motivates water molecules to permeate through the elastomer, from inside the void to outside the elastomer, leaving the liquid water inside the void in tension. When the tension is low, the void reduces size but retains the shape, a mode of deformation which we call breathing. When the tension is high, the void changes shape, possibly by two types of instability: buckling and creasing. The critical conditions for both types of instability are calculated. A tubular elastomer collapses by buckling if the wall is thin, but by creasing if the wall is thick. As the tension increases, a thin-walled tube undergoes a buckle-to-crease transition.

ABSTRACT: We introduce a class of continuum shell structures, the Buckliball, which undergoes a structural
transformation induced by buckling under pressure loading. The geometry of the Buckliball comprises a spherical shell patterned with a regular array of circular voids. In order for the pattern transformation to be induced by buckling, the possible number and arrangement of these voids are found to be restricted to five specific configurations. Below a critical internal pressure, the narrow ligaments between the voids buckle, leading to a cooperative buckling cascade of the skeleton of the ball. This ligament buckling leads to closure of the voids and a reduction of the total volume of the shell by up to 54%, while remaining spherical, thereby opening the possibility of encapsulation. We use a combination of precision desktop-scale experiments, finite element simulations, and scaling analyses to explore the underlying mechanics of these foldable structures, finding excellent qualitative and quantitative agreement. Given that this folding mechanism is induced by a mechanical instability, our Buckliball opens the possibility for reversible encapsulation, over a wide range of length scales.

ABSTRACT: Buckling-induced reversible symmetry breaking and amplification of chirality using macro- and microscale supported cellular structures is described. Guided by extensive theoretical analysis, cellular structures are rationally designed, in which buckling induces a reversible switching between achiral and chiral configurations. Additionally, it is demonstrated that the proposed mechanism can be generalized over a wide range of length scales, geometries, materials, and stimuli.

ABSTRACT: In this paper, the elastic buckling stress of axisymmetric cylindrical shells under uniform axial load is determined analytically by using the first order shear deformation theory. The equilibrium equations are derived by the virtual work principle and then the stability equations are extracted from them. They are systems of differential equations, which are solved analytically by using the perturbation method. The effects of the geometrical properties on the buckling stress are investigated by a parametric study. The results are compared with the finite elements methods.

ABSTRACT: This paper studies the dynamic shell buckling behavior of multi-walled carbon nanotubes
(MWNTs) embedded in an elastic medium under step axial load based on continuum mechanics model. It is shown that, for occurrence of dynamic shell buckling of MWNTs or MWNTs embedded in an elastic medium, the buckling stress is higher than the critical buckling stress of the corresponding static shell buckling under otherwise identical conditions. Detailed results are demonstrated for dynamic shell buckling of individual double-walled carbon nanotubes (DWNTs) or DWNTs embedded in an elastic medium. A phenomenon is shown that DWNTs or embedded DWNTs in dynamic shell buckling are prone to axisymmetric buckling rather than non-axisymmetric buckling. Numerical results also indicate that the axial buckling form shifts from the lower buckling mode to the higher buckling mode with increasing buckling stress, but the buckling mode is invariable for a certain domain of buckling stress. Further, an approximate analytic formula is presented for the buckling stress and the associated buckling wavelength for dynamic axisymmetric buckling of embedded DWNTs. The effect of radii is also examined.

ABSTRACT: Buckling experiments carried out on the shell structures show that these structures are sensitive to the initial imperfections. An early attempt to establish occasional discrepancies between theoretical and experimental buckling loads of cylindrical shells was reported by Donnell [1]. Later it was determined that the initial imperfections and the boundary conditions are the principal cause of disagreement. Development of new materials, however, has necessitated more research in the field of mechanical and thermal buckling of imperfect shell structures. Functionally graded materials (FGMs) are high-performance heat-resistant new materials able to withstand ultrahigh temperatures and minimize thermal stresses. Thermoelastic buckling analysis of imperfect FGM cylindrical shells under various thermal loads and/or axial ...

ABSTRACT: In this paper, the authors investigate a cylindrical shell reinforced by carbon nanotubes. The critical buckling load is calculated using analytical method when it is subjected to compressive axial load. The Mori-Tanaka method is firstly utilized to estimate the effective elastic modulus of composites having aligned oriented straight CNTs. The eigenvalues of the problem are obtained by means of an analytical approach based on the optimized Rayleigh-Ritz method. There is presented a study on the effects of CNTs volume fraction, thickness and aspect ratio of the shell, CNTs orientation angle, and the type of supports on the buckling load of cylindrical shells. Furthermore the effect of CNTs agglomeration is investigated when CNTs are dispersed none uniformly in the polymer matrix. It is shown that when the CNTs are arranged in 90_ direction, the highest critical buckling load appears. Also, the results are plotted for different longitudinal and circumferential mode numbers. There is a specific value for aspect ratio of the cylinder that minimizes the buckling load. The results reveal that for very low CNTs volume fractions, the volume fraction of inclusions has no important effect on the critical buckling load.

ABSTRACT: Structural elements in the form of cylindrical shells are often designed to be thin to save weight, and this can lead to buckling. The patterns and values of buckling loads depend greatly on the type of loading, the end support conditions, and effective laminate material properties and couplings. For many typical buckling loadings, there is a variety of similar buckling states, which causes sensitivity to initial imperfections. Understanding this phenomenon requires the consideration of nonlinear strain-displacement relations, usually in the von Kármán form. In addition, shells of composite materials require deformation assumptions that permit transverse shear deformation. A review of the results obtained using theoretical techniques is given as well as finite element predictions and experimental observations. A very brief summary of references is given for the optimization of shell buckling loads and for the additional effects of stringer reinforcement, thermal loadings, and other topics.

ABSTRACT: Calculating the buckling load of structures is one of the main aspects of geometric structural instability. With reference to finite element software (ANSYS) and considering the weight of the structure as a constant load, the paper calculates the buckling load of steal arch shells as the main scope. Then, the article makes a prediction for the buckling load of steel arch shells applying 85 datasets prepared by the above mentioned method and using an artificial neural network by means of NeuroSolution 5.0 software. The radius of the periphery cylinder of an arch shell, the thickness of the shell and its internal angel are considered as inputs of construct models. Next, in order to attain an optimum model calculating and comparing the value of Root Mean Squared Error, RMSE, Mean Absolute Error, MAE and the coefficient of correlation, $R^2$, for all 1 and 2-layer constructed models, a model having architecture 3-7-1 was found to be optimum. A high confirmed correlation with calculated buckling loads employing the finite element method and considering the calculated values of RMSE (0.0126), MAE (0.011) and the obtained value $R^2$ (0.998) demonstrated high efficiency of a new developed neural network model.

ABSTRACT: Presence of cracks or similar imperfections can considerably reduce the buckling load of a shell structure. In this paper, the buckling of thin conical frusta with cracks under axial loads has been studied. At first, a frustum without any imperfection has been analyzed. In continuation, sensitivity of the buckling load to the crack presence with different length and orientation has also been investigated. This procedure has been investigated on three types of frusta with different heights and constant semi-apical angles. Some effective parameters on buckling have been studied separately and the required data for analysis have been gained through experimental tests. The finite element ABAQUS software has been used for the numerical analyses.

ABSTRACT: Buckling behavior of plates and shells is one of the important characteristics in analysis of any structure. One the most significant parameter that must be considered in buckling phenomenon is imperfection. In this paper the effect of imperfection on buckling load of steel rectangular plates under uni-axial in-plane compressive loading is investigated by numerical and experimental methods. The plates were free on two opposite sides and simply supported at the load side whereas the opposite side is either clamped or simply supported. This means that the plate primarily exhibits a type of column’s buckling.

“Numerical modeling of stresses and buckling loads of isogrid lattice composite structure cylinders”,
DOI: http://dx.doi.org/10.4314/ijest.v5i1.4

ABSTRACT: Isogrid composite lattice cylindrical structure with or without skins which consists of a system of plus/minus phi (with respect to the shell axis) helical ribs and circumferential ribs, and has no skins or has skins was studied in a numerical method using ANSYS software, where in this model axial compression and/or pressure loads are applied, to determine the different failure modes which are, failure due to stress exceeds material strength, failure due to local buckling of ribs (crippling), failure due to general buckling of the cylinder and failure due to local buckling skin if the skin is existed. An example was studied to compare the results obtained from the numerical method and other research article.

ABSTRACT: The problem of dynamic stability is substantially more complex than the buckling analysis of a shell subjected to static loads. The fundamental aim of this paper is to present criteria for determining the critical load of dynamic buckling of thin shell. Another purpose of establishing such criteria is to guide engineers, scientists and researchers dealing with such problems, for a better comparison, verification and a validation of their experimental or numerical results. To illustrate the application of these criteria, two examples have been studied.

Chellapandi (Indira Gandhi Centre for Atomic Research, Kalpakkam, India), “Progressive deformation behaviour of thin cylindrical shell under cyclic temperature variation using combined hardening Chaboche model”, Latin American Journal of Solids and Structures, Vol. 11, No. 6, November 2014

ABSTRACT: This study intends to evaluate thermal ratchetting deformation due to cyclic thermal loading along the axis of a smooth cylindrical shell. Two cases of progressive deformation behaviour are discussed for different loading methods. The aim of the first case is to recognize the shakedown behaviour of the cylinder under applied loading cycles. Alternatively, second case is highlighting the ratchetting behaviour of the cylinder. Based on the loading method in second case, a smooth thin hollow cylinder is considered to simulate the progressive deformation. This condition simulates the 1/25th scale down model of the Prototype Fast Breeder Reactor (PFBR) main vessel.

ABSTRACT: In this paper, the buckling strength of the lining shells inside the pressure vessel was investigated both theoretically and experimentally. First, the bifurcation buckling analysis of the lining shells was carried out with the aid of the newly developed computer program. In the analysis, the lining could be considered to be a shell subjected to external pressure and encased in a rigid cavity. The concepts of the matrix displacement approach to discrete element structural analysis were extended to predict the instability of shells of revolution encased in rigid cavity. The equilibrium solution for prebuckling was axisymmetric, but the perturbation-displacement field within each element was represented by Fourier circumferential components of the generalized displacements. Second, several experiments on the buckling of cylindrical shell under uniform external pressure were conducted. In the experiments, outward radial displacement of the shell specimen was constrained. The experimental results agreed with the analytical ones by the computer program. Furthermore, numerical calculations were conducted for several kinds of lining shells, whose results were compared with the analytical ones for unrestrained shells.

ABSTRACT: The objective of this paper is to investigate the progressive failure behaviour of laminated cylindrical/conical panels under meridional compression considering geometric nonlinearity and evolving material damage. The evolving microscopic damage such as fiber breakage, matrix cracking, fiber matrix debonding etc. is modeled through a generalized macroscopic continuum theory within the framework of irreversible thermodynamics. The analysis is carried out using field consistent finite element approach based on
first-order shear deformation theory. The nonlinear governing equations are solved using the Newton–Raphson iterative technique coupled with the adaptive displacement control method to trace the equilibrium path. The damage evolution equations are solved at every Gauss point using Newton-Raphson iterative technique within each iteration of a loading/displacement increment. To accurately model the transverse shear strain energy, shear correction factors are calculated using layers’ properties and lamination scheme. The detailed study is carried out to highlight the influences of evolving damage, span-to-thickness ratio, lamination scheme, radius-to-span ratio, boundary conditions and semi-cone angle on the postbuckling response and failure load of laminated panels.

ABSTRACT: In this paper, the effects of segmental joints, dimensions of segments, and ground conditions on buckling of the shield tunnel linings under hydrostatic pressure are studied by analytical and numerical analysis. The results show that radial joints have significant impacts on the buckling behavior: the shield tunnel linings with flexible joints buckle in a single wave mode in the vicinity of K joint, while those with rigid joints buckle in a multi-wave mode around the linings. Hydrostatic buckling strength is found to increase with the flexural rigidity of the radial joint and the thickness of segment increasing. This study shows that ground support increases the buckling strength dramatically, while earth pressure reduces the capacity to resist hydrostatic buckling. The tunnel linings during construction are found to be easier to buckle than that during operation. Meanwhile, the buckling of tunnel linings is studied by theoretical analysis of buried tube buckling.

ABSTRACT: A comprehensive buckling analysis of axially compressed rectangular flat thin plate with simply supported edges was carried out. The study was accomplished through a theoretical formulation based on Taylor-Mclaurin's series and application of Ritz method. The Taylor Mclaurin's series was truncated at the fifth term, which satisfied all the boundary conditions of the plate and resulted to a particular shape function for SSSS plate. The resulting shape function was substituted into the total potential energy functional, which was subsequently minimized. After minimization, the critical buckling load for the plate was obtained by making Nx the subject of the formula. The resulting critical load was found to be a function of a coefficient, “H”, and the values of H from the present study were compared with the exact values within the range of aspect ratios from 0.1 to 1.0 as shown on table 1. The maximum percentage difference was found to be 0.098% for aspect ratio of 0.1, while the least percentage difference was found to be 0.05% for an aspect ratio of 1.0. Hence, the Taylor-Mclaurin series shape function obtained for the SSSS plate is a very good approximation of the exact shape function for the plate.

ABSTRACT: This study investigates the inelastic stability of a thin flat rectangular isotropic plate subjected to uniform uniaxial compressive loads using Taylor-Maclaurin series formulated deflection function. The plate has clamped and simply supported edges in both characteristic directions (CCSS boundary conditions). The governing equation is derived using a deformation plasticity theory and a work principle. Values of the plate buckling coefficient are calculated for aspect ratios from 0.1 to 2.0 at intervals of 0.1. The results compared favourably with the elastic stability values and the percentage differences ranged from -0.353% to -7.427%. Therefore, the theoretical approach proposed in this study is recommended for the inelastic stability analysis of thin flat rectangular isotropic plates under uniform in-plane compression.

ABSTRACT: Axial buckling critical load of large welded steel tanks is very sensitive to initial circumferential weld geometric imperfections on the tank walls. It is worth noting that some local geometric imperfections are also existed in the following service time. It is meaningful to explore effect of local geometric imperfections on axial buckling of welded steel tanks with circumferential weld imperfections already. FEM was used to learn effect of amplitude and distribution of local geometric imperfections on welded steel tanks with circumferential geometric imperfections. Results showed that the existence of local geometric imperfections give an additional
damage to axial buckling critical load and changed axial buckling deformation characteristics of welded steel tanks, while this adverse effect did not vary much with the increasing of amplitude and distribution of local geometric imperfections.

ABSTRACT: Drying a droplet of colloidal dispersion can result in complex pattern formation due to both development and deformation of a skin at the drop surface. The present study focuses on the drying process of droplets of colloidal dispersions in a confined geometry where direct observations of the skin thickness are allowed. During the drying process, a buckling process is followed by a single depression growth inside the drop. The deformation of the droplet is found to be generic and is studied for various colloidal dispersions. The final shape can be partly explained by simple energy analysis based on the competition between bending and stretching deformations. Particularly, the final shape enables us to determine precisely the critical thickness of the shell for buckling. This study allows us to validate theory in 2D droplets and apply it to the case of 3D droplets where the thickness is not accessible by direct observation.

ABSTRACT: This study is aimed at representing efficient buckling analysis method by analyzing the buckling behavior and the buckling pressure of filament-wound cylindrical shell. First, finite element analysis was conducted to find the buckling pressure and the buckling behavior on the stacking angles of [+,-30/90]FW, [+,-45/90]FW and [+,-60/90]FW. The buckling formula (ASME 2007, NASA SP-8007) was employed to find the buckling pressure. These results were compared and verified through hydrostatic pressure buckling experiments. Second, the values of buckling formula and buckling pressure values of finite element analysis were compared, while the stacking angle was made to change by 5 degrees from 20 to 70 degrees. According to the conducted finite element analysis, stacking property showed the safety factor of about 1.0 at the buckling pressure values of such filament-wound stacking angles as [+,-30/90]FW, [+,-45,90]FW, and [+,-60,90]FW. ASME 2007 buckling formula showed the safety factor ranging from 1.84 to 2.76. On comparison, the values of the NASA SP-8007 formula showed relatively low safety factors ranging from 1.2 to 1.45. When it comes to the result to which various stacking angles from 20 to 70 degrees were applied, the values to which an equivalent material property was applied showed safety factors ranging from 0.8 to 0.97 while the ASME 2007 and the NASA SP-8007 buckling formula values showed safety factors ranging from 1.7 to 2.9 and 0.8 to 1.4, respectively. Based on the result above, the ASME 2007 formula, a simplified version of the NASA SP-8007 formula is regarded as a buckling formula in which more reliable safety factors are considered.
ABSTRACT: The paper deals with the validation of a recently proposed hexahedral solid-shell finite element in the buckling analysis of a laminated composite plate with delaminations. The object is to study the buckling behavior of structures with delaminations using the enhanced assumed strain (EAS) solid shell element with 5, 7 and 9 parameters. The EAS three-dimensional finite element formulation presented in this paper is free from shear locking and leads to accurate results for distorted element shapes. The developed FE model is used to study the effects of some parameters in the buckling load, such as the stacking sequences, delamination size, aspect ratio, width-to-thickness ratio. The feasibility of the proposed method is confirmed by numerical examples. Results show that using hexahedral solid-shell finite element in the buckling analysis is more efficient than using the enhanced solid finite element.

ABSTRACT: We study the effects of small-scale parameter on the buckling loads and strains of nanobeams, based on nonlocal Timoshenko beam model. However, the lack of higher-order boundary conditions leads to inconsistencies in critical buckling loads. In this paper, we apply a novel approach based on nonlocal Timoshenko kinematics, strain gradient approach and variational methods for deriving all classical and higher-order boundary conditions as well as governing equations. Therefore, closed-form and exact critical buckling loads of nanobeams with various end conditions are investigated. Moreover, the dependence of buckling loads on the small-scale parameter as well as shear deformation coefficient is studied using these new boundary conditions. Then, numerical results from this new beam model are presented for carbon nanotubes (CNTs). They illustrate a more accurate buckling response as compared to the previous works. Furthermore, the critical strains are compared with results obtained from molecular dynamic simulations as well as Sanders shell theory and are found to be in good agreement. Results show that unlike the other beam theories, this model can capture correctly the small-scale effects on buckling strains of short CNTs for the shell-type buckling. Moreover, the value of nonlocal constant is calculated for CNTs using molecular dynamic simulation results.

ABSTRACT: This paper presents a study of a hybrid grid shell, which is made of quadrangular meshes diagonally stiffened by pre-tensioned thin cables. The construction of the hybrid structure by translating a spatial curve against another spatial curve is firstly described. Then the elasto-plastic buckling analyses of the perfect hybrid structure and the corresponding single-layer lattice shell are carried out, and the influence of the asymmetric load on the failure loads is discussed based on a finite element model. Furthermore, the different shapes and sizes of imperfections are considered in this study. Two schemes of imposing imperfections are chosen: the first several eigenvalue buckling modes and the deformed shape of the loaded structure obtained from a geometrical non-linear analysis are chosen as the imperfection shape. Finally, the effects of different structural parameters, such as the rise-to-span ratio, beam section dimension, area and pre-stress of cables and boundary conditions, on the failure loads are investigated.

“Buckling and post-buckling of rotationally restrained columns with imperfections”, Science China Physics, Mechanics and Astronomy, Vol. 55, No. 8, pp 1519-1522
ABSTRACT: The stability of imperfect columns has been studied by many researchers. Often the ends of a column are not necessarily fixed or pin-ended for practical structures. Therefore, rotationally restrained columns having an initial imperfection in an asymmetric mode have been studied in this paper. An elastic formula using the large deflection theory was given, and the shooting method was used to obtain the equilibrium paths and critical loads. Then the relationship between the end rotation and rotational restraints has been studied and discussed followed by a detailed discussion on the influence of imperfection on the column behaviour.

ABSTRACT: In this paper, we investigate the buckling capacity of a hybrid grid shell, which is made of quadrangular meshes diagonally stiffened by pre-tensioned thin cables. The eigenvalue buckling, geometrical nonlinear elastic buckling and elasto-plastic buckling analyses of the hybrid structure were carried out. Then the influences of the shape and scale of imperfections on the elasto-plastic buckling loads were discussed. Also, the effects of different structural parameters, such as the rise-to-span ratio, cross-section of beams, area and pre-stress of cables and boundary conditions, on the failure load were investigated. The results show that the buckling capacity is reduced when taking into account the material nonlinearity. Furthermore, the hybrid structure is highly imperfection sensitive and the reduction of the failure load due to imperfections can be considerable. The proper shape and scale of the imperfection are also important. It is also shown that there exists an optimal rise-to-span ratio resulting in a relatively high buckling capacity for a specific span. Moreover, the enlarging of the cross-section of steel beams notably improves the stability performance of the structure. However, the area and pre-stress of cables pose small effect on the structural stability.

ABSTRACT: We study the buckling of an axially symmetric elastic hemispherical shell, uniformly compressed, subject to a constraint to the radial shifting of the equatorial circumference. The static equilibrium equations, using tensorial notations, are obtained applying the virtual displacements principle to the energy functional. The presence of a constraint does not modify the field equations with respect to the case of a constraint-free buckling, but only influences the boundary conditions, so that, instead of a boundary value problem, we deal with a problem with complementarity conditions on the boundary. We revisit and improve some previously obtained mathematical results, adapting them for the subsequent numerical treatment. Finally, by suitably using a delicate quasi-static shooting technique, numerical results are obtained, which complete the theoretical analysis and give an interesting insight into the behavior of the bifurcation branches.

“Buckling Behaviour Of Compression Loaded Composite Cylindrical Shells With Reinforced Cutouts”,

ABSTRACT: In the recent times, Composite thin cylindrical shells are most widely used structural forms in Aerospace and Missile applications. In designing efficient and optimized shell structure, they become increasingly sensitive to buckling. It is well known that the experimental display is mainly attributed to geometrical imperfection like damage in the structure, or ovality or local thining of material etc. in missile and Airframe, the composite cylindrical shell structure is generally provided with cutouts for accessing internal components during integration. The cutouts invariably reduce the strength of the composite cylindrical shell and more specifically the buckling load. It has been a design practice to improve strength by addition of reinforcement around cutouts. The cutout not only introduces stress concentration but also significantly reduce buckling load. Which will results to eliminate the Interlaminar and intralaminar failure by change in material properties through dimensional computational analysis was carried out using ANSYS as the preprocessing software and FE as the solver and post processor.

ABSTRACT: Grid stiffened composite structures are the most attractive lightweight which their optimal design would lead to a stretching dominated structure. In this paper, specific buckling load of a cylindrical grid stiffened shell, which has been created by a Kagome unit cells, has been investigated. First, a single unit cell has been analyzed individually and the forces and moments caused by each unit cell have been transferred to the skin of cylinder. Thus, the equivalent cylindrical shell, which consists of the shell and the unit cells stiffeners, is obtained. Then the equivalent cylindrical shell is analyzed as a composite cylindrical shell. After introducing the approximate displacement functions and Ritz method buckling load will be achieved. The specific buckling load of the cylinder will be presented by changing some parameters simultaneously. The winding angle of the shell, the cross section size of ribs, shell thickness, the number of the iso-angle ribs and ribs axial pitch are these parameters. All these results are presented for Glass/Epoxy material. Figures of specific buckling load versus new two parameters (rib pitch and rib numbers) have been shown and discussed. Also, comparison between presented theory and other papers results will be done to verify the analytical results. At last, a parametric study is discussed to check the geometrical parameters' effects on the specific buckling load for different kinds of mentioned grids.

ABSTRACT: Nonlinear dynamic buckling for sandwich shallow conical shell structure under uniform triangular pulse is investigated. Based on the Reissner’s assumption and Hamilton’s principle, the nonlinear dynamic governing equation of sandwich shallow spherical shells is derived. The corresponding nonlinear dynamic response equations are obtained by Galerkin method and solved by Runge-Kutta method. Budiansky-Roth criterion expressed by displacements of rigid center is employed to determine the critical impact buckling load. The effects of geometric parameters and physical parameters on impact buckling are discussed.

ABSTRACT: In this paper, nonlinear dynamic buckling of FGM shallow conical shells under the action of triangular pulse impact loads are investigated. The nonlinear dynamic governing equation of symmetrically FGM shallow conical shells is built. Using Galerkin method, the nonlinear dynamic governing equation is solved, and the nonlinear dynamic response equation of symmetrically FGM shallow conical shells is obtained.
The Runge-Kutta method is introduced to numerically solve the nonlinear dynamic response equation and the impact response curve is achieved. Budiansky-Roth motion criterion expressed by the displacement of the peak of the shell is employed to determine the critical impact buckling load. The influences of geometric parameters and gradient constants on impact buckling are discussed as well.

ABSTRACT: In the current work, the vibration characteristics of single-walled carbon nanotubes (SWCNTs) under different boundary conditions are investigated. A nonlocal elastic shell model is utilized, which accounts for the small scale effects and encompasses its classical continuum counterpart as a particular case. The variational form of the Flugge type equations is constructed to which the analytical Rayleigh–Ritz method is applied. Comprehensive results are attained for the resonant frequencies of vibrating SWCNTs. The significance of the small size effects on the resonant frequencies of SWCNTs is shown to be dependent on the geometric parameters of nanotubes. The effectiveness of the present analytical solution is assessed by the molecular dynamics simulations as a benchmark of good accuracy. It is found that, in contrast to the chirality, the boundary conditions have a significant effect on the appropriate values of nonlocal parameter.

Hessam Rouhi and Reza Ansari (Dept. of Mechanical Engineering, University of Guilan, P.O. Box 3756, Rasht, Iran), “Nonlocal Analytical Flugge Shell Model for Axial Buckling of Double-Walled Carbon Nanotubes with Different End Conditions”, Nano, Vol. 7, No. 3, 1250018 (10 pages), June 2012
DOI: 10.1142/S179329201250018X
ABSTRACT: In this paper, a nonlocal Flügge shell model is utilized to investigate the axial buckling behavior of double-walled carbon nanotubes (DWCNTs) under various boundary conditions. According to the nonlocal elasticity theory, the displacement field equations coupled by the van der Waals interaction are derived. The set of governing equations of motion is then solved by the Rayleigh–Ritz method. The present analysis can treat boundary conditions in a layer-wise manner. The effects of nonlocal parameter, layer-wise boundary conditions and geometrical parameters on the mechanical behavior of DWCNTs are examined. Furthermore, molecular dynamics simulations are performed to assess the validity of the results and also to predict the appropriate values of nonlocal parameter. It is found that the type of boundary conditions affects the proper value of nonlocal parameter.

ABSTRACT: Presented herein is the thermal buckling analysis of multi-walled carbon nanotubes on the basis of nonlocal Flügge shell model capturing small scale effects. Based upon the continuum mechanics, a multiple-shell model is adopted in which the nested tubes are coupled with each other through the van der Waals interlayer interaction. The utilized van der Waals model incorporating the interlayer interactions between any two layers, whether adjacent or non-adjacent is curvature dependent. To analytically solve the problem, the Rayleigh-Ritz method was implemented to the variational form equivalent to the Flügge type equations. The present analysis provides the possibility of considering different combinations of layerwise boundary conditions. It is shown that the shell-like thermal buckling is significantly sensitive to the nonlocal parameter.
variation, whereas the column-like thermal buckling remains unaffected when the nonlocal parameter is varied.

ABSTRACT: In the present investigation, the axial buckling and post-buckling configurations of single-walled carbon nanotubes (SWCNTs) are studied including the thermal environment effect. For this purpose, Eringen’s nonlocal elasticity continuum theory is implemented into the classical Euler-Bernoulli beam theory to represent the SWCNTs as a nonlocal elastic beam model. A closed-form analytical solution is carried out to analyze the static response of SWCNTs in their post-buckling state in which the axial buckling load is assumed to be beyond the critical axial buckling load. Common sets of boundary conditions, named simply supported-simply supported (SS-SS), clamped-clamped (C-C), and clamped-simply supported (C-SS), are considered in the investigation. Selected numerical results are given to represent the variation of the carbon nanotube’s mid-span deflection with the applied axial load corresponding to various nonlocal parameters, length-to-diameter aspect ratios, temperature changes, and end supports. Moreover, a comparison between the post-buckling behaviors of SWCNTs at low- and high-temperature environments is presented. It is found that the size effect leads to a decrease of the axial buckling load especially for SWCNTs with C-C boundary conditions. Also, it is revealed that the value of the temperature change plays different roles in the post-buckling response of SWCNTs at low- and high-temperature environments.

ABSTRACT: Described in the current study is the thermal buckling behavior of multi-walled carbon nanotubes (WCNTs) via a nonlocal atomistic-based shell model. The model including the effects of small-scale length and the van der Waals (vdW) forces between adjacent nanotubes is established through the incorporation of the interatomic potential into the nonlocal Flügge shell theory. This model links the strain energy density induced in the continuum to Eringen's nonlocal constitutive relations. The set of coupled field equations are analytically solved for two types of temperature distribution. The present model is of a distinguishing feature which is its independence from the widely scattered values of Young's modulus and the effective wall thickness of carbon nanotubes.

ABSTRACT: In this paper, the vibrational behavior of double-walled carbon nanotubes (DWCNTs) is studied
by a nonlocal elastic shell model. The nonlocal continuum model accounting for the small scale effects encompasses its classical continuum counterpart as a particular case. Based upon the constitutive equations of nonlocal elasticity, the displacement field equations coupled by van der Waals forces are derived. The set of governing equations of motion are then numerically solved by a novel method emerged from incorporating the radial point interpolation approximation within the framework of the generalized differential quadrature method. The present analysis provides the possibility of considering different combinations of layerwise boundary conditions. The influences of small scale factor, layerwise boundary conditions and geometrical parameters on the mechanical behavior of DWCNTs are fully investigated. Explicit expressions for the nonlocal frequencies of DWCNTs with all edges simply supported are also analytically obtained by a nonlocal elastic beam model. Some new intertube resonant frequencies and the corresponding noncoaxial vibrational modes are identified due to incorporating circumferential modes into the shell model. A shift in noncoaxial mode numbers, not predictable by the beam model, is also observed when the radius of DWCNTs is varied. The results generated also provide valuable information concerning the applicability of the beam model and new noncoaxial modes affecting the physical properties of nested nanotubes.

ABSTRACT: Multistable shells have been proposed for a variety of applications; however, their actuation is almost exclusively addressed through embedded piezoelectric patches. Additional actuation techniques are needed for applications requiring high strains or where remote actuation is desirable. Part of the reason for the lack of research in this area is the absence of appropriate models describing the detailed deformation and energetics of such shells. This work presents a bistable spherical cap made of iron carbonyl-infused polydimethylsiloxane. The magnetizable structure can be actuated remotely through permanent magnets while the transition is recorded with a high-speed camera. Moreover, the experiment is reproduced in a finite element (FE) dynamic model for comparison with the physical observations. High-speed footage of the physical cap inversion together with the FE modeling gives valuable insight on preferable intermediate geometries. Both methods return similar values for the magnetic field strength required for the snap-through. High-strain multistable spherical cap transformation is demonstrated, based on informed material selection. We discover that non-axisymmetric transition shapes are preferred in intermediate geometries by bistable spherical caps. We develop the methods for design and analysis of such actuators, including the feasibility of remote actuation methods for multistable shells.

ABSTRACT: Design of spatial reinforced concrete (RC) structures to dynamic loads is based on structural dynamic parameters. Experimental research on dynamic response of full scale RC structures is very limited. Therefore developing proper numerical techniques, allowing calculation of valuable dynamic parameters is extremely important. The purpose of the present study is to investigate efficiency of existing software and its suitability for modeling spatial RC structures. The object of the research is a dome over a public building. It is a shallow thin walled spherical RC shell. The numerical results are compared with available experimental data. ANSYS software was used for the analysis. The affect of different structural components on natural vibration parameters like mode shapes and frequencies was studied. Comparison of numerical and experimental results enabled to verify the accuracy and adequacy of the structural scheme. Realization of numeral experiments allows to understand properly the qualitative characteristics and to interpret the impact of various parameters in order to obtain reasonable recommendations for mock-up study or full scale experiments. It is shown that

ABSTRACT: Steel-concrete composite ribbed shell is a kind of shell structure based on the thin concrete shell, which has the advantages of two different materials, at the same time with steel nets shell and thin concrete shell structure. In this paper, the seismic performance of steel concrete composite ribbed shell is analyzed, in which the elastoplastic time-history analysis method is used to analyze internal force and deformation. Furthermore a parameter analysis is made to discuss the seismic performance, which considering different high-span ratio, section dimension, boundary conditions and structure division frequency. The influence on structure seismic performance and some structure dynamic response characteristics are obtained, which can be resulted for structural seismic design and referenced in steel-concrete thin shell design specification modification.

Franz-Joseph Barthold and Nikolai Gerzen (TU Dortmund), “Imperfection Modes for Non-Linear Buckling Analysis Based on Variational Design Sensitivities”, Abstract, 20/03/2013, UNS-204
ABSTRACT: Solid shell elements are frequently used to model thin structures because of their efficiency and accuracy. In detail, we consider the variational design sensitivity analysis of a non-linear solid shell element, which is based on the Hu-Washizu variational principle. The design of such structures is extremely important
for their stability, robustness and for their load-bearing capacity. Design sensitivity analysis provides
information which allow the engineer to find the appropriate shape of a shell and to understand the influence of
gometry and layout variants on its behaviour. Unfortunately, considering the coordinates of all finite element
odes as design parameters leads to a large amount of sensitivity information which can not be easily
interpreted by engineers. We apply singular value decomposition (SVD) to the pseudo load matrix and the
sensitivity matrix to detect the most valuable part of information and to transform sensitivity results in a form
which is comprehensible for engineers. The proposed theoretical concept is demonstrated on the example of
non-linear buckling analysis of shells. Here, proper imperfection modes which lead to the lowest load-bearing
capacity are created automatically applying SVD to the pseudo load matrix. Numerical examples illustrate the
advocated technique.

