TÜRK, M.H. and HOO FATT, M.S. Localized damage response of composite sandwich plates, Composites Part B, 1999, 30, (2), pp

ABSTRACT: This paper reviews work at the Aeronautical Research Institute of Sweden, and addresses major issues of importance in evaluating the effect of impact on composite structures. Some more extensive reviews of work by other researchers are referenced. The paper addresses impact response and damage formation, damage characterization, and residual strength and stability by combination of experiments and analysis. Studies showing that impact response type depends on impactor-plate mass ratio are presented. Small mass impact is generally more critical at a given configuration and energy. Analytical models for small mass impact and for damage initiation and growth during large mass impact are discussed. Rate dependency of matrix-dominated properties is briefly discussed. Geometric and constitutive characterization of impact damage zones is presented and the influence of degraded properties demonstrated. The use of an FE-based plate model to simulate delamination growth due to sublaminate buckling and panel skin buckling in stiffened panels after impact is described. Skin buckling causes a steep increase in delamination strain energy release rate and should
be prevented.

ABSTRACT: This paper examines the effect of impact damage on local tensile stiffness of multi-directional tape laminates. A finite element model is used for parametric studies of the effect of various patterns of delaminations and cracks across the fibres. Regular and random crack patterns are considered for 8 and 16 ply quasi-isotropic laminates. The effect on local stiffness is evaluated by a recently developed inverse numerical approach. It is found that fibre cracks control the loss of stiffness but that delaminations are instrumental in extending the zone influenced by these cracks. Fractographic observations are finally used to generate a detailed model of the damage in a real laminate. A close agreement was found between the predicted and measured strain fields and the corresponding stiffness distributions obtained with the inverse method.

ABSTRACT: This paper examines the compressive behaviour of plies with fibres previously fractured during impact. The analysis is conducted using finite element (FE) modelling in ABAQUS 6.7. Two- and three-dimensional models are used to consider the possibility of fibre penetration and “brooming” of fractured fibres, or fibre buckling. A parametric study of the influence of the input parameters of the Drucker Prager plasticity model was also conducted, to enable a better understanding of the model. This was used to capture the triaxial stress state in the matrix surrounding the fibres. The results suggest that fibre buckling is more likely to occur due to the geometry of fibres and fibre spacing in carbon fibre composites, but fibre penetration could still occur in regions of low fibre volume fraction.

ABSTRACT: This paper presents a finite element model of a carbon fibre composite laminate with multiple delaminations of realistic shape and including fibre fracture cracks loaded under compression. The modelling technique is initially applied on circular and elliptical delaminations of single ply sublaminates, which are compared with existing analytical solutions. The techniques are then applied to models with multiple delaminations of realistic shape and their behaviour in buckling and post-buckling is captured. An inverse method is used to determine the stiffness reduction caused by the damage, and shows significant stiffness reduction caused by peanut shaped delaminations. When fibre fracture cracks are added, their contribution to further stiffness reduction is minimal but they have some significant effects on the buckling shapes.

ABSTRACT: The possibility to accurately analyse the buckling and postbuckling behaviour of plates with delaminations of irregular shapes by utilisation of circular or elliptic delaminations was studied. The behaviour of compressed plates with delaminations of irregular and corresponding smallest enclosing circular and elliptic shapes was predicted by computational analyses and compared in terms of buckling loads and maximum values of the energy release rates found along the delamination boundaries. The study indicates that utilisation of circular delaminations could provide highly inaccurate results. Moreover, for truly accurate analyses of the buckling and postbuckling behaviour of delaminated structures it seems to be inevitable to use as precise representation of the shape of delaminations as possible.

ABSTRACT: The issues, problems and techniques concerning the optimization of laminated composites are discussed and specific cases of design optimization are presented. After a general introduction to methods of optimization of composites with emphasis on genetic algorithms, a discussion of design and decision variables is given and problem complexities are highlighted. This is followed by specific examples of composites design under deterministic conditions, and in particular, stiffness and strength optimization, thermal buckling, and optimization with multiple objectives are studied. The design uncertainties are the subject of the separate chapter where design optimization techniques such as convex modeling and anti-optimization are illustrated again by means of specific examples involving uncertain material, load and geometric data. Section 6 provides an overview of the properties and applications of widely used smart materials which is followed by some specific examples of the use of smart materials in vibration control and composite design applications. It is noted that sections 1-5 (except the material on genetic algorithms) are an abridged version of the material in Adali (2003) which is being published in these Lecture Notes with the permission of CRC Press.

ABSTRACT: A variational principle for microtubules subject to a buckling load is derived by semi-inverse method. The microtubule is modeled as an orthotropic shell with the constitutive equations based on nonlocal elastic theory and the effect of filament network taken into account as an elastic surrounding. Microtubules can carry large compressive forces by virtue of the mechanical coupling between the microtubules and the surrounding elastic filament network. The equations governing the buckling of the microtubule are given by a system of three partial differential equations. The problem studied in the present work involves the derivation of the variational formulation for microtubule buckling. The Rayleigh quotient for the buckling load as well as the
natural and geometric boundary conditions of the problem is obtained from this variational formulation. It is observed that the boundary conditions are coupled as a result of nonlocal formulation. It is noted that the analytic solution of the buckling problem for microtubules is usually a difficult task. The variational formulation of the problem provides the basis for a number of approximate and numerical methods of solutions and furthermore variational principles can provide physical insight into the problem.

ABSTRACT: Apparent controversies exist on whether the persistence length of microtubules depends on its contour length. This issue is particularly challenging from a theoretical point of view due to the tubular structure and strongly anisotropic material property of microtubules. Here we adopt a higher order continuum orthotropic thin shell model to study the flexural behavior of microtubules. Our model overcomes some key limitations of a recent study based on a simplified anisotropic shell model and results in a closed-form solution for the contour-length-dependent persistence length of microtubules, with predictions in excellent agreement with experimental measurements. By studying the ratio between their contour and persistence lengths, we find that microtubules with length at ~1.5 μm show the lowest flexural rigidity, whereas those with length at ~15 μm show the highest flexural rigidity. This finding may provide an important theoretical basis for understanding the mechanical structure of mitotic spindles during cell division. Further analysis on the buckling of microtubules indicates that the critical buckling load becomes insensitive to the tube length for relatively short microtubules, in drastic contrast to the classical Euler buckling. These rich flexural behaviors of microtubules are of profound implication for many biological functions and biomimetic molecular devices.

ABSTRACT: The best layup for a hybrid laminated cylindrical shell subject to a buckling load constraint is determined. The objective of the optimisation is the minimum weight design of these structures. The ply angle is taken as the design variable. Various configurations of graphite and boron epoxy layers are considered in order to determine an optimal stacking sequence. The symbolic computational software package MATHEMATICA is used in the implementation and solution of the problem. This approach simplifies the computational procedure as well as the implementation of the analysis/optimisation routine. Results are given illustrating the dependence of the optimal layup on the cylinder length and radius. It is shown that a general
purpose computer algebra system like MATHEMATICA is well suited to solve structural design problems involving composite materials.

doi: 10.1108/02644409810369248
ABSTRACT: The optimal design of a laminated cylindrical shell is obtained with the objectives defined as the maximisation of the axial and torsional buckling loads. The ply angle is taken as the design variable. The symbolic computational software package MATHEMATICA is used in the implementation and solution of the problem. This approach simplifies the computational procedure as well as the implementation of the analysis/optimisation routine. Results are given illustrating the dependence of the optimal fiber angle on the cylinder length and radius. It is shown that a general purpose computer algebra system like MATHEMATICA is well suited to solve small boundary value problems such as structural design optimisation involving composite materials.

P.M.Weaver (Department of Aerospace Engineering, University of Bristol, Queens Building, University Walk, Bristol, BS8 1TR,UK), “Computer-Aided Laminate Selection Using a Graphical Method”, ICCM12, Paris, France, 1999,
ABSTRACT: This paper introduces a methodology for selection of laminates. Software that implements these ideas is also presented. Optimisation of laminate fibre angles is difficult for multiple load cases and objectives—there are many local minima to assess. An alternative approach is presented here that circumvents the need for conventional optimisation strategies that often prove difficult and complicated to implement. The basic idea is to build a database that stores appropriate properties of all permutations of lay-up angles for a laminate. Rather than access these properties by a question and answer, black-box technique, a graphical method is introduced. The designer can select viable laminates by first plotting a succession of 2-D charts containing relevant properties. Then, using simple on-screen techniques, the number of potential laminates is visually reduced by selecting those with desirable properties. The optimisation of a cylindrical shell, subject to axial compression, that undergoes simultaneous Euler-type buckling and local buckling is examined.

11. Weaver, P.M. “Design of Optimal Laminated Composite Cylindrical Shells under Axial Compression”, to be published, 1999
ABSTRACT: Approximate expressions describing shape efficiency are derived and two charts are shown that help with design. The first is a failure chart that shows the complete set of possible designs (and lay-ups) that allow the complexity of the problem to be presented in a simple way. The second is a chart showing optimal lay-ups for a cylindrical shell subject to axial compression. The load-bearing efficiency of cylindrical shells derives from both the properties of the material of which they are made and from the shape itself. Generally, thin-walled or slender shapes are more efficient (meaning lighter and more economical in the use of material) than thick-walled or solid sections. The limit in shape efficiency is either set by manufacturing constraints or, ultimately, by the properties of the material from which it is made. Laminated composite materials are more difficult to analyse than conventional isotropic materials, such as aluminium alloys, because of the additional need to consider the variation of ply orientation through the thickness of the laminate. These ultimate limits are examined and determined by a balance between competitive failure mechanisms.

ABSTRACT: The study of axial compression buckling of isotropic cylinders has received much attention by various researchers over the years. It is commonly acknowledged that the presence of minute imperfections reduces potential buckling loads significantly in comparison with classical linear predictions. This approach has been extended by a significant, yet fewer, number of researchers to composite cylindrical shells. It is shown that imperfections may not be the only major factor for the discrepancy between experimentally obtained buckling loads and those predicted from linear bifurcation theory with orthotropic properties. Flexural/twist anisotropy, present in most balanced, symmetric laminates with angle ply layers is shown to play a significant role in reducing buckling loads from those classically predicted. Indeed, the assumption of deflections in the form of a double sine series appears to be questionable for such laminates. A previously unreported classical linear analysis including the effect of flexural/twist coupling is developed. Backed up by detailed comparison with finite element studies, it is shown that buckling loads can be reduced by up to 30% for a class of quasi-isotropic laminates and is accompanied by a change in mode form from doubly periodic to spiral in nature.

ABSTRACT: This paper addresses two aspects of buckling relevant to design. The first describes the preliminary experimental results that validate the presence of a newly reported spiral buckling mode; whilst the second concerned the effects of extension/twist anisotropy on the buckling loads of cylindrical shells under compression. The influence of designing laminates with antisymmetric lay-ups in comparison with a symmetrical lay-up is also investigated. Antisymmetric quasi-isotropic laminates, based on 0, 90 and ±45° angles produces greater buckling loads than the equivalent symmetric lay-up. Whilst all anisotropic coupling effects appear to lower the buckling loads, a laminate that is 48 plies thick is necessary to eliminate them in thin-walled shells. Such a laminate is at least 6 mm thick. Many designs require thinner laminates, and in so doing, mitigate the need for guidelines on efficient anisotropic lay-ups. Neglecting the effect of prebuckling
deformation, it is found that extension/twist coupling is less deleterious than flexural/twist coupling in this respect. Therefore, antisymmetric laminates appear preferable for initial buckling of quasi-isotropic laminates.

ABSTRACT: It is widely recognised that the optimal lay-up to resist classical local buckling of a laminated cylindrical shell subject to compression loading is one that is quasi-isotropic in nature. This ideal is difficult to achieve in practice due to manufacturing and additional design constraints. The minimum number of unidirectional layers, based on 0°, 90°, ±45° angles, is 48 – an example lay-up is shown. Balanced and symmetric laminates, that exhibit quasi-isotropic properties in-plane, are shown to give reduced buckling capacity depending on two factors. The first concerns the overall homogeneity of the laminate whilst the second is a function of the amount of flexural/torsional coupling. The former is shown to have the greater influence. In the absence of closed-form solutions these effects have been numerically quantified using finite element (FE) analysis techniques. Practical design guidelines are deduced.

ABSTRACT: The use of high-performance composite materials of the sort used in the aerospace and Formula 1 industries is becoming more widespread. On one level they are exciting to work with because they give scope for designing the 'material' in addition to a 'structure' through judicious placement of the ply orientation. Layers are stiff and strong in the fibre direction while weak and compliant in the transverse direction. It is this ability to tailor material properties layer by layer that gives designers huge potential in design. One possible explanation for the prevalent use of quasi-isotropic ('black aluminium') carbon composites in structures is the lack of available design tools. Analysis packages exist that will predict performance, but only for a given choice of fibre orientation. Here a design tool is presented that aids selection of fibre orientations. Optimization of laminate fibre angles is difficult for multiple-load cases and objectives since there are many local minima to assess. The alternative approach that is presented here, for flat plates and cylindrical shells, circumvents the need (in the early stages of design) for conventional optimization strategies that often prove difficult and complicated to implement. The basic idea is to build a database that stores appropriate properties of all permutations of lay-up angles for a laminate. Rather than access these properties by a question and answer, black-box technique, a graphical method is proposed. The designer can select viable laminates by first plotting a succession of two-dimensional charts containing relevant properties. Then, using simple on-screen techniques, the number of potential laminates is visually reduced by selecting those with desirable properties. Two case studies are presented to illustrate the selection method. The first concerns the optimization of a spar web, typically found in an aircraft wing structure, while the second concerns the optimization of a cylindrical shell, subject to axial compression, that undergoes simultaneous Euler-type buckling and local buckling.

P. M. Weaver (Department of Aerospace Engineering, University of Bristol, Queens Building, University Walk, Bristol BS8 1TR, UK), “On laminate selection and design”, AIAA-2002-1220,
ABSTRACT: Composite materials, at one level, are exciting to work with because they give scope for designing the "material" in addition to a "structure" through judicious placement of the orientation of plies. It is their ability to tailor material properties layer by layer that give designers huge potential in design. One possible explanation for the prevalent use of quasi-isotropic ("black aluminium") carbon composites in structures is the lack of available design tools. Here a design tool is presented that aids selection of fiber orientations.

Optimization of laminate fiber angles is difficult for multiple load cases and objectives—there are many local minima to assess. An alternative approach to complex/numerical optimization methods, is presented here. The basic idea is to build a database that stores appropriate properties of all permutations of lay-up angles for a laminate. The designer can select viable laminates by first plotting a succession of 2-D charts containing relevant properties. Then, using simple on-screen techniques, the number of potential laminates is visually reduced by selecting those with desirable properties. Two case studies are presented. The first concerns the optimization of a spar web, typically found in an aircraft wing structure whilst the second considers the optimization of a cylindrical shell, subject to axial compression, that undergoes simultaneous Euler-type buckling and local buckling.

ABSTRACT: This paper provides an analytical optimization of shell composition with respect to the critical Brazier moment, which will be useful in the design of structures where material failure and local buckling are not likely to occur. The optimum configuration for a tube under bending is independent of Poisson's ratio and largely invariant with $E_{11}$ and $E_{22}$ for common highly directional composite materials. The optimal ply configuration for typical composite tubes is found to be $90-0-90$ deg, with 62 percent 0-deg plies. Such a configuration increases the maximum bending moment in GFRP tubes by 42 percent compared to a quasi-isotropic configuration.

ABSTRACT: The study of axial compression buckling of isotropic cylinders has received much attention by various researchers over the years. It is commonly acknowledged that the presence of minute imperfections significantly reduces potential buckling loads in comparison with classical linear predictions. This approach, of including geometric imperfections, has been extended by a significant, yet fewer, number of researchers to composite cylindrical shells. As the current study shows, imperfections may not be the only major factor for the discrepancy between experimental and linear buckling loads. Flexural/twist anisotropy, present in most balanced, symmetric laminates with angle-ply layers, is shown to play a significant role in reducing buckling loads from those predicted by classical analysis. Indeed, the assumption of deflections in the form of a double sine series appears to be questionable for such laminates. A recently reported classically linear analysis that included the effects of flexural/twist coupling on buckling loads has been further developed to include the effects of extension/twist coupling. It is shown that buckling loads can be improved by making the laminate antisymmetric rather than symmetric, for the class of quasi-isotropic laminates, whilst retaining a spiral mode shape.

ABSTRACT: Work is presented to maximize the resistance of isotropic and orthotropic cylindrical tubes to the non-linear Brazier effect, by filling them with foam cores. Analytical approaches for the mass minimization of such structures, by optimizing shell wall thickness, ply lay-up and foam core density, are presented. The optimum configurations have been shown to have significant mass benefits compared to simple hollow tubes; the sample aluminum shell, aluminum foam core, tubes have been found to be up to 50 pct. lighter (for given Brazier failure bending moment) than their hollow equivalents. The optimization of foam filled orthotropic tubes has found that the increased resistance to the Brazier effect, provided by the foam core, can reduce the necessity for circumferentially oriented plies. The example 20mm radius tubes, CFRP shells with polymeric foam cores, showed theoretical reductions in mass, for given failure bending moments, of the order of 30 pct.. The optimization can readily be modified to accommodate alternative requirements, such as cost, to better reflect actual design criteria for real structures. Whilst it is noted that real structures rarely fail by the Brazier effect (material failure or local buckling generally precede it) this analysis will be of use to those seeking a minimization of non-linearities in the deformation of long hollow structures.

ABSTRACT: Long circular cylindrical shells may locally buckle at lower loads than those predicted by classical linear Donnell solutions due to long range interaction between Euler and local buckling. In fact, Euler buckling may be viewed as a special case of local buckling in which both the longitudinal and circumferential wave numbers are unity. This paper investigates this phenomenon for composite tubes as a function of lay-up. Tubes that are reinforced in predominantly the longitudinal or circumferential directions suffer the least knockdown of approximately 10% for tubes that are designed to buckle concurrently by Euler and local mechanisms. The greatest knockdown of approximately 35% occurs for isotropic laminates. The effect of material lay-up has been taken account of by forming a non-dimensional length parameter that is a function of both tube geometry and material properties. An interaction formula is proposed to help in design situations. References listed at the end of the paper:

ABSTRACT: An approximate solution is given for the postbuckling of infinitely long and unsymmetrically laminated composite plates. This solution is obtained by superposing a polynomial transverse displacement given by bending due to unsymmetric laminate configurations and a simple functional representation for the buckling mode in conjunction with the Galerkin method. Nondimensional parameters are used to express the approximate solution in a very simple and clear formulation. The results given by this solution for axial compression in the longitudinal direction are compared with the results given by the nonlinear finite element method (FEM) for finite length rectangular long plates. The influence of the boundary conditions on postbuckling response is also studied. For the FEM analysis, two different simply supported boundary conditions on the long edges of the plate are considered. It is found that these two sets of boundary conditions give different results for the buckling and postbuckling finite element analysis. In most cases the FEM analysis overestimate and, respectively, underestimate the approximate closed form solution, depending on the type of simply supported boundary condition considered. Thus, the approximate solution appears useful for design purposes as an averaged quantity between the two FEM analyses. Also, it is found that the reduced bending stiffness method can be successfully used for determining the approximate solution.

ABSTRACT: In this paper an alternative design for variable sweep wings is investigated. It consists of a two-spar, CFRP (carbon fibres reinforced plastics) wing, with truss-like ribs. The spar-web is a shell structure laminated using an unsymmetric stack sequence in order to take advantage of the residual stress field developed during the curing process, resulting in increased transverse curvature of the spar. The effect of this curvature is twofold: to increase the moment of inertia to withstand bending stresses and, under certain loading conditions, to behave like an elastic hinge to allow the sweep angle of the wing to change.

ABSTRACT: A thin shell tube with different length to radius and radius to thickness ratios can buckle locally, globally or with interaction of local and global buckling. The current analysis is to study the dependency of the buckling load of a circular cylindrical shell on these ratios. Different theoretical shell models were used to predict the buckling load and the results were compared with finite element analysis. It was found that the buckling load decreases exponentially when the length to radius ratio increases and increases when the radius to thickness ratio increases. The length to radius ratio is crucial in determining whether the tube is in the local buckling, global buckling or interaction region. The extent of global buckling was predicted analytically using Sanders’ model, and was found to depend on the Poisson’s ratio of the material used. In addition, Loo’s model is found to be the best model in predicting the buckling load in the local buckling and interaction region to within 10% of the finite element results while the Sanders’ model converges to Euler buckling values in the global buckling region.

ABSTRACT: The need for aircraft that possess the ability to adapt themselves to achieve multi-objective mission roles is prompting designers towards the realization of “morphing” aircraft. Conventional designs for multi-role aircraft result in the use of advanced materials and manufacturing techniques. Often the result leads to both significant weight and cost penalties. The properties of bi-stable composite seem to suggest a solution for this problem because of their ability to have more than a single geometric configuration and also for the need to only supply energy to affect the snap-through from one equilibrium state to the other one.
ABSTRACT: An approach to design an aircraft wing with morphing capabilities employing aeroelastic tailoring is presented. Morphing capabilities are achieved by passive actuation, that is the aircraft wing will adapt itself to improve its performance during the designed flight conditions. The approach consists of an aeroelastic steady-state scheme with aero-structure coupling embedded within a global optimisation. The global optimisation is divided into two levels. At the first level, Mathematical Programming (MP) is used to optimise the wing under structural and aerodynamic constraints. Wing-box panels (skins and spars) are modelled using lamination parameters accounting for their anisotropy. Panels are assumed to be symmetric or mid-plane symmetric laminates with 0, 90, 45 or -45 degree ply angles. Each of the wing-box panels is subjected to a combined in-plane loading under strength, buckling and practical design constraints. At the second level, the actual lay-ups of the wing-box panels are obtained using a Genetic Algorithm (GA), accounting for manufacture and design practices.

ABSTRACT: Morphing aircraft are flight vehicles that change their shape to effect both a change in the mission of the aircraft and to perform flight control without the use of conventional control surfaces or seams. Aircraft constructed with morphing technology promise the distinct advantages of being able to fly multiple types of missions, to perform radically new manoeuvres not possible with conventional control surfaces, to be more fuel efficient, and to provide a reduced radar signature. The key to morphing aircraft is the full integration of the shape control into the wing structure; a truly smart structure. The design of these vehicles must take full account of the aerodynamic loads and must carefully consider the power requirements for shape control to ensure an overall performance benefit. This paper will overview possible morphing concepts, discuss advantages and disadvantages, and indicate possible future directions for the development of morphing aircraft.

ABSTRACT: A method to optimize long anisotropic laminated fiber composite panels with T-shaped stiffeners is presented. The technique splits the optimization problem into two steps. At the first step, composite optimization is performed using mathematical programming in which the skin and the stiffeners are characterized by lamination parameters accounting for their membrane and flexural anisotropy. Skin and stiffener laminates are assumed to be symmetric or midplane symmetric laminates with 0-, 90-, 45-, or -45- deg ply angles. The stiffened panel consists of a series of skin-stiffener assemblies or superstiffeners. Each superstiffener is further idealized as a group of flat laminated plates that are rigidly connected. The stiffened panel is subjected to a combined loading under strength, buckling, and practical-design constraints. At the second step, the actual skin and stiffener layups are obtained using a genetic algorithm and considering the ease of manufacture. This approach offers the advantage of introducing numerical analysis methods such as the finite element method at the first step, without significant increases in processing time. Furthermore, modeling the laminate anisotropy enables the designer to explore and potentially use elastic tailoring in a beneficial manner.

ABSTRACT: In this article a novel morphing structure concept is studied using non-linear Finite Element
Analysis (FEA). Bi-stable asymmetrical laminates can be snapped between two geometries through a buckling
mechanism that is activated by an applied load. A piezoelectric Macro-Fibre Composite (MFC) actuator was
chosen to provide this activation load. Bi-stable structures will maintain a given geometrical state without the
need for a constant actuation force. FEA was used to predict the two stable geometries, to understand the
buckling mechanism and to evaluate the feasibility of using MFC actuators for switching between states.
Environmental effects like moisture absorption were also included in the analysis.

morphing aircraft structures”, in Industrial and Commercial Applications of Smart Structures Technologies

ABSTRACT: One approach to morphing aircraft is to use bistable or multistable structures that have two or
more stable equilibrium configurations to define a discrete set of shapes for the morphing structure. Moving
between these stable states may be achieved using an actuation system or by aerodynamic loads. This paper
considers three concepts for morphing aircraft based on multistable structures, namely a variable sweep wing,
bistable blended winglets and a variable camber trailing edge. The philosophy behind these concepts is outlined,
and simulated and experimental results are given.

Weaver and Filippo Mattioni (Department of Aerospace Engineering, University of Bristol, Bristol BS8 1TR, UK), “Concepts for morphing airfoil sections using bi-stable laminated composite structures”, Thin-Walled Structures, Vol. 46, No. 6, June 2008, pp. 689-701, doi:10.1016/j.tws.2007.11.002 ABSTRACT: The present paper investigates the potential of using bi-stable laminated composite structures for morphing an airfoil section. The objective of the paper is to identify geometries and lay-ups of candidate configurations that offer multiple stable shapes for the airfoil section. Carbon-fiber laminated composites with non-symmetric laminate configurations are used for morphing the airfoil section. Thermal curing is used to induce residual stresses into the structure in order to achieve bi-stability. Three concepts that focus on morphing a flap-like structure and the camber and chord of an airfoil section are proposed. Several geometries and laminate configurations are investigated using finite element nonlinear static analysis. The magnitude of loads required to actuate the airfoil section between the stable shapes is evaluated. The impact of manufacturability on producing viable morphing mechanisms within the airfoil section is also discussed.

S. Daynes, K.D. Potter and P.M. Weaver (Department of Aerospace Engineering, University of Bristol, Queen’s Building, University Walk, Bristol), “Bistable prestressed buckled laminates”, Composites Science and Technology, Vol. 68, Nos. 15-16, December 2008, pp. 3431-3437, doi:10.1016/j.compscitech.2008.09.036 ABSTRACT: The bistability of cross-ply [0n/90n]T laminates has already been investigated, both experimentally and analytically, in much detail. Bistability occurs due to geometric non-linearity and the mismatch between the thermal expansion coefficients of the constituent fibre and matrix materials. In this current work a new type of bistable laminate is presented which has a symmetric lay-up. Its bistability derives from careful manipulation of the residual stresses across the width of the laminate. This is done by applying a prestress to selected fibres in [0/90/90/0] FRP prepreg laminates prior to curing. Once cured and cooled down this prestress is released and the resulting laminate then buckles. This buckling creates two bistable bowing geometries with two edges remaining relatively flat. Analytical and finite element modelling is also carried out to better understand this buckling mechanism. Potential applications of these new bistable composites include morphing aircraft skins.

Paul M. Weaver (Advanced Composites Centre for Innovation and Science (ACCIS), Department of Aerospace Engineering, University of Bristol, UK), “Chapter 6: Anisotropic elastic tailoring in laminated composite plates and shells”, in Buckling and postbuckling structures: experimental, analytical and numerical studies, edited by B. G. Falzon and M. H. Aliabadi, Imperial College Press, 2008 ABSTRACT: Significant improvements in structural efficiency are possible using specific, inhomogeneous laminates. These are laminates whose stacking sequence has been optimized against constraints such as buckling, damage tolerance and natural frequencies. Furthermore, there are many design scenarios in which further gains can be made by making use of anisotropy, particularly when buckling or postbuckling is concerned. After a brief introduction to current design practice, buckling and postbuckling formulae are derived for anisotropic plates and shells, subject to different loadings. From these expressions, concepts for anisotropic elastic tailoring are discussed and their implications for design considered.

ABSTRACT: The static and dynamic transitions between stable states for rectangular bi-stable laminated composite plates are considered. The laminated composite plates have nonsymmetric laminate configurations and are subjected to thermal curing in order to introduce residual stresses and to achieve bi-stability. As geometrically nonlinear effects occur, after curing, the plates are able to take multiple stable shapes at service or room temperature. A simple model for dynamic analysis of the snap-through phenomena is proposed based on strain field approximations for the plates. Hamilton's principle is applied in conjunction with the Rayleigh–Ritz method in order to achieve fast results. The model is used to evaluate the initial displacements for the stable states and also to investigate the static and dynamic transitions from one stable state to another. Parametric studies are carried out for various aspect ratios, laminate configurations and actuation loads and the results are compared with those obtained with finite element analysis in order to evaluate the accuracy of the model.

ABSTRACT: A meshless approach is developed and used to predict buckling of discretely assembled multibay composite panels made from skin and stiffeners. The effect of eccentricity is included in the formulation. Particular emphasis is given to stringer run-outs within a stiffened panel, where abrupt eccentricity can trigger very large transverse displacements of the skin in front of the run-out tip. The model is obtained by combining von Karman’s formulation for moderately large deflections in plates with an extended Timoshenko approach for small initial perturbations. Solutions are calculated by means of a Rayleigh–Ritz approach in conjunction with a Galerkin technique. Hilbert’s orthogonal eigenfunctions are employed to obtain a generalized Fourier series expansion of the variables of interest. Limits of applicability, convergence of results and further potential exploitations are discussed. Numerical results obtained are compared with finite element analysis.

ABSTRACT: A novel mixed formulation is derived by means of Reissner's variational approach-based on Castigliano's principle of least work in conjunction with a Lagrange multiplier method for the calculus of variations. The governing equations present an alternative theory for modeling the important three-dimensional structural aspects of plates in a two-dimensional form. By integrating the classical Cauchy's equilibrium equations with respect to the thickness co-ordinate, and enforcing continuity of shear and normal stresses at each ply interface, condenses the effect of the thickness. A reduced system of partial differential equations of sixth-order in one variable, is also proposed, which contains differential correction factors that formally modify the classical constitutive equations for composite laminates. The theory degenerates to classical composite plate analysis for thin configurations. Significant deviations from classical plate theory are observed when the thickness becomes comparable with the in-plane dimensions. A variety of case studies are presented and solutions are compared with other models available in the literature and with finite element analysis.

ABSTRACT: The bistability of unsymmetric cross-ply [0n/90n]T laminates has already been investigated in much detail. In this work a new type of bistable laminate is presented which has a symmetric lay-up. Bistability derives from an unsymmetric fiber prestress applied to the laminate. The experimental procedure used to apply this fiber prestress is presented in detail. Experimental results are compared with analytical and finite element models which have the ability to model fiber prestress accurately. As well as having minimal hygrothermal variability, it is noted that the snap-through loads for a prestressed symmetric laminate can be much higher than its unstressed [0n/90n]T equivalent.

ABSTRACT: The potential of using multistable composite materials for adaptive structures is currently receiving interest from the aerospace community because they possess more than one single equilibrium configuration. Unsymmetric CFRP laminates are studied which have an inner isotropic metallic layer. These hybrid laminates are studied using analytical, finite element and experimental techniques. The thermal contraction of the isotropic layer upon cool down from cure induces large in-plane thermal loads which act remotely from the laminate’s neutral plane, increasing snap-through moments and out-of-plane displacements. The curvatures of the hybrid laminates can be doubled compared to pure unsymmetric CFRP laminates.

“Bistable plates for morphing structures: A refined analytical approach with high-order polynomials”,
doi:10.1016/j.ijsolstr.2010.08.019
ABSTRACT: The multistability of composite thin structures has shown potential for morphing applications. The present work combines a Ritz model with path-following algorithms to study bistable plates’ behaviour. Classic low-order Ritz models predict stable shapes’ geometry with reasonable accuracy. However, they may fail when modelling other aspects of the elastic structural behaviour. A refined higher-order model is here presented. In order to improve the inherently poor conditioning properties of Ritz approximations of slender structures, a non-dimensional version of Classical Plate Lamination Theory with von Kármán nonlinear strains is developed and presented. In the current approach, we continue numerical solutions in parameter space, that is, we path-follow equilibrium configurations as the control parameter varies, find stable and unstable configurations and identify bifurcations. The numerics are carried out using a set of in-house Matlab® routines for numerical continuation. The increased degrees of freedom within the model are shown to accurately reflect buckling loads and provide useful insight into the relative importance of different aspects of nonlinear behaviour. Finally, the complex, experimentally observed snap-through geometry is captured analytically for the first time. Results are validated against finite elements analysis throughout the course of the paper.

ABSTRACT: Critical failure was observed in the shear web of a wind turbine blade during a full-scale testing. This failure occurred immediately before the ultimate failure and was partly caused by buckling and non-linear cross-sectional strain. Experimental values had been used to compare and validate both numerical and semi-analytical results in the analysis of the shear webs in the reinforced wind turbine blade. Only elastic material behaviour was analysed, and attention was primarily focused on the Brazier effect. The complex, geometrically non-linear and elastic stress–strain behaviour of the shear webs and the cap in compression were analysed using a balance of experimental, numerical and analytical approaches. It was noted that the non-linear distortion was caused by the crushing pressure derived from the Brazier effect. This Brazier pressure may have a significant impact on the design of new blades, and an optimized box girder had been studied to show the importance of including Brazier pressure in the design process for future wind turbine blades.

Simon C. White, Post-buckling of variable-stiffness shell structures, Ph.D dissertation, Advanced Composites Centre for Innovation and Science, Aerospace Engineering, University of Bristol, UK, 2015
ABSTRACT: The cylindrical shell is one of the most efficient structures for resisting axial compression. They are found in many weight-critical engineering applications due to their low mass and large internal volume. Their structural efficiency is derived from surface curvature which results in large buckling loads. Ultimate
failure is generally due to local buckling (i.e. loss of stability of the shell-wall) which is followed by global collapse. A consequence of this unstable non-linear behaviour is that the structures are sensitive to imperfections and buckle at loads that are a fraction of their linear buckling eigenvalues. In contrast, flat structures (such as plates and stiffened panels) display a relatively well-behaved post-buckling response. In this thesis an investigation into the post-buckling behaviour of variable-stiffness shell structures is presented. Its aim is to determine whether or not cylindrical shells can be designed to have stable post-buckling configurations by adopting non-uniform material properties. In order to create shells with new and novel responses, the design space must be expanded by removing the standard rules for laminate design. Therefore, the present work focuses on laminates in which the reinforcement fibres are not straight but follow curvilinear paths. Such structures are termed variable-stiffness composite structures, due to their smooth variations in anisotropy (i.e. their section stiffnesses and kinematic coupling).

Cylinders, curved panels and flat plates are tailored for improved post-buckling performance using numerical methods. In the case of cylindrical shells, dynamic analyses are performed in order to capture the effects of instability, inertia and path switching. Here, tailoring was performed on cylinders with a circumferential fibre-angle variation in a parametric study. The results show that a wide range of responses can be achieved by varying the shell’s geometry and fibre-angle distribution. New evidence is presented that cylinders with stable post-buckling responses are possible by using variable-stiffness laminates. Tailoring is also performed on curved panels through an optimisation process. Panels are modelled using Koiter’s asymptotic method and a quadrature-based discretisation of the domain. Optimisation is performed using a genetic algorithm with the objective of increasing the structure’s tangent stiffness in the vicinity of the bifurcation. An optimised shell design is presented which is practically unaffected by the increase in radial displacements in terms of axial stiffness.

ABSTRACT: A concept for a novel folding wing is presented, which, using the Brazier effect, can snap from a stable, extended position to a folded configuration. A wing typical of size used in an unmanned aircraft vehicle (UAV) is examined, including manufacturing aspects as well as an analytical and a finite element model (FEM) of the structure. The wing is simply made of a glass fiber reinforced plastic (GFRP) skin stiffened by ribs at regular intervals. At the mid-span location, a cut-out is made in the leading and trailing edge in order to allow the pressure and suction sides of the wing to collapse inward when folding occurs (due to Brazier effect). The analytical model draws upon work from Brazier to predict the maximum bending moment the folding section can withstand before buckling. A FEM, using a quasi-static analysis and requiring a contact definition to allow the wing surfaces to meet, reproduces with accuracy the folding pattern seen on the prototype. A bending test of the demonstrator confirmed the validity of the models in terms of bending stiffness, bending snap through and folding radius of curvature.

ABSTRACT: The overall objective is a top-down approach to structural instability phenomena in wind turbine blades, which is used to identify the physics governing the ultimate strength of a generic wind turbine blade under a flap-wise static test. The work is concerned with the actual testing and the adoption of a phenomenological approach, and a discussion is conducted to assess and evaluate the wind turbine blade response during loading and after collapse by correlating experimental findings with numerical model predictions. The ultimate strength of the blade studied is governed by instability phenomena in the form of delamination and buckling. Interaction between both instability phenomena occurs causing a progressive collapse of the blade structure.

ABSTRACT: The objective of this paper is to present a geometrical nonlinear and interlaminar progressive failure finite element analysis of a generic wind turbine blade undergoing a static flap-wise load and comparisons with experimental findings. It is found that the predictive numerical models show excellent correlation with the experimental findings and observations in the pre-instability response. Consequently, the ultimate strength of the wind turbine blade studied is governed by a delamination and buckling coupled phenomenon, which results in a chain of events and sudden structural collapse with compressive fibre failure in the delaminated flange material. Finally, a parametric study of the critical load factors with respect to various delamination sizes and positions inside the compressive flange of the wind turbine blade is presented.

ABSTRACT: The paper is concerned with the effect of random axisymmetric imperfections on the buckling of circular cylindrical shells under axial compression. The initial imperfections are considered as random functions of the axial coordinate. This is done by expanding them in terms of the buckling modes of the associated perfect structure, and then treating the Fourier coefficients as random variables. Initially the probabilistic properties of the initial imperfections of cylindrical shells, produced by the same manufacturing process, are studied. In contrast to earlier works the probabilistic properties (the mean function and the autocorrelation function or the spectral density) are not assumed. The mean vector and the variance-covariance matrix of the Fourier coefficients are calculated from experimental measurements of the shell profiles. Next the Monte Carlo Method is applied. The Fourier coefficients of the initial imperfection representations are simulated by a special numerical procedure. Thus large number of shells is “created”. For each shell a deterministic analysis of buckling stress evaluation is carried out. Finally, the reliability function representing the probability (i.e. fraction of an ensemble) of the buckling stress exceeding the specified stress is calculated. The reliability function permits to evaluate the design stress for the whole ensemble of shells produced by a given manufacturing process, defined as the stress level for which the desired reliability is achieved. The paper represents an extension of the approach given in Ref. [1] to shell structures.

ABSTRACT: A new, non-probabilistic method is developed in this study to predict the variability in buckling loads of composite plates and shells stemming from the unavoidable scatter in elastic moduli. The available measurements of elastic moduli are fitted by the four-dimensional uncertainty ‘box’ and appropriate ellipsoid. For the specific cases considered, the maximum buckling load of the composite plate exceeds by 11% the value of the buckling load based on the calculation using the nominal values of elastic moduli. In the case of the cylindrical shell, an appropriate exceedance constitutes 9%.
ABSTRACT: This paper deals with the buckling of the stiffened plate under uni-axial compression. The direct integration of the governing differential equation is performed and the exact solution to the problem is obtained. As examples, a square plate with single stiffener, and a stiffened three-span, continuous plate are investigated, with special attention given to the influence of stiffener misplacement on the buckling load and mode shape of the plate. It is found that a small misplacement of the stiffeners from the nominal configuration may change the buckling mode from a global one to a highly localized one.

ABSTRACT: This study addresses the effect of thickness variation on the stability of the composite cylindrical shells under axial compression. Various lamination configurations and three commonly used composite materials are considered. Numerical results show that certain types of thickness variation patterns can greatly reduce the classical buckling load. Results indicate that the most detrimental effect of the thickness variation occurs when the wave number of the thickness variation is twice that of the classical buckling mode. For this case, an asymptotic formula is established by use of a computer algebra, which relates the buckling load reduction rate to the thickness variation parameter.

ABSTRACT: This study is an extension of a previous investigation of the combined effect of axisymmetric thickness variation and axisymmetric initial geometric imperfection on buckling of isotropic shells under uniform axial compression. Here the anisotropic cylindrical shells are investigated by means of Koiter’s energy criterion. An asymptotic formula is derived which can be used to determine the critical buckling load for composite shells with combined initial geometric imperfection and thickness variation. Results are compared with those obtained by the software packages BOSOR4 and PANDA2.