“F-actin buckling coordinates contractility and severing in a biomimetic actomyosin cortex”, Proceedings of the
National Academy of Sciences of the USA (PNAS), December 3, 2012, DOI: 10.1073/pnas.1214753109
ABSTRACT: Here we develop a minimal model of the cell actomyosin cortex by forming a quasi-2D cross-
linked filamentous actin (F-actin) network adhered to a model cell membrane and contracted by myosin thick
filaments. Myosin motors generate both compressive and tensile stresses on F-actin and consequently induce
large bending fluctuations, which reduces their effective persistence length to <1 μm. Over a large range of
conditions, we show the extent of network contraction corresponds exactly to the extent of individual F-actin
shortening via buckling. This demonstrates an essential role of buckling in breaking the symmetry between
tensile and compressive stresses to facilitate mesoscale network contraction of up to 80% strain. Portions of
buckled F-actin with a radius of curvature "<300 nm are prone to severing and thus compressive stresses
mechanically coordinate contractility with F-actin severing, the initial step of F-actin turnover. Finally, the F-
actin curvature acquired by myosin-induced stresses can be further constrained by adhesion of the network to a
membrane, accelerating filament severing but inhibiting the long-range transmission of the stresses necessary
for network contractility. Thus, the extent of membrane adhesion can regulate the coupling between network
contraction and F-actin severing. These data demonstrate the essential role of the nonlinear response of F-actin
to compressive stresses in potentiating both myosin-mediated contractility and filament severing. This may
serve as a general mechanism to mechanically coordinate contractility and cortical dynamics across diverse
actomyosin assemblies in smooth muscle and nonmuscle cells.

Yury Grabovsky and Davit Harutyunyan, “Rigorous asymptotic analysis of buckling of thin-walled cylinders
under axial compression”, Cornell University Library, arXiv.1301.6079 [math.AP], January 2013
ABSTRACT: Using rigorous constitutive linearization of second variation introduced in [6] we study weak
stability of homogeneous deformation of the axially compressed circular cylindrical shell, regarded as a 3-
dimensional hyperelastic body. We show that such deformation becomes weakly unstable at the critical load that
coincides with value of the bifurcation load in von-Karman-Donnel shell theory. We also show that the linear
bifurcation modes described by the Koiter circle [11] minimize the second variation asymptotically. The key
ingredients of our analysis are the asymptotically sharp estimates of the Korn constant for cylindrical shells and
Korn-like inequalities on components of the deformation gradient tensor in cylindrical coordinates. The notion
of buckling equivalence introduced in [6] is developed further and becomes central in this work. A link between
features of this theory and sensitivity of the critical load to imprefections of load and shape is conjectured.

“Scaling instability of the buckling load in axially compressed circular cylindrical shells”, Journal of Nonlinear Science, pp 1-37, August 2015

ABSTRACT: In this paper we initiate a program of rigorous analytical investigation of the paradoxical buckling behavior of circular cylindrical shells under axial compression. This is done by the development and systematic application of general theory of "near-flip" buckling of 3D slender bodies to cylindrical shells. The theory predicts scaling instability of the buckling load due to imperfections of load. It also suggests a more dramatic scaling instability caused by shape imperfections. The experimentally determined scaling exponent 1.5 of the critical stress as a function of shell thickness appears in our analysis as the scaling of the lower bound on safe loads given by the Korn constant. While the results of this paper fall short of a definitive explanation of the buckling behavior of cylindrical shells, we believe that our approach is capable of providing reliable estimates of the buckling loads of axially compressed cylindrical shells.

ABSTRACT: Various lengths and helical types (i.e., armchair, zigzag and chiral) of single-walled CNTs are considered in molecular dynamics simulations in order to systematically examine the length-to-radius ratio and chirality effects on the buckling mechanism. Proper boundary conditions are imposed to induce different buckling modes. It is observed that the buckling strain is getting smaller as the CNT becomes slender for most nanotubes, which implies that the slender nanotubes have lower buckling resistance regardless the buckling mode and chirality. The column buckling of the CNTs at lower buckling mode will transform into shell wall buckling at higher mode if the length-to-radius of each constrained section is less than 10. The applicability of the continuum buckling theory, which has been well developed for thin tubes, on predicting the buckling strain of the CNT is also examined. In general, the corresponding buckling strain at different modes predicted by the continuum column buckling theory could agree reasonably well with simulation results except those exhibit shell wall buckling.

ABSTRACT: Equilibrium and stability equations of a thin rectangular plate with length a, width b, and thickness h(x)=C1x+C2, made of functionally graded materials under thermal loads are derived based on the first order shear deformation theory. It is assumed that the material properties vary as a power form of thickness coordinate variable z. The derived equilibrium and buckling equations are then solved analytically for a plate with simply supported boundary conditions. One type of thermal loading, uniform temperature rise and gradient through the thickness are considered, and the buckling temperatures are derived. The influences of the plate aspect ratio, the relative thickness, the gradient index and the transverse shear on buckling temperature difference are all discussed.

ABSTRACT: Equilibrium and stability equations of a rectangular plate made of functionally graded material (FGM) under thermal loads are derived, based on the higher order shear deformation plate theory. Assuming that the material properties vary as a power form of the thickness coordinate variable z and using the variational method, the system of fundamental partial differential equations is established. The derived equilibrium and stability equations for functionally graded plates (FGPs) are identical to the equations for laminated composite plates with 50 layers. A buckling analysis of a functionally graded plate under one type of thermal loads is carried out and results in closed form solutions, uniform temperature rise and gradient through the thickness are considered and the buckling temperatures are derived. The critical buckling temperature relations are reduced to the respective relations for functionally graded plates with a linear composition of constituent materials and homogeneous plates The results are compared with the critical buckling temperatures obtained for functionally graded plates ansys software (FEM) given in the literature. The study concludes that higher order shear deformation theory accurately predicts the behavior of functionally graded plates.

Shadmehri, Farjad (Mechanical and Industrial Engineering, Concordia University SPECTRUM Research Repository, Montreal, Quebec, Canada), “Buckling of Laminated Composite Conical Shells; Theory and Experiment”, 2012 PhD dissertation, Concordia University

ABSTRACT: Composite conical and cylindrical shells are gaining more application in aerospace industry (e.g., helicopter tailboom, airplane fuselage) due to their high specific strength and stiffness properties coming from material (composite) and geometry advantages. Stability is always a concern for these types of structures under different loading conditions. One of the major loading scenarios is the bending load in which composite conical shells can buckle under bending. Although there have been extensive studies on the buckling of conical and cylindrical shells under axial load, buckling under bending receives less attention in the literature from theoretical and experimental points of view. In this study, the bucking behavior of composite conical shells has been studied experimentally and theoretically.

In the theoretical approach, a first order shear deformation shell theory has been proposed to study buckling and bending behavior of composite conical shells. A semi-analytical approach (Ritz method) has been applied to study buckling under axial load and buckling under bending of composite conical shells. An analytical solution (Levy type solution) has been applied to study the bending response of cross-ply conical shells under sinusoidal bending load. Also, a new formulation has been proposed to study bending, buckling and vibration of cross-ply cylindrical shells using an analytical solution (Levy type solution). A different displacement field from what was assumed in the literature has been proposed and consequently a new formulation has been obtained for the problem. In the experimental approach, a composite tube-bending setup has been designed and developed to study bending, and buckling under bending load, behavior of composite shells. The setup has been designed to apply equal bending moments at the both ends of the structure, simulating pure bending test conditions. Experimental result has been obtained for buckling under pure bending of composite conical shells. Regarding the manufacturing technique, Automated Fiber Placement (AFP) has attracted the aerospace industry due to its fast production rate, repeatability, and minimum material waste. Advanced thermoplastic composites obtain special attention in the aerospace industry as well, considering their superior properties (e.g., fracture toughness) and their capability to make aero-structures without requiring autoclave treatment with respect to thermoset ones. Considerable challenges remained unresolved regarding optimum process parameters for manufacturing of thermoplastic composites made by AFP and their quality. This thesis also addresses the effect of autoclave treatment on the stiffness quality of the thermoplastic composite cones made by AFP. The determination of optimum process parameters for AFP in the manufacturing of thermoplastic composite (AS4/PEEK) has been performed from both stiffness and strength point of view.

ABSTRACT: A simple and efficient 3-node triangular planar shell element for the geometrical nonlinear analysis of laminated composite structures is developed based on corotational formulation (CR). The shell element is constructed by combining the generalized conforming membrane element GT9 with the drilling degree of freedom and the generalized conforming thick/thin plate element TMT with assumed rotation and transverse shear strain fields. In order to avoid membrane locking, one-point reduced integration scheme is employed for calculating the terms related to membrane strains, and a stabilization matrix is added to eliminate zero energy modes. Based on the first-order shear deformation theory (FSDT) for laminated composite plates, the correctional transverse shear stiffness is calculated, considering the real ply stacking sequence of the laminate, such that the shell can be applicable to modeling moderately thick laminated composite structures. The geometrically linear stiffness matrix in the core of CR formula can be calculated only once and can be saved to be used throughout the whole procedure for the nonlinear analysis. Numerical examples show that the present shell element is accurate and efficient for thin and thick shell structures, including laminated composite structures.

In bridge construction, the use of stiffened plates for box-girder or steel beams is common day to day practice. The advantages of the stiffening from the economical and mechanical points of view are unanimously recognized. For curved steel panels, however, applications are more recent and the literature on their mechanical behaviour including the influence of stiffeners is therefore limited. Their design with
commercial finite element software is significantly time-consuming, which reduces the number of parameters which can be investigated in an optimization procedure. The present paper is thus dedicated to the study of the behaviour of stiffened curved panels under uniform longitudinal compression. It addresses the linear buckling and the ultimate strength which are both influenced by the coupled effects of curvature and stiffening. It finally proposes a design methodology based on that for stiffened flat plates adopted by European Standards and a column-like behaviour.

ABSTRACT: The effect of assumed displacement field is investigated on the bending, buckling, and natural frequencies of cross-ply circular cylindrical shells using first-order shear deformation theory through an analytical solution. Linear strain-displacement relation is assumed. The governing equations are derived from Hamilton's principle. Assuming Levy-type solution, the governing equations are then converted to ordinary differential equations and changed to state-space form introducing ten unknown variables and solved for displacements. Different lamination sequences, including symmetric and asymmetric laminate, are studied and compared. The effect of various boundary conditions (i.e., clamped, simply supported, and free edge), radius-to-thickness, and radius-to-length ratio on the displacement of mid-surface is investigated.

Alice Mathai (Department of Ship Technology, Cochin University of Science & Technology), "Analytical investigations on collapse of cylindrical submarine shells", PhD dissertation, November 2004

ABSTRACT: Submarine hull structure is a watertight envelope, under hydrostatic pressure when in operation. Stiffened cylindrical shells constitute the major portion of these submarine hulls and these thin shells under compression are susceptible to buckling failure. Normally loss of stability occurs at the limit point rather than at the bifurcation point and the stability analysis has to consider the change in geometry at each load step. Hence geometric nonlinear analysis of the shell forms becomes a necessity. External hydrostatic pressure will follow the deformed configuration of the shell and hence follower force effect has to be accounted for. Computer codes have been developed based on all-cubic axisymmetric cylindrical shell finite element and discrete ring stiffener element for linear elastic, linear buckling and geometric nonlinear analysis of stiffened cylindrical shells. These analysis programs have the capability to treat hydrostatic pressure as a radial load and as a follower force. Analytical investigations are carried out on two attack submarine cylindrical hull models besides standard benchmark problems. In each case, the analysis has been carried out for interstiffener, interdeepframe and interbulkhead configurations. The shell stiffener attachment in each of this configuration has been represented by the simply supported-simply supported, clamped-clamped and fixed-fixed boundary conditions in this study. The results of the analytical investigations have been discussed and the observations and conclusions are described. Rotation restraint at the ends is influential for interstiffener and interbulkhead configurations and the significance of axial restraint becomes predominant in the interbulkhead configuration. The follower force effect of hydrostatic pressure is not significant in interstiffener and interdeepframe configurations where as it has very high detrimental effect on buckling pressure on interbulkhead configuration. The geometric nonlinear interbulkhead analysis incorporating follower force effect gives the critical value of buckling pressure and this analysis is recommended for the determination of collapse pressure of stiffened cylindrical submarine shells.

ABSTRACT: Submarine is a watercraft capable of independent operation under water. Use of submarines includes marine science, offshore industry underwater exploration etc. The pressure hull of submarine is constructed as combination of cylinders and domes. The shell is subjected to very high hydrostatic pressure, which creates large compressive stress resultants. Due to this the structure is susceptible to buckling. The introduction of stiffeners in both directions considerably increases the buckling strength of the shell. Since the stiffened cylindrical shell is susceptible to initial imperfections, nonlinear analysis is essential. The objective of this work is the linear and nonlinear analysis of the stiffened cylindrical shell subjected to very high hydrostatic pressure. Finite element method is a powerful tool for analysis of complex structures. Finite element package ANSYS is used for modeling and analysis the submarine hull.

ABSTRACT: Container ships with wide hatch openings are thin walled open sections and have low torsional stiffness. Hence response arising from torsional loads is significant and subsequently the torsional analysis of container ship is necessary. Using the ANSYS software, the progressive collapse behaviour of a typical
container vessel under torsion was analysed. The effect of torsional moment on the ultimate strength of ship hull subjected to design vertical shear force was also determined. Full hull between the bulkheads was modeled with fully restrained warping displacement at the unloaded end. When pure torsion is applied, the hull corner regions are typically the most highly stressed areas, which may collapse. Thus, scantlings of the hull corner region should be sufficient for ship hulls with large deck openings. The ultimate strength based safety factor under pure torsion for the vessel, is 4.5, which is reduced by 30% when subjected to design vertical shear force also.

ABSTRACT: Buckling analysis of laminated composite plates is carried out by using an efficient C0 FE model developed based on higher order zigzag theory. In this model the first derivatives of transverse displacement have been treated as independent variables to overcome the problem of C1 continuity associated with the FE implementation of the plate theory. The C0 continuity of the present FE model is compensated in the stiffness matrix calculations by using penalty parameter approach. Numerical results and comparison with other existing solutions show that the present model is very efficient in predicting the buckling responses of laminated composites.

“Buckling and free vibration of non-homogeneous composite cross-ply laminated plates with various plate theories”, Compos. Struct, 44:279–287, 1999, DOI: 10.1016/S0263-8223(98)00135-4

ABSTRACT: Various theories of homogeneous laminated plates are extended to study the buckling and free vibration behavior of non-homogeneous rectangular composite laminates. The equations governing the dynamic response of non-homogeneous composite laminates are deduced. Numerical results for the natural frequencies and critical buckling loads of symmetric cross-ply laminates are presented. The influences of the degree of non-homogeneity, aspect ratio, thickness ratio and in-plane orthotropy ratio on the natural frequencies and critical buckling loads are investigated. The results obtained for homogeneous cases are compared with their counterparts in the literature. The study concludes that the classical plate theory is inadequate for predicting the structural response of non-homogeneous laminates, and that the free vibration and the state of the stability are affected strongly by the degree of nonhomogeneity.

ABSTRACT: h resistance-weight ratio, the possibility to integrate service pipes within their height, and aesthetics. Such profiles usually exhibit a complex behavior, since they can experience many modes of failure, including local instability ones, i.e. those involving an out-of-plane instability of the web post at high shear locations and/or distortion of the cross-section. For what regards global instability, the members are usually designed by means of rough design rules, which often lead to an unduly conservative girder, the beams sometimes showing over 200% resistance reserve. Present research aims at improving this situation, by means of new adequate design formulæ. In this respect, both experimental and extensive numerical parametric studies have been undertaken. First, a series of 3 full-scale tests has been performed, the main goal of which being the validation of purposely-derived FE models. Since the numerical models showed a very good agreement with the tests, they have been further used to gather a large set of numerical reference results where many parameters were varied: the relative slenderness, steel grades, cross-section shapes, bending moment distributions, and relative sizes of the openings. Finally, a new set of dedicated design rules has been derived, that was proved to be accurate while leading to safe estimates of the resistance when compared to all reference results.

ABSTRACT: In case of lateral buckling, experimentally determined load versus deflection plots usually take a form where the critical load is masked by the large deformations which occur as a consequence of geometrical and material imperfections, and that the beam fails before the critical load of the perfect beam is reached. Therefore, it is necessary to use an extrapolation technique to obtain more accurate estimates of experimental critical loads than would be given by the experimental failure loads. Also, an extrapolation technique may be used to determine experimentally the critical load of a structure, without having to subject the structure to loading in the vicinity of critical. Based on the significance of these techniques, further studies on the use of Southwell, Modified, Massey, and Meck extrapolation techniques in case of lateral buckling of structures are reported in this paper, and the accuracy of the extrapolated loads is evaluated in various cases.

ABSTRACT: Nonlinear analysis of plate and shell structures can explain the phenomenon which cannot been explained by classical stability theory, and can obtain better validation of experimental results. Stability problems are essentially nonlinear and their nonlinear finite element solutions ultimately result in solving nonlinear algebraic equations and nonlinear eigenvalue problems. The solutions can define the shape of basic path and determine critical load by using the incremental method. The perturbation methods are used near the critical point, and the basic formulas are given for initial post-buckling analysis by FEM.

ABSTRACT: A cable-braced grid shell is a new type of single-layer latticed shell suitable for glass roofs. Compared with traditional single-layer latticed shells, this new type of shell has a unique mesh shape (planar quadrilateral mesh), mesh form (steel and crossing cables), and surface shape (from the translation surface method). The grid shell is a single-layer latticed structure, and therefore stability is one of the key factors in the structural design. Therefore, in this paper, an elliptic paraboloid cable-braced grid shell with imperfections is used as an example with which to determine the formulas for the buckling load based on the continuum analogy. The main contents of this paper include the formula for the linear buckling load of an elliptic paraboloid cable-braced grid shell with imperfections, which is determined based on the continuum analogy. The equivalent rigidity for the cable-braced grid shell is then determined, and the effect of the cables on the shear rigidity is discussed. Finally, the formula for the linear buckling load is verified with numerical examples, and the errors are analyzed and a corresponding correction factor is given.

ABSTRACT: Thin-walled cylindrical composite shell structures are often applied in aerospace for lighter and cheaper launcher transport system. These structures exhibit sensitivity to geometrical imperfection and are prone to buckling under axial compression. Today the design is based on NASA guidelines from the 1960’s [1] using a conservative lower bound curve embodying many experimental results of that time. It is well known that the advantages and different characteristics of composites as well as the evolution of manufacturing standards are not considered appropriately in this outdated approach. The DESICOS project was initiated to
provide new design guidelines regarding all the advantages of composites and allow further weight reduction of space structures by guaranteeing a more precise and robust design. Therefore it is necessary among other things to understand how a cutout with different dimensions affects the buckling load of a thin-walled cylindrical shell structure in combination with initial geometric imperfections. This work is intended to identify a ratio between the cutout characteristic dimension (in this case the cutout diameter) and the structure characteristic dimension (in this case the cylinder radius) that can be used to tell if the buckling structure is dominated by initial imperfections or is dominated by the cutout.

Li, B., Cao, Y.-P., Feng, X.-Q. & Gao, H. 2011 Surface wrinkling of mucosa induced by volumetric growth: theory, simulation and experiment. J. Mech. Phys. Solids 59, 758–774.  (doi:10.1016/j.jmps.2011.01.010) ABSTRACT: Mechanics of living tissues focusing on the relationships between growth, morphology and function is not only of theoretical interest but can also be useful for diagnosis of certain diseases. In this paper, we model the surface wrinkling morphology of mucosa, the moist tissue that commonly lines organs and cavities throughout the body, induced by either physiological or pathological volumetric growth. A theoretical framework of finite deformation is adopted to analyze the deformation of a cylindrical cavity covered by mucosal and submucosal layers. It is shown that compressive residual stresses induced by the confined growth of mucosa can destabilize the tissue into various surface wrinkling patterns. A linear stability analysis of the critical condition and characteristic buckling patterns indicates that the wrinkling mode is sensitive to the thicknesses of the mucosal and submucosal layers, as well as the properties of the tissues. The thinner the mucosal layer and the lower its elastic modulus, the shorter the buckling wavelength. A series of finite element simulations are performed to validate the theoretical predictions and to study local wrinkling or non-uniform patterns associated with inhomogeneous growth. Our postbuckling analysis shows that the surface pattern may evolve towards a period-doubling morphology due to continuous growth of mucosa or submucosa beyond the critical state. Finally, the theoretical predictions and numerical simulations are compared to experimental observations.

ABSTRACT: Based on Giannakopoulos’s 2-D functionally graded material (FGM) contact model, a modified contact model is put forward to deal with impact problem of the functionally graded shallow spherical shell in thermal environment. The FGM shallow spherical shell, having temperature dependent material property, is subjected to a temperature field uniform over the shell surface but varying along the thickness direction due to steady-state heat conduction. The displacement field and geometrical relations of the FGM shallow spherical shell are established on the basis of Timoshenko–Mindlin theory. And the nonlinear motion equations of the FGM shallow spherical shell under low velocity impact in thermal environment are founded in terms of displacement variable functions. Using the orthogonal collocation point method and the Newmark method to discretize the unknown variable functions in space and in time domain, the whole problem is solved by the
Iterative method. In numerical examples, the contact force and nonlinear dynamic response of the FGM shallow spherical shell under low velocity impact are investigated and effects of temperature field, material and geometrical parameters on contact force and dynamic response of the FGM shallow spherical shell are discussed.

Jun Yin, Nicole Coutris and Young Huang (Dept. of Mechanical Engineering, Clemson University, Clemson, South Carolina), “Groove formation modeling in fabricating hollow fiber membrane for nerve regeneration”, ASME Journal of Applied Mechanics, Vol. 78, January 2011, DOI: 10.1115/1.4002001

Abstract: Hollow fiber membrane (HFM) is one of the most popular membranes used for different industrial applications. Under some controlled fabrication conditions, axially aligned grooves can be formed on the HFM inner surface during typical immersion precipitation-based phase inversion fabrication processes. Such grooved HFM are finding promising medical applications for nerve repair and regeneration. For better nerve regeneration performance, the HFM groove morphology should be carefully controlled. Toward this goal, this study has modeled the HFM groove number based on the shrinkage-induced buckling model in HFM fabrication. HFM has been modeled as a three-layer long fiber membrane. The HFM inner layer has been treated as a thin-walled elastic cylindrical shell and buckles due to the shrinkage of the compliant intermediate
ABSTRACT: Axially aligned grooves can be formed on the hollow fiber membrane (HFM) inner surface under some controlled fabrication conditions during a typical immersion precipitation-based phase inversion fabrication process. Such grooved HFMs are finding promising medical applications for nerve repair and regeneration. For better nerve regeneration performance, the HFM groove geometry should be carefully controlled. Towards this goal, in this study the polyacrylonitrile (PAN) HFM groove number has been modeled based on the radially inward pressure-induced buckling mechanism. HFM has been modeled as a long six-layer fiber membrane, and the HFM inner skin layer has been treated as a thin-walled elastic cylindrical shell under the shrinkage-induced inward radial pressure. The groove number has been reasonably estimated based on the resulting buckling mode as compared with the experimental measurements.

ABSTRACT: We develop a model of the buckling (both planar and axial) of capillaries in cancer tumours, using nonlinear solid mechanics. The compressive stress in the tumour interstitium is modelled as a consequence of the rapid proliferation of the tumour cells, using a multiplicative decomposition of the deformation gradient. In turn, the tumour cell proliferation is determined by the oxygen concentration (which is governed by the diffusion equation) and the solid stress. We apply a linear stability analysis to determine the onset of mechanical instability, and the Liapunov–Schmidt reduction to determine the postbuckling behaviour. We find that planar modes usually go unstable before axial modes, so that our model can explain the buckling of capillaries, but not as easily their tortuosity. We also find that the inclusion of anisotropic growth in our model can substantially affect the onset of buckling. Anisotropic growth also results in a feedback effect that substantially affects the magnitude of the buckle.

ABSTRACT: Buckling is characterized by a sudden failure of a structural member subjected to high compressive stress and it is a structural instability leading to a failure mode. One of the major design criteria of thin shell structures that experience compressive loads is that the buckling load limit. Therefore it is important to know about the Buckling loads. The buckling load of thin shell structures are dominantly affected by the geometrical imperfections present in the cylindrical shell which are very difficult to alleviate during manufacturing process. In this paper, three types of geometrical imperfection patterns are considered for cylindrical shells with and without dent. Experiments are conducted for all the cases and results are compared with analytical results with ANSYS. It is found that buckling strength of plain cylindrical shell is different compared to cylindrical shell having dents.

ABSTRACT: Many thin cylindrical shells are used in structural applications in which the dominant loading condition is global bending. Key examples include chimneys, tubular piles, wind generation towers and tall silos. Their thickness lies in a tricky range which is extremely thin for the structural tube community and very thick for the shell buckling community. The buckling strength of these structures is dominated by extensive plasticity, but the fully plastic state is usually far from being attained. This paper explores the buckling strength of imperfect thin cylindrical shells under global bending in the elastic-plastic range. The capacity curves of the new Eurocode EN 1993-1-6 (2007) are used to match the final results. The results show that the capacity curves
can capture this buckling behavior accurately and safely for different types of material models. It is assumed that the shell is held circular by rings or boundaries at reasonable intervals, effectively restraining ovalisation. It is hoped that these results will make a useful contribution towards resolving the misunderstandings and controversy that has been evident in this field in recent years.

ABSTRACT: The paper deals with the influence of correlation length, of Gauss random field, and of yield strength of a hotrolled I-beam under bending on the ultimate load carrying capacity limit state. Load carrying capacity is an output random quantity depending on input random imperfections. Latin Hypercube Sampling Method is used for sampling simulation. Load carrying capacity is computed by the programme ANSYS using shell finite elements and nonlinear computation methods. The nonlinear FEM computation model takes into consideration the effect of lateral-torsional buckling on the ultimate limit state.

ABSTRACT: Metallic thin shell structures are used in different branches of industry, and the components of these structures such as dished ends show different modes of failure depending upon the geometrical and loading conditions. These are mainly gross plastic deformation under static load, loss of stability (buckling), fatigue crack initiation at highly stressed locations under cyclic loading (especially in the low cycle regime), progressive plastic deformation (ratcheting) and creep at high temperatures. In this paper, failure modes of a conical pressure vessel subjected to internal pressure has been investigated. Also, to study the effect of vessel geometry, a set of conical cylindrical vessels with the cap-cone apex half angles of 20 to 85 degrees, internal radius of 500 to 1000 mm and thickness of 1 to 10 mm has been selected. The failure modes of these vessels which include gross plastic deformation and bifurcation buckling have been taken into account. In this work, a new plastic criterion has been established which is based on the plastic work dissipation in the vessel by increasing the internal pressure. This plastic criterion can be used for structures subjected to single or a combination of loading condition. The calculated plastic limit loads, which have been obtained using the plastic criterion, are determined purely by the inelastic response of the vessel, and they are not altered by initial elastic behavior. In addition, a design graph for designing pressure vessels with conical heads subjected to internal pressure has been presented via comprehensive parametric study. The results show that when the ratio of the internal pressure to the limit pressure (Load Factor) approaches 0.5, the material yielding initiates and with further increase in the Load Factor, the plastic regions develop. Also, by increasing the ratio of cylinder radius to wall thickness (R/t), plastic buckling failure becomes more dominant.

ABSTRACT: When computational modeling is used to evaluate the true strength of an imperfect elastic-plastic shell structure, the current European standard on shell structures requires that two reference strengths are always determined: the linear bifurcation load and the plastic limit (plastic collapse) load. These two loads are used in more than one way to characterize the strength of all imperfect elastic-plastic systems. Where parametric studies of a problem are being undertaken, it is particularly important that these two loads are accurately defined, since all other strengths will be related to them. For complex problems in shell structures, it is not possible to develop analytical solutions for the plastic collapse strength, and finite element analysis must be used. Unfortunately, because a collapse mechanism often requires the development of very extensive plasticity involving large local strains, and the collapse load is simply at the end of a slowly rising load-deflection curve, it is sometimes difficult for the analyst to accurately determine this plastic collapse strength. This paper describes two methods, based on modifications of the Southwell plot, of obtaining very accurate evaluations of the plastic limit load, irrespective of whether a fairly complete plastic strain field has developed or not. These two methods allow plastic collapse limit loads to be reported with great precision.
ABSTRACT: This paper studies the dynamic buckling behavior of multi-walled carbon nanotubes (MWNTs) subjected to step axial loading. A buckling condition is derived, and numerical results are presented for MWNTs under fixed boundary conditions. It is shown that the critical buckling load of MWNTs is of multi-branches and decreases as the time elongates. The associated buckling modes for different layers of MWNTs can be either in-phase or out of phase, which is related to the branch that the critical buckling load belongs to. For MWNTs with the same innermost tube radius, the critical buckling load is decreased when increasing the layers.

ABSTRACT: Buckling is often the main design consideration for thin cylindrical shells. For most load cases, the stability behavior of the shell is acutely sensitive to circumferential weld-induced imperfections, and the corresponding residual stresses are some beneficial to buckling strength of the shell generally. However, these conclusions are all based on the cylinders with constant wall thickness, and the studies about the effect of residual stresses on buckling strength of tapered cylindrical shells under partial axial compression are few. This paper applies trapezoidal strain field approach to simulate circumferential weld-induced imperfections on tapered cylindrical shells, and studies the stability behavior of the cylinders with single circumferential weld and multiple circumferential welds under partial axial compression respectively. By comparing the results derived from the models with/without circumferential welds and corresponding residual stresses, the effects of weld depressions and residual stresses on tapered cylindrical shells under partial axial compression are obtained.

ABSTRACT: The effect of random system properties on thermal post-buckling temperature of laminated composite cylindrical shell panel with temperature independent (TID) and dependent (TD) material properties subjected to uniform temperature distribution is examined in this study. System properties such as material properties, thermal expansion coefficients and lamina plate thickness are modeled as independent basic random variables. The basic formulation is based on higher-order shear deformation (HSĐT) theory with von-Karman nonlinearity using modified C0 continuity. A direct iterative-based C0 nonlinear finite element method (FEM) combined with Taylor series-based mean-centered first-order perturbation technique (FOPT) developed by the authors for composite plate is extended for shell panel with reasonable accuracy to compute second-order statistics of post-buckling temperature of cylindrical shell panel. Typical numerical results for second order statistics (mean and coefficient of variance) of thermal post-buckling temperature of laminated cylindrical shell panel are obtained through numerical examples for various support conditions, amplitude ratios, shell thickness ratios, aspect ratios, lamination lay-up sequences, curvature to length ratios, types of material properties with the effect of random system parameters. The performance of outlined approach has been validated with those results available in the literatures and independent MCS.

ABSTRACT: A finite element analysis, including static and buckling analysis is presented for several notable concrete spherical shells around the world. Also, the structural optimization study of these shells was performed for thickness distribution and structure shape to reduce overall tensile stress, deflection and reinforcements. The finite element analysis using Sofistik software shows that a distributed concrete thickness reduces shell stresses, deflections and reinforcements. A geometrically non-linear analysis of these structures with and without imperfections was also performed. To take into account the possible plastification of the material an analysis with non-linear material was performed simultaneously with the geometrically non-linear analysis. This helps in developing an understanding of the structural behaviour and helps to identify all potential failure causes using failure analysis.

ABSTRACT: One of the unique properties of polymeric gel is that the volume and shape of gel can dramatically change even at mild variation of external stimuli. Though a variety of instability patterns of slender and thin film gel structures due to swelling have been observed in various experimental studies, many are not well understood. This paper presents the analytical solutions of swelling-induced instability of various slender and thin film gel structures. We have adopted the well developed constitutive relation of inhomogeneous field theory of a polymeric network in equilibrium with a solvent and mechanical load or constraint with the incremental modulus concept for slender beam and thin film gel structures. The formulas of buckling and wrinkle conditions and critical stress values are derived for slender beam and thin film gel structures under swelling-induced instability using nonlinear buckling theories of beam and thin film structures. For slender beam structure, we construct the stability diagram with the distinct stable and unstable zones. The critical slenderness ratio and corresponding critical stresses are provided for different dimensionless material parameters. For thin film gel structures, we consider the thin film gel on an elastic foundation with different stiffness. The analytical solutions of critical stress and corresponding wrinkle wavelength, as well as buckling condition (or critical chemical potential) are given. These analytical solutions will provide a guideline for gel structure design used in polymeric gels MEMS and NEMS structures such as sensors and actuators. More importantly, the work provides a theoretical foundation of gel structure buckling and wrinkle, instability phenomena are different from normal engineering or material buckling.

ABSTRACT: Functionally gradient materials (FGMs) have attracted much attention as advanced structural
materials because of their heat-resistance properties. In this paper, a study on the vibration of cylindrical shells
made of a functionally gradient material (FGM) composed of stainless steel and nickel is presented. The
objective is to study the natural frequencies, the influence of constituent volume fractions and the effects of
configurations of the constituent materials on the frequencies. The properties are graded in the thickness
direction according to a volume fraction power-law distribution. The results show that the frequency
characteristics are similar to that observed for homogeneous isotropic cylindrical shells and the frequencies are
affected by the constituent volume fractions and the configurations of the constituent materials. The analysis is
carried out with strains–displacement relations from Love’s shell theory and the eigenvalue governing equation
is obtained using Rayleigh–Ritz method. The present analysis is validated by comparing results with those in
the literature.

T. Y. Ng, H. Li, K. Y. Lam and C. T. Loy, “Parametric Instability of Conical Shells by the Generalized
ABSTRACT: The parametric instability of truncated conical shells of uniform thickness under periodic edge
loading is examined. The material considered is homogeneous and isotropic. This is the first instance that the
Generalized Differential Quadrature (GDQ) method is used to study the effects of boundary conditions on the
parametric instability in shells. The formulation is based on the dynamic version of Love's first approximation
for thin shells. A formulation is presented which incorporates the GDQ method in the assumed-mode method to
reduce the partial differential equations of motion to a system of coupled Mathieu–Hill equations. The principal
instability regions are then determined by Bolotin's method. Assumptions made in this study are the neglect of
transverse shear deformation, rotary inertia as well as bending deformations before instability.

“Vibration characteristics of functionally graded cylindrical shells under various boundary conditions”, Applied
ABSTRACT: In the recent years, functionally gradient materials (FGMs) have gained considerable attention in
the high temperature environment applications. In the present work, study of the vibration of a functionally
graded cylindrical shell made up of stainless steel and zirconia is presented. Material properties are graded in
the thickness direction of the shell according to volume fraction power law distribution. Effects of boundary
conditions and volume fractions (power law exponent) on the natural frequencies of the FG cylindrical shell are
studied. Frequency characteristics of the FG shell are found to be similar to those of isotropic cylindrical shells.
Further, natural frequencies of these shells are observed to be dependent on the constituent volume fractions and
boundary conditions. Strain displacement relations from Love's shell theory are employed. Rayleigh method is
used to derive the governing equations. Further, analytical results are validated with those reported in the literature.

ABSTRACT: This paper presents the nonlinear formulation for Functionally Graded Material (FGM) plates and shells using Semilooof Shell element. Results for buckling and vibration analysis of functionally graded plates and shells are reported.