ABSTRACT: Hybrid theoretical, experimental and numerical method is proposed for free vibration and buckling of composite shell with unavoidable scatter in elastic moduli. Based on the Goggin’s measurement techniques, the elastic moduli for material T300-QY8911 are measured, and a set of experimental points are obtained. The measurements of elastic moduli are quantified by either (1) the smallest ellipsoid and (2) the smallest four-dimensional uncertainty hyper-rectangle. Then uncertainty propagation in vibration and buckling problems of composite shell by ellipsoidal analysis and interval analysis are, respectively, studied from the theoretical standpoint. Comparison between these analyses is performed numerically.

ABSTRACT: The post-buckling behavior of the thin stiffened plates with uncertain initial deflection under uni-direction compression load is investigated based on Von-Karman large deflection theory. The uncertain initial deflections are considered to be unknown except that they belong to a given set in the interval range. Interval analysis model for computing the bounds of curves of the post-buckling deflection versus load of the plate is presented. Interval analysis model is compared with the stochastic model, which is taken as the benchmarks of accuracy for judgment. The results indicate that the non-probabilistic and stochastic methods will produce similar results for a large deviation of uncertainty. If the probabilistic information is unavailable, one should not propose the probabilistic method based on an arbitrary assumption on the distribution of the deflection coefficients. Rather, one should use the non-probabilistic method to uncertainty.

ABSTRACT: Non-linear buckling and postbuckling of a moderately thick anisotropic laminated cylindrical shell of finite length subjected to lateral pressure, hydrostatic pressure and external liquid pressure has been presented in the paper. The material of each layer of the shell is assumed to be linearly elastic, anisotropic and fiber-reinforced. The governing equations are based on a higher order shear deformation shell theory with von Kármán–Donnell-type of kinematic non-linearity and including the extension/twist, extension/flexural and flexural/twist couplings. The non-linear prebuckling deformations and initial geometric imperfections of the shell are both taken into account. A singular perturbation technique is employed to determine the buckling
pressure and postbuckling equilibrium paths. The numerical illustrations concern the postbuckling response of perfect and imperfect, moderately thick, anisotropic laminated cylindrical shells with different values of shell parameters and stacking sequence. The results confirm that there exists a circumferential stress along with an associate shear stress when the shell is subjected to external pressure.

ABSTRACT: The use of finite element buckling analysis in the stability design of thin shelled structures allows complex geometries and load and boundary conditions to be considered. Two approaches are possible. A linear bifurcation buckling analysis can be carried out to determine the bifurcation load of the perfect structure. Reduction factors can then be applied to account for the geometric imperfections and plasticity. Alternatively a fully non-linear analysis can be performed with deflections, geometric imperfections and plasticity properly modelled. This paper assesses the suitability of each of these methods to predict the buckling loads and post-buckling behaviour of two structures — flat plates and curved panels under combined shear and compression — a load case commonly found in aeroengine structures such as vanes. Experimental data is also presented for comparison.

ABSTRACT: Finite element analysis allows fully non-linear analysis of shells containing geometric imperfections. However, such an analysis requires information on the exact size and shape of the imperfection to be modelled, in order to produce accurate results on which designs can be based. In the absence of such data it is generally recommended that the imperfection be modelled on the first eigenmode with an amplitude selected according to manufacturing procedure. This paper presents the effects of imperfection shape and amplitude on the buckling and postbuckling behaviour of one specific case, to test the accuracy of such recommendations.

ABSTRACT: Projection moiré is frequently used to examine the out-of-plane displacement of thin-walled shells during buckling. One way of implementing this technique is to use double exposure photography to superimpose the initial and deformed images of a grating projected onto the surface of the specimen. This generates a pattern of fringes representative of points of equal displacement, thus presenting a snapshot of the full-field buckling behavior. This paper outlines a technique to extend this method to provide a computer generated real-time fringe pattern throughout the whole buckling and post-buckling process. This is achieved by using a CCD camera and specially developed processing software to continuously superimpose the initial image of the grating (i.e., the first frame of the captured video) onto subsequent frames in which this grating is deformed due to the displacement. This method produces series of fringes in digital format, which are ideal for
ABSTRACT: The initial buckling load of curved panels under compressive loads is substantially reduced by the existence of imperfections, in particular geometric imperfections. It is therefore essential that these imperfections are considered in analysing components which incorporate such panels in order to accurately predict their buckling behaviour. Finite element analysis allows fully non-linear analysis of shells containing geometric imperfections, however, to obtain accurate results information is required on the exact size and shape of the imperfection to be modelled. In most cases this data is not available. It is therefore generally recommended that the imperfections are modelled on the first eigenmode and have an amplitude selected according to the manufacturing procedure. This paper presents the effects of varying imperfection shape and amplitude on the buckling and postbuckling behaviour of one specific case, a curved panel under combined shear and compression, to test the accuracy of such recommendations.

ABSTRACT: The buckling loads and postbuckling behaviour of complex structures can only be determined analytically by simplifying them into a number of component parts and examining these individually using existing design rules. This approach does not consider the effect of geometric imperfections and large deflections or the interaction between overall and local buckling modes. Alternatively, finite element analysis can be used. This approach has the advantage of allowing geometry, boundary and loading conditions to be modelled more accurately. Large-scale deflections and material plasticity can be modelled, the effects of imperfections examined and all possible modes of failure considered. This paper outlines a series of experiments carried out to determine the accuracy of these two alternative techniques in predicting the buckling loads and postbuckling behaviour for the case of a simple aerofoil under combined shear and in-plane bending.

ABSTRACT: Spars in aircraft wing boxes constitute thin walled shells, providing a load path for vertical shear loading. Well established design rules for the prediction of the initial shear buckling load are extended to cover the cases of compression and in-plane bending, resulting from overall wing bending. A parametric study, performed using an exact strip method and verified by finite element results, for both simply supported and clamped longitudinal edges, shows that the stiffeners effectively provide simple support if their dimensions are made large enough. Using a single plate model for such cases, as simple interaction equation is shown to give accurate and conservative initial buckling predictions for combined loading cases, with some scope for improvement when the stiffener spacing is large.

ABSTRACT: Design rules based on theoretical solutions, which allow the prediction and understanding of the buckling and post-buckling behaviour of homogenous thin plates, exist for only a limited number of simple loading and boundary conditions due to the complexity of the equilibrium equations that describe the problem. When considering fibre composite plates, this issue is exacerbated by the inherent coupling between bending and extensional strains due to unsymmetric lamination, which results in three eighth order coupled partial differential equilibrium equations. This paper details a series of tests carried out to investigate the behaviour of a number of optimised fibre composite plates of differing geometry, simply supported along two edges and built in along the other two, subject to a varying combination of shear and in-plane bending, for which no theoretical solution exists, and assesses the suitability of analytical techniques and finite element analysis to predict this behaviour.

ABSTRACT: Due to the level of complexity of the governing equations for curved composite panels, few solutions, allowing the critical buckling loads and postbuckling behaviour of such structures to be determined, exist. Those that do are for basic problems based on single load types and simple boundary conditions. For other cases, such behaviour can only be determined by either grossly simplifying both the load and boundary conditions to those which can be predicted using these simplified equations (which may lead to overestimations in buckling load, and thereby premature failure or collapse), or by using alternative tools such as finite strip techniques or finite element analyses. This paper details a series of tests carried out to determine the behaviour of a number of optimised fibre composite panels of differing radii of curvature and aspect ratio, simply supported along two edges and built in along the other two, subject to a varying combination of shear and in-plane bending, for which no theoretical solution exists, and assesses the suitability of finite strip techniques and finite element analysis to predict this behaviour.

ABSTRACT: Due to their complexity and large numbers of design variables, aerospace structures, such as aircraft wings, are best optimized using a multi-level process. In addition to simplifying the optimization procedure, such an approach allows a combination of different methods to be used, increasing the efficiency of the analysis. This paper presents a technique based on the usage of exact finite strip software, VICONOPT, with the finite element analysis package, ABAQUS. The computer programme VICONOPT is computationally efficient but provides solutions for a restricted range of geometries and loading conditions. Finite element analysis allows accurate models of structures with complex geometries to be created but is computationally expensive. By combining the two, these limitations are minimised, whilst the strengths of each are exploited. The fundamental principles of this multi-level procedure are demonstrated by optimizing a series of curved composite panels under combined shear and in-plane bending subject to buckling constraints.

ABSTRACT: The paper introduces a discrete model to describe the buckling of a stiffened panel beam under a complex loading environment. The study begins by examining the existing load interaction equation for a continuous panel. Experimental and finite element investigations establish the validity of considering the critical
panel of a more complex structure in isolation. The paper then devises a discrete model for this critical panel, which was validated for a range of boundary conditions using anti-optimisation. The numerical results show that the discrete model exhibits the buckling behaviour of a continuous panel under combined loading. Recent studies established that the truss-lattice configuration has stable post-buckling behaviour and derived fast analysis technique for such a structure. It is therefore concluded that the truss-lattice model introduced in the present paper can offer a fast analysis formulation for buckling (and potentially post-buckling) of multiple-panel beams suitable for optimisation.

ABSTRACT: This paper examines the effect of imperfections on the behaviour of a series of panels, simply supported along all four edges, and subject to compressive in-plane loading. In each case Digital Image Correlation (DIC) is used to determine the initial profile and set-up of the structure and to monitor its behaviour during test. The data is used to automatically generate a series of meshes representative of each of these
specimens, suitable for analysis using Finite Element Analysis. Comparison of the results obtained from these analyses with those found during the experiments modelled shows an improved correlation when compared with standard techniques for assessing imperfection sensitivity. Set-up is straightforward and models can be obtained quickly based on the data collected.

ABSTRACT: The existence of geometric imperfections, either resulting from the use of manufacturing tolerances or because of damage in situ is known to have a detrimental effect on the buckling and post-buckling behaviour of thin-walled structures, which depending upon factors such as geometry and loading, can be significant. This paper presents an automated technique, based on the use of topography data obtained from optical measurement, for creating finite meshes representative of the geometry of real structures, which can be analysed to obtain accurate predictions of unstable behaviour. The technique incorporates an algorithm to allow mesh density to be varied across the specimen according to level of curvature thus ensuring the meshes generated are not only accurate but also computationally efficient by reducing the number of degrees of freedom where appropriate. The results of applying this technique to a series of curved panels subject to combined shear and in-plane bending (an example of a component of an aero engine blade) are reported.

ABSTRACT: Thin-walled shell structures like circular cylindrical shells are prone to buckling. Imperfections, which are defined as deviations from perfect shape and perfect loading distributions, can reduce the buckling load drastically compared to that of the perfect shell. Design criteria monographs like NASA-SP 8007 recommend that the buckling load of the perfect shell shall be reduced by using a knock-down factor. The existing knock-down factors are very conservative and do not account for the structural behaviour of composite shells. To determine an improved knock-down factor, several authors consider realistic shapes of shells in
numerical simulations using probabilistic methods. Each manufacturing process causes a specific imperfection pattern; hence for this probabilistic approach a large number of test data is needed, which is often not available. Motivated by this lack of data, a new deterministic approach is presented for determining the lower bound of the buckling load of thin-walled cylindrical composite shells, which is derived from phenomenological test data. For the present test series, a single pre-buckle is induced by a radial perturbation load, before the axial displacement controlled loading starts. The deformations are measured using the prototype of a high-speed optical measurement system with a frequency up to 3680 Hz. The observed structural behaviour leads to a new reasonable lower bound of the buckling load. Based on test results, the numerical model is validated and the shell design is optimized by virtual testing. The results of test and numerical analysis indicate that this new approach has the potential to provide an improved and less conservative shell design in order to reduce weight and cost of thin-walled shell structures made from composite material.

ABSTRACT: This work presents numerical methods of calculation of earthquake resistance of shells of revolution based on the application of the theory of random processes combined with the FEM. Probabilistic character of seismic effect is determined by using artificial accelerograms based on stochastic process. To illustrate the above methods of probabilistic analysis of seismic stability of structures, two real objects and one projected one are considered. Displacements, stresses, forces and moments resulting from the action of seismic load have been determined. Comparison of the results of calculation with those achieved using calculation of prescribed real accelerograms and building design codes have been made. Comparative analysis of the calculation results brings us to the conclusion that the difference between the results obtained using different methods can be quite significant. It means that when designing structures of the types of shells of revolution under consideration it is necessary to do calculations using all methods recommended by design codes as well as probabilistic methods.

ABSTRACT: A moving load causes the radial displacements of an axi-symmetric shell to be several times higher than that produced by the static application of the same load. The travel velocity of the moving load affects the amplitude of the radial response and a critical velocity above which the shell response becomes unstable can be identified. A finite element model (FEM) is developed to analyze the dynamic response of axi-symmetric shells subjected to axially moving loads. The model accounts for the effect of periodically placing stiffening rings along the shell, on the dynamic response and stability characteristics of the shell. Shape functions obtained from the steady-state solution of the equation of motion for a uniform shell are utilized in the development of the FEM. The model is formulated in a reference frame moving with the load in order to enable studying the shell stability using wave propagation and attenuation criteria. Hence, the critical velocity can be identified as the minimum velocity allowing the propagation of applied perturbations. Such stability boundaries are conveniently identified through a transfer mis formulation. The model is used to determine the critical velocities of the moving load for various arrangements and geometry of the stiffening rings. The obtained results indicate that stiffening the shell generally increases the critical velocity and generates a pattern of alternating stable and unstable regions. The presented analysis provides a viable means for designing a wide variety of stable dynamic systems operating with fast moving loads such as crane booms, robotic arms and gun barrels.

Massimo Ruzzene (School of Aerospace Engineering, Georgia Institute of Technology, 270 Ferst Drive, Atlanta, GA 30332-0150, USA), “Non-axisymmetric buckling of stiffened supercavitating shells: static and dynamic analysis”, Computers & Structures, Vol. 82, Nos. 2-3, January 2004, pp. 257-269

doi:10.1016/j.compstruc.2003.09.003

ABSTRACT: Supercavitating vehicles undergo high longitudinal forces as a result of their high underwater velocity. The drag force compresses axially the body and may cause its buckling. In addition, the time-dependent properties of the cavity generate time-varying longitudinal loads, which are sources of parametric resonances. Static and dynamic buckling need to be considered as limiting factors for the operating speed of this class of vehicles. The stability of supercavitating underwater vehicles is here investigated through a finite element model that predicts the behavior of plain and stiffened shells and is used to obtain stability maps for varying vehicle’s velocity, as well as frequency and amplitude of the force oscillations. Periodically placed circumferential stiffeners are proposed as means to enhance the stability of the considered class of shells. The results indicate the effectiveness of the stiffening rings in extending the range of stable operating conditions, by
increasing the critical static buckling loads, and more importantly by reducing the extension of the regions corresponding to dynamic instability.

ABSTRACT: Supercavitating vehicles undergo high longitudinal forces as result of their high underwater velocity. The drag force compresses axially the body and may cause its buckling. In addition, the unsteady characteristics of the system composed of cavity and vehicle generate time-varying longitudinal loads that are sources of parametric resonances. Supercavitating vehicles are here modeled as thin axisymetric shells acted upon by time-varying axial compressive forces. A finite element model is developed to predict the shells behavior and to perform the buckling analysis. The longitudinal forces are considered to vary periodically in time. Accordingly, the stability analysis is performed using Bolotin’s method and Floquet theory. Stability maps for varying velocity of the vehicle, frequency and amplitude of the force oscillations are obtained. Periodically placed circumferential stiffeners are proposed as means to enhance the stability of the considered class of shells. The presented results indicate how the stiffening rings significantly extend the range of stable operating conditions by reducing the regions of dynamic instability, and suggest that optimal stiffened designs may be identified to achieve stability at given operating speeds and under periodic longitudinal forces.

ABSTRACT: A laminated cylindrical shell of finite length under combined loads is optimized for minimum sensitivity of buckling load to variations in ply angles subject to a constraint on buckling load. The design variable is taken as the fiber orientation of individual layers. The general theory of laminated plates is employed to determine the buckling loads. The formulation includes the contribution of the shear deformation and the variation of the radius over the thickness of the shell. Numerical results are given for both thin and thick shells. The results are given for various values of the external pressure and different shell aspect ratios. It is shown that the minimum sensitivity design depends on the constraint on buckling load.

ABSTRACT: Friction stir welding (FSW) is a rapidly emerging joining technology that is finding greater use in aerospace applications due to significant advancements in tooling and process development. However, basic performance and design parameters for aerospace structures incorporating FSW joints have typically been developed on a case by case basis and are not yet available for general applications. Performance and properties
data are needed to advance FSW from coupon level research to direct application. Therefore, the National Institute for Aviation Research (NIAR) initiated an investigation to compare the integrity of typical airframe structure joined using FSW with that of riveted structure. Ultimately, the aim of this investigation is to aid in the development of performance specification data. The structures selected for this research were subscale flat stiffened panels that were based on previously developed designs from generic fuselage applications. The initial stiffened aluminum panels were fabricated with two hat-section stiffeners. Representative of a transport fuselage design, the skin panels were 0.040-in 2024-T3, and the stiffeners were 7075-T6 spaced on 8.0 inch centers. The 2-ft x 2-ft stiffened panels were tested statically in tension, compression, and shear. Finite element models were developed to evaluate the ability of modeling to predict the load carrying capability of FSW structures. In the presentation, test results from riveted panels with identical geometry will be compared with results from both the models and the FSW panels. To date the panels fabricated using FSW have shown an increase in overall performance including an increase in panel strength and axial displacement. The FSW shear panels failed less abruptly and with much less destruction than did the riveted panels, indicating an increase in the ability of the FSW panels to sustain damage.

ABSTRACT: Reinforced structures for aircraft fuselages are conventionally composed by base (skin) aluminium plates and reinforcement elements (stringers), joined by riveting operations. During the last decade more effective approaches for reinforced fuselage and wings, such as the Integrally Stiffened Panels (ISP), have appeared. These homogeneous reinforced structures are obtained in an integral form by extrusion, allowing for lower manufacturing costs. During service conditions, these structures can be subjected to extreme compressive loading conditions and, due to their slenderness and low weight, ISP design must account for a reliable determination of buckling loads. However, complexities of the cross-sectional geometrical shapes, together with the occurrence of elastoplastic non-linear effects prior or after buckling, completely impair the use of analytical tools, being the analysis by the Finite Element Method (FEM) imperative in a reliable design process. In the present work, the structural performance of ISP structures is assessed, accounting for buckling in the elastoplastic range, by means of numerical simulation with the Finite Element Method. Also, the buckling load-carrying capacity of multiple sets of reinforced structures, composed by a finite number of ISP and joined by friction stir welding (FSW) operations, is also studied. In doing so, it is possible to numerically infer about the influence of the presence of FSW zones in the overall stiffness and mechanical behaviour of ISP structures with complex cross-section geometries.

ABSTRACT: Stiffened panels are usually the basic structural building blocks of airplanes, vessels and other structures with high requirements of strength-to-weight ratio. They typically consist of a plate with equally spaced longitudinal stiffeners on one side, often with intermediate transverse stiffeners. Large aeronautical and naval parts are primarily designed based on their longitudinal compressive strength. The structural stability of such thin-walled structures, when subjected to compressive loads, is highly dependent on the buckling strength of the structure as a whole and of each structural member. In the present work, a number of modelling and numerical calculations, based on the Finite Element Method (FEM), is carried out in order to predict the ultimate load level when stiffened panels are subjected to compressive solicitations. The simulation models
account not only for the elasto-plastic nonlinear behaviour, but also for the residual stresses, material properties modifications and geometrical distortions that arise from Friction Stir Welding (FSW) operations. To construct the model considering residual stresses, their distribution in FSW butt joints are obtained by means of a numerical-experimental procedure, namely the contour method, which allows for the evaluation of the normal residual stress distribution on a specimen section. FSW samples have been sectioned orthogonally to the welding line by wire electrical discharge machining (WEDM). Displacements of the relaxed surfaces are then recorded using a Coordinate Measuring Machine and processed in a MATLAB environment. Finally, the residual stress distribution is evaluated by means of an elastic FE model of the cut sample, using the measured and digitalized out-of-plane displacements as input nodal boundary conditions. With these considerations, the main goal of the present work will then be related to the evaluation of the effect of FSW operations, in the ultimate load of stiffened panels with complex cross-section shapes, by means of realist numerical simulation models.