PARTIAL INTRODUCTION: Functionally graded materials (FGM) are heterogeneous composite materials usually made from a mixture of metals and ceramics. The material properties of FGM are graded but continuous and are controlled by the variation of the volume fraction of the constituent materials. The concept of FGM was first proposed by Koizumi [1]. Functionally graded materials have the advantage of their ability to withstand high temperature gradients unlike fiber matrix composites, which show mismatch of mechanical properties across an interface of two discrete materials bonded together and resulting in de-bonding at high temperatures in some cases. In FGM, the ceramic material provides high temperature resistance due to its low thermal conductivity while the ductile metal component provides structural strength and fracture toughness. Functionally graded materials are now being strongly considered as a potential structural material for future high-speed spacecraft. They are widely applied where the operating conditions are severe, for example, wear resistant linings for handling large heavy abrasive exchanger tubes, thermo elastic generators, heat engine components etc.

ABSTRACT: This review focuses mainly on the developments of element-free or meshless methods and their applications in the analysis of composite structures. This review is organized as follows: a brief introduction to shear deformation plate and shell theories for composite structures, covering the first-order and higher-order theories, is given in Section 2. A review of meshless methods is provided in Section 3, with main emphasis on the element-free Galerkin method and reproducing kernel particle method. The applications of meshless methods in the analysis of composite structures are discussed in Section 4, including static and dynamic analysis, free vibration, buckling, and non-linear analysis. Finally, the problems and difficulties in meshless methods and possible future research directions are addressed in Section 5.

ABSTRACT: In this study, the static response is presented for a simply supported functionally graded rectangular plate subjected to a transverse uniform load. The generalized shear deformation theory obtained by
the author in other recent papers is used. This theory is simplified by enforcing traction-free boundary conditions at the plate faces. No transversal shear correction factors are needed because a correct representation of the transversal shearing strain is given. Material properties of the plate are assumed to be graded in the thickness direction according to a simple power-law distribution in terms of the volume fractions of the constituents. The equilibrium equations of a functionally graded plate are given based on a generalized shear deformation plate theory. The numerical illustrations concern bending response of functionally graded rectangular plates with two constituent materials. The influences played by transversal shear deformation, plate aspect ratio, side-to-thickness ratio, and volume fraction distributions are studied. The results are verified with the known results in the literature.

[23] A.M. Zenkour, Thermal effects on the bending response of fiber-reinforced viscoelastic composite plates using a sinusoidal shear

ABSTRACT: New results of buckling and postbuckling analysis are presented for a shear deformable anisotropic laminated cylindrical shell of finite length subjected to torsion. The governing equations are based on a higher order shear deformation shell theory with von Kármán-Donnell-type of kinematic nonlinearity and including the extension/twist, extension/flexural and flexural/twist couplings. The nonlinear prebuckling deformations and initial geometric imperfections of the shell are both taken into account. A singular perturbation technique is employed to determine the buckling loads and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling response of perfect and imperfect, moderately thick, anisotropic laminated cylindrical shells with different values of shell parameters and stacking sequence. The postbuckling equilibrium path is unstable for a moderately thick laminated cylindrical shell under torsion and the shell structure is virtually imperfection-sensitive.

ABSTRACT: Carbon nanotube-based intramolecular junctions can function as rectifying diodes and switches in circuits and thus possesses the promising potential to be applied in nano-scale electronic devices. Due to their slender and unsymmetrical geometry, intramolecular junctions are prone to buckling under compression and the resulting structural instability will eventually leads to structural or electrical failure. Thus, it is important to explore the mechanical behaviors of intramolecular junctions subject to compressive loads. In this study, molecular dynamical simulations are carried out to investigate the compressive behaviors of intramolecular junctions at finite temperature, while carbon nanotubes are also studied as reference. The simulation results indicate that the strain rate effect is negligible within relatively low loading-rate range but the critical strain increases significantly under higher loading rate. At an extremely high strain rate, the intramolecular junctions will crush immediately. It is also predicted that local deformation will be introduced at high environmental temperature. Moreover, with increasing tube length, the instability mode of the intramolecular junctions transfers from shell buckling to column buckling and the critical aspect ratio is lower than that of carbon nanotubes due to presence of the Stone–Wales defects.

ABSTRACT: In this paper the local buckling of cylindrical shell under torsion is discussed. The Hamiltonian system approach is employed to analyze the propagation of shear wave. In this system, critical torsional loads and buckling modes are reduced to a problem of eigenvalues and eigensolutions of increasing orders. Buckling modes are divided into two types, the local torsional buckling modes and the helical buckling modes. For short-time shear wave propagation, local torsional buckling occurs easily. On the contrary, the helical buckling modes appear when the wave propagates for a longer time and these modes correspond to the first-order eigensolution.

ABSTRACT: In this paper, the dynamic buckling of an elastic cylindrical shell subjected to an axial impact load is analyzed in Hamiltonian system. By employing a symplectic method, the traditional governing equations are transformed into Hamiltonian canonical equations in dual variables. In this system, the critical load and
buckling mode are reduced to solving symplectic eigenvalues and eigensolutions respectively. The result shows that the critical load relates with boundary conditions, thickness of the shell and radial inertia force. And the corresponding buckling modes present some local shapes. Besides, the process of dynamic buckling is related to the stress wave, the critical load and buckling mode depend upon the impacted time. This paper gives analytically and numerically some new rules of the buckling problem, which is useful for designing shell structures.

ABSTRACT: By considering the effect of stress waves in a Hamiltonian system, this paper treats dynamic buckling of an elastic cylindrical shell which is subjected to an impact torsional load. A symplectic analytical approach is employed to convert the fundamental equations to the Hamiltonian canonical equations in dual variables. In a symplectic space, the critical torsion and buckling mode are reduced to solving the symplectic eigenvalue and eigensolution, respectively. The primary influence factors, such as the impact time, boundary conditions and thickness, are discussed in detail through some numerical examples. It is found that boundary conditions have limited influence except free boundary condition in the context of the scope in this paper. The localization of dynamic buckling patterns can be observed at the free end of the shell. The new analytical and numerical results serve as guidelines for safer designs of shell structures.

Jiabin Sun, Xinsheng Xu, C.W. Lim and Weiyu Qiao, “Accurate buckling analysis for shear deformable FGM cylindrical shells under axial compression and thermal loads”, Composite Structures, 05/2015; 123.
DOI: 10.1016/j.compstruct.2014.12.030
ABSTRACT: Based on the Reddy’s high-order shear deformation theory, buckling behaviors of the FGM cylindrical shells subjected to an axial compression in thermal environment are investigated analytically. Considering the temperature-dependent FGMs properties, the constituent distribution across the shell thickness is assumed to follow the volume fraction rule of mixture. Through the variational principle, basic equations are derived for shear deformable FGM cylindrical shell with the initial geometric imperfection. Method of separation of variables and Galerkin’s solving process are employed in dealing with the stability governing equations of perfect and imperfect shells, respectively. By changing the boundary conditions, material types, composition distributions, thermal load and temperature fields, the effect of the transverse shear deformation is evaluated by comparing with the results of the classical Donnell’s theory. Meanwhile, imperfection sensitivity for buckling of the shear deformable FGM cylindrical shell is discussed in detail.

ABSTRACT: Buried pipelines may be deformed due to earthquakes and also corrode despite corrosion control measures such as protective coatings and cathodic protection. In such cases, it is necessary to ensure the integrity of the corroded pipelines against earthquakes. This study developed a method to evaluate the earthquake resistance of corroded pipelines subjected to seismic ground motions. Axial cyclic loading experiments were carried out on line pipes subjected to seismic motion to clarify the cyclic deformation
behavior until buckling occurs. The test pipes were machined so that each one would have a different degree of local metal loss. As the cyclic loading progressed, displacement shifted to the compression side due to the formation of a bulge. The pipe buckled after several cycles. To evaluate the earthquake resistance of different pipelines, with varying degrees of local metal loss, a finite-element analysis method was developed that simulates the cyclic deformation behavior. A combination of kinematic and isotropic hardening components was used to model the material properties. These components were obtained from small specimen tests that consisted of a monotonic tensile test and a low cycle fatigue test under a specific strain amplitude. This method enabled the successful prediction of the cyclic deformation behavior, including the number of cycles required for the buckling of pipes with varying degrees of metal loss. In addition, the effect of each dimension (depth, longitudinal length and circumferential width) of local metal loss on the cyclic buckling was studied. Furthermore, the kinematic hardening component was investigated for the different materials by the low cycle fatigue tests. The kinematic hardening components could be regarded as the same for all the materials when using this component as the material property for the finite-element analyses simulating the cyclic deformation behavior. This indicates that the cyclic deformation behavior of various line pipes can be evaluated only based on their respective tensile properties and common kinematic hardening component.

ABSTRACT: A growing tumor is subjected to intrinsic physical forces, arising from the cellular turnover in a spatially constrained environment. This work demonstrates that such residual solid stresses can provoke a buckling instability in heterogeneous tumor spheroids. The growth rate ratio between the outer shell of proliferative cells and the inner necrotic core is the control parameter of this instability. The buckled morphology is found to depend both on the elastic and the geometric properties of the tumor components, suggesting a key role of residual stresses for promoting tumor invasiveness.

ABSTRACT: We study the peculiar wrinkling pattern of an elastic plate stamped into a spherical mold. We show that the wavelength of the wrinkles decreases with their amplitude, but reaches a minimum when the amplitude is of the order of the thickness of the plate. The force required for compressing the wrinkled plate presents a maximum independent of the thickness. A model is derived and verified experimentally for a simple one-dimensional case. This model is extended to the initial situation through an effective Young modulus representing the mechanical behavior of the wrinkled state. The theoretical predictions are shown to be in good agreement with the experiments. This approach provides a complement to the "tension field theory" developed for wrinkles with unconstrained amplitude.

ABSTRACT: A method to evaluate the structural safety of lateral buckling load is presented, using FEM analysis for a wind turbine tower with a thin circular wall. Europe, the U.S. and Japan already have long histories of research into wind power due to its high efficiency. The tower structure that supports a wind turbine is one important research area. There are three types of tower that vary by structural composition: a cylindrical tower with a circular cross-section, a jacket tower with a truss structure, and a hybrid tower. This paper investigates an accident involving a 600KW wind turbine that occurred in JeJu, Korea in October of 2010. The results from a numerical analysis are compared with the actual collapse mode observed at the accident. Some buckling modes and wind speeds at which non-linear buckling response occurs are predicted via the arc-length method for a land-based cylindrical stationary tower. The evaluation method is used accident (experiment), analytical, linear and nonlinear finite element method (beam and shell) to analyze the result of predicted buckling load of tower. The result of nonlinear FEM shell model was found to exhibit similar behavior to the accident situation during buckling. It is concluded that this paper provides buckling analysis process and method used for the slender shell structures: agreement with those of the analytical calculation, indicating that the arc-length method effectively improved the convergence. We found out buckling limit load of the accident wind turbine tower and wind speed at buckling point. The result of nonlinear FEM shell model was found to exhibit similar behavior of the actual accident (experiment) situation during buckling. The presented buckling evaluation method will be useful for both static design and dynamic performance evaluation of land-based wind turbines, as well as sea-based wind turbines.

ABSTRACT: The behavior of composite cracked pipes under the effect of buckling is explored by performing a linear buckling analysis using the finite element method. The pipe is pressed under compression in the presence of cracks longitudinal, radial, and inclined relative to the horizontal. The results indicate that increasing the radius of the pipe conduit to the reduction of buckling parameter and the maximum values are obtained for the lowest fiber orientations. The maximum stresses are obtained for the radius of 400 mm. Moreover, the increase in the number of plies in composite pipe leads to the increase of the parameter buckling. The size of the crack, its orientation and position in the pipe are identified.

ABSTRACT: Product: Abaqus/Standard
This example serves as a guide to performing a postbuckling analysis using Abaqus for an imperfection-sensitive structure. A structure is imperfection sensitive if small changes in an imperfection change the buckling load significantly. Qualitatively, this behavior is characteristic of structures with closely spaced eigenvalues. For such structures the first eigenmode may not characterize the deformation that leads to the lowest buckling load. A cylindrical shell is chosen as an example of an imperfection-sensitive structure.

“Inelastic Buckling Simulation of Steel Braces through Explicit Dynamic Analyses”, American Institute of
And Applied Mathematics ICNAAM 2011, 19–25 September 2011, Halkidiki, Greece

ABSTRACT: This paper presents a veritable finite element approach for simulating the inelastic buckling
response of steel braces. A number of techniques are considered to identify computationally efficient modeling
approaches that yield consistent results with experimental data. Ultimately, brace members and gusset plates are
represented with deformable and rigid shell elements, respectively; and the overall method is based on dynamic
analyses with explicit time integration. There is inherent damping in the proposed model due to inelasticity;
additional viscous damping and mass scaling factors are used to extract-simulate the system’s quasi-static
responses. Static sensitivity analyses are conducted to optimize mesh sizes and the most suitable imperfection
shapes and amplitudes for the brace elements. Additional (dynamic) sensitivity analyses are employed to
calibrate the imperfection, loading amplitude, time period, artificial viscous damping and mass scaling factors.
Results indicate that the proposed techniques can accurately mimic experimentally observed quasi-static
responses.

Hart-Smith, LJ. A revolutionary approach to the analysis of buckling of thin cylindrical shells [online]. In:
AIAC14: Fourteenth Australian Aeronautical Conference. Melbourne: Royal Aeronautical Society, Australian
Division; Engineers Australia, 2011: 306-339. Availability:

ABSTRACT: New analytical analyses are presented here of the buckling of circular cylindrical thin shells
under a variety of applied loads: (1) cylinders acted on by uniform radial external pressure, (2) longitudinal
compression of unpressurized cylinders, (3) longitudinal compression of pressurized cylinders, including the
special case (4) of ring buckling, as distinct from diamond buckling, of highly pressurized cylinders under
longitudinal compression. The solutions cover both very long and very short cylinders with a transitional
solution in between. The solutions start with the equivalent solutions for the buckling of flat plates, which are
then generalized to the equivalent cylinders. This starting point is correct, beyond questioning. The new
analyses expose many errors in the classical solution to this problem, both quantitative and qualitative. The new
and old solutions are compared thoroughly. The major change with respect to past analyses, however, is the
recognition that, in most cases, buckling occurs in the absence of induced membrane stresses, leaving the shells
with no ability to resist deformation other than by the weaker bending stresses. This work is a summary of a set
of new detailed analyses for the buckling of circular cylindrical thin shells, starting from a corrected thin-shell
theory, and showing that the same new results can be derived from shell theory was well as plate theory now
that the correct answers have been established.

L.J. Hart-Smith (retired from the Boeing Company), “Incontrovertible proof that the ‘discrepancies’ in thin-
shell-buckling studies are in the classical theory, not the test data”, Journal of Materials: Design and
ABSTRACT: It is shown here that the classical shell-buckling analyses have been fatally flawed since they
were first derived. One reason cited is a failure to freeze the buckling stresses at the values at which buckling
commenced, which resulted in consistent over estimates of the true buckling stresses by large factors. Another is the misinterpretation of the inextensibility criterion, which is customarily expressed in terms of the linear equations pertaining prior to buckling instead of the nonlinear equations that govern once buckling has commenced. The consequence of not acknowledging these errors is that, for many decades, it has been assumed incorrectly that the classical analyses for the various shell geometries are valid and that the major discrepancies can all be attributed to imperfections in the testing. It is shown here that this is not the case, by deriving different governing equations for shell buckling, starting from the geometrically nonlinear equilibrium equations for thin shells. These equilibrium equations are shown to include both the linear terms governing prior to buckling, with the remaining terms pertaining during buckling. This shows that buckling is resisted entirely by bending stresses alone, just as is known to be the case for flat-plate buckling, instead of by the combination of membrane and bending stresses. Specific equations are included for cylindrical shells, along with test data showing that the correct buckling stress for longitudinally compressed unpressurized cylinders is only half the classical prediction. Future papers will include full analyses of the buckling of spherical shells under external pressure at half the classical prediction, and of cylindrical shells under external pressure at one third of the classical prediction, as well as the buckling of pressurized and unpressurized cylindrical shells under longitudinal compression showing how, as the internal pressure is increased, the diamond-buckling stress increases from half the classical prediction for zero pressure to the classical ring-buckling stress for high pressure.

ABSTRACT: The effect of bending buckling of carbon nanotubes (CNTs) on thermal conductivity of CNT materials is investigated in atomistic and mesoscopic simulations. Nonequilibrium molecular dynamics simulations of the thermal conductance through an individual buckling kink in a (10,10) single-walled CNT reveal a strong dependence (close to inverse proportionality) of the thermal conductance of the buckling kink on the buckling angle. The value of the buckling kink conductance divided by the cross-sectional area of the CNT ranges from 40 to 10 Gwm^-2 K^-1 as the buckling angle changes from 20 to 110 degrees. The predictions of the atomistic simulations are used for parameterization of a mesoscopic model that enables calculations of thermal conductivity of films composed of thousands of CNTs arranged into continuous networks of bundles. The results of mesoscopic simulations demonstrate that the conductivity of CNT films is sensitive to the angular dependence of the buckling kink conductance and the length of the individual CNTs. For a film composed of 1 lm-long CNTs, the values of the in-plane film conductivity predicted with a constant conductance of 20 Gwm^-2 K^-1 and the angular-dependent conductance obtained in atomistic simulations are about 40 and 20% lower than the conductivity predicted for the same film with zero thermal resistance of the buckling kinks, respectively. The weaker impact of the angular-dependent buckling kink conductance on the effective conductivity of the film is explained by the presence of a large fraction of kinks that have small buckling angles and correspondingly large values of conductance. The results of the simulations suggest that the finite conductance of the buckling kinks has a moderate, but non-negligible, effect on thermal conductivity of materials composed of short CNTs with length up to 1 lm. The contribution of the buckling kink thermal resistance becomes stronger for materials composed of longer CNTs and/or characterized by higher density of buckling kinks.

“Nonlocal beam model for axial buckling of carbon nanotubes with surface effect”, Europhysics Letters (EPL),
ABSTRACT: Small-size effect and surface effect are two of the most specific intrinsic properties of
nanostructures, both of which are of great significance to the related applications. In this letter, the nonlocal
Euler-Bernoulli beam model, together with surface elasticity and surface tension are implemented to investigate
the buckling behavior of axially compressed carbon nanotubes. Explicit expression of solutions to the critical
buckling loads corresponding to typical boundary conditions is presented. Through contrast to molecular
dynamics results, it is vitally important to note that both small-size effect and surface effect have a profound
consequence and should be taken into account thoroughly.

Qishan Wang, “Active Vibration and Buckling Control of Piezoelectric Smart Structures”, Ph.D dissertation,
Civil Engineering and Applied Mechanics, McGill University, Montreal, Quebec, Canada, 2012
ABSTRACT: The objective of this dissertation is the vibration and buckling control of piezo-laminated
composite structures with surface bonded or embedded piezo-electric sensors and actuators by using the finite
element analysis and LQR/LQG feedback control techniques.
The focus is mainly on two aspects: the finite element part and the active control part.
(1) The finite element part:
Two finite element formulations for the piezo-laminated beams based on the classical Bernoulli-Euler and the
Timoshenko beam theories are developed using the coupled linear piezoelectric constitutive equations, and the
Hamilton variational principle.
A C0 continuous, shear flexible, eight-node serendipity doubly curved shell element for the piezolaminated
composite plates and shells is also developed based on the layer-wise shear deformation theory, linear
piezoelectric coupled constitutive relations, and Hamilton variational principle.
The developed elements can handle the transverse shear strains, composite materials, and piezoelectric-
mechanical coupling. Higher modes of vibration can then be predicted more precisely for thin to medium-thick
multilayered composite structures. They are evaluated both for the vibration and buckling of beam, plate, and
shell structures.
(2) The active control part:
The suppression of vibration of a cantilever piezo-laminated beam and the control of the first two buckling
modes of a simply supported piezo-laminated beam are studied first. Then, the vibration and buckling control of
a cantilever piezo-laminated composite plate are studied. Furthermore, the vibration control of a piezolaminated
semicircular cylindrical shell is also studied.
The results of the finite element analysis are used to design a linear quadratic regulator (LQR) controller and a
linear quadratic Gaussian (LQG) compensator with a dynamic state observer to achieve all the controls. The
control design begins with an approximate reduced modal model which can represent the system dynamics with
the least system modes. A state space modal model of the smart structure which integrates the host structure
with bonded piezoelectric sensors and actuators, is then used to design the control system. The designed
LQR/LQG feedback controls are shown to be successful in suppressing the vibration and stabilizing the
buckling modes of structures.
Both the finite element analysis and the active control simulation results are consistent with the existing
theoretical analysis results and the experimental data in the literature. Some important conclusions and
interesting observations are obtained.

Eoin Dunphy, “Study and comparison of shell design codes for adaptation to design geometrically complex...

ABSTRACT: The Eurocode and American Bureau of Shipping code analytical methods of determining the buckling resistance of 6 axially loaded steel shell cylinders was studied. The Eurocode MNA/LBA and GMNIA numerical methods were also studied using finite element analysis and compared against the results of the analytical methods. Following these comparisons the intention was to give an overview of the different methods and their applicability. Further suggestions were then made on how these methods could be used in the future analyses of more geometrically complex steel shell structures.

It was found that the Eurocode significantly underestimates the buckling resistance of ring and stringer stiffened cylindrical shells when compared to the ABS code (34% to 54% lower). The MNA/LBA numerical method currently allows the determination of the buckling resistance of simple structures under load conditions not covered by the classical theory. The MNA/LBA method shows potential for greater usage in more geometrically complex analyses provided that the required buckling parameters for its use are pre-determined. If these parameters are available the MNA/LBA method would be a less time consuming design method than the more rigorous GMNIA method.

The GMNIA method is the most complex analysis and as it is purely computational the importance of correctly modelling the structure and its imperfections is paramount in the determination of a realistic buckling resistance. The pitfalls of these requirements is that the correct imperfection type is difficult and time consuming to determine and the introduction of these imperfections has implications on further modelling of the structure. However, the GMNIA method is adaptable to unique cases without precedent and there is potential for research based on its usage as opposed to through physical experimentation.

Rotter, J. (2007). Recent advances in the practical design of shell structures, implemented in eurocode provisions, Proc. SEMC.

ABSTRACT: The paper describes a theoretical and an experimental investigation into the free vibration of three ring-stiffened circular cylinders subjected to various values of uniform external pressure. The experimental procedure involved a novel device, which was suitable for ferrous metals. The theoretical method involved the finite element method for both the structure and the fluid, where in the case of the latter, the wave equation was solved. The results showed that the resonant frequencies decreased with increasing values of external pressure, especially when the vibration eigenmode had the same shape as the static buckling mode.

ABSTRACT: The paper presents an experimental study on six circular corrugated cylinders which were tested to destruction under external hydrostatic pressure. The results obtained from these vessels, together with the results obtained from elsewhere, were used to provide a design chart. The design chart appears to be suitable for designing these vessels to guard against inelastic instability.

ABSTRACT: This paper presents a theoretical geometrical and material non-linear analyses of fifteen unstiffened conical shells, using the finite element computer program ANSYS, to calculate their buckling pressures. The cones buckle as a result of shell instability caused by the external hydrostatic pressure. Experimental tests were also carried to destruction of the fifteen vessels, under external hydrostatic pressure. The experimental results for the fifteen conical shells, were compared with multiple alternate theoretical methodologies, including ANSYS eigen-buckling, ANSYS nonlinear, together with other methodologies; which included PD5500 (BS5500), and the design charts produced by Ross. The ANSYS eigen-buckling results were poor; but the ANSYS nonlinear results were much more encouraging. PD5500 was too conservative, but Ross' design charts were the best and the easiest to use. Whereas most of the conical shells failed by plastic shell instability, some of the failures were initiated by axisymmetric deformation; prior to plastic shell instability taking place. The PD5500 code was hard to use and produced overly conservative results, which would lead to conservative pressure vessel designs, while the Ross design charts [1] produced good results, and were very easy to use and understand, and were not too conservative. The graphical displays from ANSYS were quite spectacular. From some of the ANSYS nonlinear analyses, it appeared that plastic axisymmetric yield initially took place at the larger ends of the cones; before triggering off plastic shell instability.

ABSTRACT: This paper presents a linear and nonlinear buckling and post buckling numerical analysis of a bar with the influence of imperfections. In the first step, we used an approach of analytic and numerical linear buckling analysis of a bar with linear-elastic material. After linear buckling analysis of the bar, we performed nonlinear buckling analysis with the Riks method. Since the nonlinear analysis was performed in the case of ideal loading, to get correct and more realistic information of post buckling response, imperfections and plastification of material must be considered. In this case, the imperfections are eccentric loads. This paper finally shows that the post buckling behaviour becomes unstable even for a very small value of eccentric load in nonlinear analysis with elasto-plastic behaviour of material. Numerical analysis was performed in software Abaqus 6.10.

ABSTRACT: We present a methodology to perform the identification and validation of complex uncertain dynamical systems using experimental data, for which uncertainties are taken into account by using the nonparametric probabilistic approach. Such a probabilistic model of uncertainties allows both model uncertainties and parameter uncertainties to be addressed by using only a small number of unknown identification parameters. Consequently, the optimization problem which has to be solved in order to identify the unknown identification parameters from experiments is feasible. Two formulations are proposed. The first one is the mean-square method for which a usual differentiable objective function and an unusual non-differentiable objective function are proposed. The second one is the maximum likelihood method coupling with a statistical reduction which leads us to a considerable improvement of the method. Three applications with experimental validations are presented in the area of structural vibrations and vibroacoustics.

ABSTRACT: A methodology for analyzing the large static deformations of geometrically nonlinear structural systems in the presence of both system parameters uncertainties and model uncertainties is presented. It is carried out in the context of the identification of stochastic nonlinear reduced-order computational models using simulated experiments. This methodology requires the knowledge of a reference calculation issued from the mean nonlinear computational model in order to determine the POD basis (Proper Orthogonal Decomposition) used for the mean nonlinear reduced-order computational model. The construction of such mean reduced-order nonlinear computational model is explicitly carried out in the context of three-dimensional solid finite elements. It allows the stochastic nonlinear reduced-order computational model to be constructed in any general case with the nonparametric probabilistic approach. A numerical example is then presented for a curved beam in which the various steps are presented in details.

ABSTRACT: The present work concerns the experimental identification of an uncertain nonlinear
computational model in the context of the post-buckling analysis of a cylindrical shell. It proposes an alternative approach to existing methodologies for which only system parameter uncertainties are modeled [5]. This methodology is adapted to the analysis of large static deformations of geometrically nonlinear structural systems in the presence of both system parameters uncertainties and model uncertainties. The available experimental data is made up of the nonlinear static deflection of a cylindrical shell. First, the deterministic nonlinear computational model is constructed using the finite element method and the corresponding nonlinear response is used as a reference deterministic solution for which a reduced-order basis is deduced using the POD (Proper Orthogonal Decomposition) analysis. The mean reduced-order nonlinear computational model is then explicitly constructed in the context of three-dimensional solid finite elements. Moreover, a positive-definite operator related to the nonlinear stiffness of the structure is defined, allowing the use of the nonparametric probabilistic methodology for constructing the uncertain nonlinear reduced-order computational model. Finally, the experimental identification of the uncertain nonlinear computational model is carried out in order to validate the proposed methodology.

ABSTRACT: The construction of advanced numerical methodologies for the prediction of the dynamical behavior of complex uncertain structures represents an important current challenge. In the present work, structures undergoing large displacements and high strains are investigated. Of particular interest is the analysis of the post-buckling dynamics of a cylindrical shell submitted to an horizontal seismic excitation. The nominal (i.e. without uncertainties) computational model of the cylindrical shell is large, i.e. comprising about 4200000 degrees of freedom, obtained with the finite element method using three-dimensional solid elements. A nonlinear reduced-order modeling is first carried out. Then, model uncertainties (on geometry, material properties, etc.) are introduced using probabilistic methods and the corresponding stochastic reduced-order nonlinear computational model is obtained. The identification of its parameters is next carried out using nonlinear static post-buckling data. Finally, a numerical nonlinear dynamic analysis of the uncertain shell is performed in a seismic context, for which the base of the cylindrical shell is submitted to a prescribed rigid shear displacement, modeled through a centered non-stationary Gaussian second-order stochastic process. The stochastic displacement field is then calculated and the effects of uncertainties and of nonlinearities are analyzed in detail.

This paper presents the nonlinear dynamical post-buckling analysis of uncertain cylindrical shells. The proposed approach is adapted to the dynamical analysis of geometrically nonlinear structures subjected to a stochastic ground-based motion in the presence of both system parameter uncertainties and model imperfections.
uncertainties. The structure is modeled by a large finite element model using 3D elasticity theory. The ground-based motion is represented by a Gaussian centered non-stationary second-order stochastic process. Then, a reduced-order basis is constructed using the POD (Proper Orthogonal Decomposition) analysis of a nonlinear static reference response combined with selected linear eigenmodes of vibrations. The mean reduced-order nonlinear computational model is then explicitly constructed. A positive-definite operator involving the nonlinear stiffness of the structure is defined, allowing the nonparametric probabilistic approach to be used for constructing the uncertain non-linear reduced-order computational model. The dispersion parameter controlling the level of stiffness uncertainty is a scalar which has been previously identified experimentally in a nonlinear static context. Finally, the instantaneous spectral density power of the dynamical response is analyzed in order to quantify the influence of both geometrical nonlinearities and random uncertainties on the stochastic dynamical response.

ABSTRACT: The paper presents a complete experimental validation of an advanced computational methodology adapted to the nonlinear post-buckling analysis of geometrically nonlinear structures in presence of uncertainty. A mean non-linear reduced-order computational model is first obtained using an adapted projection basis. The stochastic nonlinear computational model is then constructed as a function of a scalar dispersion parameter, which has to be identified with respect to the nonlinear static experimental response of a very thin cylindrical shell submitted to a static shear load. The identified stochastic computational model is finally used for predicting the nonlinear dynamical post-buckling behavior of the structure submitted to a stochastic ground motion.

ABSTRACT: This paper presents the results of a numerical investigation into ultimate strength of locally corroded tubular members under axial compressive loads. A parametric finite element approach was used in order to simulate structural behavior of damaged members. The results were then examined against an available experimental test. Validated models were used to derive a semi-empirical formula for predicting ultimate strength of locally damaged tubes as a function of corrosion dimensions. Geometry of corrosion can be defined by its depth, length, width and location of damage along the tube. In this study it is focused on the effect of some parameters that have not been addressed yet by other researchers, e.g. slenderness of the tubes and location of patch corrosion. It was found that location of corrosion has great effect on reduction of ultimate strength. Effect of corrosion geometry was studied and formulated as well as tubular slenderness, and it was shown that tubes with different corrosion dimensions show different behaviors under compressive loads. In cases with severe corrosion damages, the occurrence of local buckling plays an important role on reduction of ultimate strength and deformation of damaged region.

N-004. (1998). NORSOK STANDARD - Design of Steel Structure

ABSTRACT: Corrosion makes structures more vulnerable to buckling and yielding failures. It is common practice to assume a uniform thickness reduction for general corrosion. To estimate the remaining strength of corroded structures, typically a much higher level of accuracy is required, since the actual corroded structures have irregular surfaces. Elastic buckling of simply supported rectangular corroded plates are studied with one- and both-sided irregular surfaces. Eigenvalue analysis by using finite element method (FEM) is employed for computing Euler stress. The influence of various geometric and corrosion characteristics are investigated and it is found that the aspect ratio of the plate, the average thickness diminution, the standard deviation of thickness diminution and the amount of corrosion loss have influence on the reduction of buckling strength of the corroded plates. Buckling strength of one- and both-sided corroded plates are the same. In plates with low value of aspect ratio, reduction of buckling strength is negligible. Reduction of buckling strength is more prominent in plates with higher aspect ratio. Reduction of buckling strength is very sensitive to the amount of corrosion loss: the higher the amount of corrosion loss, the more reduction of buckling strength. Reduction of buckling strength is less sensitive to the standard deviation of thickness diminution.

ABSTRACT: Numerical simulation is used to study the influence of corrosion damage in stiffened plates focusing on elastic buckling strength. Three-dimensional specta are used to simulate geometries of corroded surfaces and finite element method is employed for computing Euler stress of stiffened plates. The influence of corrosion patterns, amount of corrosion loss and roughness of surface are investigated. Ratio of Euler stress of corroded stiffened plate over Euler stress of un-corroded stiffened plate is used to characterize the effects of corrosion on reduction of buckling strength. Results show that reduction of buckling strength is very sensitive to the amount of corrosion loss and roughness of surface, but less sensitive to the location of corroded region. The potential for decrease in buckling strength as a consequence of corrosion is found to depend on the dominant buckling mode. Residual buckling strength is reduced by as much as 12% for the interaction of plate-web-torsional buckling mode, and by 2% for column buckling.

ABSTRACT: Stiffened plate buckles in different modes, including web/flange buckling, torsional buckling, plate buckling, and interactions of them. Generally, interactions of different buckling modes in stiffened plates are ignored and elastic buckling analysis of each mode is treated separately. In some design codes, to cope with interactions of different buckling modes, the influence of adjacent elements are considered as rotational springs. The main aim of this study is to compare literature- and rule-based expressions to assess the elastic buckling strength of T-bar stiffened plates and to identify the applicability of selected expressions for certain conditions. Different buckling modes and their interactions are investigated, and critical Euler stresses are evaluated. Upon comparison with given expressions and the finite element method, it is found that some of the proposed expressions are not applicable in certain conditions.

ABSTRACT: This study investigated characteristics of bifurcation and critical buckling load by shape imperfection of space truss, which were sensitive to initial conditions. The critical point and buckling load were computed by the analysis of the eigenvalues and determinants of the tangential stiffness matrix. The two-free-nodes example and star dome were selected for the case study in order to examine the nodal buckling and global buckling by the sensitivity to the eigen buckling mode and the analyses of the influence and characteristics of the parameters as defined by the load ratio of the center node and surrounding node, as well as rise-span ratio were performed. The sensitivity to the imperfection of the initial shape of the two-free-nodes example, which occurs due to snapping at the critical point, resulted in bifurcation before the limit point due to the buckling mode, and the buckling load was reduced by the increase in the amount of imperfection. The two sensitive buckling patterns of the numerical model are established by investigating the displaced position of the free nodes, and the asymmetric eigenmode greatly influenced the behavior of the imperfection shape whether it was a limit point or bifurcation. Furthermore, the sensitive mode of the two-free-nodes example was similar to the inextensional basis mechanism of a simplified model. The star dome, which was used to examine the influence among several nodes, indicated that the influence of nodal buckling was greater than that of global buckling as the rise-span ration was higher. Besides, global buckling is occurred with reaching bifurcation point as the value of load ratio was higher, and the buckling load level was about 50% - 70% of the load level at limit point.