ABSTRACT: NASA Lewis Research Center is currently developing probabilistic structural analysis methodology for select Space Shuttle Main Engine (SSME) components. This methodology consists of the following program elements: (1) composite load spectra, (2) probabilistic structural analysis methods, (3) probabilistic finite element theory - new variational principles, and (4) probabilistic structural analysis application. The methodology has led to significant technical progress in several important aspects of probabilistic structural analysis. The program and significant accomplishments to date are summarized in this paper.

ABSTRACT: The durability of a stiffened composite cylindrical shell panel is investigated under several loading conditions. An integrated computer code is utilized for the simulation of load induced structural degradation. Damage initiation, growth, and accumulation up to the stage of propagation to fracture are included in the computational simulation. Results indicate significant differences in the degradation paths for different loading cases. Effects of combined loading on structural durability and ultimate structural strength of a stiffened shell are assessed.

ABSTRACT: A general computational simulation methodology for an integrated probabilistic assessment of composite structures is discussed and demonstrated using aircraft fuselage (stiffened composite cylindrical shell) structures with rectangular cutouts. The computational simulation was performed for the probabilistic assessment of the structural behavior including buckling loads, vibration frequencies, global displacements, and local stresses. The scatter in the structural response is simulated based on the inherent uncertainties in the primitive (independent random) variables at the fiber matrix constituent, ply, laminate, and structural scales that describe the composite structures. The effect of uncertainties due to fabrication process variables such as fiber volume ratio, void volume ratio, ply orientation, and ply thickness is also included. The methodology has been embedded in the computer code IPACS (Integrated Probabilistic Assessment of Composite Structures). In addition to the simulated scatter, the IPACS code also calculates the sensitivity of the composite structural behavior to all the primitive variables that influence the structural behavior. This information is useful for assessing reliability and providing guidance for improvement. The results from the probabilistic assessment for the composite structure with rectangular cutouts indicate that the uncertainty in the longitudinal ply stress is mainly caused by the uncertainty in the laminate thickness, and the large overlap of the scatter in the first four buckling loads implies that the buckling mode shape for a specific buckling load can be either of the four modes.

ABSTRACT: The design of composite structures requires an evaluation of their safety and durability under service loads and possible overload conditions. This paper presents a computational tool that has been developed to examine the response of stiffened composite panels via the simulation of damage initiation, growth, accumulation, progression, and propagation to structural fracture or collapse. The structural durability of a composite panel with a discontinuous stiffener is investigated under compressive loading induced by the gradual displacement of an end support. Results indicate damage initiation and progression to have significant effects on structural behavior under loading. Utilization of an integrated computer code for structural durability assessment is demonstrated.

Christos C. Chamis (NASA Lewis Research Center, Cleveland, Ohio), “Probabilistic composite design”, in

ABSTRACT: Probabilistic composite design is described in terms of a computational simulation. This simulation tracks probabilistically the composite design evolution from constituent materials, fabrication process, through composite mechanics and structural components. Comparisons with experimental data are provided to illustrate selection of probabilistic design allowables, test methods/specimen guidelines, and identification of in situ versus pristine strength. For example, results show that: in situ fiber tensile strength is 90 per cent of its pristine strength; flat-wise long-tapered specimens are most suitable for setting ply tension strength allowables; a composite radome can be designed with a reliability of 0.999999; and laminate fatigue exhibits wide-spread scatter at 90 per cent cyclic-stress to static-strength ratios.

ABSTRACT: A methodology is developed to simulate computationally the uncertain behavior of composite structures. The uncertain behavior includes buckling loads, natural frequencies, displacements, stress/strain, etc., which are the consequences of the random variation (scatter) of the primitive (independent random) variables in the constituent, ply, laminate and structural levels. This methodology is implemented in a computer code IPACS (integrated probabilistic assessment of composite structures). A fuselage-type composite structure is analyzed to demonstrate the code's capability. The probability distribution functions of the buckling loads, natural frequency, displacement, strain and stress are computed. The sensitivity of each primitive (independent random) variable to a given structural response is also identified from the analyses.

C.C. Chamis, R.A. Aiello and P.L.N. Murthy, “Fiber composite sandwich thermostructural behavior: Computational simulation”, (publisher and date not given, ProQuest-CSA)

ABSTRACT: Several computational levels of progressive sophistication/simplification are described to computationally simulate composite sandwich hygral, thermal, and structural behavior. The computational levels of sophistication include: (1) three-dimensional detailed finite element modeling of the honeycomb, the adhesive and the composite faces; (2) three-dimensional finite element modeling of the honeycomb assumed to be an equivalent continuous, homogeneous medium, the adhesive and the composite faces; (3) laminate theory simulation where the honeycomb (metal or composite) is assumed to consist of plies with equivalent properties; and (4) derivations of approximate, simplified equations for thermal and mechanical properties by simulating the honeycomb as an equivalent homogeneous medium. The approximate equations are combined with composite hygrothermomechanical and laminate theories to provide a simple and effective computational procedure for simulating the thermomechanical/thermostructural behavior of fiber composite sandwich structures.

“Future Experimental Methods Needed to Verify Composite Life-cycle Simulations”, Recent Advances in

ABSTRACT: The future experimental methods needed for composite life-cycle are identified by computationally simulating the fracture of an integrally stiffened composite structure. The simulation describes events occurring during the fracture progression at all composite structure scales, the fracture modes that contribute to those events and the respective local failure mechanisms. The fracture modes in their respective scales provide opportunities to suggest future testing techniques to measure them. For example, energies emitted can be calibrated to identify non-destructive techniques to measure corresponding energies such as acoustic, thermal and even optical. Successful testing methods can then be used to implement monitoring systems for in-service structural life-cycles.

ABSTRACT: The objective of this report is to summarize the deterministic and probabilistic structural evaluation results of two structures made with advanced ceramic composites (CMC): internally pressurized tube and uniformly loaded flange. The deterministic structural evaluation includes stress, displacement and buckling analyses. It is carried out using the finite element code MHOST1, developed for the 3-D inelastic analysis of structures that are made with advanced materials. The probabilistic evaluation is performed using the integrated probabilistic assessment of composite structures computer code IPACS2. The affects of uncertainties in primitive variables related to the material, fabrication process, and loadings on the material property and structural response behavior are quantified. The primitive variables considered are: thermo-mechanical properties of fiber and matrix, fiber and void volume ratios, use temperature, and pressure. The probabilistic structural analysis and probabilistic strength results are used by IPACS to perform reliability and risk evaluation of the two structures. The results will show that the sensitivity information obtained for the two composite structures from the computational simulation can be used to alter the design process to meet desired service requirements. In addition to detailed probabilistic analysis of the two structures, the following were performed specifically on the CMC tube: (1) predicted the failure load and the buckling load, (2) performed coupled non-deterministic multi-disciplinary structural analysis, and (3) demonstrated that probabilistic sensitivities can be used to select a reduced set of design variables for optimization.

ABSTRACT: A computational simulation method is presented to evaluate the deterministic and non-deterministic dynamic buckling of smart composite shells. The combined use of intraply hybrid composite mechanics, finite element computer codes, and probabilistic analysis enable the effective assessment of the dynamic buckling load of smart composite shells. A universal plot is generated to estimate the dynamic buckling load of composite shells at various load rates and probabilities. The shell structure is also evaluated with smart fibers embedded in the plies right next to the outer plies. The results show that, on the average, the use of smart fibers improved the shell buckling resistance by about 10% at different probabilities and delayed the buckling occurrence time. The probabilistic sensitivities results indicate that uncertainties in the fiber volume ratio and ply thickness have major effects on the buckling load while uncertainties in the electric field strength and smart material volume fraction have moderate effects. For the specific shell considered in this evaluation, the use of smart composite material is not recommended because the shell buckling resistance can be improved by simply re-arranging the orientation of the outer plies, as shown in the dynamic buckling analysis results presented in this report.

ABSTRACT: A methodology is developed to computationally assess the probabilistic composite behavior at all composite scales (from micro to structural) due to the uncertainties in the constituent (fiber and matrix) properties, in the fabrication process and in structural variables (primitive variables). The methodology is computationally efficient for simulating the probability distributions of composite behavior, such as material properties, laminate and structural responses. Byproducts of the methodology are probabilistic sensitivities of the composite primitive variables. The methodology has been implemented into the computer codes: Probabilistic Integrated Composite ANalyzer (PICAN) and Integrated Probabilistic Assessment of Composite Structures (IPACS). The accuracy and efficiency of this methodology are demonstrated by simulating the uncertainties in composite typical laminates and comparing the results with the Monte Carlo simulation method.
Available experimental data of composite laminate behavior at all scales fall within the scatters predicted by PICAN. Multi-scaling is extended to simulate probabilistic thermo-mechanical fatigue and to simulate the probabilistic design of a composite redome in order to illustrate its versatility. Results show that probabilistic fatigue can be simulated for different temperature amplitudes and for different cyclic stress magnitudes. Results also show that laminate configurations can be selected to increase the redome reliability by several orders of magnitude without increasing the laminate thickness—a unique feature of structural composites.

ABSTRACT: A computationally effective method is described to evaluate the nonlinear dynamic buckling of thin composite shells. The method is a judicious combination of available computer codes for finite element, composite mechanics and incremental structural analysis. The solution method is an incrementally updated Lagrangian. It is illustrated by applying it to a thin composite cylindrical shell subjected to dynamic loads. Buckling loads are evaluated to demonstrate the effectiveness of the method. A universal plot is obtained for the specific shell that can be used to approximate buckling loads for different dynamic loading rates. Results from this plot show that the faster the rate, the higher the buckling load and the shorter the time. Results also show that the updated solution can be carried out in the post buckling regime until the shell collapses completely.

Christos C. Chamis (1) and Galib H. Abumeri (2)

ABSTRACT: A computationally effective method is described to evaluate the probabilistic dynamic buckling of thin composite shells. The method is a judicious combination of available computer codes for finite element, composite mechanics and probabilistic structural analysis. The solution method is an incrementally updated Lagrangian. It is illustrated by applying it to a thin composite cylindrical shell subjected to dynamic loads. Both deterministic and probabilistic buckling loads are evaluated to demonstrate the effectiveness of the method. A universal plot is obtained for the specific shell that can be used to approximate buckling loads for different loading rates and different probability levels. Results from this plot show that the faster the rate, the higher the buckling load and the shorter the time. The lower the probability, the lower the buckling load for a specific time. Probabilistic sensitivity results show that the ply thickness, the fiber volume ratio, the fiber longitudinal modulus, dynamic load and loading rate are the dominant uncertainties in that order.

ABSTRACT: The research and development in composite mechanics are reviewed from 1965 to 2006. The
review covers micromechanics, macromechanics failure theories, impact resistance, structural analysis, plate and panel buckling, shell buckling, progressive fracture, containment, and probabilistic composite simulation. A few remarks are included about aerodynamic loads and a new all composite engine concept. Most of the sample cases are from the author's own research since this research covers all aspects of composites and since this avoids the permissions required by other authors when their results are included. References are cited as appropriate so that the reader can further look in any specific area.

ABSTRACT: We report on a nonlinear equation-based closed-form solution for a spring-loading-enclosed electrothermal post-buckling microbeam that expresses (a) the relation between the compressive loads and its corresponding lateral deflections and (b) the threshold loads required to trigger the buckling phenomenon, under the condition of a variety of transverse loads. Our theoretical research reveals that the post-buckling behavior varies considerably under different transverse load ranges. Three types of double-clamped microbeams connected to microsprings with different dimensions and compliances representing transverse loads were fabricated and measured using microelectromechanical systems (MEMS) technology. Excellent agreement was found between our theoretical analysis and experimental results to confirm our exact solutions. It proves that the influences on thermal post-buckling behavior are dependent on different microbeam dimensions and microspring compliances (i.e., transverse loads). Therefore, an electrothermal buckling/post-buckling beam under external transverse loads can be accurately predicted using our theoretical model, which can be applied to either existing microdevices that are based on similar principles or other potential applications.

ABSTRACT: MBB-LAGRANGE is a powerful optimization code which allows the optimization of structures. To achieve the optimal design of a structure all special requirements must be fulfilled. That means that constraints e.g. stress, strains or displacements have to be in a feasible range while the objective function e.g. the structural weight reaches a minimum value. The results are strongly dependent on the optimization constraints which must be fulfilled. In this context local and global stability constraints may be essential for the design process. In the continuing development of MBB-LAGRANGE stability constraints are one of the major topics the MBB-LAGRANGE team is busy developing. One topic is the realization of local stability constraints of sandwich structures which will be discussed in this paper. The theoretical background and the integration into the optimization code MBB-LAGRANGE will be shown. An example of a helicopter sandwich structure will demonstrate the influence of this constraint type in the design process while optimal results are found. These results satisfy all requirements: local stability, stress and dynamic constraints.

ABSTRACT: Low-velocity instrumented impact tests were carried out on sandwich panels made of glass fiber-reinforced plastic facesheets and polyurethane foam core. The tests were carried out using a drop weight instrumented impact tester, connected to a data acquisition system. Four different types of sandwich samples using polyester/e-glass and epoxy/e-glass facesheet materials and polyurethane foam were considered for investigation. Two different face sheet materials were chosen to experimentally examine the effect of their elastic modulus on the impact response of the sandwich structures. The data acquisition system records the impact data such as impact force, penetration time and depth of penetration, and plots impact force versus depth of penetration and penetration time versus depth of penetration curves. From the recorded data the impact parameters such as maximum impact force, penetration time and depth of penetration versus impact energy were plotted to study the impact behavior. The results show that higher impact energy is required to break the epoxy/e-glass facesheet and backsheet sandwich specimens than other types of specimens examined. The impact damage caused to the facesheet, the core and the backsheet were thoroughly studied experimentally and the extent of damage caused to the facesheets and the core were also compared by finite element analyses.

ABSTRACT: In the four years since the previous review [Vinson(1)] composite materials and their use in structures have grown and matured considerably. In addition to the continuous & short fibre and particulate composites, there has been much progress in the areas of sheet moulding compounds, woven fabric & three dimensional composites and braided composites employing many of the same fibre materials. New thermoplastic polymers show real promise and progress in metal matrix composites has been made. The analysis of composite material structures subjected to static, vibratory, impact, environmental and long time loading continues to progress. Important effects such as creep, viscoelasticity, damping, postbuckling behaviour and delamination are better understood. However, strength and failure criteria remain areas that need much further investigation and agreement. There has been a rapid increase in simpler-to-use computer codes that are available from the government and universities that ease structural-material analysis and provide more comprehensive descriptions of structural behaviour. In education concerning composite materials, new textbooks have appeared, more universities and organisations are offering courses, and there is a trend of migration of professors to those institutions where composite material research is emphasised. Technology transfer and export controls have had an increasing affect upon the composite materials community, particularly with regard to metal matrix composites. These manifest themselves in sponsored research, both at universities and international meetings. In the aerospace industry, all composite aircraft such as the Sikorsky ACAP helicopter have been developed. The Grumman X-29 Forward swept wing aircraft will fly soon. New turbine engines using more composite materials are under study, as well as increased use of composites in many aircraft and spacecraft vehicles. Composites in the automotive and leisure industries continue on the increase. With increased volume of use and better methods of computer assisted design, analysis and manufacturing, application of composites will extend to other areas such as mass transport.
ABSTRACT: Foam core sandwich cylindrical shells with specially orthotropic composite face materials are treated. Methods by which to analyze and design these shells are presented to prevent overstressing, overall buckling, core shear instability and face wrinkling. In addition, analytic methods to determine the configuration and materials to achieve absolute minimum weight are developed and presented herein. These procedures provide the means to select the face thickness, the core depth, and the optimum foam core shear modulus to attain minimum weight for a given face material. A factor of merit is developed for selecting the composite face material to attain a minimum weight sandwich. The methods clearly define the maximum loads the sandwich shell can withstand without buckling or overstressing of the faces.

ABSTRACT: Sandwich construction offers several advantages over monocoque and various discretely stiffened structures. These include greater load carrying ability, reduced weight, higher buckling loads, and higher fundamental natural frequencies. Equations for the analysis and design of sandwich cylindrical shells subjected to beam-type bending are presented herein. These equations are then manipulated to provide the face thickness, core depth, and core shear modulus to produce a minimum weight structure for a given load index and face material system. A factor of merit to select the best face material is also presented. As examples, carbon/epoxy and E-glass /epoxy cross-ply composite faced sandwich shells are compared, and comparison with a monocoque cross-ply laminated shell is also presented.

ABSTRACT: The study of mechanics of sandwich structures and a development of new and innovative structural concepts have been conducted in the course of the effort. In particular, our research was concerned with a development of Sanders'-type theory of cylindrical sandwich shells with different facing operating in hostile environment. This theory was further extended to elliptical shells. The effects of internal ribs located on the inner surface of thefacings and the woven facing construction on the response of sandwich structures was studied. In particular, rib-reinforced facings were probably first suggested in the course of the present effort. These new structural concepts are important since woven facings can reduce the tendency to delamination, while rib-reinforced facing results in enhanced local strength and stiffness. Also, the effect of damage in the form of matrix cracks in the facings on the response and performance of sandwich panels was investigated. The similarity conditions for sandwich shells were formulated, jointly with Drs. Simitses, Song and Frostig. The study of a new concept of sandwich structures with truss-reinforced core (Z-fiber reinforced core) was undertaken. The latter design may prove attractive in applications where significant shear and off-axis loads are applied to the structures. Other subjects that were investigated include the evaluation of the shear correction coefficient for sandwich structures analyzed by the first-order theory. The latest effort was a development of an analytical model capable of predicting damping of sandwich structures.
ABSTRACT: A non-circular shell cross-section with flat sides and circular arc corners is analyzed using the theorem of minimum potential energy. Two-dimensional, plane strain assumptions are utilized, and the potential energy (PE) expression for the structure is developed, including first-order transverse shear deformation effects. The unknown displacements are represented by power series, and the PE expression is rewritten in terms of the summation convention for the power series. The variation of the PE expression is taken, leading to a linear system of equations that is solved for the unknown power series coefficients. With the displacements determined, stresses are calculated for a composite sandwich construction. Excellent agreement is found with other analytical methods and with finite element analyses.

ABSTRACT: A cylindrical shell with a non-circular cross-section consisting of flat sides and circular arc corners is analyzed using the theorem of minimum potential energy. The three-dimensional analysis builds on previous two-dimensional work. The potential energy expression for the structure is developed, including first-order transverse shear deformation effects. All unknown displacements are represented by power series, and the potential energy expression is rewritten in terms of the summation convention for the power series. The variation of the potential energy expression is taken, leading to a linear system of equations that is solved for the unknown power series coefficients. With the displacements determined, stresses are calculated for a composite sandwich construction. An examination of both short shells (less than twice the boundary layer length) and long shells (more than twice the boundary layer length) is made. The MPE method with power series is found to predict behavior well for short shells, but not for long shells.

ABSTRACT: The use of sandwich structures continues to increase rapidly for applications ranging from satellites, aircraft, ships, automobiles, rail cars, wind energy systems, and bridge construction to mention only a few. The many advantages of sandwich constructions, the development of new materials, and the need for high performance, low-weight structures insure that sandwich construction will continue to be in demand. The equations describing the behavior of sandwich structures are usually compatible with the equations developed for composite material thin-walled structures, simply by employing the appropriate in-plane, flexural, and transverse shear stiffness quantities. Only if a very flexible core is used, is a higher order theory needed.

ABSTRACT: An experimental investigation was conducted to study the behavior under biaxial tensile loading of quasiisotropic graphite/epoxy plates with circular holes and to determine the influence of hole diameter on failure. The specimens were 40 cm×40 cm (16 in.×16 in.) laminates of [0/±45/90]s layup. Four hole diameters, 2.54 cm (1.00 in.), 1.91 cm (0.75 in.), 1.27 cm (0.50 in.) and 0.64 cm (0.25 in.), were investigated. Deformations and strains were measured using strain gages and birefringent coatings. Equal biaxial loading was introduced by means of four whiffle-tree grip linkages and controlled with a servohydraulic system. Initially, the circumferential strain is uniform around the boundary of the hole. Subsequently, with increasing load, regions of high strain concentration with nonlinear response develop at eight characteristic locations 22.5 deg off the fiber axes. Failure in the form of cracking and delamination initiates at these points. Maximum strains at failure on the hole boundary reach values up to twice the ultimate strain of the unnotched laminate. The effect of hole diameter on strength was described satisfactorily using an average biaxial-stress criterion. Good correlation was also obtained with theoretical predictions based on a tensor-polynomial failure criterion for the lamina and a progressive degradation model.

ABSTRACT: An experimental investigation was conducted to study the behavior under biaxial-tensile loading of [O2/±45]s graphite/epoxy plates with circular holes and to determine the influence of hole diameter on failure. The specimens were 40-cm×40-cm (16-in.×16-in.) graphite/epoxy plates of [O2/±45]s layup. Four hole diameters, 2.54 cm (1.00 in.), 1.91 cm (0.75 in.), 1.27 cm (0.50 in.) and 0.64 cm (0.25 in.), were investigated. Deformations and strains were measured using strain gages and birefringent coatings. Biaxial tension in a 2ratio1 ratio was applied by means of four whiffle-tree grip linkages and controlled with a servohydraulic system. Stress and strain redistributions occur around the hole at a stress level corresponding to localized failure around the 67.5-deg location and nonlinear strain response at the 0-deg location. Maximum measured strains at failure on the hole boundary are higher (approximately 0.016) than the highest ultimate strain of the unnotched laminate (0.010). Two basic patterns of failure were observed: (a) horizontal cracking initiating at points off the horizontal axis and accompanied by extensive delamination of the subsurface ±45 deg plies, and (b) vertical cracking along vertical tangents to the hole and accompanied by delamination of the outer 0-deg plies. The strength reduction ratios are lower than corresponding values for uniaxial loading by approximately 16 percent, although the stress-concentration factor under biaxial loading is lower.

ABSTRACT: The deformation and failure response of composite sandwich beams and panels under low velocity impact was reviewed and discussed. Sandwich facesheet materials discussed are unidirectional and woven carbon/epoxy, and woven glass/vinylester composite laminates; sandwich core materials investigated include four types of closed cell PVC foams of various densities, aluminum honeycomb, polyurethane foam, foam-filled honeycomb, and balsa wood. These materials were fully characterized under quasi-static loading and, in some cases, under high strain loading conditions as well. Sandwich beams were tested in an instrumented drop tower system under various energy levels, where load and strain histories and failure modes were recorded for the various types of beams. Peak loads predicted by spring-mass and energy balance models were in satisfactory agreement with experimental measurements. Failure patterns depend strongly on the impact energy levels and core properties. Failure modes observed include core indentation/cracking, facesheet buckling, delamination within the facesheet, and debonding between the facesheet and core. Sandwich beams with PVC cores tend to be more stable than beams with different cores. Although sandwich beams with balsa wood cores perform well under static loading, they fail catastrophically under impact loading due to the low fracture toughness along the grain direction. Sandwich beams with honeycomb cores show early catastrophic failure caused by the lack of continuity of the interface between the honeycomb core and the facesheet, resulting in debonding failure. In the case of sandwich panels, it was shown that static and impact loads of the same magnitude produce very similar far-field deformations. The induced damage is localized and is lower for impact loading than for an equivalent static loading. Static testing in general is more conservative regarding strain and damage levels. The load history, predicted by a model based on the sinusoidal shape of the impact load pulse, was in agreement with experimental results. A finite element model was implemented to capture the full response of the panel indentation. The investigation of post-impact behavior of sandwich structures shows that, although impact damage may not be readily visible, its effects on the residual mechanical properties of the structure can be quite detrimental.

ABSTRACT: This study is concerned with the modelling and simulation of delamination prediction of fibrous composite panels under low velocity impact of variable shape impactors. Mathematical formulations were developed and explained for the phenomena and simulations were carried out on ply orientations, stacking sequences, through-the-thickness, and width location of the delaminated areas. The delamination induced strategy was adopted to predict regions of high stress concentration in the vicinity of contact area leading to buckling load factor predictions. An eight, sixteen, and twenty four ply of codes [45/0/-45/90]S, [45/0/-45/90]2S, [45/0/-45/90]3S quasi-isotropic lay-ups, having fabric lamina properties were analyzed using ProEngineer/Mechanica a general purpose finite element method (FEM) software. The software was selected as it is widely distributed, well documented and user-friendly and has as a shell element facilities to generate stack of plies. The delaminated zones are represented by a series of circular area cases with zones for 0, 20, 40, 60, 80 and 100 mm diameters located from the top to the halfway through the thickness resulting in 4, 8, and 12 ply sub-laminates were studied by inducing delamination. Delamination induced models consisting of removing a considerable part from the specimen as well of a very thin and weaker material properties ply were tested. Results were compared against the normalized form of the buckling load for an undamaged virgin laminate. Predicted results were used to calculate and predict buckling load factors for delaminated specimens. Graphics, images and tables were drawn to compare the results. These predictions correlated closely with the results from available literature. The approach has been found to be reliable for the cases considered.

ABSTRACT: A unified analysis method based on two-dimensional elasticity theory is outlined for evaluation of bending, buckling and vibration of multilayer orthotropic sandwich beams and panels. The effects of initial geometric imperfections are included. It is shown that beams or panels deforming under conditions of plain stress or plane strain may be treated as special instances of folded-plate structures using computer programs which are now widely available. Examples are given, including evaluation of stress contours in a sandwich panel under patch load and analysis of overall and local (face-wrinkling) buckling modes in sandwich panels with stiff and soft cores.

ABSTRACT: This paper formulates the stiffness matrix and a procedure for exact solutions of the bending and overall buckling problem of a general class of sandwich beam and frame structures subjected to arbitrary loading and boundary conditions. The solutions for deflections, stresses and buckling load are exact in the sense that they satisfy the governing differential equation, interelement compatibility and all boundary conditions. A preliminary study of the behaviour of sandwich beams using the developed theory shows that the Saint Venant principle may not apply to sandwich beams regarding the effects of applied end moments. Restraint against shear deformations will generally reduce the deflections and shear stresses in the core, and increase stresses in the facings and the buckling load. Quantitative assessment of these and other factors can be easily carried out with the present theory.

ABSTRACT: A predictor–corrector method is presented for the efficient and reliable analysis of structural nonlinear behaviors. The key idea lies on modifying the starting point of iterations of the Newton iterative method. The conventional Newton method starts iterations at the previously converged solution point. However, in the present predictor–corrector method, a point close to the converged solution of the current step is predicted first, and then the Newton method starts iterative procedure at the predicted point. The predictor, the neural network in the present study, recognizes the pattern of the previously converged solutions to predict the starting point of the current step. Then the corrector, the standard Newton method in the present study, is used to obtain the converged solution by iterative computation starting at the predicted point. Numerical tests are conducted to demonstrate the effectiveness and reliability of the present predictor–corrector method. The performance of the present method is compared with the conventional Newton method and Riks' continuation method. The present predictor–corrector method saves computational cost significantly and yields stable results without diverging, for the nonlinear analysis with monotonous deformation path as well as complicated deformation path including buckling and post-buckling behaviors.

ABSTRACT: Laminated composite and sandwich panels are susceptible to mechanical damages in the transverse direction due to their relatively low strength in the transverse direction. For such damages to occur, laminated composite and sandwich panels usually experience geometrically nonlinear deformations. Therefore, analysis taking large deformations into account is required for predicting mechanical damages such as delamination. In the present study, a nonlinear predictor–corrector procedure is adopted for the accurate recovery of stresses in laminated composite and sandwich panels undergoing geometrically nonlinear deformations. It is a post-processing procedure based on the three-dimensional stress equilibrium equations, combined with an 18 node assumed strain solid finite element model based on the Hellinger–Reissner principle tailored for large rotation analysis of laminated composite and sandwich panels. The effectiveness of the proposed approach is demonstrated by means of numerical examples of laminated composite and sandwich panels subjected to mechanical loading and uniform temperature gradient in the thickness direction.

ABSTRACT: Local regions of bond failure between face sheet and core are often observed when sandwich structures are exposed to low energy impacts. Similarly, impact loads frequently result in delaminations within the face sheets. In the absence of any delaminations in the sandwich structure the buckling strain of the debonded region is in this work shown to be the key parameter in assessing the structural integrity of a sandwich component in compression. The objective of this study was to predict the buckling of the debonded region and to investigate the parameters controlling this instability. A large number of analyses of the delamination buckling problem, which in many ways may appear similar to the debond problem, have been carried out in the past. However, the debond-buckling problem has not been addressed before and as shown in this work there are significant differences. The Finite Element method was found able to predict all the experimentally observed phenomena accurately. These calculations were expensive, and a simple one-dimensional closed form solution is proposed for qualitative parametric investigations. Effects of material properties and initial imperfections were examined. Analyses of the buckling of a delamination suggest that the effect of the core can be ignored. In contrast, the results presented in this paper show that the core cannot be ignored in the case of buckling of a debond nor can it be simulated in terms of simple boundary conditions.

ABSTRACT: The use of composite sandwich construction is rapidly increasing in current and future airframe designs especially for general aviation aircraft and rotorcraft. Typically, sandwich constructions for these applications use thin-gage composite facesheets (0.020" to 0.045") which are cocured to honeycomb and foam cores. Due to the nature of these structures, damage tolerance is more complex than conventional laminated structures. Besides typical damage concerns such as through penetration and delamination, additional modes including core crushing and facesheet debonding must also be addressed. This complicates the certification process by introducing undefined Allowable Damage Limits (ADL) and Critical Damage Thresholds (CDT) as related to the ultimate and limit load carrying capability of the structure. This document provides a background review of previous damage tolerance investigations including an overview of traditional metallic damage tolerance methodologies. Illustrative summaries are presented which show the scope of previous investigation.
parameters such as impact energy, facesheet thickness, and core thickness of typical sandwich constructions. Also included is a compilation of damage tolerance certification procedures and regulations taken from FAR Part 23-29 for composite damage tolerance as well as recommendations from associated Advisory Circulars. Past and current airframe industry sandwich constructions which show the scope of current and future sandwich designs were also surveyed. In conclusion, a proposed future research approach and its methodology are presented which should aid in establishing certification guidelines and confidence involving the damage tolerance of sandwich constructions as they apply to general aviation aircraft and rotorcraft.

ABSTRACT: The use of sandwich structures with composite facesheets in commercial aviation is increasing. Such structures provide redundant load paths and high specific bending stiffness. Because of their structural efficiency, light-weight designs result in thin facesheets that are susceptible to impact damage. This study concentrated on the modeling aspects of damage tolerance of thin-gage composite sandwich structures. As such, it is a companion work to the FAA report "Review of Damage Tolerance for Composite Sandwich Airframe Structures," DOT/FAA/AR-99/49, August 1999, which contains a literature review and describes current technical challenges. Current analytical attempts to assess the damage tolerance of composite sandwich structures first characterize the damage state. Based on the type and extent of damage, models are constructed to determine the stress and strain distributions. A failure criterion is then implemented with the calculated stress and strain state. Often components of the damage are neglected to simplify the model of the sandwich structure. Two models to be developed are proposed. The first is a model to determine the extent of load transfer around a damaged area. Localized stiffness reductions will result in a shift in the neutral axis as well as load transfer in the damaged facesheet and to the undamaged facesheet. The amount of load transfer coupled with detailed models of facesheet stability and strength will provide a methodology to determine damage tolerance. The second model is of the specific damage resulting from low-speed impacts. This model will provide a methodology to predict the growth of such damage.

ABSTRACT: The first part of this paper is dedicated to the analytical and numerical characterization of local and global sandwich beam instabilities in a perfect linear framework. Analytical loads are extracted from an original unified model and used to understand in depth, through a parametric study, the role played by each geometrical and material parameter in the development of global as well as local instabilities. Also, the effects of the combinations of these characteristics is used to draw precious design indications. A low CPU time-consuming simplified model is then built and assessed. Critical loads and wavelengths computed from this model are shown to correlate very well with analytical predictions. It is established that this first approach is essential in order to lead to more detailed investigations in a numerical nonlinear framework which is the aim of the second part. The first geometrical nonlinear investigations in which linear elastic materials are considered permit to isolate sandwich configurations developing superior sub-critical post-buckling behaviours. As a
general trend, unstable behaviours are rather related to the occurrence of geometrical localizations along the beam. This is illustrated by the drastic effects of the so-called interactive buckling onto the whole stiffness of the sandwich beam. Moreover, it is shown that sandwiches are very sensitive towards imperfection sizes and forms. Eventually, an elastoplastic constitutive law is introduced for the core. It is demonstrated that plastic flow and strain localization in the core, combined with the occurrence of instabilities, are associated with a drastic drop in the global beam stiffness and with a strong decrease of the maximum limit load for some cases. The phenomenon of shear crimping is also observed which can be assimilated to a post-bifurcated development of the global buckling mode.

ABSTRACT: Stability analysis of laminated soft core sandwich beam has been studied by a C0 FE model developed by the authors based on higher order zigzag theory (HOZT). The in-plane displacement variation is considered to be cubic for the face sheets and the core, while transverse displacement is quadratic within the core and constant in the faces beyond the core. The proposed model satisfies the condition of stress continuity at the layer interfaces and the zero stress condition at the top and bottom of the beam for transverse shear. Numerical examples are presented to illustrate the accuracy of the present model.

ABSTRACT: Static analysis of skew composite shells is presented by developing a C_0 finite element (FE) model based on higher order shear deformation theory (HSDT). In this theory the transverse shear stresses are taken as zero at the shell top and bottom. A realistic parabolic variation of transverse shear strains through the shell thickness is assumed and the use of shear correction factor is avoided. Sander’s approximations are considered to include the effect of three curvature terms in the strain components of composite shells. The C_0 finite element formulation has been done quite efficiently to overcome the problem of C_1 continuity associated with the HSDT. The isoparametric FE used in the present model consists of nine nodes with seven nodal unknowns per node. Since there is no result available in the literature on the problem of skew composite shell based on HSDT, present results are validated with few results available on composite plates/shells. Many new results are presented on the static response of laminated composite skew shells considering different geometry, boundary conditions, ply orientation, loadings and skew angles. Shell forms considered in this study include spherical, conical, cylindrical and hyperbolic shells.

“Buckling of sandwich composites; Effects of core-skin debonding and core density”, Applied Composite Materials, Vol. 12, No. 2, March 2005

ABSTRACT: Foam–core sandwich composites have been fabricated using innovative co-injection resin infusion technique and tested under in-plane compression. The sandwich construction consisted of Klegcell foam as core materials and S2-glass/vinyl ester composites as face sheets. Tests were conducted with various foam densities and also with implanted delamination between the core and the face sheet. The intent was to investigate the effect of core density, and the effect of core–skin debonds on the overall buckling behavior of the sandwich. Analytical and finite element calculations were also performed to augment the experimental observations. It has been observed that core density has direct influence on the global buckling of the sandwich panel, while embedded delamination seem to have minimal effect on both global as well as local buckling. Detailed description of the experimental work, finite element modeling and analytical calculations are presented in this paper.

ABSTRACT: Thin solar sail membranes of very large span are being envisioned for near-term space missions. One major design issue that is inherent to these very flexible structures is the formation of wrinkling patterns. Structural wrinkles may deteriorate a solar sail’s performance and, in certain cases, structural integrity. A geometrically nonlinear, updated Lagrangian shell formulation is employed using the ABAQUS finite element code to simulate the formation of wrinkled deformations in thin-film membranes. The restrictive assumptions of true membranes as defined by tension field theory are not invoked. Two effective modeling strategies are introduced to facilitate convergent solutions of wrinkled equilibrium states. They include 1) the application of small, pseudorandom, out-of-plane geometric imperfections that ensure initiation of the requisite membrane-to-bending coupling in a geometrically nonlinear analysis and 2) the truncation of corner regions, where concentrated loads are prescribed, to improve load transfer, mesh quality, and kinematics and to reduce severe concentration of membrane stresses. The corner truncation necessitates replacing the concentrated force with a statically equivalent distributed traction. Several numerical studies are carried out, and the results are compared with recent experimental data. Good agreement is observed between the numerical simulations and experimental data.

“A multi-scale refined zigzag theory for multilayered composite and sandwich plates with improved transverse shear stresses”, V International Conference on Computational Methods for Coupled Problems in Science and Engineering (COUPLED PROBLEMS 2013), S. Idelsohn, M. Papadrakakis and B. chrefler (Editors)
ABSTRACT: The Refined Zigzag Theory (RZT) enables accurate predictions of the in-plane displacements, strains, and stresses. The transverse shear stresses obtained from constitutive equations are layer-wise constant. Although these transverse shear stresses are generally accurate in the average, layer-wise sense, they are
nevertheless discontinuous at layer interfaces, and thus they violate the requisite interlaminar continuity of transverse stresses. Recently, Tessler applied Reissner’s mixed variational theorem and RZT kinematic assumptions to derive an accurate and efficient shear-deformation theory for homogeneous, laminated composite, and sandwich beams, called RZT(m), where “m” stands for “mixed”. Herein, the RZT(m) for beams is extended to plate analysis, where two alternative assumptions for the transverse shear stresses field are examined: the first follows Tessler’s formulation, whereas the second is based on Murakami’s polynomial approach. Results for elasto-static simply supported and cantilever plates demonstrate that Tessler’s formulation results in a powerful and efficient structural theory that is well-suited for the analysis of multilayered composite and sandwich panels.

Tessler, A., Gherlone, M., Versino D. and Di Sciuva, M., “Analytic and computational perspectives of multi-scale theory for homogeneous, laminated composite and sandwich beams and plates”, NASA Technical Report, NASA/TP-2012-217573; L-20141; NF1676L-14627, 2012 (See also possibly AIAA/SDM Conference, 2012) ABSTRACT: This paper reviews the theoretical foundation and computational mechanics aspects of the recently developed shear-deformation theory, called the Refined Zigzag Theory (RZT). The theory is based on a multi-scale formalism in which an equivalent single-layer plate theory is refined with a robust set of zigzag local layer displacements that are free of the usual deficiencies found in common plate theories with zigzag kinematics. In the RZT, first-order shear-deformation plate theory is used as the equivalent single-layer plate theory, which represents the overall response characteristics. Local piecewise-linear zigzag displacements are used to provide corrections to these overall response characteristics that are associated with the plate
heterogeneity and the relative stiffnesses of the layers. The theory does not rely on shear correction factors and is equally accurate for homogeneous, laminated composite, and sandwich beams and plates. Regardless of the number of material layers, the theory maintains only seven kinematic unknowns that describe the membrane, bending, and transverse shear plate-deformation modes. Derived from the virtual work principle, RZT is well-suited for developing computationally efficient, C0-continuous finite elements; formulations of several RZT-based elements are highlighted. The theory and its finite elements provide a unified and reliable computational platform for the analysis and design of high-performance load-bearing aerospace structures.

ABSTRACT: This paper reviews multi-scale computational homogenisation frameworks for the non-linear behaviour of heterogeneous thin planar shells. Based on a review of some of the currently available methods, a computational homogenisation scheme for shells is applied on to representative volume elements for plain weave composites. The effect of flexural loading on the potential failure modes of such materials is analysed, focusing on the reinforcement-matrix delamination mechanism. The attention is next shifted toward failure localisation in masonry unit cells. Subsequently, a recently developed computational FE solution scheme accounting for damage localisation at structural scales based on RVE computations is applied.

ABSTRACT: This paper describes the results of an experimental investigation and a numerical simulation on the impact damage on a range of sandwich panels. The test panels are representative of the composite sandwich structure of the engine nacelle Fan Cowl Doors of a large commercial aircraft. The low-velocity impact response of the composites sandwich panels is studied at five energy levels, ranging from 5 to 20 J, with the intention of investigating damage initiation, damage propagation, and failure mechanisms. These impact energy levels are typically causing barely visible impact damage (BVID) in the impacted composite facesheet. A numerical simulation was performed using LS-DYNA3D transient dynamic finite element analysis code for calculating contact forces during impact along with a failure analysis for predicting the threshold of impact damage and initiation of delaminations. Good agreement was obtained between numerical and experimental results. In particular, the numerical simulation was able to predict the extent of impact damage and impact energy absorbed by the structure. The results of this study is proving that a correct numerical model can yield significant information for the designer to understand the mechanism involved in the low-velocity impact event, prior to conducting tests, and therefore to design a more efficient impact-resistant aircraft structure.