ABSTRACT: A finite strain formulation is developed for elastic circular arches and rings in which the effects of shear deformations are included. Timoshenko beam hypothesis is adopted for incorporating shear. Finite strains are defined in terms of the normal and shear component of the longitudinal stretch. The constitutive relations for stress and finite strain are based on a hyperelastic constitutive model. Virtual work and equilibrium
equations are derived. Closed-form in-plane buckling solutions are developed for circular rings and high arches under hydrostatic pressure. The effects of axial deformation prior to buckling as well as shear deformations are included in the buckling analysis. The formulation developed is compared with solutions in the literature and to the predictions of the finite element package ANSYS. The importance of including the effects of shear deformations for deep arches is investigated.

ABSTRACT: Sandwich cylindrical shells are the major components of aerospace structures. In this paper, an analytical investigation was carried out to examine the response of carbon fiber reinforced composite (CFRC) sandwich cylinders with lattice cores. An equivalent monocoque shell theory, was developed in this paper to predict mechanical behaviors of the quasi-isotropic sandwich cylinder, including the deformation and the multi-mode failure criterion. Five failure modes were suggested for the sandwich cylinder, including global buckling, face sheet mono-cell buckling/dimpling, face sheet local buckling, lattice rib crippling and strength failure. Using the suggested criterion, failure mode maps of the sandwich cylinder were acquired to instruct the design of the hierarchical sandwich cylinder with five geometrical variables. The method also correctly predicted the failure modes of the tested sandwich cylinder within acceptable errors.

ABSTRACT: The concept behind sandwich construction and its application in naval and commercial fields is highlighted in this paper with special reference to underwater shell forms. This paper also examines the various shell finite elements generated by researchers for the analysis of sandwich shells. A comprehensive overview of finite elements available for analysis of sandwich structures in commercial software packages is presented. The accuracy of the axisymmetric finite element sandwich shell is evaluated by comparing the results with the numerical results available by analysing the shell using ANSYS. The results of reasonable accuracy have been realized at the cost of heavy computation using the software. The need for a sandwich shell finite element based on sandwich shell theory has been justified.

ABSTRACT: In this paper, the buckling under an applied external pressure and the self-buckling of nanostructures, such as peapods, nanotubes and fullerenes, is numerically treated with Molecular Dynamics simulations and compared with theoretical calculations. The self-buckling is due to the interaction among the nanostructures caused by the surface energy; it is peculiar to the nanoscale and does not have a macroscopically analogous counterpart. Atomistic simulations confirm that the influence on a single nanostructure from the surrounding nanostructures in a crystal, is nearly identical to that of a liquid with surface tension equal to the surface energy of the solid.

ABSTRACT: In this paper, we study the elastic buckling of a new class of honeycomb materials with hierarchical architecture, which is often observed in nature. Employing the toposedown approach, the virtual buckling stresses and corresponding strains for each cell wall at level $n = 1$ are calculated from those at level $n$; then, comparing these virtual buckling stresses of all cell walls, the real local buckling stress is deduced; also, the progressive failure of the hierarchical structure is studied. Finally, parametric analyses reveal influences of some key parameters on the local buckling stress and strength-to-density ratio; meanwhile the constitutive behaviors and energy-absorption properties, with increasing hierarchy $n$, are calculated. The results show the possibility to tailor the elastic buckling properties at each hierarchical level, and could thus have interesting applications, e.g., in the design of multiscale energy-absorption honeycomb light materials.

Jingxuan, He; Mingfa, Ren; Qizhong, Huang; Shanshan, Shi; Haoran, Chen, “Buckling behavior of compression-loaded advanced grid stiffened composite cylindrical shells with reinforced cutouts”, Polymers and Polymer Composites, April 2011

PARTIAL INTRODUCTION: Advanced grid stiffened (AGS) composite cylindrical shells are widely used in the aerospace, marine, automobile and other engineering infrastructures. The necessary of cutouts in an AGS composite cylindrical shell surface is typically required to meet the practical application requirements that serve
as doors, windows, or access ports. However, the continuity of stress and deformation distribution in the AGS structures was interrupted by the cutouts. The stress concentration would occur in the cutout zone which leads to a decline in load capacity of the AGS structure. Generally, some types of reinforcing structures are applied to control local structural deformations and stresses around the cutouts. Thus the buckling and postbuckling response of the AGS structures with cutouts must be understood in order to determine the effective designs and safe operating conditions.

There are three investigative methods including analytical solution, experimental research and numerical simulation. However, for an AGS composite cylindrical shell with reinforced cutouts, it is of great difficulty using the analytical solution. And it appears less likely to obtain a series of design charts employing a large number of parameters of experimental research for a high cost, long cycle, in particular, the complex parameters of the cutouts. So the numerical simulation is a better approach to study the buckling behaviors of compression-loaded AGS composite cylindrical shells with reinforced cutouts.

It is found that a cutout in an isotropic shell structure can have a significant effect on the response of the shell in many studies. In particular, a cutout in a shell would cause a local response to occur near the cutout when the shell is subjected to compression loading. The local response can consist of large out-of-plane deformations and large magnitude rapidly varying stresses near the opening (1). And the opening can cause a local buckling response to occur on the structure at compressive load levels lower than the general instability load of the corresponding shell without a cutout (2).

Relatively a few studies have been presented on the buckling of curved panels. Kim and Noor (3,4) carried out the buckling and postbuckling responses of composite panels with central circular cutouts. Their results show the effects of variations in the cutout diameter; the aspect ratio of the panel; the laminate stacking sequence and the fiber orientation on the stability boundary, postbuckling response and sensitivity coefficients. Hilburger, Britt and Nemeth 5 performed the study of response of compression-loaded quasi-isotropic curved panels with a centrally located circular cutout using a geometrically nonlinear finite element analysis ...

ABSTRACT: This article focuses on the application of the Fourier-expansion based differential quadrature method (FDQM) for the buckling analysis of ring-stiffened composite laminated cylindrical shells. Displacements and rotations are expressed in terms of Fourier series expansions in longitudinal direction and their first order derivatives are approximated with FDQM in circumferential direction. The 'smeared stiffener' approach is adopted for the stiffeners modeling. Two FORTRAN programs prepared for linear and nonlinear analysis and results were compared by ABAQUS finite element software. Buckling loads of stiffened and unstiffened shells considering the effects of changes in shell and stiffener geometric and material properties and also shell lay-ups are investigated.

Chapter 12: Assessment of Buckling of Ship Structure

INTRODUCTION: This chapter presents a simplified procedure for the assessment of buckling of ship strength members. The main strength members of longitudinally and transversely stiffened bottom and deck structures sustaining compressive forces are identified. The compressive loadings are the compound in-plane stresses...
induced by the hull girder, secondary, and tertiary stresses. The assessment of buckling of strength members of bottom structure is carried out when the ship is in hogging condition and for strength members of deck structure when the ship is in sagging condition. For both cases, the compounding of stresses is carried out when the secondary and tertiary loadings are inducing compressive stresses. The assessment of buckling of web plates and face plates of deck and bottom girders is presented. The assessment of buckling of side shell plating for the various induced in-plane loading conditions is introduced. Assessment of buckling strength of plating for different end support conditions and for a variety of loading patterns is given. The importance of providing ship strength members sustaining compressive forces with adequate strength against buckling failure is stressed.

ABSTRACT: This paper investigates the stability analysis of a functionally graded (FG) plate integrated with a piezoelectric sensor and actuator at the top and bottom faces, subjected to electrical and mechanical loading. The material properties of the FG plates are assumed to be graded along the thickness direction according to simple power law distribution in terms of the volume fraction of the constituents, while the Poisson's ratio is assumed to be constant. The analysis is carried out on plates with different boundary conditions: for example, the plate is simply supported at all edges (SSSS) or the plate is simply supported along two opposite sides perpendicular to the direction of compression and clamped along the other two sides (CSCS). The finite element model is derived with the von Karman hypothesis and as a degenerate shell element using the FSDT. The displacement component of the present model is expanded in Taylor's series in terms of the thickness coordinate. The governing equilibrium equation is obtained using the minimum energy principle and the solution for critical buckling load is obtained by solving the eigenvalue problem. The stability analysis of the piezoelectric FG plate is carried out to present the effect of power law index, applied mechanical pressure and different boundary conditions.

ABSTRACT: In this article, a semi-analytical three-dimensional model based on the modified Hellinger–Reissner (H–R) variational principle and a nonlinear spring-layer model are presented for the buckling analysis of composite laminated cylindrical shells with a delamination. The method allows the effect of transverse shear deformation in the control equations of the composite laminated structures. In addition, it uses a two-dimensional mesh and can ensure that the number of variables is independent of the layer number. The nonlinear spring-layer model between the exterior and interior sub-laminates ensures the continuity of transverse stresses and displacements in the undelaminated region by specifying infinite values of springs and therefore avoids the possibility of material penetration phenomenon in the delaminated region. As an application of the present method, the influence of the delamination length on the critical buckling loads of delaminated composite laminated stiffened cylindrical shells is investigated.

ABSTRACT: (None given)

ABSTRACT: I will present a series of experimental explorations on the rich mechanical behavior of thin elastic shells, subject to different forms of loading. First, I will discuss the geometry-induced rigidity of non-spherical pressurized shells under indentation, that can be used for non-destructive testing. I will proceed by characterizing the emergence and evolution of point and linear-like loci of localization on thin shells indented well into the nonlinear regime. I will then present a new mechanism that utilizes the compression of a thin-shell/soft-core system for switchable and tunable wrinkling on curved surfaces, that can be exploited for active aerodynamic drag control. Finally, I shall introduce the framework for buckling-induced folding (or “Buckligami”) that involves functional structural transformations of patterned shells that can be excited to achieve encapsulation, flexure and twist. The main common feature underlying these series of examples is the prominence of geometry in dictating the complex mechanical behavior of slender soft structures, thereby making our results relevant and applicable over a wide range of length scales. Moreover, our findings suggest that we rethink our relationship with mechanical instabilities which, rather than modes of failure, can be embraced as opportunities for functionality that are scalable, reversible, and robust.

ABSTRACT: The object of this study is a thin-walled beam made of carbon-epoxy composite with open cross-section. The material used was a composite of epoxy matrix reinforced with carbon fiber (system HexPly M12, Hexcel). The M12 system is used above all in aircraft structures. It exhibits high fatigue durability and good maintenance properties at relatively low specific gravity. The research was lead as the FEM numerical analyses and experimental tests in buckling and post-buckling state, as well. In the conducted research in order to evaluate the effort ratio of the composite the Tsai-Wu tensor criterion was exploited. The numerical tool used was the ABAQUS software.

ABSTRACT: Vibration, linear elastic buckling and dynamic stability behaviors of a cracked cylindrical shell with time-varying rotating speed are analyzed. Finite element method is used to obtain the system mass and stiffness matrix, and Bolotin’s method is applied to explore the dynamic stability region. The effects of constant rotating speed, crack length and orientation, and length-diameter ratio of the cylindrical shell on the free-vibration and buckling behaviors are investigated. The stability characteristics of the cracked shell are also researched and the influences of crack length, crack orientation, rotating speed basic value, steady load factor, dynamic load factor and damping ratio are considered. Numerical examples show that crack length and orientation can affect the vibration, buckling and dynamic stability behavior of cylindrical shell significantly.

ABSTRACT: This article deals with the finite element modeling and analysis of functionally graded (FG) shell structures under different loading such as thermal and mechanical. Free vibration analysis of functionally...
graded (FG) spherical shell structure has also been presented. In order to study the influences of important parameters on the responses of FG shell structures, different types of shells have been considered. The responses obtained for FG shells are compared with the homogeneous shells of pure ceramic (AL2O3) and pure metal (steel) shells, and it has been observed that the responses of the FGM shells are in between the responses of the homogeneous shells. Based on the analysis, some important results are presented and discussed for thick as well as thin shells.

ABSTRACT: The problem of buckling stability is very important in thin-walled cylindrical shell structure. In order to investigate the buckling phenomena, digital image correlation (DIC) method was applied in this experiment. The specimens have a thickness of 0.131mm and the ratio of external diameter (R0) to thickness (H) R0/H is 252. Due to its curved and thin walled elements, measurement of displacement and strains by using the traditional methods is difficult, because there is not enough space for sticking necessary torsion gauges to measure the out-of-plane behaviour, even if it is possible, the rigidity of the gauge itself will have an effect on the buckling strength. However, by using the optical image correlation method, the problem is solved. DIC method is an optical instrument which utilizes the full-field and non-contact measurement to gauge the three-dimensional displacement and strains on materials and structural parts. In this paper three dimensional digital image correlation system is applied to observe the buckling generation process in details and make a record of the surface displacement during the compression test by using two high resolution digital cameras, then the test data are analyzed and compared by a special correlation technique which can determine the surface displacements of cylindrical shells and it is shown in colour contour in full-field region. The buckling strengths obtained by the theoretical and experimental methods are compared and discussed in this paper. The experimental study shows that the buckling strength of theoretical value is much higher than that of experimental one, because the buckling strength is highly dependent on the imperfections.

ABSTRACT: This paper deals with the elastic lateral-torsional buckling (LTB) strength of tapered I-girders with corrugated webs under two types of loading conditions: uniform moment and moment gradient with various end restraint conditions. A finite element (FE) program using beam elements is developed to study LTB behaviors. The results from this program are compared with those from the commercial software ABAQUS using shell elements. From the comparisons it is found that the developed FE program’s results agree well with the results from ABAQUS. For design purpose, the closed-form equations for the critical buckling moment of the tapered I-girder with corrugated webs under uniform moment and moment gradient with four types of end restraint conditions: simply supported, warping fixed, lateral bending fixed, and completely fixed are proposed based on the results from the developed FE program. From the numerical investigations the new design equations give reasonably accurate results. These equations increase efficiency in bridges and buildings design.

ABSTRACT: A systematically study on the new space structure steel - concrete composite ribbed shell is made, which is loaded by stepped load. The ultimate bearing capacity and failure modes are investigated based on the characteristic response indicators. In the foundation of large number of parameters analysis, the influence of the span ratio, span, boundary conditions and initial imperfection on the ultimate bearing capacity and instable dynamic failure are discussed in details. All the results will provide mass of data to the investigation of failure mechanism and the property under complex dynamical loads.

ABSTRACT: In the present paper the non-linear buckling analysis of functionally graded spherical shells subjected to external pressure is investigated. The material properties are graded in the thickness direction according to the power-law distribution in terms of volume fractions of the constituents of the material. In the formulation of governing equations geometric non-linearity in all strain-displacement relations of the shell is considered. Using Bubnov-Galerkin's method to solve the problem an approximated analytical expression of
non-linear buckling loads of functionally graded spherical shells is obtained, that allows easily to investigate stability behaviors of the shell.

ABSTRACT: This paper presents an analytical approach to investigate the nonlinear buckling and post- buckling of thin annular spherical shells made of functionally graded materials (FGM) and subjected to mechanical load and resting on Winkler-Pasternak type elastic foundations. Material properties are graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of constituents. Equilibrium and compatibility equations for annular spherical shells are derived by using the classical thin shell theory in terms of the shell deflection and the stress function. Approximate analytical solutions are assumed to simply supported boundary conditions and Galerkin method is applied to obtain closed-form of load-deflection paths. An analysis is carried out to show the effects of material and geometrical properties and combination of loads on the stability of the annular spherical shells.

ABSTRACT: In this article, stability of composite conical shells subjected to dynamic external pressure is investigated by numerical and experimental methods. In experimental tests, cross-ply glass woven fabrics were selected for manufacturing of specimens. Hand-layup method was employed for fabricating the glass-epoxy composite shells. A test-setup that includes pressure vessel and data acquisition system was designed. Also, numerical analyses are performed. In these analyses, effect of actual geometrical imperfections of experimental specimens on the numerical results is investigated. For introducing the imperfections to the numerical models,
linear eigen-value buckling analyses were employed. The buckling modes are multiplied by very small numbers that are derived from measurement of actual specimens. Finally, results are compared together while a good agreement between results of imperfect numerical analyses and experimental tests is observed.

“Chapter 2 Buckling of free pipe under external pressure”

ABSTRACT: In separated-type water tunnel structure, when the point supported steel liner is subjected to the uniform external pressure, the contact between tunnel lining and liner is difficult to happen because the developed compressive hoop thrust in pipe only shortens the circumference of liner and then enlarges the gap between liner and host. Therefore, the buckling of the uniformly point supported liner can be considered a rotary symmetric buckling likely the buckling of free pipe under external pressure. In this chapter, the buckling of free pipe is investigated.

ABSTRACT: The stability problem of a circular cylindrical shell composed of functionally graded materials with elasticity modulus varying continuously in the thickness direction under combined external pressure and axial compression loads is studied in this paper. The formulation is based on the first-order shear deformation theory. A load interaction parameter is defined to express the combination of applied axial compression and external pressure. The stability equations are derived by the adjacent equilibrium criterion method. These equations are employed to analyze the buckling behavior and obtain the critical buckling loads. A detailed
A numerical study is carried out to bring out the effects of the power law index of functionally graded material, load interaction parameter, thickness ratio, and aspect ratio on the critical buckling loads. The validity of the present analysis was checked by comparing the present results with those results available in literature.

ABSTRACT: This paper presents the stability of two-dimensional functionally graded (2D-FG) cylindrical shells subjected to combined external pressure and axial compression loads, based on classical shell theory. The material properties of functionally graded cylindrical shell are graded in two directional (radial and axial) and determined by the rule of mixture. The Euler’s equation is employed to derive the stability equations, which are solved by GDQ method to obtain the critical mechanical buckling loads of the 2D-FG cylindrical shells. The effects of shell geometry, the mechanical properties distribution in radial and axial direction on the critical buckling load are studied and compared with a cylindrical shell made of 1D-FGM. The numerical results reveal that the 2D-FGM has a significant effect on the critical buckling load.

ABSTRACT: Fire safety design of building structures has received greater attention in recent times due to continuing losses of properties and lives in fires. However, the structural behaviour of thin-walled cold-formed steel columns under fire conditions is not well understood despite the increasing use of light gauge steels in building construction. Cold-formed steel columns are often subject to local buckling effects. Therefore a series of laboratory tests of lipped and unlipped channel columns made of varying steel thicknesses and grades was undertaken at uniform elevated temperatures up to 700°C under steady state conditions. Finite element models of the tested columns were also developed, and their elastic buckling and nonlinear analysis results were compared with test results at elevated temperatures. Effects of the degradation of mechanical properties of steel with temperature were included in the finite element analyses. The use of accurately measured yield stress, elasticity modulus and stress-strain curves at elevated temperatures provided a good comparison of the ultimate loads and load-deflection curves from tests and finite element analyses. The commonly used effective width design rules and the direct strength method at ambient temperature were then used to predict the ultimate loads at elevated temperatures by using the reduced mechanical properties. By comparing these predicted ultimate loads with those from tests and finite element analyses, the accuracy of using this design approach was evaluated.

ABSTRACT: The flexibility of connection between the steel plate and concrete slab gives rise to interface slip and additional deflection. A method of analysis for steel-concrete composite plate with slip effect resulting from studs is presented. The basic idea is to place a hypothetical thin shear-layer between steel and concrete slab, where all the shear deformation is concentrated in the thin layer. Analytical solutions for elastic critical buckling load of composite plate considering slip effect under axial compressive and pure shear are derived. The theory model and the solutions are then validated by means of three-dimensional finite element analysis.

ABSTRACT: Cold-formed steel members are increasingly used as primary structural elements in the building industries around the world due to the availability of thin and high strength steels and advanced cold-forming technologies. Cold-formed lipped channel beams (LCB) are commonly used as flexural members such as floor joists and bearers. However, their shear capacities are determined based on conservative design rules. For the shear design of LCB web panels, their elastic shear buckling strength must be determined accurately including the potential post-buckling strength. Currently the elastic shear buckling coefficients of LCB web panels are determined by assuming conservatively that the web panels are simply supported at the junction between their flange and web elements. Hence finite element analyses were conducted to investigate the elastic shear buckling behavior of LCBs. An improved equation for the higher elastic shear buckling coefficient of LCBs was proposed based on finite element analysis results and included in the ultimate shear capacity equations of the North American cold-formed steel codes. Finite element analyses show that relatively short span LCBs without flange restraints are subjected to a new combined shear and flange distortion action due to the unbalanced shear flow. They also show that significant post-buckling strength is available for LCBs subjected to shear. New equations were also proposed in which post-buckling strength of LCBs was included.

ABSTRACT: The concept of buckling control using piezoelectric actuators is illustrated in Figure 1 and Figure 2. The slender column has a PZT strip pasted at the center, to apply a moment counteracting the moment due to the externally applied axial load. The actuator moment is produced when an actuating voltage is applied to the PZT as shown in Figure 1. The actuator moment enable the column to maintain its un deflected shape and thus achieve an increase in the load carrying capacity (capacity of the column for given lateral deflection) of the column.

ABSTRACT: In the design of plate girder web panels, it is required to evaluate accurately the elastic buckling strength under shear, whether or not the post-buckling strength is accounted for. Currently, elastic shear buckling coefficients of web panels stiffened by transverse intermediate stiffeners are determined by assuming conservatively that web panels are simply supported at the juncture between the flange and web. However, depending upon the geometry and the properties of the plate girder, the elastically restrained support may behave rather closer to a clamped support. In the present study, a series of numerical analyses based on a three-dimensional finite element modeling is carried out to investigate the effects of the geometric parameters on the boundary conditions at the juncture, and the resulting data are quantified in a simple design equation.

ABSTRACT: Buckling control of space structures using piezoelectric actuators is an emerging area of research. In particular, cylindrical shells present several challenges as they exhibit multiple buckling modes. This work focuses on placement of ring actuators on cylindrical shells exhibiting axisymmetric buckling. A new method based on the characteristic wavelength of the cylindrical shell is proposed for actuator placement. It is shown by means of numerical studies that passive control of these shells shows a distinct advantage over the conventional actuator placement. It is possible to obtain a stiffer load–axial shortening response as well as a peak load enhancement of the shell using the present approach. The results obtained give important insights into the actuator placement problem for cylindrical shells undergoing axisymmetric buckling.

ABSTRACT: The buckling behaviors as well as the load transfer mechanisms between the shells of double-walled nanotubes (DWNTs) are investigated through a series of molecular dynamics simulations. When buckling occurs, the strain energy of cross-linked (defective) DWNTs undergoes a modest transition indicating that energy gathered in one shell is shared by the other through the inter-shell crosslinks. It is confirmed that the compressive stress applied to the outer shell can be efficiently transferred to the inner shell through the covalent bonds between shells resulting in a uniform load distribution. The existence of inter-shell crosslinks leads to dramatic decreases of the sustainable loads and modest decreases of the Young’s modulus. The computational studies imply that the crosslinks can improve the loading conditions and reduce strain energy in carbon nanotubes based nanocomposites and nanoelectromechanical systems.

ABSTRACT: Low cost and less weight are the two primary objectives of any aircraft structure. Efficient design of aircraft components is therefore, required to reduce cost and weight of the aircraft structure. For components with compressive loading, ribs and stringer spacings and stringer cross-section play a major role in achieving less weight. The main objective of the present study was aimed at establishing optimum stringer and ribs spacings and stringer cross-section for minimum weight of buckling design driven components using FEM packages. The analysis of effect of plate with ribs and stringer spacing was modeled in FEM to study the effect of these on the weight of aircraft structure using aluminum as material. The analysis was carried out through linear buckling analysis of the model. The software tools used were HyperMesh as a pre and post processor and Radioss as a solver.

ABSTRACT: A mixed atomistic and continuum model is applied to carbon nanotubes in order to study their buckling behavior. Herein the term “atomistic” refers to the underlying constitutive model that is formulated on the basis of interatomic potentials, whereas “continuum” means the application of the Cauchy-Born rule, which links the bond vectors before and after deformation via the deformation gradient of the continuum. Because the bond vectors are not infinitesimal and the continuum is modeled as surface, the Cauchy-Born rule has to be appropriately adapted to crystalline sheets. This is done via an exponential mapping in a new and surprisingly simple form such that in the analysis the current configuration has never to be left. The numerical buckling analysis of carbon nanotubes using the mixed atomistic and continuum model is carried out by means of the finite element method. For this purpose the linearization of the equilibrium equations is provided.

ABSTRACT: The effect of fibre orientation on buckling behaviour in a rectangular composite laminate with central circular hole under uniform in-plane loading has been studied by using finite element method. The critical buckling loads with different fibre orientation in an orthotropic composite laminate (E-glass/epoxy) were obtained. The deformation behaviour of the plate is shown for modes, i=1,2. Studies are carried out for three D/A ratio (where D is hole diameter and A is plate width) with different plate thickness (number of layers). The finite element formulation is carried out in the analysis section of the ANSYS software.

References listed at the end of the paper:
ABSTRACT: The present research work is to determine the buckling load in FRP (fibre reinforced plastic) thin cylinder, which is subjected to uniaxial compression using 2-D finite element analysis. The commercial finite element analysis software ANSYS has been successfully executed and the finite element model is validated. The buckling load is evaluated by varying the boundary conditions, length to diameter ratio \((L/d)\), thickness to diameter ratio \((h/d)\) and number of layers \((n)\). The effect of boundary conditions, \((L/d)\), \((h/d)\), \((n)\) on the buckling load is discussed. The results show that buckling load is more in clamped-clamped boundary condition, decreases with increase in length to diameter ratio, increases with increase in thickness to diameter ratio and remains constant with number of layers.

ABSTRACT: In this paper the meshless local Petrov-Galerkin (MLPG) method is implemented to study the buckling of isotropic cylindrical shells under axial load. Displacement field equations, based on Donnell and first order shear deformation theory, are taken into consideration. The set of governing equations of motion are numerically solved by the MLPG method in which according to a semi-inverse method, a new variational trial-functional is constructed to derive the stiffness matrices and critical buckling loads are obtained in various boundary conditions. The moving least squares interpolation is employed to construct both trial and test functions. The present method is a truly meshless method based on a number of randomly located nodes upon which no global background integration mesh is needed and no element matrix assembly is required. In the present MLPG formulation, a local variational form is constructed over a local sub-domain instead of using the conventional weighted-residual procedure. The influences of some commonly used boundary conditions and effects of shell geometrical parameters are studied. The results show the convergence characteristics and accuracy of the mentioned method.

In this paper, based on the viscoelastic theory, the creep buckling and post-buckling behaviors of a viscoelastic functionally graded material (FGM) cylindrical shell with initial deflection subjected to a uniform in-plane load are investigated. The material properties of the viscoelastic FGM cylindrical shell are assumed to vary through the structural thickness according to a power law distribution of the volume fraction of constituent materials and Poisson's ratio is assumed as a constant. Considering the transverse shear deformation and geometric nonlinearity, the constitutive relation of the viscoelastic FGM cylindrical shell is established. By means of the Newton-Newmark method and the Boltzmann superposition principle, the problem for the creep buckling and post-buckling of the FGM cylindrical shell is solved. The numerical results reveal that the transverse shear deformation, volume fraction and geometric parameters have significant effects on the creep buckling and post-buckling of the viscoelastic FGM cylindrical shell.

ABSTRACT: Based on the Talreja’s tensor valued internal state variables damage model and the Helmhotlz free energy of piezoelectric material, the constitutive relations of the piezoelectric plates with damage are derived. Then, the nonlinear dynamic equations of the piezoelectric plates considering damage are established. By using the finite difference method and the Newmark scheme, these equations are solved and the effects of damage and electric loads on the nonlinear dynamic response of piezoelectric plates are discussed.

ABSTRACT: In this work, a fully geometrically nonlinear dynamic finite element (FE) model, which considers the kinematics of small strains but large rotations, is developed for transient analysis of piezolaminated thin-walled structures based on first-order shear deformation (FOSD) hypothesis. Linear electro-mechanically coupled constitutive equations and the assumption of linearly distributed electric potential through the thickness of the piezoelectric layers are employed. An eight-node quadrilateral plate/shell element with five mechanical degrees of freedom (DOFs) per node and one electrical DOF per smart layer is adopted in the finite element formulation. The second order differential dynamic equation is solved by the central difference algorithm. The mathematical method is validated by transient analysis of three different examples of a beam, a plate, and a cylindrical shell. The results illustrate that the geometrical nonlinearity affects the structural dynamic responses

ABSTRACT: Subjected to external pressure, buckling analysis is key problem in the roof shell design of large scale cylinder gasholder. Two simplified buckling analysis methods, the continuous orthotropic plate method and the split-rigidity method, are introduced to check the general instability of stiffened spherical shallow shell. Considering the plate and the stiffeners in two directions with the same contribution to the bending stiffness, the equivalent bending thickness formula is put forward. The finite element model for a 100,000 m³ cylinder gasholder roof is setup. The buckling critical loads obtained prove that the split-rigidity analysis method and formulae are applicable. The results can be referred in design of stiffened spherical shallow shell.

ABSTRACT: Spider silk is extraordinarily strong, mollusk shells and bone are tough, and porcupine quills and feathers resist buckling. How are these notable properties achieved? The building blocks of the materials listed above are primarily minerals and biopolymers, mostly in combination; the first weak in tension and the second weak in compression. The intricate and ingenious hierarchical structures are responsible for the outstanding performance of each material. Toughness is conferred by the presence of controlled interfacial features (friction, hydrogen bonds, chain straightening and stretching); buckling resistance can be achieved by filling a slender column with a lightweight foam. Here, we present and interpret selected examples of these and other biological materials. Structural bio-inspired materials design makes use of the biological structures by inserting synthetic materials and processes that augment the structures' capability while retaining their essential features. In this Review, we explain this idea through some unusual concepts.

“Bio-inspired structural bistability employing elastomeric origami for morphing applications”, Smart Mater.
Struct. Vol. 23, No. 12, 125011, 2014
ABSTRACT: A structural concept based upon the principles of adaptive morphing cells is presented whereby
controlled bistability from a flat configuration into a textured arrangement is shown. The material consists of
multiple cells made from silicone rubber with locally reinforced regions based upon kirigami principles. On
pneumatic actuation these cells fold or unfold based on the fold lines created by the interaction of the geometry
with the reinforced regions. Each cell is able to maintain its shape in either a retracted or deployed state, without
the aid of mechanisms or sustained actuation, due to the existence of structural bistability. Mathematical
quantification of the surface texture is introduced, based on out-of-plane deviations of a deployed structure
compared to a reference plane. Additionally, finite element analysis is employed to characterize the geometry
and stability of an individual cell during actuation and retraction. This investigation highlights the critical role
that angular rotation, at the center of each cell, plays on the deployment angle as it transitions through the
elastically deployed configuration. The analysis of this novel concept is presented and a pneumatically actuated
proof-of-concept demonstrator is fabricated.

“Performance Testing of Underground Storage Tank against Buckling”, ASCE Pipelines 2012: pp. 1-10, doi:
10.1061/9780784412480.001
ABSTRACT: The Steel Tank Institute (STI) performed testing to demonstrate the stiffening effects from the
soil-structure interface with an underground storage tank. The test demonstrated the importance of the soil in
calculating the resistance to buckling in a buried environment. Current third party listing agencies do not take
the stiffening effect of the soil support into consideration with standardized steel wall thickness calculations.
Performance characteristics of a tank are similar to pipelines, although the tank heads provide additional
stiffness to the structure. As a result, atmospheric tank wall thicknesses are thinner than typical pressurized
potable water pipelines. Tanks are normally buried 4'-5' at petroleum service stations, however, sometime the
tanks need to be buried deeper. STI buried a 64 inch diameter by 24 foot long steel tank 7 foot below grade,
compacting the angular gravel backfill during placement to grade. A camera was placed in the tank to record
deformations during the actual test. The excavation was filled with water such that the bottom of the tank was
subjected to 12 feet-4 inches of static water head pressure. A vacuum pump was connected to a tank riser and a
vacuum was pulled. The intent was to pull the vacuum until the tank buckled. A vacuum of 16.5 inches Hg was
established and the pump was unable to pull additional vacuum. The backfill was removed and the tank
examined and the video of the inside of the tank reviewed. The tank did not buckle. The shell did not deform.
The heads experienced approximately 2 inches of permanent deformation. Calculations indicate that the tank
was subjected to a 15.0 psi total buckling load. Formulations suggest that the soil-structure would provide
resistance to buckling up to 21.0 psi. Third party standard formulations that do not take the soil support into
consideration suggest that the tank would buckle in a range from 1.3 psi to 6.0 psi. The test clearly demonstrates the importance of the soil in calculating the resistance to buckling in a buried environment. The soil-structure interaction provides significant additional stiffness to the structure, whether the structure is a pipeline or a tank, as demonstrated in this test.

ABSTRACT: A finite differences procedure is used to study the buckling of non-trivial equilibrium solutions for open thin-walled beams in a dynamic setting. A direct one-dimensional model with a coarse descriptor of warping is adopted. The algorithm describes non-trivial equilibrium paths by integrating discretized field equations, suitably written in terms of velocities. Some benchmark cases under conservative loading are discussed. Known results for the first critical loads are found to validate the procedure. New results are found accounting for non-trivial equilibrium paths, thus providing an estimate for the error made by linearizing around trivial equilibrium paths. The effect of warping on the critical loads is also investigated.

ABSTRACT Large crystalline molecular shells, such as some viruses and fullerenes, buckle spontaneously into icosahedra. Meanwhile multicomponent microscopic shells buckle into various polyhedra, as observed in many organelles. Although elastic theory explains one-component icosahedral faceting, the possibility of buckling into other polyhedra has not been explored. We show here that irregular and regular polyhedra, including some Archimedean and Platonic polyhedra, arise spontaneously in elastic shells formed by more than one component. By formulating a generalized elastic model for inhomogeneous shells, we demonstrate that coassembled shells with two elastic components buckle into polyhedra such as dodecahedra, octahedra, tetrahedra, and hosohedra shells via a mechanism that explains many observations, predicts a new family of polyhedral shells, and provides the principles for designing microcontainers with specific shapes and symmetries for numerous applications in materials and life sciences.

ABSTRACT: We explore the effects of line tension on the shape of two component elastic shells. Segregation between components with different elastic properties combined with the subtleties related to the spherical topology leads to a rich variety of shapes. They range from irregular polyhedra at weak segregation to Janus-like morphologies with spherical and buckled regions coexisting on the same shell for large values of the line
tension. We use Monte Carlo simulations to map a detailed phase diagram as a function of the relative fraction of the two components, the ratio of their bending rigidities, and the strength of the line tension.