Shokrieh, M.M. and Askari, A. (Composites Research Laboratory, Center of Excellence in Experimental Solid Mechanics and Dynamics, School of Mechanical Engineering, Iran Univ. of Science and Technology, Narmak, Tehran, Iran), “Similitude Study of Impacted Composite Laminates under Buckling Loading.” ASCE J. Eng. Mech., 139(10), 1334–1340, 2013
ABSTRACT: In this study, critical buckling load of an impacted composite laminate is predicted, using the structural similitude method. Because of impact loading, damaged regions have formed in the laminate. To establish similarity conditions between impacted laminates for buckling loading, the idea of sequential similitude method is introduced. According to the sequential similitude method, similarity conditions can be established for a structure subjected to different loading situations, provided that each loading event is simulated independently. On the basis of this method, to develop similarity conditions for buckling loading of impacted composite laminates, similarity conditions are developed first for impact loading and then for buckling loading separately. Afterward, the obtained conditions are implemented in the commercial finite-element software, ABAQUS, to obtain the critical buckling load. Results show that sequential similitude method can be used as a simple and accurate method for prediction of buckling load of impacted laminates.

ABSTRACT: The bending behavior of a general sandwich beam, delaminated (debonded) at one of the skin-core interfaces, with transversely flexible core, based on variational principles is analytically investigated. The beam construction consists of upper and lower, metallic or composite laminated symmetric skins, and a soft core of a foam or low-strength honeycomb type. The delamination considered is a crack (debond) in which the crack faces may be in contact vertically, but can slip horizontally with respect to one another. The elastic analysis consists of a two-dimensional formulation for the core, in longitudinal and transverse directions, combined with a beam theory formulation for the skins. The effects of the vertical flexibility of the core, in the undelaminated and the delaminated regions, with and without contact, on the behavior are considered. The use of a high-order theory yields a non-linear displacement field in the core, in the undelaminated region, and determines the shear and the peeling (normal) stresses at the skin-core interfaces in the delaminated and the fully bonded regions, as well as at the crack tips. Any type of loading, distributed, localized or concentrated, located either at the upper or the lower skin, or at both, as well as any type of boundary and continuity conditions differing from one skin to the other and to the core at the same section, are allowed. The effect of the delamination length and location on the overall behavior and on the peeling stresses at the skin-core interfaces, are studied.

ABSTRACT: For the determination of debonded sandwich panel residual strength with lateral loading a parametric finite element model is developed. The parametric model allows an arbitrary positioning of the debond within the panel and consists of both solid and shell elements. A fracture mechanical approach using the crack flank displacements obtained from the FEA solution combined with measured mixed-mode fracture toughness values are used to determine the ultimate failure load. Experiments were conducted to compare against the analysis results. The comparison of numerical and experimentally achieved results showed that the used modeling approach predicts the failure load and failure mode well.

ABSTRACT: This thesis highlights research aimed at predicting the compressive failure of sandwich beams with interfacial delaminations. A nonlinear finite element analysis was performed to simulate axial compression of the debonded sandwich beams. The load-deflection diagrams were generated for a variety of specimens used in a previous experimental study. The energy release rate at the crack tip was computed using the J-integral, and plotted as a function of the displacement and load. A detailed stress analysis was performed and the critical stresses in the face sheet and the core were computed. Further, the core was modeled as a elastic, perfectly plastic material and a nonlinear post-buckling analysis was performed. For this model, load-deflection curves, energy release rate plots and von Mises stress plots were generated. By comparing the experimental failure load and the finite element analysis results, the conclusions were reached and the scope of future research in this project was defined.

ABSTRACT: A nonlinear finite element analysis was performed to simulate axial compression of sandwich beams with debonded face sheets. The load-end-shortening diagrams were generated for a variety of specimens used in a previous experimental study. The energy release rate at the crack tip was computed using the J-integral, and plotted as a function of the load. A detailed stress analysis was performed and the critical stresses in the face sheet and the core were computed. The core was also modeled as an isotropic elastic-perfectly plastic material and a nonlinear post buckling analysis was performed. A Graeco-Latin factorial plan was used to study the effects of debond length, face sheet and core thicknesses, and core density on the load-carrying capacity of the sandwich composite. It has been found that a linear buckling analysis is inadequate in determining the maximum load a debonded sandwich beam can carry. A nonlinear post-buckling analysis combined with an elasto-plastic model of the core is required to predict the compression behavior of debonded sandwich beams.

**ABSTRACT:**

Based upon the interfacial spring-layer model, a state-space approach for the energy release rate analysis of stiffened laminates with a planar delamination was presented. The main advantages of the present method are that the same mesh is used for each layer, and only the so-called state variables at the top and bottom surfaces of structure in the final control equation of structures are involved. On the other hand, the oscillatory singular stresses around the delamination front are avoided as a result. Instead, stress resultant jumps are found in the sublaminate across the delamination front. Moreover, the technique accounts for the compatibility of displacements and stresses between layers and the transverse shear deformation in the control equation of structure. To avoid the possibility of material penetration phenomenon of the delaminated region, the unilateral frictionless contact interface is adopted in the interfacial spring layer between sublaminates. With the aid of the virtual crack closure technique, the accuracy of the method was assessed by comparing the results with existing examples. The effects of stiffeners were analyzed by the present method.

Song-Jeng Huang (Department of Mechanical Engineering, National Chung Cheng University, 160 San-Hsing, Ming-Hsiung Chia-Yi, 621, Taiwan, ROC), “An analytical method for calculating the stress and strain in adhesive layers in sandwich beams”, Composite Structures, Vol. 60, No. 1, April 2003, pp. 105-114, doi:10.1016/S0263-8223(02)00288-X

**ABSTRACT:** Various studies on stress–strain modeling of adhesively bonded sandwich beams are briefly described in this paper. An analytical model of sandwich beams taking into account contribution of adhesive layers towards the overall beam stiffness is then proposed. In this model the displacements of each of the five constituent layers of a sandwich beam are computed considering the overall continuity conditions of the sandwich beam. The Euler–Ostrogradskii equations are used to derive the equations of equilibrium, which contain four differential equations with 12 orders. For validation purpose, a case study of a simply supported three-point bending sandwich beam subjected to a load at the mid-span of the beam is carried out using the proposed analytical method, finite element method and a theory proposed by Allen [Analysis and Design of Structural Sandwich Panels, Oxford, UK, 1969]. From the comparison of results obtained from the three methods, there are reasons to suggest improvements in reliability and accuracy of the proposed analytical method, which takes the effect of the adhesive layers into account, over Allen’s theory. The proposed method has clearly shown that the contribution of the adhesive layers to the overall strength of a given sandwich beam cannot be neglected.

**ABSTRACT:** The practical value of the geometrically nonlinear higher-order theory is demonstrated using four-point bend tests carried out on sandwich beam specimens comprised of aluminum face sheets and a PVC foam core. The experimental results were compared with the predictions of classical sandwich theory, and with linear and geometrically nonlinear higher-order sandwich panel theory. The analytical predictions based on the higher-order theory are in excellent agreement with the experimental results. Response parameters show fundamentally distinct behavior with increasing external load, both in the particular section and along the span.
Considering the longitudinal displacements, there is a significant geometrically nonlinear stage of the response that precedes the appearance of the material nonlinearity. The peeling stresses also exhibit significant geometrical nonlinearity in the vicinity of the internal supports. The linear higher-order theory can be used efficiently to estimate the vertical displacements of the soft-core sandwich beams up to high load levels with a great accuracy. Premature failure of sandwich beam specimens with weak adhesive layers is caused by high peeling stresses in the upper interface layer at the ends of the specimen, and the loading capacity decreases by more than 40%.

ABSTRACT: Failure modes for sandwich beams of GFRP laminate skins and Nomex honeycomb core are investigated. Theoretical models using honeycomb mechanics and classical beam theory are described. A failure mode map for loading under 3-point bending is constructed, showing the dependence of failure mode and load on the ratio of skin thickness to span length and honeycomb relative density. Beam specimens are tested in 3-point bending. The experimental data agree satisfactorily with the theoretical predictions. The effect of honeycomb direction is also examined. The concept of a failure mode map is extended to give a useful design tool for sandwich panels manufacturers and their customers.

ABSTRACT: Sandwich construction incorporating a honeycomb cellular core offers the attainment of structures that are very stiff and strong in bending while the weight is kept at a minimum. Generally, an aluminum or Nomex honeycomb core is used in applications requiring sandwich construction with fiber-reinforced composite facesheets. However, the use of a fiber-reinforced composite core offers the potential for even lower weight, increased stiffness and strength, low thermal distortion compatible with that of the facesheets, the absence of galvanic corrosion and the ability to readily modify the core properties to suit specialized needs. Furthermore, the material of the core itself will exhibit anisotropic material properties in this case. In order to design, analyze and optimize these structures, knowledge of the effective mechanical properties of the core is essential. In this paper, the effective three-dimensional mechanical properties of a composite hexagonal cell core are determined using a numerical method based on a finite element analysis of a representative unit cell. In particular, the geometry of the simplest repeating unit of the core as well as the appropriate loading and boundary conditions that must be applied is presented.

ABSTRACT: Sandwich panels can fail in several ways. The faces and core can yield plastically or fracture depending on the nature of the materials from which they are made; the compressive face can buckle locally or “wrinkle”, and the bond between the faces and core can fracture, causing delamination. The critical failure mode, which occurs at the lowest load, depends in part on the properties of the face and core materials and, in part, on the design of the beam. Here, we develop equations describing the load at which failure occurs for each
possible failure mode for a sandwich beam with face and core materials that yield plastically. We then develop a failure mode map, with axes of core relative density and the ratio of face thickness to span length, which, for a given loading configuration and set of face and unfoamed solid core materials, shows the dominant failure mode for every possible beam design. Tests on sandwich beams with aluminum faces and rigid polyurethane foam cores show that the equations and map describe failure well. The map can then be used to design the minimum-weight sandwich beam for a given strength. Similar failure mode maps can be developed for sandwich beams made from face and core materials that fracture and for sandwich plates.

ABSTRACT: In a sandwich beam made of materials that yield plastically, the main modes of failure are yielding and wrinkling of the face and yielding of the core in shear. The minimum weight design of beam is such that the face and core fail simultaneously; otherwise, one component is overdesigned. In this paper, we find the minimum weight design of a foam core sandwich beam or plate of a given strength by constraining the face and core to fail simultaneously using the failure equations developed in the companion paper. We also make use of property-density relationships for foam cores to include the density of the core as one of the beam design parameters to be found in the optimization analysis. The results give the face and core thicknesses and the core density which minimize the weight of a foam core sandwich beam or plate of a given strength.

ABSTRACT: Sandwich beams with metallic foam cores can fail by several modes: face yielding, face wrinkling, core yielding and indentation. We estimate the initial failure load, corresponding to the first deviation from linearity in the load–deflection curve as well as the peak load for each mode. Failure mode maps are constructed which illustrate the dominant failure mode for practical beam designs. The results of the analysis are compared with experiments on sandwich beams with aluminum foam cores in three-point bending. The peak loads and the failure modes are described well by the analysis.

ABSTRACT: Foams exhibit size effects: if the specimen dimensions are of the same order as the cell size, the moduli and strength depend on specimen size. Metallic foams have particularly large cells (typically 2–20 mm), potentially giving rise to size effects when they are used in sandwich beams. Previous studies have shown that
the shear strength of metallic foams bonded to rigid plates increases by over 50% if the specimen thickness is equal to the cell size. In this study, sandwich beams with aluminum alloy faces and aluminum alloy foam cores were tested in three-point bending to characterize the effect of the beam depth on the limit load. Beams of constant ratio of core thickness to span length but different absolute values of core thickness were tested, and the measured limit loads were compared to analytical values. The analysis gives a good description of the measured limit load when the shear size effect is accounted for.

ABSTRACT: Plastic collapse modes of sandwich beams have been investigated experimentally and theoretically for the case of an aluminium alloy foam with cold-worked aluminium face sheets. Plastic collapse is by three competing mechanisms: face yield, indentation and core shear, with the active mechanism depending upon the choice of geometry and material properties. The collapse loads, as predicted by simple upper bound solutions for a rigid, ideally plastic beam, and by more refined finite element calculations are generally in good agreement with the measured strengths. However, a thickness effect of the foam core on the collapse strength is observed for collapse by core shear: the shear strength of the core increases with diminishing core thickness in relation to the cell size. Limit load solutions are used to construct collapse maps, with the beam geometrical parameters as axes. Upon displaying the collapse load for each collapse mechanism, the regimes of dominance of each mechanism and the associate mass of the beam are determined. The map is then used in optimal design by minimising the beam weight for a given structural load index.

ABSTRACT: Sandwich panels and beams are used in bending and compression dominated components. The retention of their load capacity in the presence of imperfections is a central consideration. To address this issue, sandwich beams with metallic foam cores have been tested in four-point bending following the introduction of imperfections, created by impressing the face sheets. Limit load expressions for face yielding, core shear, and indentation failure have been developed and used to construct failure mechanism maps. From these maps, specimen designs were determined. Imperfections were introduced by indenting to varying penetrations. The indents were located on both the compressive and tensile side of bending configurations. Experimental measurements of the load/deflection response are obtained and compared with finite element results.

Craig A. Steeves and Norman A. Fleck (Cambridge University Engineering Department, Trumpington Street, Cambridge, CB2 1PZ, UK), “Collapse mechanisms of sandwich beams with composite faces and a foam core, loaded in three-point bending. Part I: analytical models and minimum weight design”, International Journal of
ABSTRACT: Analytical predictions are made for the three-point bending collapse strength of sandwich beams with composite faces and polymer foam cores. Failure is by the competing modes of face sheet microbuckling, plastic shear of the core, and face sheet indentation beneath the loading rollers. Particular attention is paid to the development of an indentation model for elastic faces and an elastic–plastic core. Failure mechanism maps have been constructed to reveal the operative collapse mode as a function of geometry of sandwich beam, and minimum weight designs have been obtained as a function of an appropriate structural load index. It is shown that the optimal designs for composite–polymer foam sandwich beams are of comparable weight to sandwich beams with metallic faces and a metallic foam core.

ABSTRACT: This study focuses on the competing collapse mechanisms for simply supported sandwich beams with composite faces and a PVC foam core subjected to three point bending. The faces comprise Hexcel Fibredux 7781-914G woven glass fibre-epoxy prepreg, while the core comprises closed cell Divinycell PVC foam of relative density 6.6% and 13.3%. The mechanical properties of the face sheets and core are measured independently. Depending upon the geometry of the beam and the relative properties of the constituents, collapse is by core shear, face sheet microbuckling or by indentation beneath the middle loading roller. A systematic series of experiments and finite element simulations have been performed in order to assess the accuracy of simple analytic expressions for the strength. In general, the analytic expressions for peak load are adequate; however, simple beam theory becomes inappropriate and the analytic models are inaccurate for stubby beams with thick faces relative to the core thickness. A failure mechanism map is constructed to reveal the dependence of the dominant collapse mechanism upon the geometry of the beam.

ABSTRACT: Closed-form high-order theory of sandwich panels, including transverse flexibility and shear rigidity of a core, as well as geometrical nonlinearity of unsymmetric faces is generalized for sandwich panels of constant curvature. Variational calculus is used to derive the set of governing equations describing a stress-deformation response of the panel to arbitrary loads. Boundary conditions are presented both in the local and global formulations. The procedure for the numerical solution of the governing nonlinear differential equations is based on the finite-difference method with deferred corrections. The solution technique is illustrated through numerical examples. Influence of the geometrical nonlinearity on the overall behaviour of the sandwich panel and localized effects are demonstrated.

ABSTRACT: A model for the load-deformation response of a shallow singly-curved sandwich panel is developed on the basis of Reissner plate theory. For arbitrary initial panel geometry and lateral load distribution, the load-deflection relations are derived in the form of two implicit equations. Explicit equations describing the deformation behaviour of symmetric sandwich panels subjected to symmetric loading are also presented. A stability analysis is performed for a simply-supported sandwich panel of constant curvature and loaded by uniform pressure. Structural and buckling parameters which depend on the panel geometry and material properties are introduced. These parameters allow the buckling behaviour of shallow sandwich panels to be predicted. The ideas behind the analysis and the solution technique are illustrated through numerical examples.

ABSTRACT: Overall behaviour of a simply-supported singly-curved shallow sandwich panel under lateral loading is considered. Three types of linear models — general shell, shallow shell and curved plate theories — are employed to describe a static overall behaviour of such a panel. The shallow panel with a constant curvature loaded by a uniform pressure is used as a trial case to assess the accuracy of the models. A nonlinear model for a panel of arbitrary shape under an arbitrary loading is developed on the basis of the curved plate theory. A closed-form nonlinear analytic solution for the panel of constant curvature under a uniform lateral pressure is obtained, and its accuracy is estimated. An experimental investigation of a sandwich beam under a uniform lateral loading is carried out, and the data obtained are compared with the theoretical calculations.

ABSTRACT: The overall behaviour of the shallow sandwich panel with an arbitrary initial profile and general boundary conditions under an arbitrary load is discussed. The structural parameters of the panel that allow one to generalize description of the overall behaviour of the panel are introduced. The mathematical model based on the Reissner–Mindlin plate theory is developed, and the set of governing equations is derived. The implicit nonlinear and explicit linear solutions are obtained for the uniformly loaded panel with uniform curvature and similar boundary restraints. An analysis of the global stability is performed for panels that have general configurations. Three stability modes, namely stable deformation, symmetric and asymmetric snap-throughs are found possible. The influence of the structural parameters of the panel on its global behaviour is studied.

ABSTRACT: The shallow singly curved and rectangular in-plane sandwich panels affected by lateral loads are considered. The set of governing equations on the basis of the Timoshenko–Reissner plate theory is derived for these panels in the case of general boundary conditions. Usage of any real boundary condition is ensured via an introduction of the Airy's function and two potentials including a potential of the vortex-type. The technique of the numerical solution is based on a combination of the solutions by Navier and Levy. Numerical analysis is carried out for the panel that is simply supported along all four edges and for the panel that is simply supported along its curved boundaries and has hinge-like supports along the straight boundaries.

ABSTRACT: This paper addresses the effect of local indentation/impact damage on the bearing capacity of foam core sandwich beams subjected to edgewise compression. The considered damage is in a form of through-width zone of crushed core accompanied by a residual dent in the face sheet. It is shown that such damage causes a significant reduction of compressive strength and stiffness of sandwich beams. Analytical solutions estimating the Euler’s local buckling load are obtained for two typical modes of damage. These solutions are validated through experimental investigation of three sandwich configurations. The results of the analytical analysis are in agreement with the experimental data.

Antonio F. Ávila (Universidade Federal de Minas Gerais, Department of Mechanical Engineering, Mechanics of Composite and Nano-Structured Materials Laboratory, Belo Horizonte, Minas Gerais 31270-901, Brazil),

ABSTRACT: A failure mode criterion for piece-wise functionally graded sandwich composites is proposed and compared against experimental data. The average peak load for low and high density core configurations at upper region is 138% and 192% higher than the reference group. The proposed failure mode model predicts with accuracy the failure mechanisms. The best performance was obtained by the beam configuration where the core layer with highest density is located right below the upper face-sheet. This case not only leads to the highest value of normal wrinkling stress but it also prevents the core plastic collapse occurrence. However, the core failure by yielding will occur regardless of the core layer stacking sequence.

ABSTRACT: The paper aims at evaluating the damage resistance of sandwich structure, composed of Nomex® honeycomb core (thickness: 10 mm and 20 mm) and two kinds of facesheets (carbon/epoxy and glass/epoxy laminates) subjected to low velocity impact. The impact tests are performed using the instrumented impact-testing machine and resulting impact damages are inspected by scanning acoustic microscope (SAM). Based on the force and energy histories, six parameters have been introduced as following: load at incipient damage, energy absorbed at incipient load, maximum load, total energy absorbed during impact, plastic energy absorbed by damage, and impact damage area. The impact resistance of the sandwich structure is greatly influenced by the facesheet type and core thickness. And their impact damages are mainly delamination in the facesheets, which is peanut-shaped with major axis along their lower fiber orientation, and their behavior is dependent on the facesheets.