ABSTRACT: The structural stability of thin-walled steel tanks becomes a major safety issue when these operate at low levels of contained liquid. Despite numerous tank failures due to buckling of their circumferential shell, provisions in current codes do not provide cost-efficient or high-safety-level solutions regarding this phenomenon. For example, the American standard API 650, which has worldwide applications, proposes only an empirical design method for stiffening the tank shell based on its thickness, height and the design wind velocity. More recent codes, such as the European standard EN1993-1-6, provide analytical relationships for evaluating the buckling resistance of shells, with stability being verified by relevant checks against appropriate design stresses. However, their provisions have not yet seen many field applications and results raise, in certain cases, doubts regarding the efficiency of the design. This paper presents a direct comparison between these two standards by attempting to evaluate the buckling resistance of two existing thin-walled steel tanks, filled at a low liquid level. Both tanks have large diameters (47m and 88m approximately), variable wall thickness, are self-supported (unanchored) and one of them supports a conical roof. The design stresses required by EN1993-1-6 were obtained from finite element simulations of the tanks (linear elastic analyses were performed) which included application of the actions specified in the provisions of the Eurocode. Results from both standards are discussed in detail, comparisons are made and discrepancies between the two standards are highlighted. Comments and conclusions to be drawn will help improve current specifications and resolve issues related to the safe design of liquid storage tanks filled at low liquid levels.

ABSTRACT: Review of the literature on first-ply failure of composite shells shows that research reports on first-ply failure of moderately thin, laminated composite cylindrical shell panels, using a geometrically nonlinear approach, are not available. The present paper aims to fill this deficiency. It uses a finite-element code developed using eight-noded, doubly-curved elements combined with modified Sanders’ first-approximation theory for thin shells and von Kármán-type nonlinear strains. The accuracy of the present geometric nonlinear and first-ply failure formulations are verified separately through solutions of two benchmark problems. Failure loads, failure modes (for individual stress or strain failure) or tendencies (for interactive stress failures), and the locations from where the failures initiate are reported. The results are discussed critically to formulate design guidelines, suggesting practical values for factors of safety applicable to failure loads. Such suggestions also consider the serviceability requirements.

ABSTRACT: Theoretical bases of methods and algorithms developed for the analysis of stability and post critical behavior of thin elastic shells. The problem of numerical analysis the nonlinear deformation processes of spherical domes under the uniform external pressure is discusses. Describes the computer algorithm based on the parameter continuation method, using the technique of subspaces of the of the control parameter subspace changing. Efficiency of the proposed approach is illustrated by same examples.

ABSTRACT: The purpose of this paper is to analyse the nonlinear flexural behaviour of laminated curved panel under uniformly distributed load. The study has been extended to analyse different types of shell panels by employing the newly developed nonlinear mathematical model. We have developed a novel nonlinear mathematical model based on the higher order shear deformation theory for laminated curved panel by taking the geometric nonlinearity in Green-Lagrange sense. In addition to that all the nonlinear higher order terms are considered in the present formulation for more accurate prediction of the flexural behaviour of laminated panels. The sets of nonlinear governing equations are obtained using variational principle and discretised using nonlinear finite element steps. Finally, the nonlinear responses are computed through the direct iterative method for shell panels of various geometries. The importance of the present numerical model for small strain large deformation problems has been demonstrated through the convergence and the comparison studies. The results
give insight into the laminated composite panel behaviour under mechanical loading and their deformation behaviour. The effects of different design parameters and the shell geometries on the flexural responses of the laminated curved structures are analysed in detail. It is also observed that the present numerical model are realistic in nature as compared to other available mathematical model for the nonlinear analysis of the laminated structure.

ABSTRACT: An approach for estimating critical buckling strain of pipe subjected plastic bending is established in the present paper. A rigid—perfectly plastic material model and cross section ovalization of pipe during bending are employed for the approach. The energy rates of the ovalised pipe bending and the cross section ovalising are proposed firstly. Furthermore, these energy rates are combined to perform the buckling analysis of pipe bending, an estimation formula of critical buckling strain for pipe subjected plastic bending is proposed. The predicting result of the new critical buckling strain formula is compared with the available experimental data, it shows that the formula is valid.

ABSTRACT: Flat top and hemispherical shaped shells made by press forming were deformed by indentation using flat or round headed indentor. Effect of the shell shape, sheet thickness, indentor shape and the speed on the deformation behavior was investigated. The material was mild steel SPCE or aluminum alloy A5052. Speed effect of SPCE on the indentation force became remarkably large, when the indenting or loading direction was reversed to that in the forming. It was small for A5052 material. Energy absorption performance was also evaluated in considering the mass of the shell, which is used as an index for the light-weight structure design. The energy absorption efficiency was highest for case of the flat top shell indented by flat headed indentor. Almost constant collapse force was obtained when the spherical shell was deformed with hemispherical indentor.

ABSTRACT: The choice of finite element to use in order to predict nonlinear static or dynamic response of complex structures becomes an important factor. Then, the main goal of this research work is to focus a study on the effect of the in-plane rotational degrees of freedom in linear and geometrically non linear static and dynamic analysis of thin shell structures by flat shell finite elements. In this purpose: First, simple triangular and quadrilateral flat shell finite elements are implemented in an incremental formulation based on the updated lagrangian corotational description for geometrically nonlinear analysis. The triangular element is a combination of DKT and CST elements, while the quadrilateral is a combination of DKQ and the bilinear quadrilateral membrane element. In both elements, the sixth degree of freedom is handled via introducing fictitious stiffness. Secondly, in the same code, the sixth degrees of freedom in these elements is handled differently where the in-plane rotational d.o.f is considered as an effective d.o.f in the in-plane filed interpolation. Our goal is to compare resulting shell elements. Third, the analysis is enlarged to dynamic linear analysis by direct integration using Newmark’s implicit method. Finally, the linear dynamic analysis is extended to geometrically nonlinear dynamic analysis where Newmark’s method is used to integrate equations of motion and the Newton-Raphson method is employed for iterating within each time step increment until equilibrium is achieved. The obtained results demonstrate the effectiveness and robustness of the interpolation of the in-plane rotational d.o.f. and present deficiencies of using fictitious stiffness in dynamic linear and nonlinear analysis.

ABSTRACT: A simple, effective finite element incremental formulation and procedure for geometrically nonlinear static and dynamic analysis of a shell structure with finite rotations are presented, based on both the total Lagrangian and updated Lagrangian description of motion. The co-rotation formulation is used for finite rotation. The element employed here to implement the present method is a faceted shell element with Loof nodes (DKL + LST). An incremental iterative method based on the constant arc length method in conjunction with Newton-Raphson method is implemented in the present study for static and Newmark's integration scheme for dynamic analysis. To demonstrate the accuracy and efficiency of the formulations and to compare the difference between the total and updated Lagrangian formulation, numerical studies are presented.

ABSTRACT: A simple and effective finite element incremental formulation based on the updated lagrangian corotational description for geometrically nonlinear dynamic analysis of shell structure is presented in this work. The flat shell element used is the classical four-node quadrilateral DKQ shell finite element, combined with the improvements of the in-plane behaviour by incorporation of the drilling rotation degree of freedom. The main goal is to have a good flat shell element of quadrilateral geometry, leading to reliable solutions in linear and geometrically nonlinear dynamic analysis. The Newmark’s direct time integration method is adopted to integrate the equations of motion, while the Newton–Raphson method is used for iterating within each time step increment until equilibrium is achieved. The results obtained through a series of selected examples demonstrate the effectiveness of the used shell finite element to predict the nonlinear dynamic response of...
complex structures, and the robustness of this nonlinear dynamic investigation taking account of both linear and non-linear dynamic problems.

Chrysanthos Maraveas (School of Mechanical, Aerospace and Civil Engineering, University of Manchester, Manchester, M13 9PL, UK and C. Maraveas Partnership Consulting Engineers, 11 Metsovou street, Athens, 10682, Greece). “Thermal buckling analysis of thin-walled steel oil tanks exposed to an adjacent fire”, 23rd australiasian Conference on the Mechanics of Structures and Materials (ACMSM23), Byron Bay, Australia, 9-12 December 2014, S.T. Smith (Ed.)

ABSTRACT: This paper presents a finite element study of a steel oil storage tank with cylindrical shell shape and conical roof subjected to an adjacent fire. Fire is one of the main hazards associated with tanks containing combustible materials. Several catastrophic accidents have taken place during the last decades revealing the consequences and losses arising from such events and highlighting the importance for proper design against thermal buckling. Oil storage tanks are usually placed in large groups and closed distances. Therefore, it is assumed herein that the fire occurs outside the tank. Critical buckling temperatures are calculated considering that the temperature profile along the circumference of the tank is defined according to a cosine square distribution. The influence of the roof stiffness, of the circumferential area exposed to fire and of the filling level is examined. Apart from the thermal loads, the self-weight of the tank and the hydrostatic pressure exerted by the liquid are taken into account in the static analyses. The mechanical properties of steel are taken according to Eurocode 3.

PARTIAL ABSTRACT: Fire is one of the main hazards associated with storage tanks containing flammable liquids. These tanks are usually closely spaced and in large groups, so where a petroleum fire occurs, adjacent tanks are susceptible to damage leading to further development of the fire. The structural behaviour such as thermal stability and failure modes of the tanks under such fire scenario are very important to the safety design and assessment of oil depots. However, no previous studies on this problem are known to the best knowledge of the author. This thesis presents a systematic exploration of the potential thermal and structural behaviours of an oil tank when one of its neighbour tanks is on fire. Under such scenario, the oil tanks are found to easily buckle under rather moderate temperature rises. The causes of such buckling failures are the reduced modulus of steel
at elevated temperatures, coupled with thermally-induced stresses due to the restraint of thermal expansion. Since the temperatures reached in such structures can be several hundred Centigrade degrees, any restraint to thermal expansion can lead to the development of compressive stresses. The high susceptibility of thin shell structures to elastic buckling under low compressive stresses means that this type of failure can be easily provoked. The main objectives of this thesis were to reveal the thermal distribution patterns developed in an oil tank under the heating from an adjacent tank fire, to understand the underlying mechanism responsible for the buckling of tank structure, and to explore the influences of various thermal and geometrical parameters on the buckling temperature of the tanks. The study began with analytical solutions for stresses and deformations in a partially filled roofless cylindrical tank under an idealised axisymmetrical heating regime involving thermal discontinuity at the liquid level. The results demonstrate that large compressive circumferential membrane stresses occur near the bottom boundary for an empty tank and near the liquid level for a partially-filled tank.

ABSTRACT: Structural stability is a major consideration in the design of lightweight shell structures. However, the theoretical predictions of geometrically perfect structures often considerably over predict the buckling loads of inherently imperfect real structures. It is reasonably well understood how the shell geometry affects the imperfection sensitivity of axially compressed cylindrical shells; however, the effects of shell anisotropy on the imperfection sensitivity is less well understood. In the present paper, the development of an analytical model for assessing the imperfection sensitivity of axially compressed orthotropic cylinders is discussed. Results from the analytical model for four shell designs are compared with those from a general-purpose finite-element code, and good qualitative agreement is found. Reasons for discrepancies are discussed, and potential design implications of this line of research are discussed.

ABSTRACT: Thin-walled cylindrical shell structures often have buckling as the critical failure mode, and the buckling of such structures can be very sensitive to small geometric imperfections. The buckling analyses of an 8-ft-diameter, 10-ft-long honeycomb-core composite cylinder loaded in pure axial compression is discussed in this document. Two loading configurations are considered: configuration 1 uses simple end conditions, and configuration 2 includes additional structure that may more closely approximate experimental loading conditions. Linear eigenvalue buckling analyses and nonlinear analyses with and without initial geometric imperfections were performed on both configurations. The initial imperfections were introduced in the shell by applying a radial load at the midlength of the cylinder to form a single inward dimple. The critical bifurcation buckling loads are predicted to be 924,190 lb and 924,020 lb for configurations 1 and 2, respectively. Nonlinear critical buckling loads of 918,750 lb and 954,900 lb were predicted for geometrically perfect configurations 1 and 2, respectively. Lower-bound critical buckling loads for configurations 1 and 2 with radial perturbations were found to be 33% and 36% lower, respectively, than the unperturbed critical loads. The inclusion of the load introduction cylinders in configuration 2 increased the maximum bending-boundary-layer rotation up to 11%.
ABSTRACT: The objective of the present paper is to investigate the bending, buckling and vibration behaviors of carbon nanotube-reinforced composite (CNTRC) beams. The beams resting on the Pasternak elastic foundation, including a shear layer and Winkler spring, are considered. The single-walled carbon nanotubes (SWCNTs) are aligned and distributed in polymeric matrix with different patterns of reinforcement. The material properties of the CNTRC beams are estimated by using the rule of mixture. Various shear deformation theories are employed to deal with the problems. The mathematical models provided in this paper are numerically validated by comparison with some available results. New results of bending, buckling and vibration analyses of CNTRC beams based on several higher-order shear deformation theories are presented and discussed in details. Several aspects of beam types, spring constant factors, carbon nanotube volume fraction, etc., are taken into investigation.

ABSTRACT: The paper presents a framework for design and optimization of curvilinear stiffened panels with any cross-section shape of stiffener. Within this framework, the weight of stiffened panel applied complex loads, is minimized under the constraints of structural responses include global buckling, maximum stress and crippling. Then, a stiffened panel with two blade curvilinear stiffeners is optimized using this framework, and the optimum performs better than another existing design. Finally, it is concluded that stiffening beam is suitable for simulate stiffener sustains part of applied load directly.

ABSTRACT: Since the subpanels of polygonal-section shell have the corners of an obtuse angle larger than 90 degree unlike general plate or box-section structures, this could have an influence on forming nodal lines against local plate buckling or stress distributions. However, there is not sufficient material in the relevant study results or design recommendations. The very feasible models of the initial imperfections were acquired through the literature studies and then the parametric studies were conducted along with the initial imperfection models by using the finite element method. The parameters like the size of residual stresses, the portion of compressive residual stresses, and steel grades were considered. From the parametric studies, it was found that the maximum residual stress is more influential factor than the distribution pattern of residual stresses. In addition, The design strength equations for the simply supported plates can be applicable to the determination of the local buckling strength of the polygonal cross-section shell structures.

Byung H. Choi, Choi Su-Young, Park Sang-Kyun (Dept. of Civil and Environmental Engineering, Hanbat National University, Korea), “Buckling analysis of laminated composite plates longitudinally stiffened with U-

ABSTRACT: Even though the longitudinally stiffened laminated composite plates with closed section ribs should be an effective system for axially compressed members, the existing researches on the applications of closed-section ribs, especially for the laminated composite plates, are not sufficient. This study is aimed to examine the influence of the sectional stiffness of U-shaped ribs on the buckling modes and strengths of laminated composite plates. Applying the orthotropic plates with eight layers of the layup [(0°)4]s and [(0°/90°)2]s, 3-dimensional finite element models for the U-rib stiffened plates were setup by using ABAQUS and then a series of eigenvalue analyses were conducted. From the parametric studies, the minimum required ply thicknesses as well as the buckling strengths were presented for the analysis models. The buckling strengths were compared with the theoretical critical stress equation for simply supported plates based on the Classical laminated plate theory. This study will contribute to the future study for evaluating the minimum required stiffness and optimum design of U-rib stiffened plates.

ABSTRACT: In the present study, an Element-Based Lagrangian Formulation for the nonlinear analysis of shell structures is presented. The strains, stresses and constitutive equations based on the natural co-ordinate have been used throughout the Element-Based Lagrangian Formulation of the present shell element which offers an advantage of easy implementation compared with the traditional Lagrangian Formulation. The Element-Based Lagrangian Formulation of a 9-node resultant stress shell element is presented for the anisotropic composite material. The element is free of both membrane and shear locking behavior by using the assumed natural strain method such that the element performs very well in thin shell problems. The arc-length control method is used to trace complex equilibrium paths in thin shell applications. Numerical examples for laminated composite curved shells presented herein clearly show the validity of the present approach and the accuracy of the developed shell element.

Introduction

Conical shells occur frequently as components of aeronautic, marine and civil engineering structures. Often they are frequently used as transition elements joining cylinders of different diameters. Buckling and loss of stability of stiffened conical shells is one of the most important and crucial failure phenomena of such structures. It is well known that stability of conical shells is one of the most important and crucial failure phenomena of such structures.

ABSTRACT: The purpose of this paper is to describes the fabrication and testing of the grid stiffened composite conical shells. This paper presents the rib influence on the buckling behavior of filament wound, grid stiffened composite conical shells subjected to axially compressive load. A cheap and quick manufacturing process is presented. The buckling behavior of a grid stiffened composite conical shell is investigated by experiment and finite element analysis. The conical shells used in experiment are made from glass/epoxy by filament winding machine. The specimen was tested under pure axial compression based on the ASTM standard with a cross-head speed of 1 mm/min. The axial load versus the axial displacement curve for the specimen was recorded using the X-Y recorder available in the INSTRON testing system. The initial buckling load was obtained in stage. Using ABAQUS commercial finite element software for finite element analysis. Finite element modeling of the grid stiffened composite is carried out with eight node 3D layered brick elements and the skin is modeled with four node shell elements. Results are summarized to identify the performance of this method of grid structures manufacturing. Conclusions are drawn on the efficacies of performance of the grid stiffened composite conical shells. It is seen that there is increase in the buckling load as well specific buckling load indicating a net increase in the efficiency. Introduction Conical shells occur frequently as components of aeronautic, marine and civil engineering structures. Often they are frequently used as transition elements joining cylinders of different diameters. Buckling and loss of stability of stiffened conical shells is one of the most important and crucial failure phenomena of such structures. It is well known that stability of conical shells has...
been studied by many researchers with a variety of shell and plate theories [1-7]. The advent of high strength, light weight, composite materials has resulted in broad use of multi-layered shells. The Filament-wound composite shells of revolution have been extensively applied to the area of aerospace, aircrafts and military industries. The search for lightweight and efficient aerospace structural component is a continuing process. Grid stiffened composite shells a class of shells with very high reliability and mass efficiency. As is evident from the increased number of publications in the recent past, there is a growing interest in the grid stiffened structures. However, on the manufacturing front published literature is somewhat limited. Vasiliev et al. [9-11] have given a brief account on manufacturing, testing and optimization. A description of manufacturing of lattice structures by filament winding along grooves cut in plaster substrate is given by Hou and Gramoll [12]. Totaro and Gurdal [13] have given a numerical optimization of composite lattice structures. An analytical model for the local buckling modeling of isogrid and anisogrid lattice cylindrical shells with triangular cells has been performed by Totaro [14]. Morozov et al. [15] have given a special finite element model for buckling analysis of anisogrid composite lattice conical shells. In this article presents a manufacturing method for making a typical grid stiffened composite conical shell. Furthermore, buckling analysis of stiffened conical shells are present by experimental and finite element methods.

ABSTRACT: A unified analytical approach is applied to investigate the vibrational behavior of grid-stiffened cylindrical shells with different boundary conditions. A smeared method is employed to superimpose the stiffness contribution of the stiffeners with those of shell in order to obtain the equivalent stiffness parameters of the whole panel. Theoretical formulation is established based on Sanders’ thin shell theory. The modal forms are assumed to have the axial dependency in the form of Fourier series whose derivatives are legitimized using Stoke's transformation. A 3D finite element model is also built using ABAQUS software which takes into consideration the exact geometric configuration of the stiffeners and the shell. The achievements from the two types of analyses are compared with each other and good agreement has been obtained. The Influences of variations in shell geometrical parameters, boundary condition, and changes in the cross stiffeners angle on the natural frequencies are studied. The results obtained are novel and can be used as a benchmark for further studies. The simplicity and the capability of the present method are also discussed.

Kolios (Ryerson University, Toronto, Ontario M5B2K3 Canada), “Bifurcation structure of the ultrasonically excited microbubbles undergoing buckling and rupture”, Proceedings of Meetings on Acoustics, Vol. 19, pp. 075097 (June 2013); (6 pages), Conference
ABSTRACT: Bubbles exposed to ultrasound are long known to exhibit highly nonlinear and chaotic dynamics. Bubbles stabilized by a shell material (MBs), are widely used as contrast agents in diagnostic ultrasound. However, the nonlinear behaviour of the shell significantly increases the complexity of the dynamics. In order to realize the full potential of the MBs, better understanding of the MB behaviour is necessary. In this study the bifurcation structure of the MB with nonlinear shell behaviour is investigated for the first time. The Marmottant model was numerically solved and the bifurcation diagrams of the radial oscillations of the MB were plotted versus the control parameters (e.g. buckling radius). In agreement with recent experimental observations, results predict the generation of subharmonics at very low acoustic pressures. In addition, the numerical simulations predict the generation of higher order subharmonics (e.g. period 3) at very low acoustic pressures (<300 kPa and 25 MHz), which contradicts the predictions by free bubble and viscoelastic shell MB models. Results revealed the strong influence of the buckling radius on the order of the subharmonics. The numerical results were verified by experimental observation of higher order subharmonics in the oscillations of Definity at 25 and 55 MHz.

ABSTRACT: An experimental–numerical investigation of the effect of welding residual stress on plastic buckling of axially compressed cylindrical shells with patterned welds is carried out. Two cylindrical shell specimens with different pattern of welds are made according to manufacturing process used in engineering. Their initial geometric imperfections, axial and circumferential strain, buckling load, etc., are experimentally obtained. Inherent strain method used for simulating welding residual stress field is presented. Two different numerical modeling methods for the purpose of evaluating the effect of welding residual stress on plastic buckling are illustrated and the validity is verified by experiment. It is found that, load–displacement curve before buckling is altered, plastic buckling critical load is decreased to some extent, and the buckling deformation such as the number and the uniformity of waveforms of circumferential welds are changed when welding residual stress exists. For the above phenomena, the reason why welding residual stress has an influence on plastic buckling is also quantitatively analyzed from the point of stress variation.

ABSTRACT: Thin-walled structures, when properly designed, possess a high strength-to-weight and stiffness-to-weight ratio, and therefore are used as the primary components in some weight critical structural applications, such as aerospace and marine engineering. These structures are prone to be limited in their load carrying capability by buckling, while staying in the linear elastic range of the material. Buckling of thin-walled structures is an inherently nonlinear phenomena. When the material stays within its linear elastic range, the source of the nonlinearity is purely geometric. Thus, the analysis of nonlinear response of structures, especially thin-walled structures which are buckling sensitive, is important for determining their load carrying capability. For this reason, structural geometric nonlinearities are increasingly taken into account in engineering design. Nowadays, with the expanding computational power of modern computers nonlinear finite element analysis using commercial software is becoming the standard technique used to obtain the nonlinear response of complex structures, however, the repeated analyses that are needed in the design phase are still computationally
intensive, in terms of the computation time required to run large models, even for modern computers. For this reason, reduced order techniques that reduce the problem size are attractive whenever repetitive analyses are required, such as in design optimization. Research on reduced order modeling of the nonlinear response of structures has attracted much attention from researchers. Some analytic techniques constitute very powerful tools for reducing the number of degrees of freedom (DOFs) in a nonlinear system, such as the Rayleigh-Ritz techniques and perturbation techniques. These two reduced basis techniques can be implemented in both analytical and numerical contexts, and due to the modeling versatility of the finite element method (FEM), most researchers prefer to reconstruct them within the FEM context, referred to as reduction methods. There are two families of reduction methods which can be recognized. The first family consists the path-following reduction methods which are based on some analytic techniques to reduce the number of DOFs in the full model and are able to trace the entire nonlinear equilibrium path of structures automatically, while they may find difficulties in the presence of buckling. Koiter reduction methods belong to the second family, and they are very good at handling the buckling sensitive cases due to the use of Koiter’s classical initial postbuckling theory, but the Koiter perturbation approach also limits the validity of these methods to a small range around the bifurcation point. The focus of the research reported in this thesis therefore is to find ways to synthesize the advantages of current reduction methods and obtain a new reduced basis path-following approach. In this thesis, a new approach called the Koiter-Newton (K-N) is presented for the numerical solution of a class of elastic nonlinear structural analysis problems. The method combines ideas from Koiter’s initial post-buckling analysis and Newton arclength methods to obtain an algorithm that is accurate over the entire equilibrium path of structures and efficient in the presence of buckling and/or imperfection sensitivity. The proposed approach is performed in a step by step manner to trace the entire equilibrium path, as is commonly used in the classical Newton arclength method. In every expansion step, the approach works by combining a prediction step using a nonlinear reduced order model (ROM) based on Koiter’s initial postbuckling expansion with a Newton arclength correction procedure. This nonlinear prediction provided by the reduced order model is much better compared to linear predictors used by the classical Newton-Raphson method, thus allowing the algorithm to use fairly large step sizes. The basic premise behind the proposed approach is the use of Koiter’s asymptotic expansion from the beginning rather than using it only at the bifurcation point in contrast to the traditional Koiter approaches. In each asymptotic expansion, the force space is reduced by the span of a set of perturbation loads that are chosen to excite the possible buckling branches. According to the stability of the equilibrium point, at which the asymptotic expansion is applied, different ways for selecting the perturbation loads are proposed. The proposed selection rules guarantee that the expansion step of the proposed approach can be applied at any point along the equilibrium path. The proposed technique requires derivatives of the element load vectors with respect to the degrees of freedom up to the third order. This is two orders more than what is traditionally needed for Newton’s method. To facilitate differentiation, nonlinear elements based on the element independent co-rotational frame are applied in the Koiter-Newton analysis. Automatic differentiation is used to find the derivatives of the co-rotational frame with respect to element degrees of freedom. In this way, full nonlinear kinematics are taken into account when constructing the reduced order model. In some cases, the nonlinear in-plane rotations of structures can be neglected, although the rotations of the normals to the mid-surface are finite. In such cases, Von Karman kinematics, which ignore some nonlinear items in the Green’s strain-displacement relations, possess an acceptable accuracy compared with the full nonlinear kinematics. Hence, the Koiter-Newton approach is also implemented based on Von Karman kinematics to achieve a better computational efficiency. Various numerical examples of beam and shell models are presented and used to evaluate the performance of the method. The Koiter-Newton analyses using the corotational kinematics and the Von K’armán kinematics are accurate and more computational efficient, compared with the results obtained using ABAQUS which adopts a full nonlinear analysis. The improved efficiency demonstrated by the Koiter-Newton technique will open the door to the direct use of detailed nonlinear finite element models in the design
optimization of next generation flight and launch vehicles.

Karol Daszkiewicz, Jacek Chroscielewski and Wojciech Witkowski (Dept. of Structural Mechanics, Civil and Environmental Engineering, Gdansk University of Technology, Gdansk, Poland), “Geometrically nonlinear analysis of functionally graded shells based on 2-D Cosserat constitutive model”, Engineering Transactions, Vol. 62, No. 2, pp 109-130, 2014

ABSTRACT: In this paper geometrically nonlinear analysis of functionally graded shells in 6-parameter shell theory is presented. It is assumed that the shell consists of two constituents: ceramic and metal. The mechanical properties are graded through the thickness and are described by power law distribution. Formulation based on 2-D Cosserat constitutive model is used to derive constitutive relation for functionally graded shells. Numerical results for typical benchmark geometries of smooth and irregular FGM shells under mechanical loading are presented. The influence of power-law exponent and micropolar material constants on the overall behaviour of functionally graded shells is investigated.

ABSTRACT: Buckling-critical launch-vehicle structures require structural concepts that have high bending stiffness and low mass. Fluted-core, also known as truss-core, sandwich construction is one such concept. In an effort to identify an analysis method appropriate for the preliminary design of fluted-core cylinders, the current paper presents and compares results from several analysis techniques applied to a specific composite fluted-core test article. The analysis techniques are evaluated in terms of their ease of use and for their appropriateness at certain stages throughout a design analysis cycle (DAC). Current analysis techniques that provide accurate determination of the global buckling load are not readily applicable early in the DAC, such as during preliminary design, because they are too costly to run. An analytical approach that neglects transverse-shear deformation is easily applied during preliminary design, but the lack of transverse-shear deformation results in global buckling load predictions that are significantly higher than those from more detailed analysis methods. The current state of the art is either too complex to be applied for preliminary design, or is incapable of the accuracy required to determine global buckling loads for fluted-core cylinders. Therefore, it is necessary to develop an analytical method for calculating global buckling loads of fluted-core cylinders that includes transverse-shear deformations, and that can be easily incorporated in preliminary design.

ABSTRACT: Many elliptical shells are used in structural applications in which the dominant loading condition is axial compression. Due to the fact that the radius varies along the cross-section midline, the buckling behavior is more difficult to identify than those of cylindrical shells. The general concerned aspects in cylindrical shell buckling analyses such as the buckling mode, the pre-buckling deformation and post-buckling deformation are all quite different related to specific elliptical shell geometry. The buckling behavior of elliptical cylindrical shells with uniform thickness has been widely studied by many researchers. However, the thickness around the circumference may change for some specific structural forms, the femoral neck for example, which makes the buckling behavior more complex. It is known that the buckling strength of thin cylindrical shells is quite sensitive to imperfections, so it is natural to explore the imperfection sensitivity of elliptical shells. This paper explores the buckling behavior of imperfect elliptical shells under axial compression. It is hoped that the results will make a useful contribution in this field.

ABSTRACT: In this paper, the effect of compressive axial loading on natural frequency of the composite shell and the influences of geometrical parameter and the fiber orientation on the buckling load and natural frequency are studied. Bucking and free vibration of cylindrical laminate composite shell are inspected regarding to three approaches: classical theory of laminate, first order shear deformation, finite element method. The composite is taken into account as orthotropic laminate. Substituting strain-displacement based on Love’s first approximation into strain-stress equation lead to yield equilibrium equations respect to displacement components. The boundary conditions are considered clamp on one side and free on other. The components of displacement are
considered as double Fourier’s series which is more general and precise. A remarkable accuracy has been admitted by comparing the results with other available references.

ABSTRACT: In this paper, creep buckling and post-buckling of a hybrid laminated viscoelastic functionally graded material (FGM) cylindrical shell under in-plane loading are investigated. Considering the high-order transverse shear deformation and geometric nonlinear theory, the von Karman geometric relation of the hybrid laminated viscoelastic FGM cylindrical shell with initial deflection is established. Based on the Donnell theory, elastic piezoelectric theory and Boltzmann superposition principle, nonlinear creep governing equations of the hybrid laminated viscoelastic FGM cylindrical shell under in-plane loading are derived. By means of the finite difference method and the Newton–Newmark method, the problem for creep buckling and post-buckling of the laminated shell’s structure is solved. Numerical results are presented to show effects of geometric parameters, power law index and loading on creep buckling and post-buckling of the hybrid laminated viscoelastic FGM cylindrical shell.

ABSTRACT: Postbuckling behavior of laminated shell panel in thermal environment is reported in this article. The geometric nonlinearity is introduced in Green–Lagrange sense and the model is developed for the geometrically large translations and/or rotations and the excess thermal deformation of the curved panel based on higher order shear deformation theory (HSDT) using nonlinear finite element. The governing equation of shell panel is derived by minimizing the energy expression. The postbuckling strength in terms of temperature ratio (postbuckling to buckling temperature) of the panel by obtained by a direct iterative method. The results are obtained using the developed model and compared with those of the available published literature. Some of the new results are computed for different parameters such as layup sequences, thickness ratios, amplitude ratios, boundary conditions, aspect ratios, and various curvature ratios and presented.

ABSTRACT: A nonlinear finite element analysis of impact response and impact-induced damage in curved composite laminates subjected to transverse impact by a foreign object is carried out. An eight-noded isoparametric quadrilateral shell element incorporating a nonlinear strain displacement relation due to large deflection is developed based on the total Lagrangian approach. The nonlinear system of equations is solved using a Newton–Raphson incremental-iterative method. Example problems of graphite/epoxy cylindrically curved laminates with different curvature are considered and the influence of geometrical nonlinearity on the impact response and the resulting damage is demonstrated. The concurrent effect of material degradation due to impact damage is also investigated.

ABSTRACT: The problem on normal low-velocity impact of an elastic sphere upon an elastic spherical shell is studied with considering the changes in the geometrical dimensions of the contact domain. At the moment of impact, shock waves (surfaces of strong discontinuity) are generated in the target, which then propagate along the body during the process of impact. Behind the wave fronts up to the boundary of the contact domain, the solution is constructed with the help of the theory of discontinuities and one-term ray expansions. Nonlinear Hertz’s theory is employed within the contact region. For the analysis of the processes of shock interactions of the elastic sphere with the spherical shell, nonlinear integro-differential equation has been obtained with respect to the value characterizing the local indentation of the impactor into the target, which has been solved analytically in terms of time series with integer and fractional powers.

ABSTRACT: The problem on normal low-velocity impact of an elastic falling body upon an elastic spherical shell is studied. At the moment of impact, shock waves (surfaces of strong discontinuity) are generated in the target, which then propagate along the body during the process of impact. Behind the wave fronts upto the boundary of the contact domain, the solution is constructed with the help of the theory of discontinuities and one-term or multiple-term ray expansions. Nonlinear Hertz’s theory and linearized elastic contact laws are employed within the contact region. For the analysis of the processes of shock interactions of the elastic sphere or elastic spherically-headed rod with the spherical shell, nonlinear integro-differential equation has been obtained with respect to the value characterizing the local indentation of the impactor into the target, which has been solved analytically in terms of time series with integer and fractional powers. In the case of the linear elastic shock interactions, the governing differential equations for the target and the impactor are solved analytically by the ray method.