ABSTRACT: In the present paper, the dynamic stability of thin, isotropic cylindrical shells under combined static and periodic axial forces is studied using four common thin shell theories; namely, the Donnell, Love, Sanders and Flugge shell theories. For these four cases, the contribution of the stresses due to the external axial forces are accounted for according to the Donnell theory. In the present analysis, a normal-mode expansion of the equations of motion yields a system of Mathieu–Hill equations, the stability of which is examined. The parametric resonance responses are analyzed based on Bolotin’s method and the effects of the length-to-radius and thickness-to-radius ratios of the cylinder on the instability regions are examined and compared using the four theories. The effects of variation in the magnitude of the axial forces were also examined.

T.Y. Ng and K.Y. Lam (Centre for Computational Mechanics, Department of Mechanical & Production Engineering, National University of Singapore), “Effects of boundary conditions on the parametric resonance of cylindrical shells under axial loading”, Shock and Vibration, Vol. 5, pp 343-354, 1998

ABSTRACT: In this paper, a formulation for the dynamic stability analysis of circular cylindrical shells under axial compression with various boundary conditions is presented. The present study uses Love’s first approximation theory for thin shells and the characteristic beam functions as approximate axial modal functions. Applying the Ritz procedure to the Lagrangian energy expression yields a system of Mathieu–Hill equations the stability of which is analyzed using Bolotin’s method. The present study examines the effects of different boundary conditions on the parametric response of homogeneous isotropic cylindrical shells for various transverse modes and length parameters.

ABSTRACT: This article deals with the transient response of a stiffened composite plate subjected to low velocity impact. An approximate solution for the prediction of plate response to low velocity impact is presented. This solution includes the combined action of the plate and stiffeners as well as the effects of the contact and transverse shear deformation. A finite element (FE) approach is also proposed. In the FE approach, an impact force function based on Hertz contact law is linked into a commercial FE code, which facilitates the study of a more realistic model. Results predicted by the present solution for a simplified stiffened plate are compared with those by the FE approach for a realistic stiffened plate. Effects of the stiffener spacing and thickness, anisotropic material properties, impact mass and contact stiffness on the impact response are also examined.

“Failure analysis of low velocity impact on thin composite laminates: Experimental and numerical approaches”,
ABSTRACT: The dynamic behavior of composite laminates is very complex because there are many concurrent phenomena during composite laminate failure under impact load. Fiber breakage, delaminations, matrix cracking, plastic deformations due to contact and large displacements are some effects which should be considered when a structure made from composite material is impacted by a foreign object. Thus, an investigation of the low velocity impact on laminated composite thin disks of epoxy resin reinforced by carbon fiber is presented. The influence of stacking sequence and energy impact was investigated using load–time histories, displacement–time histories and energy–time histories as well as images from NDE. Indentation tests results were compared to dynamic results, verifying the inertia effects when thin composite laminate was impacted by foreign object with low velocity. Finite element analysis (FEA) was developed, using Hill’s model and material models implemented by UMAT (User Material Subroutine) into software ABAQUS, in order to simulate the failure mechanisms under indentation tests.

Hao Wu and Ying Yan (School of Aeronautic Science and Engineering, Beihang University, Beijing, 100083, China), “A Parametric Study for the Design of Stiffened Composite Panel”, COCOMAT (publisher, date, not given in the pdf file, most recent reference is 2008)

ABSTRACT: A parametric study is conducted for the design of stiffened composite panel (SCP). A SCP with two stiffeners, loaded under uniaxial compression load is studied, where effects of stiffener thickness and distance on the critical buckling behaviour of the SCP are investigated. It is illustrated that stiffener has an effect of boundary condition on the skin, and an optimal structural efficiency exists when this effect is significant enough. The boundary condition effect makes the whole SCP buckles as local skin buckling and its critical buckling behaviour is dominated by the local skin buckling with the lowest critical buckling load. The parametric study provides designer with comprehension of the stiffener/skin enhancement in the buckling behaviour of the SCP, serving for the design of SCP in the future.

ABSTRACT: Composite materials are finding increasing use on primary aerostructures to meet demanding performance targets while reducing environmental impact. This paper presents a finite-element-based preliminary optimization methodology for postbuckling stiffened panels, which takes into account damage mechanisms that lead to delamination and subsequent failure by stiffener debonding. A global-local modeling approach is adopted in which the boundary conditions on the local model are extracted directly from the global model. The optimization procedure is based on a genetic algorithm that maximizes damage resistance within the postbuckling regime. For a given loading condition, the procedure optimized the stacking sequence of several areas of the panel, leading to an evolved panel that displayed superior damage resistance in comparison with nonoptimized designs.

ABSTRACT: This work aims at developing a genetic algorithm (GA) to pursue the optimization of hybrid laminated composite structures. Fiber orientation (predefined ply angles), material (glass-epoxy or carbon-epoxy layer) and total number of plies are considered as design variables. The GA is chosen as an optimization tool because of its ability to deal with non-convex, multimodal and discrete optimization problems, of which the design of laminated composites is an example. First, the developed algorithm is detailed explained and validated by comparing its results to other obtained from the literature. The results of this study show that the developed algorithm converges faster. Then, the maximum stress, Tsai-Wu and Puck (PFC) failure criteria are used as constraint in the optimization process and the results yielded by them are compared and discussed. It was found that each failure criterion yielded a different optimal design.

ABSTRACT: The paper focuses on modelling uncertainty typical of the aircraft industry. The design problem involves maximizing a safety measure of an isotropic plate for a given weight. Additionally, the dependence of the weight on the level of uncertainty, for a specified allowable possibility of failure, is also studied. It is assumed that the plate will be built from future materials, with little information available on the uncertainty. Fuzzy set theory is used to model the uncertainty. Response surface approximations that are accurate over the entire design space are used throughout the design process, mainly to reduce the computational cost associated with designing for uncertainty. All of the problem parameters are assumed to be uncertain, and both a yield stress and a buckling load constraint are considered. The fuzzy set based design is compared to a traditional deterministic design that uses a factor of safety to account for the uncertainty. It is shown that, for the example problem considered, the fuzzy set based design is superior. Additionally, the use of response surface approximations results in substantial reductions in computational cost, allowing the final results to be presented in the form of design charts.

ABSTRACT: An integrated step-by-step analysis procedure for the design of axially compressed stiffened composite panels is outlined. The analysis makes use of the effective width concept. A computer code, BUSTCOP, is developed incorporating various aspects of buckling such as skin buckling, stiffener crippling and column buckling. Other salient features of the computer code include capabilities for generation of data based on micromechanics theories and hygrothermal analysis, and for prediction of strength failure. Parametric studies carried out on a hat-stiffened structural element indicate that, for all practical purposes, composite panels exhibit higher structural efficiency. Some hybrid laminates with outer layers made of aluminium alloy also show great promise for flight vehicle structural applications.

ABSTRACT: A generalized formulation for the doubly curved laminated composite shell is attempted using eight-noded curved quadratic isoparametric finite elements with all three radii of curvature. The formulation is also applied to the isotropic material as a special case. In the present investigation, only the paraboloid of revolution is taken up for computing the deflections and stress resultants. Various parametric studies are carried out and the current results for both isotropic and laminated composite shells are compared with those available in the published literature. The shape functions are obtained from interpolation polynomial and the element stiffness matrices are formed on the basis of macromechanical analysis of laminates using the principle of minimum potential energy.

ABSTRACT: Blade-stiffened composite plates have been analysed for transverse loads using the finite element method. An eight-noded isoparametric quadratic stiffened plate bending element has been employed for the analysis. The element can incorporate transverse shear deformation. First order shear deformation has been considered in the formulation; the stiffener can be placed anywhere within the plate element and need not necessarily follow nodal lines. Therefore, mesh divisions are independent of the stiffener location within the plate. The stiffness matrix of the stiffener element can be appropriately modified to include stiffness properties for all types of open-section stiffeners. The deflections and bending moments have been presented for simply supported square laminated plates with one central stiffener and for stiffened skew plates. The results are compared with those obtained by modeling the stiffened plate by an assemblage of eight-noded isoparametric flat shell elements. The effect of the number of layers of the plate and the stiffener on the flexural response of the stiffened plate is presented. The element is used to show the flexural response of different open-section stiffened plates having the same area of the stiffener cross section. Also, the effect of depth-to-thickness ratio of the stiffener having the same cross section and lamination has been presented.

ABSTRACT: This is a review covering the static and dynamic analysis of stiffened shells which have found widespread applications in a variety of engineering structures. The coverage aims at the analysis including (1) static, (2) free vibration, (3) transient dynamic response and (4) response under stochastic excitation. 214 references (cannot cut and paste them)

Kaustav Bakshi and Dipankar Chakravorty (Civil Engineering Department, Jadavpur University Kolkata-700 032, West Bengal, India), “First ply failure study of thin composite conoidal shells subjected to uniformly distributed load”, Thin-Walled Structures, 03/2014; 76:1–7. DOI: 10.1016/j.tws.2013.10.021

ABSTRACT: The civil engineers often need to cover large column free open spaces with thin shell structures. The doubly curved shells are characteristically stiff and the ruled surfaces are easy to fabricate. The aesthetically pleasing conoidal shells satisfy both these criteria and are preferred by structural engineers. The engineers now look out for strong but lightweight materials and as a result the laminated composites have
evolved. The first ply failure is a very important issue for laminated composites. Such studies for plates are reported but similar work on thin shells is very scanty. This paper is aimed to fulfill this lacuna.

“Geometrically Linear and Nonlinear First-Ply Failure Loads of Composite Cylindrical Shells”,
doi: http://dx.doi.org/10.1061/(ASCE)EM.1943-7889.0000808
ABSTRACT: Review of the literature on first-ply failure of composite shells shows that research reports on first-ply failure of moderately thin, laminated composite cylindrical shell panels, using a geometrically nonlinear approach, are not available. The present paper aims to fill this deficiency. It uses a finite-element code developed using eight-noded, doubly-curved elements combined with modified Sanders’ first-approximation theory for thin shells and von Kármán-type nonlinear strains. The accuracy of the present geometric nonlinear and first-ply failure formulations are verified separately through solutions of two benchmark problems. Failure loads, failure modes (for individual stress or strain failure) or tendencies (for interactive stress failures), and the locations from where the failures initiate are reported. The results are discussed critically to formulate design guidelines, suggesting practical values for factors of safety applicable to failure loads. Such suggestions also consider the serviceability requirements.

ABSTRACT: A finite element analysis for studying the free vibration behaviour of generalized doubly curved laminated composite shells is presented using eight-noded curved quadrilateral isoparametric finite elements. The formulation assumes first-order shear deformation theory for thin and shallow shells, and also considers the two principal radii of curvature and the radius of cross-curvature. Some of the results obtained are compared with those present in the existing literature. Several other numerical results are presented by varying fibre orientations, lamination schemes, support spacings, aspect ratio, lower height to higher height ratio (for conoids), the thickness to radius ratio and radii of curvature ratio (for elliptic and hyperbolic paraboloids), which are relevant to the doubly curved shells.

ABSTRACT: Composite stiffened plates have been analysed for large deflection using the finite element
method. An eight noded isoparametric laminated stiffened plate bending element developed earlier has been used. The element has the capability of including transverse shear deformation for the plate and the stiffener and incorporating one or more stiffeners anywhere within the element. The finite element analysis has been made using Mindlin's formulation and with the assumption of small rotation. The nonlinear equilibrium equations are solved by the Newton-Raphson iteration procedure. Plates and stiffened plates of isotropic and anisotropic material with different boundary conditions have been analysed and results have been compared with those available. Parametric studies have also been carried out.

ABSTRACT: Free vibration analysis of composite stiffened shell panels has been carried out for the first time. As there is no published literature available on the problem, the finite element technique has been applied using two elements, namely the nine-noded Lagrangian element and the heterosis element, for obtaining new results. An improved version of the stiffener modelling is presented here. In this modelling, stiffeners can be placed anywhere inside the element and it need not pass through the nodal lines. Moreover, both elements have the capacity of accommodating curved boundaries and incorporating transverse shear deformation. Results for stiffened composite cylindrical shells and doubly curved shells with different boundary conditions and various laminae orientations have been presented for both concentric and eccentric stiffeners. Parametric studies considering different variables have also been carried out.

ABSTRACT: This analytical study is concerned with the free vibration, forced vibration, low velocity impact response as well as impact induced first ply failure of delaminated composite shells. It is based on a simple multiple delamination modeling which can take care of any arbitrary number and size of delaminations placed at any location of the laminate. Sander's shallow shell theory is applied for the shell analysis. First order shear deformation theory in conjunction with an eight noded isoparametric quadratic delaminated shell element with five degrees of freedom per node are used to develop the finite element formulation. Newmark's time integration algorithm is employed for solving the time dependent multiple equations of the plate and the impactor. Tsai-Wu failure criterion is used to predict the first ply failure of a laminate due to impact at every time step. Numerical results are generated for different cases by varying the size and location of delaminations as well as the stacking sequences. It is observed that the delaminations reduce the natural frequencies and increase the dynamic displacements. Critical impactor velocity to cause the first ply failure in a laminate is also reduced in the presence of a delamination.

N.V.S. Naidu and P.K. Sinha (Department of Aerospace Engineering, Indian Institute of Technology, Kharagpur 721302, India), “Nonlinear finite element analysis of laminated composite shells in hygrothermal
ABSTRACT: The large deflection bending behaviour of composite cylindrical shell panels subjected to hygrothermal environments is investigated in this paper. The present finite element formulation considers doubly curved thick shells and includes large deformations with Green–Lagrange strains. The analysis is carried out using quadratic eight-noded isoparametric element and the problem is solved using the incremental modified Newton–Raphson scheme. A parametric study is carried out varying the curvature ratios of composite cylindrical shell panels with simply supported and clamped support conditions.

ABSTRACT: The nonlinear free vibration behaviour of laminated composite shells subjected to hygrothermal environments is investigated using the finite element method. The present finite element formulation considers doubly curved shells, and the Green–Lagrange type nonlinear strains are incorporated into the first-order shear deformation theory. The analysis is carried out using quadratic eight-noded isoparametric elements. The validity of the model is demonstrated by comparing the present results with the solutions available in the literature. A parametric study is carried out varying the curvature ratios and side to thickness ratios of composite cylindrical shell, spherical shell and hyperbolic paraboloid shell panels with simply supported boundary conditions.

Manoj Kumar Kath, “Dynamic instability of laminated composite curved panels in hygrothermal environment”, Ph.D. dissertation, Dept. of Civil Engineering, National Institute of Technology, Rourkela, India

ABSTRACT: Composite materials are increasingly used in aerospace, naval and high performance civil engineering structures such as aerospace, submarines, automobiles. The structural components, subjected to in-plane harmonic loads may undergo parametric resonance or dynamic stability due to certain combinations of the applied in-plane forcing parameters and natural frequency of transverse vibration. The parametric instability itself requires investigation of vibration and buckling of structures. The present study deals with free vibration, buckling and parametric resonance behavior of laminated composite plates under in-plane periodic loading under varying temperature and moisture. In this analysis, the effects of various parameters such as number of layers, aspect ratios, side-to-thickness ratios, ply orientations, static load factors, lamination angle and the degree of orthotropic are studied. A simple laminated plate model based on the first order shear deformation theory (FSDT) is developed for the free vibration, buckling and parametric instability effects of composite plates subjected to hygrothermal loading. The principal instability regions are obtained using Bolotin’s approach employing finite element method (FEM). An eight-node isoparametric quadratic element is employed in the present analysis with five degree of freedom per node. The element is modified to accommodate the laminated composite plates under hygrothermal environment, considering the effects of transverse shear deformation and rotary inertia. The element stiffness matrix, geometric stiffness matrix due to residual stresses, element mass matrix, geometric stiffness matrix due to applied in-plane loads and nodal load vector of the element are derived using the principle of minimum potential energy. They are evaluated using the Gauss quadrature numerical integration technique. Reduced integration technique is applied to avoid the possible shear locking. A computer program based on FEM in MATLAB environment is developed to perform all necessary computations. The basic vibration and buckling experiments are performed on the industry driven woven fiber Glass/Epoxy specimens subjected to hygrothermal environment. The specimens were hygrothermally conditioned in a humidity cabinet where the conditions were maintained at temperatures of 300K–425K and relative humidity (RH) ranging from 0-1.0% for moisture concentrations. The numerical and experimental results show that there is reduction in natural frequencies and buckling loads with increasing temperature and moisture concentration for laminates both for simply supported and clamped boundary conditions. The dynamic instability study using FEM revealed that, due to the static component of load, the instability regions tend to shift to lower frequencies. The onset of instability occurs earlier and the width of dynamic instability regions increases with rise in temperature and moisture concentration for different parameters. With increase in lamination angle, the width of the instability region becomes smaller. The onset of instability occurs later for square plates than rectangular plates with wider instability region with increase of aspect ratio. The ply orientation significantly affects the onset of instability. It is observed that the excitation frequency increases with introduction of curvatures from flat panel to doubly curved panel in hygrothermal environments. Thus the
instability behaviour of laminated composite panels is influenced by increase in number of layers, aspect ratio, side to thickness ratio, increase in static and dynamic load factor, geometry, material, ply lay-up and its orientation. This can be utilized to tailor the design of laminated composite panels in hygrothermal environment.

Sahu, S.K and Datta, P.K. (2001): Parametric resonance characteristics of Laminated composite doubly curved shells subjected to non

ABSTRACT: In this study the geometrically nonlinear transient response of the laminated composite doubly curved shells is investigated using the finite element method. The finite element model includes nonlinearity due to large deflection. A nine-noded isoparametric composite shell element including the first-order shear deformation is developed in curvilinear coordinates for the nonlinear transient analysis. The present formulation is based on the total Lagrangian approach and the material behavior is assumed to be linear and elastic. The governing equations have been solved by the Newton–Raphson iteration technique, wherein the Newmark method has been used for the time integration. The present results are found to compare well with those available in the literature. The nonlinear transient response of the cross-ply and three specially laminated spherical, cylindrical, and hyperbolic paraboloidal shell panels are also analyzed and the results are discussed.

ABSTRACT: In the present investigation, the geometrically nonlinear analysis of laminated doubly curved shells in a hygrothermal environment is presented using the finite element method. The laminated composite shells may be exposed to moisture and temperature during their service life. Hygrothermal effects induce residual stresses and the laminated shell may undergo large bending deformation. The shell geometry used in the formulation is derived using the orthogonal curvilinear coordinate system. Based on the principle of virtual work the nonlinear finite element equations are derived. A total Lagrangian approach associated to the arc-length method is implemented to solve the equilibrium equations. The present results are found to compare well with those available in the open literature and parametric studies are performed to analyze the nonlinear deflections of [0 degrees/45 degrees/90 degrees](s) laminated spherical, cylindrical and conoidal shell panels under hygrothermal condition.

ABSTRACT: In the present investigation the geometrically nonlinear post buckling analysis of laminated composite doubly curved shells is presented using finite element method. The finite element model includes the general geometric nonlinearity due to large deflection. The present nonlinear strain displacement relations are expressed in the curvilinear coordinates. The material behaviour is, however, assumed to be linear and elastic. The principle of virtual work forms the basis to derive the nonlinear finite element equations. To solve the nonlinear finite element equations an incremental iterative technique based on the arc length method is employed. The present results are found to compare well with those available in the literature and are also able to capture both snap through and snap back post buckling behaviour. The nonlinear responses of three specially laminated spherical, cylindrical and conoidal shells are analyzed and the results are discussed.