ABSTRACT: Large amplitude (geometrically non-linear) vibrations of doubly curved shallow shells with rectangular base under the low-velocity impact by an elastic sphere are investigated. It is assumed that the shell is simply supported and partial differential equations are obtained in terms of shell's transverse displacement and Airy's stress function. The local bearing of the shell and impactor's materials is neglected with respect to the shell deflection in the contact region. The equations of motion are reduced to a set of infinite nonlinear ordinary differential equations of the second order in time and with cubic and quadratic nonlinearities in terms of the generalized displacements. Assuming that only two natural modes of vibrations dominate during the process of impact and applying the method of multiple time scales, the set of equations is obtained, which allows one to find the time dependence of the contact force and to determine the contact duration and the maximal contact force.

vibrations of thin bodies has been utilized for solving nonlinear equations. The new approach enables one to uncouple the linear parts of equations of motion of the plate, while the same method, coupled, were solved by the method of multiple time scales. A new approach proposed in [2] allows one to find an additional combinational resonance of the additive-difference type, as well as to solve the problems of vibrations of thin bodies more efficiently.
ABSTRACT: Based on the elasto-plastic mechanics, the damage analysis and dynamic response of an elasto-plastic laminated composite shallow spherical shell under low velocity impact are carried out in this paper. Firstly, a yielding criterion related to spherical tensor of stress is proposed to model the mixed hardening orthotropic material, and accordingly an incremental elasto-plastic damage constitutive relation for the laminated shallow spherical shell is founded when a strain-based Hashin failure criterion is applied to assess the damage initiation and propagation. Secondly, using the presented constitutive relations and the classical nonlinear shell theory, a series of incremental nonlinear motion equations of orthotropic moderately thick laminated shallow spherical shell are obtained. The questions are solved by using the orthogonal collocation point method, Newmark method and iterative method synthetically. Finally, a modified elasto-plastic contact law is developed to determine the normal contact force and the effect of damage, geometrical parameters, elasto-plastic contact and boundary conditions on the contact force and the dynamic response of the structure under low velocity impact are investigated.

ABSTRACT: Large deflection dynamic responses of laminated composite cylindrical shells under impact are analyzed by the geometrically nonlinear finite element method based on a generalized Sander’s shell theory with the first order transverse shear deformation and the von-Karman large deflection assumption. A modified indentation law with inelastic indentation is employed for the contact force. The nonlinear finite element equations of motion of shell and an impactor along with the contact laws are solved numerically using Newmark’s time marching integration scheme in conjunction with Akay type successive iteration in each step. The ply failure region of the laminated shell is estimated using the Tsai-Wu quadratic interaction criteria. Numerical results, including the contact force histories, deflections and strains are presented and compared with the ones by linear analysis. The effect of the radius of curvature on the composite shell behaviors is investigated and discussed.

ABSTRACT: A boundary problem for thin elastic shells is formulated. The generally acceptable geometrical (straight normal) and physical (linear elasticity) hypotheses which underlie the relations are considered. Geometrical nonlinearity of shell deformation is taken into account. Equilibrium equations expressed via the displacements of shell middle surface are presented as governing relations. Tangent and bending boundary conditions along the arbitrary shell contour (free and clamped edge, free-hinge and fixed-hinge, elastic support) are formulated. A set of previously satisfied conditions (regularity of shell surface and material, piecewise continuity of shell contour and of boundary support parameters) is implemented and the concept of a generalized solution is introduced. The small perturbation of a vector-function of a generalized solution is considered, becoming the basis of investigation of non-uniqueness of the generalised solution, and of branching of the solutions.

Yury A. Rossikhin and Marina V. Shitikova (Research Center of Wave Dynamics, Voronezh State University of Architecture and Civil Engineering, Voronezh, 394006, Russia), “A new approach for studying nonlinear dynamic response of a thin fractionally damped plate with 2:1 and 2:1;1 internal resonances”, Chapter in Shell and Membrane theories in Mechanics and Biology, Vol. 45 of the series Advanced Structured Materials, pp 267-288, September 2014, DOI: 10.1007/978-3-319-02535-3_15
ABSTRACT: Dynamic behaviour of a nonlinear plate embedded in a fractional derivative viscoelastic medium and subjected to the conditions of the internal resonances two-to-one and one-to-one, as well as the internal combinational resonances has been studied by Rossikhin and Shitikova in [12, 13]. Nonlinear equations, the linear parts of which occur to be coupled, were solved by the method of multiple time scales. A new approach proposed in this paper allows one to uncouple the linear parts of equations of motion of the plate, while the same method, the method of multiple time scales, has been utilized for solving nonlinear equations. The new approach enables one to solve the problems of vibrations of thin bodies more efficiently.

ABSTRACT: Non-linear vibrations of a cylindrical shell embedded in a fractional derivative viscoelastic medium and subjected to the different conditions of the internal resonance of the order of \( \varepsilon \), where \( \varepsilon \) is a small value, are investigated. The displacement functions are determined in terms of eigenfunctions of linear vibrations. The procedure resulting in decoupling linear parts of equations is proposed with the further utilization of the method of multiple scales for solving nonlinear governing equations of motion, in so doing the amplitude functions are expanded into power series in terms of the small parameter and depend on different time scales. The influence of viscosity on the energy exchange mechanism is analyzed. It is shown that each mode is characterized by its damping coefficient connected with the natural frequency by the exponential relationship with a negative fractional exponent. Comparison of the results obtained in this paper for the nonlinear shallow cylindrical shell in the cases of the internal resonance of the order of \( \varepsilon \) with those for a nonlinear plate, the motion of which is described also by three coupled nonlinear equations in terms of three displacements, reveals the fact that the shell equations could produce much more diversified variety of internal resonances, including combinational resonances of the additive and difference types, than the plate equations.

ABSTRACT: Nonlinear vibrations of a cylindrical shell embedded in a fractional derivative viscoelastic medium and subjected to the different conditions of the internal resonance are investigated. The viscous properties of the surrounding medium are described by Riemann-Liouville fractional derivative. The displacement functions are determined in terms of eigenfunctions of linear vibrations of a free-simply supported shell. A novel procedure resulting in decoupling linear parts of equations is proposed with the further utilization of the method of multiple scales for solving nonlinear governing equations of motion by expanding the amplitude functions into power series in terms of the small parameter and different time scales. It is shown that the phenomenon of internal resonance can be very critical, since in a circular cylindrical shell the one-to-one, two-to-one, and three-to-one internal resonances, as well as additive and difference combinational resonances are always present. The three-to-one internal resonance is analyzed in detail. Since the internal resonances belong to the resonances of the constructive type, i.e., all of them depend on the geometrical dimensions of the shell under consideration and its mechanical characteristics, that is why such resonances could not be ignored and eliminated for a particularly designed shell. It is shown that the energy exchange could occur between two or three subsystems at a time: normal vibrations of the shell, its torsional vibrations and shear vibrations along the shell axis. Such an energy exchange, if it takes place for a rather long time, could result in crack formation in the shell, and finally to its failure. The energy exchange is illustrated pictorially by the phase portraits, wherein the phase trajectories of the phase fluid motion are depicted.

ABSTRACT: The buckling behaviour of functionally graded cylindrical panels under thermal loading is investigated in this article. In functionally graded material, material properties vary smoothly from metal phase to ceramic phase. In this study, the effective material properties of the functionally graded panels are considered as temperature dependent and the gradation is taken in the transverse direction according to the power-law distribution of volume fractions of each constituent. Thermal buckling behaviour of cylindrical panel has been obtained numerically through ANSYS based on the ANSYS parametric design language code. The model has been discretised using an eight node serendipity element with six degrees of freedom per node (SHELL281) from the ANSYS library. The solutions are obtained by solving the eigenvalue type buckling using Block Lanczos method. The accuracy of the model has been checked through corresponding convergence and comparison study with those available literatures. Finally, the simulation model has been extended to study the effect of different parameters such as power-law index, thickness ratio, curvature ratio and aspect ratioon buckling strength for both temperature independent and dependent material properties of each constituent.

ABSTRACT: The U.S. Department of Energy, Office of River Protection has commissioned a structural analysis of record for the Hanford single shell tanks to assess their structural integrity. The analysis used finite element techniques to predict the tank response to the historical thermal and operating loads. The analysis also addressed the potential tank response to a postulated design basis earthquake. The combined response to static and seismic loads was then evaluated against the design requirements of American Concrete Institute standard, ACI-349-06, for nuclear safety-related concrete structures. Further analysis was conducted to estimate the plastic limit load and the elastic-plastic buckling capacity of the tanks. The limit load and buckling analyses estimate the margin between the applied loads and the limiting load capacities of the tank structure. The potential for additional dome loads from waste retrieval equipment and the addition of large dome penetrations to accommodate retrieval equipment has generated additional interest in the limit load and buckling analyses. This paper summarizes the structural analysis methods that were used to evaluate the limit load and buckling of the single shell tanks.

ABSTRACT: An elastic stability problem of the thin round cylindrical shells subjected to torsional moment at two extremities has been investigated in the paper [6]. By the small elastoplastic deformation theory and by the flow theory, this problem again has been studied in [2] and [4]. Basing on the theory of elastoplastic processes the above mentioned problem has been solved by approach simulation of instability form of the cylinder (see [1,][5]). In this paper, the solution of problem in the real bending form of structure has been found. We have also established the relations for determining critical force. Some numerical results for a linear hardening material have been given and discussed.

ABSTRACT: This paper presents an analytical approach to analyze the nonlinear stability of thin closed circular cylindrical shells under axial compression with material properties varying smoothly along the thickness in the power and exponential distribution laws. Equilibrium and compatibility equations are obtained by using Donnell shell theory taking into account the geometrical nonlinearity in von Karman and initial geometrical imperfection. Equations to find the critical load and the load-deflection curve are established by Galerkin’s method. Effects of buckling modes, of imperfection, of dimensional parameters and of volume fraction indexes to buckling loads and postbuckling load-deflection curves of cylindrical shells are investigated. In case of perfect cylindrical shell, the present results coincide with the ones of the paper [13] which were solved by Ritz energy method.

ABSTRACT: In this paper, the nonlinear buckling and post-buckling of an eccentrically stiffened cylindrical shell made of functionally graded materials, surrounded by an elastic medium and subjected to mechanical compressive loads and external pressures are investigated by an analytical approach. The cylindrical shells are reinforced by longitudinal and circumferential stiffeners. The material properties of cylindrical shells are graded in the thickness direction according to a volume fraction power-law distribution. The non-linear stability equations for stiffened cylindrical shells are derived by using the first order shear deformation theory and smeared stiffeners technique. Closed-form expressions for determining the buckling load and load-deflection curves are obtained. The effectiveness of stiffeners in enhancing the stability of cylindrical shells is shown. The effects of volume fraction indexes, material properties, geometrical parameters and foundation parameters are analyzed in detail.

ABSTRACT: This paper is concerned with the mechanical buckling load of an eccentrically stiffened truncated conical shells made of functionally graded materials and subjected to axial compressive load and external uniform pressure by analytical method. Shells are reinforced by stringers and rings. The change of spacing between stringers in the meridional direction is taken into account. Material properties of shell are graded in the thickness direction according to a volume fraction power-law distribution. The equilibrium and linearized stability equations for stiffened shells are derived based on the classical shell theory and smeared stiffeners technique. The resulting equations which they are the couple set of three variable coefficient partial differential equations in terms of displacement components are investigated by Galerkin method and the closed-form expression for determining the buckling load is obtained. The effects of stiffeners, material and dimensional parameters are analyzed in detail.

ABSTRACT: A semi-analytical approach eccentrically stiffened functionally graded circular cylindrical shells surrounded by an elastic medium subjected to external pressure is presented. The elastic medium is assumed as two-parameter elastic foundation model proposed by Pasternak. Based on the classical thin shell theory with the geometrical nonlinearity in von Karman–Donnell sense, the smeared stiffeners technique and Galerkin method, this paper deals with the nonlinear dynamic problem. The approximate three-term solution of deflection shape is chosen and the frequency–amplitude relation of nonlinear vibration is obtained in explicit form. The nonlinear dynamic responses are analyzed by using fourth order Runge–Kutta method and the nonlinear dynamic buckling behavior of stiffened functionally graded shells is investigated according to Budiansky–Roth criterion. Results are given to evaluate effects of stiffener, elastic foundation and input factors on the frequency–amplitude curves, natural frequencies, nonlinear responses and nonlinear dynamic buckling loads of functionally graded cylindrical shells.

ABSTRACT: Using a simple constitutive law for elastic behavior that includes the feature of a maximum allowable strain, equations are derived for inflation pressure as a function of the amount of inflation for three rubber shells: a thin-walled spherical balloon, a small spherical cavity in a large rubber block, and a thin-walled cylindrical tube. The results are compared with those obtained using the neo-Hookean constitutive law. Uniform expansion is generally predicted to become unstable at a modest degree of inflation but the new relations give a second stable inflation state, in accord with experience.

ABSTRACT: The use of soft elastic biomaterials in medical devices enables substantial function integration. The consequent increased simplification in design can improve reliability at a lower cost in comparison to traditional (hard) biomaterials. Functional bi-stable buckling is one of the many new mechanisms made possible by soft materials. The buckling behavior of shells, however, is typically described from a structural failure point of view: the collapse of arches or rupture of steam vessels, for example. There is little or no literature about the functional elastic buckling of small-sized silicone rubber shells, and it is unknown whether or not theory can predict their behavior. Is functional buckling possible within the scale, material and pressure normally associated with physiological applications? An automatic speech valve is used as an example application. Silicone rubber spherical shells (diameter 30mm) with hinged and double-hinged boundaries were subjected to air pressure loading. Twelve different geometrical configurations were tested for buckling and reverse buckling pressures. Data were compared with the theory. Buckling pressure increases linearly with shell thickness and shell height. Reverse buckling shows these same relations, with pressures always below normal buckling pressure. Secondary hinges change normal/reverse buckling pressure ratios and promote symmetrical buckling. All tested configurations buckled within or closely around physiological pressures. Functional bi-stable buckling of silicone rubber shells is possible with adjustable properties in the physiological pressure range. Results can be predicted using the proposed relations and equations.

ABSTRACT: After a theoretical overview of the buckling phenomena of grid shells, current research on the stability check by numerical analysis will be discussed with a special attention on the applied geometrical imperfection. It is laborious to analyse the effect of initial member curvature and node deviation as constructional imperfections, therefore simplified methods exist such as the use of eigenshapes as imperfections. To demonstrate the effect of different imperfection shapes, a spherical cap with a Kiewitt-8 mesh type is analysed based on different analysis methods.

ABSTRACT: This paper derives new analytical solutions for thermal bifurcation buckling of cylindrical shells made of functionally graded materials (FGMs) with temperature-dependent material properties. The Donnell’s shell theory is adopted and a symplectic solution methodology is established through the Hamiltonian variational principle. The fundamental buckling problem is then converted into the solving for the symplectic eigenvalues and eigenvectors. The solutions reveal that boundary conditions and temperature-dependent FGM properties have significant influence on thermal buckling behavior. It is also concluded that temperature field conditions cannot be neglected for FGCSs being rich in thermal sensitive compositions.

ABSTRACT: The free vibration and buckling of cylindrical composite shell with internal liquid is studied in
this study. The shell composed of several composite layers and stiffeners which are rings and stringers. The first order shear theory was used for shell and stiffeners. Stiffeners were used in equations as discrete elements. The effects of axial force, internal pressure and shell rotation about cylinder axis, were calculated. The Reily-Ritz method was used for solving the problem. The potential and kinetic energy of shell and each stiffener and kinetic energy of liquid are substituted in the functional of energy. The natural frequencies and the critical axial forces in each mode is obtained. The section shape of each stiffener is rectangle. The stringers can have variable height in their length (a parabolic shape for example) and its effect is studied for shell with and without liquid. Also stiffened composite shell with different internal pressure, different axial forces and different rotation speeds is studied. The liquid is ideal and sloshing was neglected.

DESCRIPTION: Buckling Test Facility: The buckling test facility has been continuously developed over the past 20 years and is especially designed for buckling tests on thin walled composite structures such as cylinders and panels. Due to its extreme stiffness, careful load introduction and shortening control, buckling tests of high precision can be conducted under well defined boundary conditions. The hydraulic cylinder is equipped with a small servo valve for static tests and additionally with a second valve for high dynamics. Axial compression up to 1,000 kN, torsion up to 20 kNm as well as internal pressure between 1 hPa (simulating external pressure) and 10 hPa can be applied simultaneously. The load history of axial compression ranges from static loading to shock loading. Tests of panels and shells with up to 1,600 millimeters in length and 1,200 millimeters in width (diameter) can be performed. The high-precision buckling test results serve as a reference for the development of fast computational procedures to simulate buckling and post buckling behavior of thin walled structures, as they are required for concurrent/integrated engineering. In addition, proof tests of real structural components with respect to their buckling and post-buckling behavior can be conducted. So far, several buckling tests were conducted within ESA contracts and EU projects such as DEVILS (Design and Validation of Imperfection-Tolerant Laminated Shells), POSICOSS (Improved Post-buckling Simulation for Design of Fiber Composite Stiffened Fuselage Structures) and the current project COCOMAT (Improved Material Exploitation at Safe Design of Composite Airframe Structures by Accurate Simulation of Collapse). Technical Details: The capacity of the axial load is 1,000 kN. The hydraulic cylinder is equipped with a small servo-valve for quasi-static tests which enables very smooth controlling of the displacement. Additionally, a second valve is provided for very high dynamics as required for dynamic buckling or shock tests. Axial compression = 1,000 kN, Piston acceleration = 1,500 m/s², Piston velocity = 0.675 m/s, Piston frequency (ampl.1 mm) = 100 Hz, Torsion moment = 50 kNm, Shear load (for panels) = 200 kN, Specimen length = 1,600 mm, Specimen width = 1,200 mm. Measurement Equipment: 200 measurement points for strain gauges and displacement transducers are scanned by 1 kHz for static tests, and 72 measuring points by 400 kHz for dynamic tests. Four self-sustaining fast ARAMIS systems, each of which is able to measure the 3-dimensional deformation field at a speed of 1,000/sec, can be coupled, resulting in a maximum speed of 4,000/sec. This system provides much more information on the dynamics of buckling deformations than previously achieved.

ABSTRACT: Nanomechanics and real-time buckling deformation of an individual multi-walled carbon nanotube (MWCNT) were investigated through in situ nanoindentation within a transmission electron microscope (TEM). These in situ observations reveal a significant shell-to-Euler phase transformation in the buckling response of the nanotube. Objective evidences that the MWCNT possesses time-dependent characteristic were first suggested by combining in situ TEM nanoindentation performed strain rate influences on an individual MWCNT with classical molecular dynamics simulations. Structural evolutions and buckling instabilities for thin-wall and thick-wall CNTs are theoretically studied, indicating the role of the tube thickness and interwall van der Waals interactions in governing buckling behavior.

“Torsional buckling behavior of SWDNTs using a molecular structural mechanics approach considering vacancy defects”, Fullerenes, Nanotubes and Carbon Nanostructures, Vol. 20, No. 8, pp. 709-720, 2012
DOI: 10.1080/1536383X.2011.572311

ABSTRACT: In this paper, the influence of various vacancy defects on the critical buckling torques and twist angles in single-walled carbon nanotubes (SWCNTs) under torsional load is investigated using a new structural model built using the ABAQUS software. This model is a combination of other structural models and is designed to eliminate the deficiencies inherent in each of the individual approaches. For the first time, the effect of different types of vacancy defects on critical buckling torque and twist angle is studied for zigzag and armchair nanotubes of various lengths. The results show that vacancy defects have a considerable impact on the critical buckling torque. Moreover, zigzag nanotubes are found to be more sensitive to these defects than armchair nanotubes. The results obtained here are compared with those obtained using the continuum model, and reasonable agreement is observed.

ABSTRACT: Within this contribution, buckling of tubular steel shells with circular cutout will be analyzed. The experimental results will be compared by FEM simulation results within circular cutouts of the specimen. The experimental buckling tests have been conducted using a Servo-hydraulic machine (Instron 8802). Considering the broad application range of tubular thin-walled shells, prediction of the behavior of these elements in combined loading case (especially for buckling behavior) has gained a great level of importance. In this study, the influence of shell length, shell diameter, shell angle and diameter of circular cutouts on the predicted buckling values for the tubular shell has been explored. Numerical simulations of tubular shell subjected to combined loading were conducted. The analytical solutions show excellent agreement with the numerical results predicted by FEM.

“Effect of sandwich shear deformation and shell taper angle on elastic buckling of large-scale composite

ABSTRACT: The elastic buckling problem of large-scale composite sandwich tubes in a satellite structure is analyzed. The geometry equations, constitutive equations and strain energy expressions of cylinder shell, conical shell and frames are constructed separately. And the potential energy of external forces is obtained under given loading conditions. According to the boundary conditions, the trigonometric series are applied to describing the displacement field. The principle of minimum potential energy is used to determine the critical load. The critical loads are obtained considering or neglecting the effects of sandwich shear deformation and shell taper angle separately, and then they are compared between the two conditions, demonstrating that the maximum error is less than 10%. Based on this research, a simplified method can be applied in the design stage of the large-scale composite sandwich tube in engineering.

ABSTRACT: Using the static-dynamic analogy, work at Bath and Bristol has uncovered the vital organizing role of the Maxwell ‘energy criterion’ load in the advanced post-buckling of long-thin structures which exhibit severe shell-like imperfection sensitivity. It has become clear that above the Maxwell load, PL, there are localized solutions offering an order-of-magnitude increase in sensitivity to lateral side-loads, whether static or dynamic. We propose to call this ‘shock-sensitivity’, and notice that so far only the seminal paper by Horak, Lord and Peletier in 2006 has quantified this in terms of an E(P) energy-barrier versus load graph. In this paper we present three graphs of this nature for archetypal problems: the free twisted rod, the cylindrically constrained rod, and the strut on a softening elastic foundation. We find in all cases that the energy barrier of the localizing solution above PL is quite close to the energy of a single periodic wave. Now a single such wave is not kinematically admissible, and the corresponding periodic barrier must be for all the waves in the long structure, N, say. So in practice N will be large, and does indeed tend to infinity with the length of the structure. Thus the shock sensitivity increases by a factor of a large N as the Maxwell load is exceeded. This is important in its own right, and we do not seek to explain or fit curves to the scattered experimental buckling loads of shell structures.

ABSTRACT: The object of this paper is to obtain all the stress resultants of an anisotropic (2n+1) layers plywood shell. The differential equations of equilibrium of (2n+1) layers plywood shell under three simultaneous loads are obtained. The solution of the differential equations for anisotropic (2n+1) layers plywood shell in case of two way compressions is obtained here. The stable region for a plywood shell in this case is obtained. Buckling diagram for five layers plywood shell and seven layers plywood shell are shown graphically as special cases.

“Studying Effect of Geometrical Parameters on the Buckling of Cylindrical Shells under Hydrostatic Pressure”,
Indian Journal of Science & Technology, Vol. 6, No. 11, November 2013
ABSTRACT: In this paper, we study the effect of diameter and thickness of a shell as well as the reinforcement rings on buckling of cylindrical shells under external hydrostatic pressure. Bucking equations are based on standard of ABC underwater vessels. Using the relations in different diameters, tolerable buckling load has been obtained with shell, by changing the thickness of shell and distance of reinforcement rings in definite range. Results obtained from buckling pressure in different diameters and for different ratios of D/t and D/L are given and finally a diagram has been presented for designing and determining different parameters of reinforced cylindrical shell after comparing them.

ABSTRACT: The present work aims the vibration and parametric instability of functionally graded material rectangular plates with simply supported boundary condition, subjected to a biaxial in-plane periodic loading. First order shear deformation theory is used for theoretical formulation of FGM plates. The properties of the
functionally graded material plates are assumed to vary along the thickness direction according to a power law distribution in terms of the volume fractions of the constituents. Hamilton’s principle is employed to convert the governing equations into a linear system of Mathieu–Hill equations from which the boundary of stable and unstable regions are determined by using Floquet’s theory on the parameter space. Natural frequency and buckling analysis are also discussed. Numerical results are presented in both dimensionless parameters and graphical forms for FGM plates made of steel and alumina. The influences of various parameters such as index value, aspect ratio on the buckling load and natural frequencies are examined. Power law index value and aspect ratio effects on the dynamic stability regions also studied in detail.

ABSTRACT: This paper presents the results of complementary numerical study done in the continuation of the activities carried out by the Committee III.1 “Ultimate Strength” of ISSC’2003 (Ref. [28]). The main focus of the paper concerns the post-buckling behaviour and strength characteristics of the aluminium multi-stiffened panels under combined axial compression and lateral pressure. The finite element model proposed by the Committee III.1 “Ultimate Strength” of ISSC’2003 is used in the present investigation. Material is aluminium alloy AA6082-T6 and the multi-stiffened panel is a triple-span structure. Stiffeners are of either extruded or non-extruded angle-bar profiles. An initial deflection is imposed on the model in a procedure similar to that applied by the Committee III.1. General purpose finite element code ANSYS is used for non-linear elastic-plastic analyses. Main objectives are to study the influence of initial deflections and also HAZ on the post-buckling behaviour and collapse characteristics of aluminium stiffened panels under combined axial compression and lateral pressure. Different values of lateral pressure are exerted on the model in a systematic manner to simulate various levels of lateral pressure loading on multi-stiffened aluminium panels used in the construction of high-speed crafts.

ABSTRACT: The decomposition of buckling modes of thin-walled members subjected to axial stresses is a topic of great practical interest which can be achieved using the generalised beam theory (GBT) or the constrained finite strip method (cFSM). However, the latter is not general enough to study prismatic members with arbitrary cross-sections and the objective of this paper is to extend the cFSM to allow the buckling modes decomposition for prismatic members with branches and/or closed parts. To define the combined GD buckling mode, two assumptions are used: (i) cylindrical plate bending and (ii) negligible in-plane transverse/shear strains. The corresponding constraint matrix, RGD, is derived in a simple and general way. The methodology used to separate the global and distortional modes is similar to that used in the original cFSM while the derivation of the constraint matrix for local modes remains identical. Some examples are considered and the pure buckling curves are compared to the conventional FSM results. The conclusion is that the new cFSM has successfully computed the GD and the L modes of these sections.

ABSTRACT: In this paper, we study buckling of ionic polymer metal composite (IPMC) pipes under uniaxial compression. A novel methodology to fabricate shell-like IPMCs is developed by combining hot pressing and chemical reduction. In the compression tests, IPMC pipes of varying thickness are clamped at their ends through custom-made fixtures and both short-circuit current and deformation are recorded as a function of the applied load. Experimental results are interpreted using classical findings on the buckling of thin shells and finite element simulations. Our results demonstrate that IPMC buckling can be accurately sensed through the short-circuit current, which is nearly zero during the loading phase, before suddenly increasing at the onset of the elastic instability. The buckling patterns of the samples are largely non-axisymmetric with a number of lobes appearing along the axial and circumferential directions of the IPMC pipes.

Linfeng Shen; Youngsu Cha; Adel Shams; Maurizio Porfiri (Polytechnic Institute of New York University, USA), “Buckling of an ionic polymer metal composite shell under uniaxial compression”, SPIE Proceedings, Vol. 9056, Conducting Polymers and IMPC, Electroactive Polymer Actuators and Devices (EAPAD) 2014, 90561X (March 8, 2014); doi:10.1117/12.2044619

ABSTRACT: In this paper, we analyze buckling of an ionic polymer metal composite (IPMC) shell subjected to uniaxial compression. A new technique is developed to fabricate tubular IPMCs using hot molding and a chemical reduction process. The short-circuit current and the mechanical deformation of the sample are recorded during the compression test. Experimental findings demonstrate that IPMC buckling can be accurately sensed via the short-circuit current, which is approximately zero during the loading phase, before exhibiting a sudden increase at the onset of the elastic instability.

Badri Prasad Patel (Department of Applied Mechanics, Indian Institute of Technology Delhi, Hauz Khas, New Delhi, 110016, India), “Thermal buckling/postbuckling characteristics of laminated composite shells”, Encyclopedia of Thermal Stresses, pp 4926-4931

EXCERPT: The laminated conical-cylindrical shells may be subjected to extreme thermal environment during their service life. The developed compressive thermal membrane state of stress due to the boundary constraints may lead to thermoelastic instability/buckling. An estimate of the critical bifurcation temperature can be made through a linear eigenvalue analysis, whereas the sensitivity to the imperfections and postbuckling behavior can be evaluated by means of nonlinear analysis, generally, incorporating an imperfection affine to the critical buckling mode evaluated from the eigenvalue analysis. The circular shells can be analyzed using computationally efficient semi-analytical axisymmetric finite element incorporating axisymmetric and asymmetric deformation components in the circumferential approximation of the displacement field variables.
Noncircular shells are analyzed using two-dimensional (2D) shell finite elements formulated in curvilinear coordinate system. To eliminate ...

ABSTRACT: Syntactic foams are particulate composites that are obtained by dispersing thin hollow inclusions in a matrix material. The wide spectrum of applications of these composites in naval and aerospace structures has fostered a multitude of theoretical, numerical, and experimental studies on the mechanical behavior of syntactic foams and their constituents. In this work, we study static and dynamic axisymmetric buckling of single hollow spherical particles modeled as non-linear thin shells. Specifically, we compare theoretical predictions obtained by using Donnell, Sanders–Koiter, and Teng–Hong non-linear shell theories. The equations of motion of the particle are obtained from Hamilton’s principle, and the Galerkin method is used to formulate a tractable non-linear system of coupled ordinary differential equations. An iterative solution procedure based on the modified Newton–Raphson method is developed to estimate the critical static load of the microballoon, and alternative methodologies of reduced complexity are further discussed. For dynamic buckling analysis, a Newmark-type integration scheme is integrated with the modified Newton–Raphson method to evaluate the transient response of the shell. Results are specialized to glass particles, and a parametric study is conducted to investigate the effect of microballoon wall thickness on the predictions of the selected non-linear shell theories. Comparison with finite element predictions demonstrates that Sanders–Koiter theory provides accurate estimates of the static critical load for a wide set of particle wall thicknesses. On the other hand, Donnell and Teng–Hong theories should be considered valid only for very thin particles, with the latter theory generally providing better agreement with finite element findings due to its more complete kinematics. In this context, we also demonstrate that a full non-linear analysis is required when considering thicker shells, while simplified treatment can be utilized for thin particles. For dynamic buckling, we confirm the accuracy of Sanders–Koiter theory for all the considered particle thicknesses and of Teng–Hong and Donnell theories for very thin particles.

ABSTRACT: Shallow spherical shell is an important kind of sensor elastic element. Because of the particular metal material texture, it can work under high temperature field. The nonlinear buckling problems of shallow spherical shell in load and temperature field are very important. In this paper, nonlinear buckling of shallow spherical shell under uniform pressure and temperature field in simply supported boundary conditions is studied by the modified iteration method, and the analytic formulas for determining the critical buckling load are obtained. The effect of temperature field on critical buckling load and critical geometrical parameter are discussed.

ABSTRACT: Suction caissons are a foundation system, most commonly used in the offshore petroleum industry, and also considered applicable as a foundation for offshore wind turbines. Due to relative thin wall thickness compared to the caisson diameter, buckling of the cylindrical caisson during installation with underpressure becomes a structural design issue. Partial to full embedment of the suction caissons offer lateral support from the soil against shell buckling. Different simplified methods for incorporating the lateral soil support in the structural FEM-models are used by the industry in buckling design of suction caissons. This article compares two different methods for constructing non-linear soil springs. The two different sets of soil springs are applied to a case history, where the installation of four suction caissons is back-calculated.

ABSTRACT:

ABSTRACT: Axially crushed thin-walled tubular structures are extensively used as energy absorbers in various automotive and aerospace applications because of their high energy absorption efficiency and long strokes. Various experimental and numerical studies in the past have revealed that a thin-walled square tube can undergo mainly three modes of deformation, progressive crushing/buckling, dynamic plastic buckling and global bending depending up on the loading conditions and tube geometry among many factors. Out of these three, progressive crushing/buckling is the most desired mode of collapse for efficient energy absorption. Moreover, crushing starting from one end progressing systematically towards the other end is preferred because of availability of more space/material for plastic deformation without jamming resulting in increased peak forces. A thin square tube can show four possible modes of collapse during progressive crushing depending up on the ratio of width to thickness. The mean crush load for extensional mode of collapse is higher than the other three modes resulting in higher energy absorption during the overall crushing event. The crush behavior of thin square columns in case of oblique impact is highly dependent on the angle of impact. In the situations when impact angle is higher than a critical value, the mean crush load may drop by 40% than the axial crushing load because of global bending. In this paper, a novel approach based on compliant mechanism design which is extensively employed in topology optimization of MEMS is used to design the thin-walled square tubes. The ability of a compliant mechanism to transfer or transform displacement, force or energy from an input load location to the desired output locations is utilized to enforce the desired buckle zones in the axial member. A biologically inspired, gradient free hybrid cellular automata (HCA) method is used to synthesize compliant mechanisms with elemental thickness distribution governed by an energy like functional, mutual potential energy (MPE). Nonlinear explicit finite element code LS-DYNA is used to simulate quasi-static axial crushing of the thin square columns in this paper. Numerical results show that progressive crushing in a desired mode of collapse can be enforced in axial and oblique loading conditions using the proposed methodology.

Aviation Technology (ASAT-13), May 26-28, 2009, Military Technical College, Kobry Elkobbah, Cairo, Egypt

ABSTRACT: Typical steel square plates of 300mm side length and 1mm thickness were used to simulate six tubes with different cross-sections. These cross-sections were selected symmetric from round-shapes as circle and ellipse and polygon-shapes as triangle, square, pentagon and hexagon. The effect of varying configurations of tube cross-section shape on the deformation response, collapse mode and energy absorption characteristics of tubes under quasi-static axial compression have been studied numerically. The commercial finite element package ABAQUS/Explicit was used in the present analysis. The axial load-displacement results accompanied by the fold formation of various tubes were investigated and compared with published experimental work. Variation of the initial peak load and the mean crushing force with the tube side breadth and the fold depth were carefully examined. Based on the finite element simulation results, empirical formulas for the absorbed energy and the fold depth were developed as a function of the side breadth-to-thickness ratio of the tubes.

ABSTRACT: This paper presents an investigation concerning the mechanics of deformation of thin-walled steel tubular members with single-cell regular polygonal cross-sections, such as those employed to build transmission line structures, towers, antennas and masts. This type of cross-sections exhibit rotational symmetry of order equal to the number of walls, which leads to remarkable peculiarities concerning the cross-section in-plane and out-of-plane (warping) deformation. The investigation is based on a specialization of Generalised Beam Theory (GBT), aiming at fully uncoupling the main cross-section deformation mode sets, which makes it possible to obtain analytical results and thus extract in-depth information concerning the structural behaviour of this type of members. Several illustrative examples, employing both analytical and numerical (using GBT-based beam finite elements) strategies, are presented throughout the text. For validation and comparison purposes, results obtained with standard shell finite element models are also provided.

ABSTRACT: This paper investigates the elastic buckling (bifurcation) behaviour of uniformly compressed thin-walled tubular members with single-cell regular polygonal cross-sections (RCPS), such as those employed to build transmission line structures, towers, antennas and masts. A specialisation of Generalised Beam Theory (GBT) for RCPS, reported in a recent paper (Gonçalves and Camotim, 2013) [1], is used to obtain both analytical and numerical results concerning the most relevant buckling modes and provide novel and broad conclusions on the structural behaviour of this type of members. In particular, local, cross-section extensional, distortional and multi-mode (including global flexural) buckling phenomena are addressed. For validation purposes, the GBT-based results are compared with solutions taken from the literature and also with numerical values obtained from finite strip analyses.

“Buckling behavior of thin-walled regular polygonal tubes subjected to bending or torsion”, Thin-Walled Structures, Vol. 73, pp 185-197, December 2013, DOI: 10.1016/j.tws.2013.08.006
ABSTRACT: In a recent paper (Gonçalves and Camotim, 2013 [1]), the authors presented an investigation concerning the buckling (bifurcation) behaviour of uniformly compressed thin-walled tubes with regular polygonal cross-sections (RCPS). The present paper complements the previous work by addressing the local and distortional buckling behaviour of RCPS members subjected to bending or torsion and aims at providing a novel insight into these phenomena. In particular, the specialization of Generalized Beam Theory (GBT) for RCPS, as recently proposed in Gonçalves and Camotim (2013) [2], is employed to obtain closed-form analytical solutions and also to carry out parametric studies by means of numerical analyses which are both computationally efficient (due to the small number of d.o.f. involved) and clarifying (due to the modal decomposition features of GBT). For validation purposes, solutions taken from the literature and also standard shell finite element model results are employed.

ABSTRACT: Main bridge of Nanning Bridge is taken as Research Object. Using the finite element program ANSYS, space finite element model of an arch bridge with two inclined thin-walled steel box ribs is build, stability safety factor of the bridge is calculated, eigenvalue buckling analysis and non-linear buckling analysis of inclined thin-walled ribs are carried out, and stability performance is discussed. The result shows that stability problems of this bridge mainly occur on the ribs and are out-of-plane buckling in general, and horizontal loads have greater influences on out-of-plane buckling. The calculation results can provide parameters for construction, health detection and maintenance in the operational phase of the bridge.

ABSTRACT: The main objective of this paper is to propose a new closed form solution, useful in the pre-design stage, that allows one to calculate the mean load in the case of post-collapse of polygonal thin-walled columns in the axial crushing case. This model gives a rapid and accurate evolution of the normalized mean load as function of the corner element angle as well as the ratio between the corner length and the column thickness. To identify the parameters of this model, numerical simulations with an explicit finite element software have been carried out and then compared to experimental results reported in the literature. Finally, all these results combined with the findings based on the known generalized mixed model developed by other researchers working on this topic enabled one to establish the closed form solution. This is a unified and continuous closed form solution, which is suitable for different columns shapes, even non-conventional shapes obtained thanks to the development of extrusion techniques.

ABSTRACT: We present a strategy for the design of gridshells where form-found structures are optimised for buckling resistance. A genetic algorithm is employed for the initialisation of pre-stress forces required in form-finding using dynamic relaxation. Dynamic relaxation takes this initial pre-stress, a flat grid, as well as self-weight and nodal loads to calculate a static equilibrium. The structure is then analysed for the estimation of the critical buckling load. Different boundary conditions, structural parameters and typology of connections are compared, including a gridshells with triangular and quadrangular patterns. Optimised structures are measured against the trivial solution, which is a structure where dynamic relaxation is initialised with uniform pre-stress. Our results show the proposed strategy can successfully form find gridshells with improved buckling performance.

ABSTRACT: In this paper, we study the structural performance of grid shells covered with triangles and hexagons. These meshes, also known as Kagome lattices have the same node valence as quad-meshes, and thus an equivalent complexity. We present a method that guarantees the covering of free-form shapes with a Kagome lattice with planar facets, making this mesh economically viable. The performance of the Kagome lattice is assessed with two comprehensive parametric studies that vary relevant geometrical parameters like rise-over-span ratio or grid density. The linear buckling load of quadrangular and Kagome lattices is compared and shows that the Kagome lattice is up to 100% more efficient than the quadrangular mesh in the models studied.

ABSTRACT: Elastic gridshells are doubly curved grids with a shell-like behaviour, obtained by elastic deformation and bracing of a flat grid with no shear rigidity. After a brief review of their design process, the buckling of elastic gridshells is numerically investigated through a geometrically nonlinear analysis; then a formula for predicting the local buckling load is derived from the results of a parametric study. The numerical study required the development of an accurate form-finding method named "the advanced compass method" and of a specific algorithm ensuring the quick convergence of the non-linear finite element simulations, both
presented in this paper. The influence of the prestress, the eccentricity and the anisotropy of the shell are discussed, giving hence indications for correct modeling and efficient design of elastic gridshells.

ABSTRACT: The paper presents some results on the influence of the pre-stress induced by the erection method
of elastic grid shells on their buckling capacity. It starts with the numerical methods and their validation with the study of a pre-buckled arch. Then, a form-finding scheme using low-speed dynamics is used to generate automatically a family of elastic grid shells, and their buckling capacity is compared to the one of grid shells with the exact same geometry, but without any pre-stress. The paper demonstrates finally that the pre-stress decreases by a few percent the buckling capacity of elastic grid shells.

ABSTRACT: The elastic grid shell is a solution that combines double curvature and ease of mounting. This structural system, based on the deformation of an initially at grid without shear stiffness was invented more than fifty years ago. The apparition of new materials such as GFRP increased the potential of such structures whose properties depend on the deformation, or equivalently pre-stress of an initial structure. Elastic grid shells seem particularly promising as shelters, lightweight roofs, or kinetic structures. Although fundamental to the behavior of the structure, the influence of the pre-stress on the stability of elastic grid shells has yet to be studied. Understanding this phenomenon could allow engineers to design more efficiently elastic grid shells. This thesis studies the influence of pre-stress on the stability of elastic grid shells. The research conducts a parametric study that focuses both a pre-buckled arch and initially at circular elastic grid shells with different grid spacing and levels of pre-stress. Realistic values of the parameters are determined from existing projects. The buckling analysis as well as the form-finding of the different structures are performed using finite element analysis. The tools are validated with comparison of the shape and buckling capacity of a pre-buckled arch with existing experiments. The parametric studies lead to recommendations aiming to facilitate the design of elastic grid shells.

ABSTRACT: The optimization of cold formed closed steel built-up columns without stiffeners is performed using finite element analysis. An accurate finite element model is used for study in which different size of webs are investigated. The closed cold formed built-up steel column strength were studied with and without coupling of section. The final section of column buckling behaviour is predicted by the nonlinear finite element method and discusses the unfactored design column strength.

ABSTRACT: When numerical models are used to predict behaviour of open thin-walled steel cross-sections, the nonlinear analysis results can be influenced by the magnitudes introduced as initial imperfection. At present, a wide range of values is considered in research concerning this topic. This paper explores up to what point the nonlinear analysis results are sensitive to the choice of imperfection magnitudes and attempt to refine the
spectrum of magnitudes that should be used. The study focuses on rack uprights (with and without perforations) under compression and the numerical model has been validated with experimental tests conducted by the authors. Three different column lengths have been selected to reproduce a mainly local, distortional and global failure mode, so that coupled instabilities have not to be considered in this case. The results show that the ultimate load and collapse mode are both sensitive to imperfection amplitude, mainly in the case of distortional buckling.

SUMMARY: In this thesis a new two dimensional differential quadrature treatment for cylindrical shell is introduced. Special types of matrix products are used to treat the non-linearity of the presented problem. The presented solution is verified with previous works and shows good agreement. Using differential quadrature method, this study analyzes the stability and critical buckling load of circular cylindrical shells with delamination. The study uses the Griffith-Irwin concept to study the stability of delamination. Non-linear equations describing the development of delamination under axial load are obtained on the basis of fracture-mechanics. In order to study delamination growth, the present thesis examines the critical buckling load and the energy release rate under different boundary conditions, different elastic constants, different delamination thicknesses and lengths. Results are represented in both graphical and tabulated forms.

ABSTRACT: In this paper, ductility aspects of a light-weight composite gridshell are developed. A gridshell is a very light structure that can support relative high loads. For many reasons, the materials used by the Navier laboratory are glass fibre reinforced polymers (GFRPs) that have elastic brittle behaviour. To ensure the safety of people these structures have to behave in a ductile way, that is to say they must not collapse without showing signs of weakness. This paper deals with the pseudo-ductile behaviour of the GFRP gridshells designed by the Architected Structures and Materials research unit of Navier laboratory. After a reminding context about gridshells, the buckling of the Solidays’ festival gridshell prototype (June 2011) is considered. It is demonstrated that buckling has to be avoided carefully because it fosters high stresses in the beams and may lead to a brutal collapse of the structure. Then it is shown that, under Ultimate Limit State (ULS), the gridshell prototype is far from buckling. Finally, a simulation of accident is performed: from the ULS, several elements are broken in order to understand the behaviour of the structure in case of accident. The pseudo-ductility of the structure is demonstrated thanks to the redundancy of the structural concept of the gridshell.

ABSTRACT: Buckling instabilities of thin sheets of plates of viscous fluid occur in situations ranging from food and polymer processing to geology. Slim, Teichman & Mahadevan (J. Fluid Mech., Vol 694, pp. 5-28, 2012) study numerically the buckling of a sheared viscous plate floating on a denser fluid using three approaches: a classical ‘thin viscous plate’ model; full numerical solution of the three-dimensional Stokes equations; and a novel ‘advection-augmented’ thin-plate model that accounts (in an asymptotically inconsistent way) for the advection of perturbations by the background shear flow. The advection-augmented thin-plate
The model is markedly superior to the classical one in its ability to reproduce the predictions of the Stokes solution, illustrating the utility of judicious violations of asymptotic consistency in fluid-mechanical models.

ABSTRACT: Buckling of a cantilever steel pipe column under combined loads was studied through linear and nonlinear numerical analysis method. Firstly, linear buckling analysis of the cantilever column with linear-elastic material was used to select appropriate element type and element size for this problem. Then linear buckling and nonlinear buckling analyses for an imperfect cantilever column under different horizontal loads or displacements in the context of elasticity were performed to verify the ability of the linear buckling analysis to include large geometric changes. Thirdly, nonlinear analyses were carried out to examine the effect of plastification of material on the buckling limit loads for the imperfect cantilever column. Through these comparative studies, some aspects concerned with the numerical buckling analysis of structures such as columns were clarified.

ABSTRACT: The main purpose of this study is to investigate the effect of delamination shapes and sizes on the lateral buckling behavior of the woven E-glass/epoxy laminated composite plates, experimentally and numerically. In order to perform experimental study, composite plates having eight laminates reinforced with woven E-glass fabric layers as [W]s are produced by using hand lay-up technique. For the delamination, basically two different delamination shapes, square and circular, are used. To investigate the effect of the delamination shape on the lateral buckling behavior, these delamination shapes are diversified. Six different rectangular delamination shapes are obtained by the changing aspect ratio of the horizontal and vertical diameter of the circular delamination. These aspect ratios are 0.50, 0.67, 0.75, 1.33, 1.67 and 2.00. To better understand the effect of delamination on the lateral buckling behavior, the experimental and numerical results of the specimens with and without delamination are compared. The experimental results have good agreement with numerical results, and these results show that the delamination shapes and sizes affected the critical lateral buckling load.

ABSTRACT: This paper presents an analytical investigation on the nonlinear dynamic analysis of functionally graded double curved thin shallow shells using a simple power-law distribution (P-FGM) with temperature-dependent properties on an elastic foundation and subjected to mechanical load and temperature. The formulations are based on the classical shell theory, taking into account geometrical nonlinearity, initial geometrical imperfection, temperature-dependent properties and unlike other publications, Poisson ratio is assumed to be varied smoothly along the thickness $\nu = \nu(z)$. The nonlinear equations are solved by the Bubnov-Galerkin and Runge-Kutta methods. The obtained results show the effects of temperature, material and geometrical properties, imperfection and elastic foundation on the nonlinear vibration and nonlinear dynamical response of double curved FGM shallow shells. Some results were compared with those of other authors.

ABSTRACT: This paper first time presents an analytical investigation on the nonlinear postbuckling of imperfect eccentrically stiffened thin FGM plates under temperature and resting on elastic foundation using a simple power-law distribution (P-FGM). Both of the FGM plate and stiffeners are deformed under thermal loads. The formulations are based on the classical plate theory taking into account geometrical nonlinearity, initial geometrical imperfection, temperature-dependent properties and the Lekhnitsky smeared stiffeners technique with Pasternak type elastic foundation. By applying Galerkin method and using stress function, effects of material and geometrical properties, temperature, elastic foundation and eccentrically stiffeners on the buckling and postbuckling loading capacity of the eccentrically stiffened FGM plate in thermal environments are analyzed and discussed. Some results were compared with the one of the other authors.

ABSTRACT: This paper presents the results of a numerical investigation for applying a combination of buckling mode shapes as an initial imperfection to shell geometries under external pressure. The effect that imposed imperfections had on the critical buckling pressure was found to be dependent upon both the shell geometry and the characteristics of the imposed imperfection. Imperfections were generated via linear combinations of the linear elastic buckling mode shapes, with the fundamental mode having the greatest influence. For a number of tests, inclusion of higher order modes into the initial imperfection caused an increase in the critical buckling pressure. This behaviour was observed for both elastic and plastic material models. For the purpose of limiting the extent of the analysis, the magnitudes of imposed imperfections were maintained within the industry required fabrication tolerances and in particular, acceptable out-of-roundness. The purpose of this paper is to present the methodology and results from this imperfection investigation. Additional testing and discussion may allow a design methodology to be developed that addresses the application of initial imperfections in shells under external pressure.

ABSTRACT: Designing a suitable, applicable and efficient support system for underground road structures have always been one of the most important engineering tasks for tunnel engineers. There are some different support systems applied to making underground structures safe against overburden and lateral pressures. Among these systems, permanent or temporary steel frames, wire meshes, rock bolts and shotcretes have been commonly used for suffering the exerted burdens and making the structure a safe place. This paper proposes a numerical analysis of the geometrical instability of steel-arch shells as one of the main bodies of underground road structure liners by means of calculating their buckling load and utilizing the finite element method. In this regard, a considerable number of structures (84) having different geometrical parameters have been modelled and their buckling loads have been calculated. For this purpose, the thickness, internal angle and radius of the periphery cylinder of the arch-shell system were considered taking into account geometrical parameters. Moreover, to accurately model the buckling load using the proposed algorithm, the weight of the structure has also been included in the made calculations. Finally, as the main scope is based on the Cosine Amplitude Method, sensitivity analysis is carried out to investigate the strength of the relationship between each input geometrical parameter and their buckling load. Based on the obtained relationships, the thickness of the structure is reported as the most affective geometrical parameter on buckling steel arch-shell support systems. In addition, the internal angle of arch supports is the least influential parameter.

ABSTRACT: In the present work a model able to predict the buckling behavior of thin, orthotropic, stiffened plates and shells subject to axial compression is proposed. In the context of the Kirchhoff-Love plate theory and making use of different strain-displacement models – namely the von Kármán model, the Koiter-Sanders shell model, an enhanced von Kármán model and a spurious model commonly adopted in literature – the equilibrium equations have been solved by the Levy-type approach. The results obtained highlight the influence of each non-linear strain-displacement term and show that the von Kármán model can noticeably overestimate the buckling load when the critical mode involves significant in-plane displacements.

ABSTRACT: To increase the thermal resistance of various structural components in high-temperature environments, research reports focusing nonlinear axisymmetric response of thin FGM shallow spherical shells with ceramic – metal – ceramic layers (S-FGM) under uniform external pressure and temperature. Equilibrium and compatibility equations for shallow spherical shells are derived by using the classical shell theory and specialized for axisymmetric deformation with both geometrical nonlinearity and initial geometrical
imperfection. One-term deflection mode is assumed and explicit expressions of buckling loads and load–deflection curves are determined due to Galerkin method. Stability analysis for a clamped spherical shell shows the effects of material and geometric parameters, edge restraint and temperature conditions, and imperfection on the behavior of the shells. The results were compared with the P-FGM spherical shell symmetry axis (ceramic – metal).

The material properties are graded in the thickness direction according to the power-law distribution in terms of volume fractions of the constituents of the material. In the formulation of governing equations geometric non-linearity in all strain-displacement relations of the shell is considered. Using Bubnov-Galerkin's method to solve the problem an approximated analytical expression of non-linear buckling loads of functionally graded spherical shells is obtained, that allows easily to investigate stability behaviors of the shell.

Dao Huy Bich and Vu Do Long (Vietnam Academy of Science and Technology), “Non-linear dynamical analysis of imperfect functionally graded material shallow shells”, Vietnam Journal of Mechanics, Vol. 32, No. 1, 2010, DOI: 10.15625/0866-7136/32/1/312 ABSTRACT: Dynamical behaviors of functionally graded material shallow shells with geometrical imperfections are studied in this paper. The material properties are graded in the thickness direction according to the power-law distribution in terms of volume fractions of the constituents of the material. The motion, stability and compatibility equations of these structures are derived using the classical shell theory. The non-linear equations are solved by the Newmark's numerical integration method. The non-linear transient responses of cylindrical and doubly-curved shallow shells subjected to excited external forces are obtained and the dynamic critical buckling loads are evaluated based on the displacement responses using the criterion suggested by Budiansky and Roth. Obtained results show the essential influence of characteristics of functionally graded materials on the dynamical behaviors of shells.

ABSTRACT: The present paper deals with the non-linear vibration of functionally graded shallow spherical shells. The properties of shell material are graded in the thickness direction according to the power law distribution in terms of volume fractions of the material constituents. In the derived governing equations geometric non-linearity in all strain-displacement relations of the shell is considered. From the deformation compatibility equation and the motion equation a system of partial differential equations for stress function and deflection of shell is obtained. The Galerkin method and Runge-Kutta method are used for dynamical analysis of shells to give expressions of natural frequencies and non-linear dynamic responses. Numerical results show the essential influence of characteristics of functionally graded materials and dimension ratios on the dynamical behaviors of shells.

ABSTRACT: The paper deals with the formulation of governing equations of eccentrically stiffened functionally graded plates and shallow shells based upon the classical shell theory and the smeared stiffeners technique taking into account geometrical nonlinearity in Von Karman-Donnell sense. Material properties are assumed to be temperature-independent and graded in the thickness direction according to a simple power law distribution in terms of the volume fraction of constituents. The shells are reinforced by eccentrically longitudinal and transversal stiffeners made of full metal or full ceramic depending on situation of stiffeners at metal-rich side or ceramic-rich side of the shell respectively. Obtained governing equations can be used in research on nonlinear post-buckling of mentioned above structures. By use of the Galerkin method an approximated analytical solution to the nonlinear stability problem of reinforced FGM plates and shallow shells is performed. The postbuckling load-deflection curves of the shells are investigated and analytical expressions of the upper and lower buckling loads are presented. A comparison of the effectiveness of stiffeners in enhancing the stability of FGM plates and shallow shells is given.

“Buckling analysis of functionally graded annular spherical shells and segments subjected to mechanic loads”

ABSTRACT: An analytical approach is presented to investigate the buckling of functionally graded annular spherical segments subjected to compressive load and radial pressure. Based on the classical thin shell theory, the governing equations of functionally graded annular spherical segments are derived. Approximate solutions are assumed to satisfy the simply supported boundary condition of segments and Galerkin method is applied to obtain closed-form relations of bifurcation type of buckling loads. Numerical results are given to evaluate effects of inhomogeneous and dimensional parameters to the buckling of structure.

ABSTRACT: An analytical approach is presented to investigate the linear buckling of eccentrically stiffened functionally graded thin circular cylindrical shells subjected to axial compression, external pressure and torsional load. Based on the classical thin shell theory and the smeared stiffeners technique, the governing equations of buckling of eccentrically stiffened functionally graded circular cylindrical shells are derived. The functionally graded cylindrical shells with simply supported edges are reinforced by ring and stringer stiffeners system on internal and (or) external surface. The resulting equations in the case of compressive and pressive loads are solved directly, while in the case of torsional load is solved by the Galerkin procedure to obtain the explicit expression of static critical buckling load. The obtained results show the effects of stiffeners and input factors on the buckling behavior of these structures.

References listed at the end of the paper:

ABSTRACT: This paper presents an analytical approach to investigate the nonlinear buckling of imperfect eccentrically stiffened functionally graded thin circular cylindrical shells subjected to axial compression and surrounded by an elastic foundation. Based on the classical thin shell theory with the geometrical nonlinearity in von Karman-Donnell sense, initial geometrical imperfection, the smeared stiffeners technique and Pasternak’s two-parameter elastic foundation, the governing equations of eccentrically stiffened functionally graded cylindrical shells are derived. The functionally graded cylindrical shells are reinforced by homogeneous ring and stringer stiffener system on internal and (or) external surface. The resulting equations are solved by the Galerkin method to obtain the explicit expression of static critical buckling load, post-buckling load-deflection curve and nonlinear dynamic motion equation. The nonlinear dynamic responses are found by using fourth order Runge-Kutta method. The dynamic critical buckling loads of shells are considered for step loading of infinite duration and linear-time compression. The obtained results show the effects of foundation, stiffeners and input factors on the nonlinear buckling behavior of these structures.

ABSTRACT: Stiffened composite panels are extensively used in aircraft structures because of their high stiffness to weight and high strength to weight ratios. Stiffened panels prone to buckle under in-plane loads and understanding the load carrying capacity beyond buckling is very important. The load carrying capacity of the panels depends on the post buckling behavior and strength. If the panels possess significant post buckling
strength then the structure can be allowed to buckle before the design load and this will significantly reduce the
cost and weight of the structures. The aim of the project is to analyze the buckling, post-buckling behavior and
failure characteristics of simply supported stiffened panels under uni-axial compressive load. Finite Element
Analysis (FEA) is a very good computational technique that can be used for the study. These FE results
obtained can be verified with the help of experimental results.

material annular spherical shells under thermo-mechanical load”, Mechanics of Advanced Materials and
Structures, Vol. 23, No. 12, 2016, DOI: 10.1080/15376494.2015.1091528
ABSTRACT: The authors of this article investigate the nonlinear stability of axisymmetric functionally graded
annular spherical shells with temperature-dependent material properties subjected to thermo-mechanical loads
and resting on elastic foundations. Equilibrium and compatibility equations are derived by using the classical
thin shell theory in terms of the shell deflection and the stress function. Approximate analytical solutions are
assumed to satisfy simply supported boundary conditions and Galerkin method is applied to obtain the closed-
form of load–deflection paths. An analysis is carried out to show the effects of material and geometrical
properties and combination of loads on the stability of the shells.

"Buckling Analysis of Eccentrically Stiffened Functionally Graded Toroidal Shell Segments under Mechanical
ABSTRACT: An analytical approach is presented to investigate the linear buckling of eccentrically stiffened
functionally graded thin toroidal shell segments subjected to axial compression, lateral pressure, and hydrostatic
pressure. On the basis of classical thin shell theory, the smeared stiffener technique and the adjacent equilibrium
criterion, the governing equations of buckling of eccentrically stiffened functionally graded toroidal shell
segments are derived. The functionally graded toroidal shell segments with simply supported edges are
reinforced by a ring and stringer stiffener system on an external surface. The resulting equations in the case of
compressive and pressure loads are solved directly. The obtained results show the effects of stiffeners and input
factors on the buckling behavior of these structures. In this paper, the results are also compared with the
solutions published in the literature for the specific cases of a toroidal shell.

"Non-linear buckling analysis of FGM toroidal shell segments filled inside by an elastic medium under external pressure loads including temperature effects", Composites Part B: Engineering, Vol. 87, pp 75-91, February 2016, DOI: 10.1016/j.compositesb.2015.10.021

ABSTRACT: The analytical approach is presented to investigate non-linear buckling analysis and post-buckling behavior of FGM toroidal shell segments filled inside by an elastic medium under external pressure loads including temperature effects. The governing equations of non-linear buckling of FGM toroidal shell segments are derived based on the classical thin shell theory with the geometrical nonlinearity in von Karman–Donnell sense, Stein and McElman assumption and elastic medium modeled by Pasternak's two-parameter elastic foundation. The static critical buckling loads and the post-buckling pressure–deflection curves in two cases: movable and immovable boundary conditions including temperature effects are obtained by using the Galerkin's method. In the paper, the results are also compared with the solutions published in the literature for the specific cases. Effects of geometrical and material parameters, elastic foundation and temperature on the nonlinear buckling behavior of shells are shown in obtained results.

ABSTRACT: The nonlinear buckling and post-buckling of functionally graded stiffened toroidal shell segment surrounded by elastic foundation in thermal environment and under torsional load are investigated in this paper. The functionally graded toroidal shell segments are reinforced by ring and stringer stiffeners system in which material properties of shell are assumed to be continuously graded in the thickness direction. The two-parameter elastic foundation proposed by Pasternak is studied. Theoretical formulations are derived basing on the classical shell theory with the geometrical nonlinearity in von Karman sense and the smeared stiffeners technique. The three-term approximate solution of deflection is chosen more correctly and the explicit expression for finding critical load and post-buckling torsional load-deflection curves are found. The effects of geometrical parameters, temperature, stiffeners and elastic foundation are investigated.

Sushma (Mechanical Engineering Dept., Chaitanya Bharathi Institute of Technology, Hyderabad-75, Andhra Pradesh, India), "Buckling analysis of thin carbon/epoxy plate with circular cut-outs under biaxial compression by using FEA", International Journal of Research in Engineering and Technology (IJRET), Vol. 02, No. 10, October 2013

ABSTRACT: The present research work is to determine buckling load per unit length in rectangular plate with circular cut-outs under bi-axial compression using 2D finite element analysis. The commercial finite element analysis software ANSYS has been successfully executed. The buckling factors are evaluated by changing the position of the holes, length to thickness ratio. The effect of changing the position of holes, a/b ratio, b/t ratio and buckling load per unit length is discussed. The results show that buckling load per unit length is in clamped-clamped boundary conditions and buckling load is more at top positioned hole, decrease with increase in aspect ratio, decrease with increase breadth to thickness ratio.

S. Kainuma, J. H. Ahn, I. T. Kim, "Corrosion Pattern for Critical Shear Buckling Load of a Web Panel with
DOI: 10.4028/www.scientific.net/AMM.421.778

ABSTRACT: Shear buckling strength of a web panel with local corrosion damage can be changed by web corrosion pattern. In this study, To find critical corrosion pattern for shear buckling of a web panel with local corrosion. Critical shear buckling loads of the corroded web panels were quantitatively evaluated. Thus, FE analysys models were created cosidering corrosion pattern in the plate girder bridge which was reported from the corroded bridge inpection. As corrosion pattern of the web panel in the plate girder bridge, three corrosion patterns were selected as main corrosion cases such as longitudinal, vertical, and triangular cases. Their critical shear buckling loads were compared according to their corroded web codition.

2013 SSRC Annual Stability Conference Proceedings, April 17-19 – St. Louis, MO

Session 1 - Technical Presentations: Topics in Stability Research
Intermediate Transverse Stiffeners in Stiffened Plate Girders, D. Beg, F. Sinur, University of Ljubljana, Ljubljana, Slovenia

Compression Members with Hollow Sections and Concentric Slotted Gusset Plates - Behavior and Recommended Design Model, H. Unterweger, A. Taras, Graz University of Technology, Graz, Austria

Three-Dimensional Joist Member Studies using Equivalent Beam Theory, S.J. Kilber, A.E. Surovek, South Dakota School of Mines and Technology, Rapid City, South Dakota

The Overall Interaction Concept: An Alternative Approach to the Stability and Resistance of Steel Sections and Members, N. Boissonnade, J. Nseir, E. Saloumi, University of Applied Sciences of Western Switzerland-Fribourg, Fribourg, Switzerland

Session 2 - Technical Presentations: Stability of Steel Shear Walls

The Post-Buckling Strength and Tension-Field Action Mechanism of Cold-Formed Steel Shear Walls with Steel Sheeting, S. Mohebbi, S.R. Mirghaderi, University of Tehran, Tehran, Iran, F. Farahbod, Building and Housing Research Center of Iran, Teran, Iran, S. Torabian, University of Tehran, Tehran, Iran

Analytical Model for Stiffened Steel Infill Plates, S. Sabouri, S. Mamazizi, K.N. Toosi, University of Technology, Tehran, Iran

Effective Strip Model for Cold-Formed Steel Shear Wall using Steel Sheet Sheathing, N. Yanagi, C. Yu, University of North Texas, Denton, Texas

Shell Buckling Evaluation of Thin-Walled Steel Tanks Filled at Low Liquid Level According to Current Design Codes, C. Maraveas, K. Miamis, C. Maraveas Partnership, Athens, Greece

Localized Web Buckling of Double-Coped Beams, Bo Dowswell, ARC International, LLC, Birmingham,

ABSTRACT: In a recent feature article in this journal, co-authored by Gert van der Heijden, I described the static-dynamic analogy and its role in understanding the localized post-buckling of shell-like structures, looking exclusively at integrable systems. We showed the true significance of the Maxwell energy criterion load in predicting the sudden onset of 'shock sensitivity' to lateral disturbances. The present paper extends the survey to cover non-integrable systems, such as thin compressed shells. These exhibit spatial chaos, generating a multiplicity of localized paths (and escape routes) with complex snaking and laddering phenomena. The final theoretical contribution shows how these concepts relate to the response and energy barriers of an axially compressed cylindrical shell. After surveying NASA's current shell-testing programme, a new non-destructive technique is proposed to estimate the 'shock sensitivity' of a laboratory specimen that is in a compressed meta-stable state before buckling. A probe is used to measure the nonlinear load-deflection characteristic under a rigidly applied lateral displacement. Sensing the passive resisting force, it can be plotted in real time against the displacement, displaying an equilibrium path along which the force rises to a maximum and then decreases to zero: having reached the free state of the shell that forms a mountain-pass in the potential energy. The area under this graph gives the energy barrier against lateral shocks. The test is repeated at different levels of the overall compression. If a symmetry-breaking bifurcation is encountered on the path, computer simulations show how this can be suppressed by a controlled secondary probe tuned to deliver zero force on the shell.

“Stretch-induced wrinkles in reinforced membranes: From out-of-plane to in-plane structures”, EPL (Europhysics Letters), Vol. 96, No. 6, December 2011
ABSTRACT: We study, through model experiments, the buckling under tension of an elastic membrane reinforced with a more rigid strip or fiber. In these systems, the compression of the rigid layer is induced through Poisson contraction as the membrane is stretched perpendicularly to the strip. Although strips always lead to out-of-plane wrinkles, we observe a transition from out-of-plane to in-plane wrinkles beyond a critical strain in the case of fibers embedded into elastic membranes. We describe through scaling laws the evolution of the morphology of the wrinkles and the different transitions as a function of material properties and stretching strain.

PARTIAL INTRODUCTION: The intriguing buckling patterns exhibited by bilayer systems composed of a thin stiff film bonded to a thick elastomeric substrate have been studied extensively in recent years both experimentally and theoretically. Under compression, the film is constrained by the substrate and buckles with a wavelength that is usually large compared to the film thickness, yet small compared to the substrate thickness. The most common patterns observed are the sinusoidal wrinkle mode when compression in one direction is dominant,[1] and the herringbone[2,3] and labyrinth[2–4] modes when compression is equi-biaxial. The present paper is part of the ongoing research effort in the soft-materials community to produce and manipulate specific
buckling patterns.\[^{5,6}\] Most of the previous work has focused on buckling patterns of bilayer systems under small compression. Recent work, however, has demonstrated that large compression of a bilayer system can engender other surface patterns such as period-doubling\[^{7}\] and folding\[^{8,9}\] opening the way for the creation of a wider array of surface patterns. These post-wrinkling modes involve the large strain behavior of the substrate and geometrical non-linearity of the films in an essential way. The focus of the present paper is on the most recent of the post-wrinkling modes to be discovered, the ridge localization mode. While folds and creases protrude into the substrate, the ridge is a large amplitude localization that pushes out from the substrate. This mode should be characterized as a localization because the large amplitude of the ridge is fed by flattening the nearby wrinkle undulations resulting in ridges that are separated from each other by expanses of relatively flat film. Thus, a distinct feature of the transition from wrinkles to ridges is the abrupt increase of spacing from crest to crest. The ridge localization was predicted to occur,\[^{10}\] and has been observed experimentally,\[^{5,6,11}\] only when a relatively large pre-stretch was imposed on the elastomeric substrate prior to film attachment. Controlled incremental release of the pre-stretch of the thick substrate then imposes compression on the film, which drives buckling.

ABSTRACT: Geometrically nonlinear model and numerical solutions of large deformation of imperfect functionally graded materials conical shell subjected to both mechanical load and transversely non-uniform
temperature rise are given. The material properties of functionally graded shell are assumed to be graded in the thickness direction according to a simple power law distribution in terms of the volume fractions of the constituents. On the basis of geometrically nonlinear theory of shell, governing equations of the axisymmetrical deformation are derived. Numerical solutions are obtained by using a shooting method.

“Delamination behavior of axymmetric sandwich shells under axial compressive loading”, 16th European Conference on Composite Materials (ECCM16), Seville, Spain, 22-26 June 2014

ABSTRACT: This work covers the experimental and numerical analysis of asymmetric sandwich shells introduced as innovative fuselage structure for transport aircraft in the research program “Citizen-friendly Aircraft”. The shells consist of a CFRP skin carrying the main loads, a rigid closed cell PMI foam core and a thin aluminum layer. The manufacturing process is illustrated and several test specimens are damaged by predefined delaminations in between the aluminum skin and the foam. It is shown that face sheet delaminations can significantly reduce the structures’ load bearing capacities and propagate suddenly through the entire structure when reaching the critical load. Comparison with a FE simulation showed good morphological agreement, however, the prediction of failure loads and out-of-plane deformation of the buckling skin can be improved.

ABSTRACT: Carbon Fiber Reinforced Polymers (CFRPs) have been widely used in numerous applications where high specific stiffness and strength offer structural weight reduction and fuel efficiency. RVS (re-entry vehicle system) structural protection to the weapon system during re-entry. These kinds of structures are realized using filament winding process. In this paper mechanical characterization of CFRP with Carbon Nano-fiber has been prented. Studies are carried out to characterize the strength and Young’s modulus of the composite structure. Carbon Nano-fibers are among the greatly potential reinforcing additives for polymeric composites due to their high axial Young’s modulus, high aspect ratio, large surface area, and excellent thermal and electrical properties. Various studies can be found in the literature regarding the incorporation of CNFs in polymeric matrices and the final mechanical and/or electrical properties of these materials. To prove the technology a composite cylinder having size Length of 600mm, Diameter 300mm and thickness 1.5mm is considered for experimental study. In the present work a method has been developed to analyze composite shell using Layered 46. In addition, 3D layered analysis of composite cylinder with end metallic plates have been performed to predict the Buckling behavior of the Composite shell. Composite shell were fabricated & tested with buckling load condition to verify the design and analysis procedure. It has been observed that the experimental results are in close agreement with the finite element analysis results, also the design stresses were within safe limits. Based on test results, the Longitudinal Strength of CFRP with CNF is achieved 1860 MPa, Young’s modulus is 118 GPa and improvement against CFRP with epoxy resin (LY556).

ABSTRACT: In this paper, the nonlinear behaviour of steel plate shear walls with corrugated plates under lateral pushover loading conditions in the models' top level has been analytically investigated by the finite element method. The one-storey frames have beams and columns as boundary elements. Steel plate shear walls are simulated using the finite element method, based on the available experimental models in the literature. After calibration of the analytical models, more parameters of steel shear walls with corrugated plates, such as the thickness of the corrugated plate, the stiffness of the boundary elements, the corrugation depth in the corrugated plates and the corrugation length of the infill of the corrugated plates, are investigated. The results of this study have demonstrated that in the wall with constant dimensions, the trapezoidal plates have higher energy dissipation, ductility and ultimate bearing than sinusoidal waves, while decreasing the steel material consumption.

ABSTRACT: In this study, we try to analyze the free nonlinear vibration of a stringer shell analytically. The nonlinear governing equation of the problem is derived. Homotopy perturbation method is applied completely to obtain the analytical solution of the problem. We try to provide engineers and designers to achieve the nonlinear frequency of nonlinear problems especially shell vibrations with an easy method. The effects of different parameters on the ratio of nonlinear to linear natural frequency of shells are completely studied. The homotopy perturbation method gives us an excellent agreement with numerical results for whole range of the oscillation amplitude. The first order of homotopy perturbation method leads us to highly accurate solutions as indicated in this paper.

ABSTRACT: In this paper, the nonlinear free vibration of a stringer shell is studied. The mathematical model of the string shell, which is the most convenient for frequency analysis, is considered. Due to the geometrical properties of the vibrating shell, strong nonlinearities are evident. Approximate analytical expressions for the nonlinear vibration are provided by introducing the extended version of the Hamiltonian approach. The method suggested in the paper gives the approximate solution for the differential equation with dissipative term for which the Lagrangian exists. The aim of this study is to provide engineers and designers with an easy method for determining the shell nonlinear vibration frequency and nonlinear behavior. The effects of different parameters on the ratio of nonlinear to linear natural frequency of shells are studied. This analytical representation gives excellent approximations to the numerical solutions for the whole range of the oscillation amplitude, reducing the respective error of the angular frequency in comparison with the Hamiltonian approach. This study shows that a first-order approximation of the Hamiltonian approach leads to highly accurate solutions that are valid for a wide range of vibration amplitudes.

Huehne (Institute for Composite Structures and Adaptive Systems, German Aerospace Center (DLR), Lilienthalplatz 7, 38108 Braunschweig, Germany), A new design concept for cylindrical composite shells under axial compression”, 16th European Conference on Composite Materials (ECCM16), Seville, Spain, 22–26 June 2014

ABSTRACT: Thin-walled cylindrical shells are prone to buckling. Imperfections which are defined as deviations from the perfect geometrical shape or homogeneous loading distribution can reduce the buckling load significantly compared to that of the perfect shell. For the design of unstiffened cylindrical shells mostly
the NASA SP-8007 guideline is used, which recommends reducing the buckling load of the perfect shell using a knock-down factor. Existing knock-down factors are conservative and structural behavior of composite shells is not considered. A new proposal for an improved guideline is the advanced Single-Perturbation Load Approach (a-SPLA). The design loads of the new approach are, depending on the ply-layup, at least 40% larger compared to the design loads of the NASA SP-8007 and the behavior of composite structures is taken into account. Based on test results the concept is validated.

ABSTRACT: Based on the classical thin shell theory with the geometrical nonlinearity in von Karman-Donnell sense, the smeared stiffener technique, Galerkin method and an approximate three-term solution of deflection taking into account the nonlinear buckling shape is chosen, the governing nonlinear dynamic equations of eccentrically stiffened functionally graded circular cylindrical shells subjected to time dependent axial compression and external pressure is established in part 1. In this study, the nonlinear dynamic responses are obtained by fourth order Runge-Kutta method and the nonlinear dynamic buckling behavior of stiffened functionally graded shells under linear-time loading is determined by according to Budiansky-Roth criterion. Numerical results are investigated to reveal effects of stiffener, input factors on the vibration and nonlinear dynamic buckling loads of stiffened functionally graded circular cylindrical shells.

“Anti-buckling Fixture for Large Deformation Tension–Compression Cyclic Loading of Thin Metal Sheets”, Strain, 17 January, 2014, DOI: 10.1111/str.12078

ABSTRACT: Determination of cyclic properties of a material used for many engineering structures, e.g. airframes, requires preparation of specimens from two-dimensional, shell structures. A specimen must be cut
out from the structure component in the way allowing application of a load corresponding to that reflecting service cases. In order to fulfil this requirement, tension-compression testing of the flat specimen is necessary to obtain credible data. Problems associated with such kind of testing are discussed in this paper. In the first part, an extensive review of the anti-buckling fixtures developed up to now is given. Several representative solutions are discussed, with special emphasis on the technique limitations. In the second part of the paper, detailed description of the proposed design is given. Finally, the results of preliminary tests carried out using new fixture to mount the flat specimens cut from steel sheets are presented. Application of the proposed testing technique allowed tension-compression tests to be performed at the displacement amplitude within the range ±5 mm what corresponds to the maximum strain amplitude of ±0.4 for the specimen gauge length to be equal 12.5 mm. Taking into account all data captured by means of new fixture, one can conclude that the technique is promising with respect to providing data for modelling of cyclic deformation behaviour for shell structures.

IN MEMORIAM Dr. Charles C. Rankin (August 1942 – August 2012)

Charles Rankin is known for his salient fundamental contributions over more than 30 years to the field of solid and structural mechanics. All of these contributions have been formulated by Charles and implemented into his general-purpose nonlinear static and dynamic finite element code called STAGS (STructural Analysis of General Shells), widely used especially at NASA Langley Research Center. Charles was no mere programmer implementing into a code the mechanics theories of others; he developed these theories mainly by himself. Many of Charles’ fundamental contributions are now finding their way into the most widely used commercial structural computer programs such as MSC_NASTRAN, ANSYS and ABAQUS. In this way Charles’ important original contributions will for the foreseeable future have a major impact on research and engineering in academia, government and industry. Specifically Charles Rankin’s technical contributions include the formulation and implementation into STAGS of: 1. a finite-element-independent co-rotational theory that has now become an important standard in computational mechanics the world over, 2. an arc-length method that permits the traversal of limit points from pre-buckling to post-buckling, 3. an algorithm to determine multiple bifurcation eigenvalues and eigenvectors from nonlinearly determined pre-buckled equilibrium states, 4. a solution strategy that permits the successive introduction of a sequence of buckling modal imperfections into a nonlinear equilibrium analysis, 5. a strategy that permits successive smooth transitions from nonlinear static to transient and from nonlinear transient to static analyses, 6. a strategy that permits the simulation of unzipping of a through crack in a shell possibly with multiple crack tips and turning of a crack during loading, 7. a “sandwich” finite element that efficiently accounts for soft, shear-deformable cores and stiff face sheets, 8. unique nonlinear material models in separate “material modules” which are independent of the rest of the software. Charles was a great man, loved by many for his great sense of humor, respected by many for his towering intellect and superb accomplishments in the field of structural mechanics. He will remain forever in the minds and hearts of his many friends and colleagues.

AGENDA OF THE SYMPOSIUM IN MEMORY OF CHARLES RANKIN:

55th AIAA SDM meeting, National Harbor, Maryland, January 13 – 17, 2014
(Part of SCITECH 2014; there are two "Charles Rankin" sessions with 5 papers each.
Both sessions were held on Jan. 15, 2014.

Wednesday morning, January 15, 2014
Session Number: STR-11. Shell Bucking-Charles Rankin Special Session I
Chair(s): Mark Hilburger (NASA-Langley Research Center)
Co-Chair(s): Richard Young (NASA-Langley Research Center)

Stochastic identification of imperfections in a submerged shell structure
15 April 2014
H.M. Reed | C.J. Earls | J.M. Nichols
Abstract: Accurate predictions of the buckling load in imperfection sensitive shell structures requires precise knowledge of the location and magnitude of any geometric imperfections in the shell (e.g. dents). This work describes a non-contact approach to identifying such imperfections in a submerged shell structure. By monitoring the acoustic pressure field at discrete points proximal to a shell structure excited by a cyclic membrane (i.e. in-plane) loading, it is noticed that parameters, describing small scale denting, can be identified. In order to perform the identification, a fluid-structure model that predicts the spatio-temporal pressure field is required. This model is described in detail and includes the predicted effects of the imperfection on the observations. A Bayesian, Markov chain Monte Carlo approach is then used to generate the imperfection parameter estimates and quantify the uncertainty in those estimates. Additionally: for cases involving the occurrence of an unknown number of dents, reversible jump Markov chain Monte Carlo (RJMCMC) methods are employed in this work.

Post-buckling nonlinear static and dynamical analyses of uncertain cylindrical shells and experimental validation
1 April 2014
E. Capiez-Lernout | C. Soize | M.-P. Mignolet
Abstract: The paper presents a complete experimental validation of an advanced computational methodology adapted to the nonlinear post-buckling analysis of geometrically nonlinear structures in presence of uncertainty. A mean nonlinear reduced-order computational model is first obtained using an adapted projection basis. The stochastic nonlinear computational model is then constructed as a function of a scalar dispersion parameter, which has to be identified with respect to the nonlinear static experimental response of a very thin cylindrical shell submitted to a static shear load. The identified stochastic computational model is finally used for
predicting the nonlinear dynamical post-buckling behavior of the structure submitted to a stochastic ground motion.

An isogeometric continuum shell element for non-linear analysis
1 April 2014
Saman Hosseini | Joris J.C. Remmers | Clemens V. Verhoosel | René de Borst
Abstract: An isogeometric continuum shell formulation is proposed in which NURBS basis functions are used to construct the reference surface of the shell. Through-the-thickness behavior is interpolated using a higher-order B-spline which is in contrast to the standard continuum shell (solid-like shell) formulation where a linear Lagrange shape function is typically used in the thickness direction. The present formulation yields a complete isogeometric representation of the continuum shell. The shell element is implemented in a standard finite element code using Bézier extraction which facilitates numerical integration on the reference surface of the shell. Through-the-thickness integration is done using a connectivity array which determines the support of a B-spline basis function over an element. The formulation has been verified using different linear and geometrically non-linear examples. The ability of the formulation in modelling buckling of static delaminations in composite materials is also demonstrated.

Numerical validation of a concurrent atomistic-continuum multiscale method and its application to the buckling analysis of carbon nanotubes
1 March 2014
Stefan Hollerer
Abstract: This work applies the framework of a concurrent multiscale approach to the buckling analysis of carbon nanotubes. In particular, the bridging domain method is used to couple a molecular statics model and a continuum mechanics model. The total potential energy of the entire structure is specified by weighted individual energy contributions of overlapping subdomains. In this handshake region, additional kinematics constraints enforce the compatibility between designated atoms and the continuum body. Three different methods are taken into consideration for the kinematics coupling and the corresponding governing equations are presented. The continuum subdomain is handled by means of a finite element approach and the molecular statics is formulated suitable for a common computational implementation. A series of numerical examples investigates the capability of the bridging domain method for its application in the analysis of carbon nanotubes. Initially, the individual approaches for integrating the kinematics constraints into the global equilibrium equations are compared. Then, in the major contribution of the work, the influences of several modelling parameters of the multiscale model on the buckling analysis of a bent single-walled carbon nanotube are numerically studied. In particular, the size of the atomistic section, the extent of the handshake region and the finite element discretisation are varied. Furthermore, the results obtained by the standard and the relaxed variant of the bridging domain method are compared against each other. In addition, the buckling behaviour of a defective carbon nanotube with varying defect locations is presented. The obtained results of the bridging domain multiscale method are persistently validated against full atomistic molecular statics simulations.

ABSTRACT: A cell-based smoothed three-node Mindlin plate element (CS-MIN3) based on the first-order shear deformation theory (FSDT) was recently proposed for static and dynamics analyses of Mindlin plates. In this paper, the CS-MIN3 is extended to geometrically nonlinear analysis of functionally graded plates (FGPs) subjected to thermo-mechanical loadings. In the FGPs, the material properties are assumed to vary through the
thickness by a simple power rule of the volume fractions of the constituents. The nonlinear formulation is based on the C0-type high-order shear deformation plate theory (C0-HSDT) and the von Kármán strains, which deal with small strains and moderate rotations. In the analysis process, both thermal and mechanical loadings are considered and a two-step procedure is performed including a step of analyzing the temperature field along the thickness of the plate and a step of analyzing the geometrically nonlinear behavior of the FGPs subjected to both thermal and mechanical loadings. The accuracy and reliability of the proposed method is verified by comparing its numerical solutions with those of available other numerical results.

Finite element modeling of a linear membrane shell problem using tangential differential calculus
1 March 2014
Peter Hansbo | Mats G. Larson
Abstract: We construct a new Galerkin finite element method for the membrane elasticity problem on a meshed surface by using two-dimensional elements extended into three dimensions. The membrane finite element model is established using a tangential differential calculus approach that avoids the use of classical differential geometric methods. The finite element method generalizes the classical flat element shell method where standard plane stress elements are used for membrane problems. This makes our method applicable to a wider range of problems and of surface descriptions, including surfaces defined by distance functions.

A consistent 3D corotational beam element for nonlinear dynamic analysis of flexible structures
1 February 2014
Thanh-Nam Le | Jean-Marc Battini | Mohammed Hjiaj
Abstract: The purpose of the paper is to present a corotational beam element for the nonlinear dynamic analysis of 3D flexible frames. The novelty of the formulation lies in the use of the corotational framework (i.e., the decomposition into rigid body motion and pure deformation) to derive not only the internal force vector and the tangent stiffness matrix but also the inertia force vector and the tangent dynamic matrix. As a consequence, cubic interpolations are adopted to formulate both inertia and internal local terms. In the derivation of the dynamic terms, an approximation for the local rotations is introduced and a concise expression for the global inertia force vector is obtained. To enhance the efficiency of the iterative procedure, an approximate expression of the tangent dynamic matrix is adopted. Four numerical examples are considered to assess the performance of the new formulation against the one suggested by Simo and Vu-Quoc (1988) [48]. It was observed that the proposed formulation proves to combine accuracy with efficiency. In particular, the present approach achieves the same level of accuracy as the formulation of Simo and Vu-Quoc but with a significantly smaller number of elements.

================================================================

ABSTRACT: In this paper, the thermal buckling behavior of composite laminated plates under a uniform temperature distribution is studied. A finite element of four nodes and 32 degrees of freedom (DOF), previously developed for the bending and mechanical buckling of laminated composite plates, is extended to investigate the thermal buckling behavior of laminated composite plates. Based upon the classical plate theory, the present
finite element is a combination of a linear isoparametric membrane element and a high precision rectangular Hermitian element. The numerical implementation of the present finite element allowed the comparison of the numerical obtained results with results obtained from the literature: 1) with element of the same order, 2) the first order shear deformation theory, 3) the high order shear deformation theory and 4) the three-dimensional solution. It was found that the obtained results were very close to the reference results and the proposed element offers a good convergence speed. Furthermore, a parametrical study was also conducted to investigate the effect of the anisotropy of composite materials on the critical buckling temperature of laminated plates. The study showed that: 1) the critical buckling temperature generally decreases with the increasing of the modulus ratio $E_L/E_T$ and thermal expansion ratio $\alpha_T/\alpha_L$, and 2) the boundary conditions and the orientation angles significantly affect the critical buckling temperature of laminated plates.

ABSTRACT: After an automotive body shell is built in a typical vehicle assembly plant, the body shell is then cleaned of stamping and/or protective oils, electro-coated for corrosion protection, and then painted. The electro-coating and painting processes in the automobile industry have three main stages each: pretreatment, electro coating or painting, and drying. The surface finishing coats applied during electro-coating and painting processes must be dried using an oven. With existing electro-coating and paint heating processes through the assembly plant ovens, body panels may have buckling issues. The buckling phenomenon must be understood to eliminate the concern. The phenomenon is caused by uneven temperature distribution on the panel, attached panels of dissimilar materials, or possibly both conditions. The uneven temperature distribution may be due to the heat source itself, heat sinks within the body, or radiant shielding. Another consideration for body panel buckling involves the joining and heating of panels attached to dissimilar material types. In this paper, a comprehensive methodology for vehicle body panel buckling simulation in paint oven temperature environment is described by coupling computational heat transfer analysis and structure analysis. The heat transfer analysis is used to predict temperature distribution throughout a vehicle body panel in the oven. The vehicle body temperature profile from the heat transfer analysis result is applied as an input for a stress analysis to predict buckling. This study is focused on the radiant section of the electro-coat and paint ovens where the section has largest thermal mass to heat the vehicle body. This methodology couples a fully transient thermal analysis for the body moving through the electro-coat and painting ovens and the Abaqus/Standard structural buckling simulation. The proposed method provides of the virtual assessment capability for simulating the sheet metal thermal buckling phenomenon as a directional tool in order to avoid late production changes to vehicle class “A” surfaces.

ABSTRACT: In this paper, an analysis on nonlinear dynamics of a simply supported functionally graded material (FGM) cylindrical shell subjected to the different excitation in thermal environment. Material properties of cylindrical shell are assumed to be temperature-dependent. Based on the Reddy’s third-order plates and shells theory[1], the nonlinear governing partial differential equations of motion for the FGM cylindrical shell are derived by using Hamilton’s principle. Galerkin’s method is utilized to transform the partial differential equations into a two-degree-of-freedom nonlinear system including the quadratic and cubic nonlinear terms under combined parametric and external excitation. The effects played by different excitation and system initial conditions on the nonlinear vibration of the cylindrical shell are studied. In addition, the Runge–Kutta method is used to find out the nonlinear dynamic responses of the FGM cylindrical shell.

ABSTRACT: Imperfection sensitivity of cylindrical shells subjected to axial compressive load is investigated by means of non-linear buckling analysis and post-buckling analysis. Non-linear buckling analysis involves the determination of the equilibrium path (or load-deflection curve) up to the limit point load by using the Newton-Raphson approach, whereas post-buckling analysis involves the determination of the equilibrium path beyond the limit point load and up to the collapse load by using the arc-length approach. Limit point loads evaluated from these two approaches for various imperfection magnitudes show an excellent agreement which clearly confirms the numerical results obtained.

(no abstract given)

Course Objective: Buckling and postbuckling behavior is critical to the success of certain designs. For example, crash worthiness of an automobile requires that particular vehicle components collapse in ways that maximize energy absorption. On the other hand, successful designs of imperfection-sensitive, thin-walled shell structures, ranging from beverage containers to large pressure vessels, must prevent unintentional buckling. This course blends the theoretical background on such topics as geometric nonlinearity and the Riks method together with examples, guidelines and workshops to demonstrate how to: Identify an imperfection-sensitive structure, Extract closely spaced eigenvalues efficiently, Introduce imperfections into a "perfect" mesh, Use the Riks method effectively, Use damping to control unstable motions.

ABSTRACT: We introduce a new experimental method to encapsulate and release oils and fluorescent molecules, into preformed elastic colloidal microcapsules of PDMS filled siloxane shells, which are cross-linked with tetraethoxysilane. The method uses controlled buckling, where the volume of the capsule is reduced by dissolving the PDMS oil inside the capsule by surfactant micelles. This results in a change in the morphology of the capsule that depends on the ratio of shell thickness to total particle radius (d/Rt). Microcapsules of d/Rt in the range 0.007–0.05 formed microbowls upon decreasing the inner volume. The amount of oil released or dissolved by the micelles can be directly related to the concentration of surfactant. By tuning the amount of oil released we can make microbowls of variable depth. In addition, we demonstrate that the microbowls can be further used to load different oils like silicone oil, hydrocarbons, and apolar dyes. The elasticity of the capsule wall and the left-over PDMS oil inside the capsule provide the principal driving forces by which one can promote the uptake of different oils, including dissolved dye molecules.

ABSTRACT: Experiments were performed to study the deformation and buckling of axially compressed circular cylindrical shells of Zr2.5Nb zirconium alloy under creep conditions. Computer simulation using the MSC.Marc 2012 software was conducted by step-by-step integration of the equations of quasistatic deformation of thin shells using Norton’s law of steady creep. The results of the experiment and computer simulation show that the buckling modes are a combination of axisymmetric bulges located near one end or both ends of the shell and asymmetric buckling modes with the formation of three or four waves in the circumferential direction. A comparison is made of the time dependences of the axial strain of the shells obtained in the experiment and by computer simulation. It is shown that for large axial compressive stresses, these dependences are in satisfactory agreement. For lower values of these stresses, the difference between the theoretical and experimental dependences is greater.

ABSTRACT: Nonlinear explicit finite element (FE) simulations are used to study the axial collapse behavior of multi-corner, single- and multi-cell crush tubes under quasi-static and dynamic loading conditions. It is shown that the higher hardening modulus and yield stress increases the crush force and its resulting energy absorption. Moreover, the multi-cell tubes are found to have complicated collapse modes because of the geometrical complexity of the corner region unlike single-cell tubes. It was also shown that the stress wave propagation has a significant effect on the formation of crush modes in the tubes without imperfections whereas this effect can be ignored in tubes with imperfection or trigger mechanism. An analytical formula for the prediction of mean crush force of multi-corner multi-cell tubes is derived based on the super folding element theory. The analytical predictions for the mean crush force are found to be in good agreement with the FE solutions. Results also show a strong correlation between the cross-sectional geometry and the crush behavior with the method of connecting the inner to the outer walls having large influence on the energy absorption.

ABSTRACT: Mathematical design optimization is utilized to perform design optimization on new sandwich panel concept called Opencell™. Opencell contains two facesheets including an integral cut-and-formed
facesheet joined to a flat or curved facesheet. Design optimization of this sandwich panel is challenging due to geometrical interrelations between the cell dimension and the cell depth as well as different forming/cutting geometries. In this study, the optimization performed only on a flat single type of Opencell topology called Opencell Delta, and the design optimization is performed to find an optimal geometric attributes for this design. Buckling, vibration and local-global static stress analysis is performed to form a multi-objective optimization problem through response surface approximation.

shells structures of positive curvature with. It would result in a structural system based on compressive membrane stresses combined a very efficient materials in compression. However, to reach a high degree of efficiency a shell structure has to be doubly curved, and doubly curved glass elements are very expensive to produce. When considering dome-type structures based on membrane action in plane elements, Ture Wester [1] thought of the idea to combine the very efficient plate based dome structures with the structural use of glass. In a Ph.D.-research at the Technical University of Denmark [2] this idea is being developed further by Anne Bagger. In this research a number of different problem areas have been acknowledged and one of them is the buckling behaviour of a facetted glass dome structure. Because of the compressive capacity of glass and the efficiency of the structural system, it is possible to create a slender structure. However, such a slender structure will also be highly susceptible to buckling, which is why a buckling analysis is likely to be critical. This buckling analysis is partly carried out at the Delft University of Technology. A glass plate dome is analyzed with the finite element program DIANA. The study is aimed at finding the buckling behaviour of a facetted glass dome, and to provide the designer with the influence of different design parameters, like thickness of the facets and stiffness of the joints, on the stability behaviour of such a structure.

References listed at the end of the paper:

HISTORY: The idea of the facetted glass shell structure was first put forward by Ture Wester in one of his papers on the behaviour of plate structures: “[...] if a reliable structural joint method, i.e. gluing is available, then eliminate the metal muntins as well, and leave the glass itself to carry and transfer all the forces. Such a plate dome challenges the vision for a dome design with forces distributed so evenly, that it can be made so ‘thin’ that it becomes totally transparent and nearly disappears - a structure as clear as air, only made visible by mirroring the clouds and the sky.” (Wester 1990) Combining flat glass with a plate structure is a very effective way to use the in-plane strength of glass panels in an efficient structural system. In addition, production of flat (or float) glass is very cheap compared to bent glass.

CONCLUSIONS: The most important conclusion that can be drawn from the research is that the structural concept is very promising. Sufficiently high safety factors are found even when introducing large imperfections. However, some aspects still need to be taken into consideration. One might think of the support conditions, different load conditions, etc. Furthermore, a suitable joint needs to be developed. Other interesting conclusions can be drawn from the different investigations. The fact that the normal and shear stiffness of the joint are crucial in the design is very important, as well as the imperfection sensitivity and glass stiffness. No real problems are found even though the influence of some factors is quite large. These aspects will need to be combined in future studies; also with the realistic support and load conditions.

ABSTRACT: This thesis is a study of plate shell structures – a type of shell structure with a piecewise plane geometry, organized so that the load bearing system is constituted by distributed in-plane forces in the facets. The high stiffness-to-weight ratio of smoothly curved shell structures is mainly due to their curved shape. A plate shell structure maintains a high stiffness-to-weight ratio, while facilitating the use of plane structural elements. The study focuses on using laminated glass panes for the load bearing facets. Various methods of generating a plate shell geometry are suggested. Together with Ghent University, a script has been developed for an automated generation of a given plate shell geometry and a corresponding finite element (FE) model. A suitable FE modelling technique is proposed, suggesting a relatively simple method of modelling the connection detail’s stiffness characteristics. This modelling technique is used to model a plate shell structure with a span of 11.5 meters in the FE software Abaqus. The structure is analyzed with six different connection details with varying stiffness characteristics, to investigate the influence of these characteristics on the structural effects. Based on these investigations, and FE analysis of other plate shell models, the structural behaviour is described. Possible methods of estimating the stresses in a given plate shell structure are proposed. The nonlinear behaviour of a plate shell structure is investigated for varying parameters, such as facet size, imperfections, and connection characteristics. The critical load is compared to that of a similar, but smoothly curved, shell structure. Based on the investigations throughout the study, a set of guidelines for the structural design of plate shells of glass is proposed.

ABSTRACT: Six typical composite grid cylindrical shells are constructed by superimposing three basic types of ribs. Then buckling behavior and structural efficiency of these shells are analyzed under axial compression, pure bending, torsion and transverse bending by finite element (FE) models. The FE models are created by a parametrical FE modeling approach that defines FE models with original natural twisted geometry and orients cross-sections of beam elements exactly. And the approach is parameterized and coded by Patran Command Language (PCL). The demonstrations of FE modeling indicate the program enables efficient generation of FE models and facilitates parametric studies and design of grid shells. Using the program, the effects of helical angles on the buckling behavior of six typical grid cylindrical shells are determined. The results of these studies indicate that the triangle grid and rotated triangle grid cylindrical shell are more efficient than others under axial compression and pure bending, whereas under torsion and transverse bending, the hexagon grid cylindrical shell is most efficient. Additionally, buckling mode shapes are compared and provide an understanding of composite grid cylindrical shells that is useful in preliminary design of such structures.

ABSTRACT: The paper investigates the buckling behaviour of anisogrid composite lattice cylindrical shells under axial compression, transverse bending, pure bending, and torsion. The lattice shells are modelled as three-dimensional frame structures composed of curvilinear ribs subjected to the tension/compression, bending in two planes and torsion. The specialised finite-element model generation procedure (model generator/design modeller) is developed to control the orientation of the beam elements allowing the original twisted geometry of the curvilinear ribs to be closely approximated. The effects of varying the length of the shells, the number of helical ribs and the angles of their orientation on the buckling behaviour of lattice structures are examined using parametric analyses. Buckling of the lattice shells with cutouts is also analysed. The results of these studies indicate that the modelling approach presented in this work can be successfully applied to the solution of design problems.

ABSTRACT: Distortional buckling which is one of the most important buckling modes for cold-formed lipped channel sections as well as local buckling and global buckling may change mechanical properties and decrease the ultimate load of members. This paper reviews research achievements in distortional buckling, compares the existed design methods according to five national (regional) codes and the latest research achievements. Based on the comparison between five calculating data and test results, it is shown that the design method of North American specification has widespread application and relatively high accuracy, which could supply references for structural design.

ABSTRACT: This paper presents a finite element simulation and buckling analysis of layered composite structures. The shell element is based on the Reissner-Mindlin first-order shear deformation theory and the finite element method account for full geometric nonlinearity imposing large deformations and rotations. Finite rotations are treated by Rodrigues parameterization. The combinations of enhanced assumed strain (EAS) in the membrane strains and assumed natural strains in the shear strains are implemented to improve the shell element behavior. Stability analysis of anisotropic short open cylinder, layered cylindrical shells with different lamina sequence and a hinged roof structure are presented including snap-through and snap-back problems. The present
simulations are compared with those obtained by finite element analyses based on first-order transverse shear deformation moderate or large rotation or refined von Kármán-type theories in earlier literature.

loses contact with the shell in a series of well-defined "blisters" along the long axis of the ellipsoid. We defined "blisters" along the long axis of the ellipsoid. We observed a new instability that is not observed in spherical shells. While plastic deformation is well documented and is a familiar first stage in the crushing of a spherical shell such as a ping-pong ball. While spherical shells manifest such periodic structures as polygons, we present a new instability that is observed in the indentation of a highly ellipsoidal shell by a horizontal plate. Above a critical indentation depth, the plate loses contact with the shell in a series of well-defined "blisters" along the long axis of the ellipsoid. We
characterize the onset of this instability and explain it using scaling arguments, numerical simulations, and experiments. We also characterize the properties of the blistering pattern by showing how the number of blisters and their size depend on both the geometrical properties of the shell and the indentation but not on the shell’s elastic modulus. This blistering instability may be used to determine the thickness of highly ellipsoidal shells simply by squashing them between two plates.

“Mechanics of elastic ellipsoidal shells”, Society of Engineering Science 51st Annual Technical Meeting, 1-3 October 2014, Purdue University, West Lafayette, Indiana, USA

ABSTRACT: Complicated structural features at a much smaller scale than overall structure size form during the deformation of elastic shells under mechanical loading. These features which can be seen by simple experiments in everyday life, as well as in biological and engineering systems, are associated with high energy density and evolve in intricate ways as the shell is further loaded deep into the nonlinear regime. The key
challenge in understanding these features is interaction of physics and geometry that leads to a mechanical response which is very different from the response of solid objects. The formation of localized periodic structures in the crushing of a spherical shell, such as a ping pong ball, is well documented in the literature and studies show that spherical shells manifest periodic structures as polygons under point and plate loading. We studied ellipsoidal shells under plate and point indentation and results are presented here. For plate indentation, we present a new instability that is observed in the indentation of a highly ellipsoidal shell. In this phenomenon, above a critical indentation depth, the plate loses contact with the shell in a series of well-defined “blisters” aligned with the smaller radius of curvature. We used detailed numerical model to study this instability and explained it using scaling arguments. We characterized the onset of instability and showed relation between number of blisters and their sizes with indentation depth and geometry of shell. Our study showed that properties of blister are independent of elastic properties of shell itself and this suggests a novel method for simply determining the thickness of highly ellipsoidal shells.

ABSTRACT: Local delamination buckling formulas for laminated composite beams are derived based on the rigid, semirigid, and flexible joint models with respect to three bilayer beam (i.e., conventional composite, shear-deformable bilayer, and interface-deformable bilayer, respectively) theories. Two local delamination buckling modes (i.e., sublayer delamination buckling and symmetrical delamination buckling) are analyzed and their critical buckling loads based on the three joint models are obtained. A numerical finite-element simulation is carried out to validate the accuracy of the formulas, and parametric studies of delamination length ratio, the transverse shear effect, and the influence of interface compliance are conducted to demonstrate the improvement of the flexible joint model compared to the rigid and semirigid joint models. The explicit local delamination buckling solutions developed in this study facilitate the design analysis and optimization of laminated composite structures and provide simplified and improved practical design equations and guidelines for buckling analyses.

ABSTRACT: Main buckling and post-buckling analysis methods for composite structures are presented, along with the discussion on their potential challenges in handling the accuracy of prediction. Common buckling and post-buckling behaviors of composite structures are described, and the capabilities of corresponding analysis
techniques are reviewed. Compared with the structures made of metals, the anisotropy of composite materials is one of the key difference which could be considered in constitutive relations for buckling analysis. Commonly used analytical buckling prediction methodologies are based on the energy principle for approximation; while post-buckling investigations usually require iteration algorithms such as the arc-length method etc. to trace the entire equilibrium path. Semi-analytical methods, such as finite strip method, are also effective algorithms to predict critical buckling loads, and they could significantly save computing resources compared with full numerical analysis models. Practical engineering structures are usually under elastically supported boundary conditions, and the buckling behaviors of composite panels under elastic constraints are also discussed. This brief review is intended to help the readers in identifying starting points for research in analysis of buckling and post-buckling behavior of composite structures and in designing composite structures against buckling.

ABSTRACT: The explicit arc-length method is simulated to trace the post-buckling equilibrium path of structures by using dynamic relaxation method with kinetic damping. This method based on the cylindrical arc-length method does not require the computation and formulation of any tangent stiffness matrix to search the snap-through or snap-back problems. The convergence to the solution is achieved by using only vector equation with kinetic damping technique. Two approaches for cylindrical arc-length control are formulated with incremental and total displacement constraint. The merits of the explicit arc-length method, in tracing the post-buckling behavior of structures, are demonstrated by analyzing the numerical examples.

ABSTRACT: In this review buckling in single-walled carbon nanotubes (SWCNTs) in static loading has been studied. Carbon nanotubes buckling has many influence on electrical and physical properties. Carbon nanotubes are as two forms of axial buckling. If the ratio of length to diameter become more column buckling and otherwise shell buckling will happen. In this study of structural mechanics has been used to determine the axial buckling of carbon nanotubes in both type of armchair and zigzag. after getting the normal amount of nanotubes buckling them while affected by defects (single vacancy, double vacancy and stone wales) have been studied and obtained the effect of defects on the buckling force. Results showed that reducing the amount of buckling force with making a defect in the nanotube structure and this reduction is due to the type of defects created in the structure is different. In this review of Ansys software and solutions of nonlinear Newton - Raphson is used to increase the accuracy. Analysis process to determine buckling is like this high that the nodes are moved the effect of pressure force and Considering the large deformation in the software can be obtained point that the structure will buckling from the graph (force - deflection). Buckling force values in the armature and zigzag nanotubes in the same length and diameter, is close together, and also the values of static analysis is more of dynamic analysis.