ABSTRACT: In the present investigation, the geometrically nonlinear post buckling analysis of piezoelectric laminated doubly curved shells is presented using finite element method. The piezoelectric material is used in the form of layers or patches embedded and/or surface bonded on laminated composite shells. The finite element model includes the general geometric nonlinearity due to large deflection. The shell geometry used in the formulation is derived using the orthogonal curvilinear coordinate system. Based on the principle of virtual work the nonlinear finite element equations are derived. A total Lagrangian approach associated to arc-length method is used to solve the equilibrium equations. Smart shells having integrated piezoelectric actuators undergo large displacements resulting snap through phenomenon from one equilibrium state to another. The present results are found to compare well with those available in the open literature and the post buckling responses of $[\pm 45\degree/\text{minus-or-plus sign}45\degree]$s laminated spherical, cylindrical and conoidal shell panels with piezoelectric layer are analyzed and the nonlinear load–deflection curves are presented.

C. K. Kundu and Jae-Hung Han (Department of Aerospace Engineering Korea Advanced Institute of Science and Technology Daejeon, Republic of Korea), “Vibration Characteristics Of Pre And Post Buckled Laminated Composite Spherical Shells”, ICSV15, 15th International Congress on Sound and Vibration, 6-10 July 2008, Daejeon, Korea

ABSTRACT: Laminated composite shell structures may experience large bending deformation resulting in pre-buckling and post-buckling due to higher external loading and the shells may exhibit snap-through and snap-back type post buckling behavior. The vibratory characteristics of post-buckled structures are a problem of primary importance in many engineering fields, including aerospace applications. The vibration characteristics of pre and post buckled laminated composite spherical shells are presented in this paper. The nonlinear finite element method is used for the analysis. The orthogonal curvilinear coordinate system is used for modeling of doubly curved shell geometry. The strain-displacement relations include the general nonlinear terms in the curvilinear coordinate. Based on the principle of virtual work the nonlinear finite element equations are derived. The arc-length method is implemented to capture the snapping response of laminated shells. The vibration characteristics of pre and post buckled shells are performed using tangent stiffness obtained from the converged deflection. The code is first validated and then employed to generate numerical results. Parametric studies are carried out to analyze the snapping and vibration characteristics. It is observed that the frequency in the pre-snapping region decreases with increase in load. But after snap-through, the frequency increases as increase in load, due to the geometric nonlinearity.

ABSTRACT: The vibration characteristics of post-buckled laminated composite doubly curved shells are investigated. The finite element method is used for the analysis of post-buckling and free vibration of post-buckled laminated shells. The geometric non-linear finite element model includes the general non-linear terms in the strain-displacement relationships. The shell geometry used in the present formulation is derived using an orthogonal curvilinear coordinate system. Based on the principle of virtual work the non-linear finite element equations are derived. Arc-length method is implemented to capture the load-displacement equilibrium curve. The vibration characteristics of post-buckled shell are performed using tangent stiffness obtained from the converged deflection. The code is first validated and then employed to generate numerical results. Parametric studies are performed to analyze the snapping and vibration characteristics. The relationship between loads and fundamental frequencies and between loads and the corresponding displacements are determined for various parameters such as thickness ratio and shallowness.

ABSTRACT: Hygrothermal stresses due to the change in environmental condition may induce buckling and dynamic instability in the composite shell structures. In the present investigation, the hygrothermoelastic buckling behavior of laminated composite shells are numerically simulated using geometrically nonlinear finite element method. The orthogonal curvilinear coordinate is used for modeling a general doubly curved deep or shallow shell surface. The geometrically nonlinear finite element formulation is based on general nonlinear strain–displacement relations in the orthogonal curvilinear coordinate system. The present theory can be applicable to thin and moderately thick shells. The mechanical linear and nonlinear stiffnesses, and the nonmechanical nonlinear geometric stiffness matrices and the hygrothermal load vector are presented. It is also observed that during the present numerical solution of nonlinear equilibrium equation, in order to construct the

ABSTRACT: The overall behavior of plates and shells as affected by the presence of a through crack in the elastic range has been studied. Due attention has been paid to finite element modeling aspects of the problem. Forty different cracked plate and shell FE models have been generated and analyzed by a special computer program developed for the purpose of this study. The significance of various parameters such as the order of mesh refining at the crack tip, the effect of boundary conditions, Poisson's ratio, crack length and shell curvature are studied. FE model consisting of isoparametric 4-noded shell elements moderately refined at the crack tip predicted the overall stress and displacement field with acceptable precision.

ABSTRACT: Presence of cracks or similar imperfections can considerably reduce the buckling load of a shell structure. In this paper, the buckling of cylindrical shells with through cracks has been studied. A general finite element model has been proposed, verified and applied to some novel cracked shell buckling problems for which documented results are not available. A special purpose program has been developed for generating finite elements models of cylindrical shells with cracks of varying length and orientation. The buckling behavior of cracked cylinders in tension and compression has been studied. The results of the analysis are presented in parametric form when it seems to be appropriate. Sensitivity of the buckling load to the crack length and orientation has also been investigated.

ABSTRACT: The presence of cracks in a structure can considerably affect its behaviour. This paper presents a finite element study on the vibration, buckling and dynamic stability behaviour of a cracked cylindrical shell with fixed supports and subject to an in plane compressive/tensile periodic edge load. The effects of crack length and orientation are analysed. Under tension load, the results show that the frequency of the shell initially increases with the load, but then decreases as the load further increases leading to buckling due to tension load.
The size and the orientation of the crack and the loading parameter can all have a significant effect on the dynamic stability behaviour of the shell under both compressive and tensile loading. The effects of these parameters are discussed in detail.

ABSTRACT: The plastic behavior of an elastoplastic cylindrical shell with circular and rectangular cutouts under bending moment loads was investigated numerically and experimentally. A testing device (pure bending measurement) was designed and made to perform experiments on bending moment tests. The ratio of diameter to thickness of the stainless steel 304 specimens was 40.4 and the ratio of length to diameter was 7.94. The shape of the cutout on the shell was circular or rectangular. The tested specimens were categorized into five dissimilar groups. The effect of size, position and numbers of the cutout on the plastic moment is discussed. In order to investigate the strain distribution around of cutout, nine strain gauges were mounted in the longitudinal and circumferential directions on two specimens with different type of cutout. To investigate the accuracy of analytical and experimental results, numerical analysis considering the behavior of elastoplastic material were performed and good agreement was obtained between them. The strength of bending moment of cylindrical shells was decreased with increasing of sizes of cutout and it was increased with changing the location of the cutout from compression side to tension side. The effect of the number of cutouts (increasing from 1 to 3 (axisymmetrical)) on bending strength of tubes is negligible.

ABSTRACT: In this paper, the buckling behavior of a composite lattice cylindrical shell is studied and effects of rib defects on the distribution of stress field and buckling response of the shell is investigated. A three dimensional finite element buckling analysis of the lattice shell is carried out using ANSYS suit of program. Geometrical data and material properties of the shell are obtained from the specimens made by filament winding method. Effects of various parameters including the geometrical ratios, defects of ribs on buckling response of the shell are studied. Buckling loads of composite lattice cylindrical shells under axial and shear forces have been obtained experimentally and results are compared with finite element results.

ABSTRACT: The paper investigates the buckling behaviour of anisogrid composite lattice cylindrical shells under axial compression, transverse bending, pure bending, and torsion. The lattice shells are modelled as three-dimensional frame structures composed of curvilinear ribs subjected to the tension/compression, bending in two planes and torsion. The specialised finite-element model generation procedure (model generator/design modeller) is developed to control the orientation of the beam elements allowing the original twisted geometry of the curvilinear ribs to be closely approximated. The effects of varying the length of the shells, the number of helical ribs and the angles of their orientation on the buckling behaviour of lattice structures are examined using parametric analyses. Buckling of the lattice shells with cutouts is also analysed. The results of these studies indicate that the modelling approach presented in this work can be successfully applied to the solution of design problems.

ABSTRACT: A unified analytical approach is applied for investigating the vibrational behavior of grid-stiffened composite cylindrical shells considering the flexural behavior of the ribs. A smeared method is employed to superimpose the stiffness contribution of the stiffeners with those of the shell in order to obtain the equivalent stiffness parameters of the whole panel. The stiffeners are modeled as a beam and considered to support shear loads and bending moments in addition to the axial loads. Therefore, the corresponding stiffness terms are taken into consideration while obtaining the stiffness matrices due to the stiffeners. Theoretical formulations are based on first-order shear deformation shell theory, which includes the effects of transverse shear deformation and rotary inertia. The modal forms are assumed to have the axial dependency in the form of Fourier series whose derivatives are legitimised using Stokes’ transformation. In order to validate the obtained results, a 3-D finite element model is also built using ABAQUS CAE software. Results obtained from two types of analyses are compared with each other, and good agreement has been achieved. Furthermore, the influence of variations in the shell thickness and changes of the boundary conditions on the shell frequencies is studied. The results obtained are novel and can be used as a benchmark for further studies.

ABSTRACT: The results of an experimental study on the buckling behavior of thin-walled GFRP cylindrical shells are presented. The specimens were fabricated from continuous glass fiber using a specially-designed filament winding machine. The buckling behaviors of unstiffened shells and stiffened shells with lozenge, triangular and hexagonal grids were then studied under quasi-static axial loading at room temperature. Due to the thin skin of the shells, all specimens first experienced a general buckling mode as well as barreling under the applied loading. Following this general buckling damage, local buckling mode was seen on all specimens. Based on the experimental results, the critical buckling load was higher for the shells with hexagonal and triangular grids while the unstiffened shells and stiffened shells with lozenge grids exhibited much lower critical buckling load. On the other hand, in very small skin thicknesses, when the specific buckling loads for all specimens were compared, the unstiffened shells showed the highest specific buckling load.

ABSTRACT: In this paper, a size-dependent first-order shear deformable shell model is developed based upon the modified strain gradient theory (MSGT) for the axial buckling analysis of functionally graded circular cylindrical microshells based on the modified strain gradient elasticity theory”, Meccanica, Vol. 49, No. 7, pp 1679-1695, July 2014

ABSTRACT: In this paper, a size-dependent first-order shear deformable shell model is developed based upon the modified strain gradient theory (MSGT) for the axial buckling analysis of functionally graded (FG) circular cylindrical microshells. It is assumed that the material properties of FG materials, which obey a simple power-law distribution, vary through the thickness direction. The principle of virtual work is utilized to formulate the governing equations and corresponding boundary conditions. Numerical results are presented for the axial buckling of FG circular cylindrical microshells subject to simply-supported end conditions and the effects of material length scale parameter, material property gradient index, length-to-radius ratio and circumferential mode number on the size-dependent critical buckling load are extensively studied. For comparison purpose, the critical buckling loads predicted by modified couple stress theory (MCST) and classical theory (CT) are also
presented. Results show that the size effect plays an important role for lower values of dimensionless length scale parameter. Moreover, it is observed that the critical buckling loads obtained based on MSGT are greater than those obtained based on MCST and CT.

ABSTRACT: In this paper, the effects of initial imperfections on the buckling behavior of thick cylindrical shells and curved panels are investigated. It is assumed that the shell has an axisymmetric and periodic initial imperfection in the axial direction. The shell is assumed to have different boundary conditions and subjected to pure external pressure loading. Governing differential equations are developed on the basis of the second Piola-Kirchhoff stress tensor and are reduced to a homogenous linear system of equations using the differential quadrature method. The effects of different boundary conditions, geometric ratios, curvature and imperfection parameter on the buckling behavior of isotropic thick cylindrical shells and curved panels are carefully discussed. The results obtained by the present method are verified with finite element solutions and those reported in the literature.

ABSTRACT: In this paper, buckling analysis of a functionally graded thick cylindrical shell with variable thickness subjected to combined external pressure and axial compression is carried out. Moreover, the effect of an axisymmetric imperfection on the buckling load of the shell is investigated. It is assumed that material properties of the shell vary smoothly through the thickness according to a power law distribution of the volume fraction of constituent materials, while the Poisson’s ratio is assumed to be constant. The shell is considered to be simply supported at both ends. The governing differential equations are obtained based on the second Piola–Kirchhoff stress tensor and are then reduced to a homogenous linear system of equations using differential quadrature method. Effects of several parameters of the shell including the volume fraction of constituents, geometric ratios, thickness variation amplitude factor, imperfection parameter and loading conditions on the buckling behavior of the functionally graded thick cylindrical shell are investigated. The results obtained by the present method are compared with results reported in the literature.

ABSTRACT: (cannot cut and paste)

ABSTRACT: The discrepancy between the predictions of flow and deformation theories is investigated. The sensitivity of flow theory analysis to the interaction of multiaxial stresses in the pre-buckling state is reviewed. The predictions of the two theories are further examined based on critical strains at buckling, similar to the sheet metal forming limit curves. The extent to which the material nonlinearity of plastic flow is reflected in critical strains is also discussed for a variety of circumstances.

ABSTRACT: A plastic buckling analysis is presented for infinitely long shear panels in the presence of tensile or compressive loading acting along the principal directions of the plate. Assuming a homogeneous pre-buckling stress state with uniform axial and shear stresses, the critical state at buckling is determined by employing a bifurcation-of-equilibrium approach. The material is assumed elastic-plastic with non-linear strain hardening characteristics. Interaction buckling curves are presented for both flow and deformation theories of plasticity.

ABSTRACT: Porcupine quills are natural structures formed by a thin walled conical shell and an inner foam core. Axial compression tests, differential scanning calorimetry (DSC), thermogravimetric analysis (TGA) and Fourier transform infrared spectroscopy (FT-IR) were all used to compare the characteristics and mechanical properties of porcupine quills with and without core. The failure mechanisms that occur during buckling were
analyzed by scanning electron microscopy (SEM), and it was found that delamination buckling is mostly responsible for the decrease in the measured buckling stress of the quills with regard to predicted theoretical values. Our analysis also confirmed that the foam core works as an energy dissipater improving the mechanical response of an empty cylindrical shell, retarding the onset of buckling as well as producing a step wise decrease in force after buckling, instead of an instantaneous decrease in force typical for specimens without core. Cell collapse and cell densification in the inner foam core were identified as the key mechanisms that allow for energy absorption during buckling.

References listed at the end of the paper:

ABSTRACT: Thin walled cylindrical shell structures are widespread in nature; examples include plant stems, porcupine quills and hedgehog spines. All have an outer shell of almost fully dense material supported by a low density, cellular core. In nature, all are loaded in some combination of axial compression and bending; failure is typically by buckling. Natural structures are often optimized. Here we have analysed the elastic buckling of a thin cylindrical shell supported by an elastic core to show that this structural configuration achieves significant weight saving over a hollow cylinder. Biomimicking of natural cylindrical shell structures may offer the
potential to increase the mechanical efficiency of engineering cylindrical shells. The results of the analysis are compared with data in the following, companion paper.

ABSTRACT: The analysis of the previous, companion paper showed that the buckling resistance of a cylindrical shell with a compliant core is greater than that of an equivalent weight shell without a core. Here, we describe uniaxial compression and four point bending tests on silicone rubber shells with and without compliant foam cores. The analysis describes the results of the mechanical tests well.

ABSTRACT: Thin-walled, cylindrical structures are found extensively in both engineering components and in nature. The weight to load bearing ratio is a critical element of design of such structures in a variety of engineering applications, including space shuttle fuel tanks, aircraft fuselages, and offshore oil platforms. In nature, thin-walled cylindrical structures are often supported by a honeycomb- or foam-like cellular core, as for example, in plant stems, porcupine quills, or hedgehog spines. Previous studies have suggested that a compliant core increases the buckling resistance of a cylindrical shell over that of a hollow cylinder of the same weight. In this paper, we extend the linear-elastic buckling theory by coupling it with basic plasticity theory to provide a more comprehensive analysis of isotropic, cylindrical shells with compliant cores. We examine the optimal design of a thin-walled cylinder with a compliant core, of given radius and specified materials, for a prescribed load bearing capacity in axial compression. The analysis gives the values of the shell thickness, the core thickness, and the core density that maximize the load bearing capacity of the shell with a compliant core over an equivalent weight hollow shell. The analysis also identifies the optimum ratio of the core modulus to the shell modulus and is supported by a Lagrangian optimization technique. The analysis further discusses the selection of materials in the design of a cylinder with a compliant core, identifying the most suitable material combinations. The performance of a cylinder with a compliant core is compared with competing designs (optimized hat-stiffened shell and optimized sandwich-wall shell). Finally, the challenges associated with achieving the optimal design in practice are discussed, and the potential for practical implementation is explored.

ABSTRACT: Structural analysis of shallow shells is performed and relatively accurate displacements and stresses are obtained. An energy method, which is an extension of the Ritz method, is used in the analysis. Algebraic polynomials are used as displacement functions. The numerical problems which resulted in inaccurate stresses in previous publications are improved by making use of symmetry and performing the computations on the CRAY Y-MP supercomputer which has 29-digit double-precision arithmetics. Curvature effects upon deflections and stress resultants of shallow shells with cantilever and ‘semi-cantilever’ boundaries are studied.

ABSTRACT: Laminated composite shells are frequently used in various engineering applications in the aerospace, mechanical, marine, and automotive industries. This article follows a previous book and review articles published by the leading author (Qatu, 2004, 2002, 1989, 1992, 1999 [1], [2], [3], [4] and [5]). It reviews most of the research done in recent years (2000–2009) on the dynamic behavior (including vibration) of composite shells. This review is conducted with emphasis on the type of testing or analysis performed (free vibration, impact, transient, shock, etc.), complicating effects in material (damping, piezoelectric, etc.) and structure (stiffened shells, etc.), and the various shell geometries that are subjected to dynamic research (cylindrical, conical, spherical and others). A general discussion of the various theories (classical, shear deformation, 3D, non-linear etc.) is also given. The main aim of this review article is to collate the research performed in the area of dynamic analyses of composite shells during the last 10 years, thereby giving a broad perspective of the state of art in this field. This review article contains close to 200 references. References listed at the end of the paper:

ABSTRACT: The paper deals with the geometrically non-linear analysis of laminated composite beams, plates and shells in the framework of the first-order transverse shear deformation (FOSD) theory. A central point of the present paper is the discussion of the relevance of five- and six-parameter variants, respectively, of the FOSD hypothesis for large rotation plate and shell problems. In particular, it is shown that the assumption of constant through-thickness distribution of the transverse normal displacements is acceptable only for small and moderate rotation problems. Implications inherent in this assumption that are incompatible with large rotations are discussed from the point of view of the transverse normal strain–displacement relations as well as in the light of an enhanced, accurate large rotation formulation based on the use of Euler angles. The latter one is implemented as an updating process within a Total Lagrangian formulation of the six-parameter FOSD large rotation plate and shell theory. Numerical solutions are obtained by using isoparametric eight-node Serendipity-type shell finite elements with reduced integration. The Riks–Wempner–Ramm arc-length control method is used to trace primary and secondary equilibrium paths in the pre- and post-buckling range of deformation. A number of sample problems of non-linear, large rotation response of composite laminated plate and shell structures are presented including symmetric and asymmetric snap-through and snap-back problems.

ABSTRACT: In recent years, smart structures with piezoelectric sensors and actuators have attracted serious attention for they can sense and alter the mechanical response during in-service operation. On the other hand, light-weight shell type structures may be one of the most popularly used structures in space vehicles. For this reason, shell type smart structures have become the focus of study for many researchers. Tzou and his coworkers [1–3] studied piezoelectric shell type continua using finite element method and analytical analysis method. Chen and Shen[4, 5] performed the study of exact studies of piezoelectric circular cylindrical shells and piezothermoelastic shells, also, they studied the stability of piezoelectric circular cylindrical shells[6].

References listed at the end of the paper:

ABSTRACT: A mixed-mode method is investigated for the dynamic analysis of partially prismatic structures, such as box girders with intermediate diaphragms and supports, or with variable-depth webs. Thus the prismatic ‘main structure’ is discretised by finite strips, and the non-prismatic ‘sub-structure’ by finite elements. After dynamic reduction of the finite element degrees of freedom, advantage may be taken of the finite strip harmonic expansions in determining mode shapes. The method is tested by a variety of examples. Thus for structures with transverse substructures (e.g. diaphragms), the method is shown to be successful, being up to an order of magnitude faster than finite elements. However, for structures with longitudinal substructures (e.g. variable-depth webs) the method is shown to be unreliable. This is because for such structures, approximations in the dynamic reduction procedure are found to be significant.

ABSTRACT: Thick shells made of composite materials have been analyzed by using a higher order shell theory. In this theory thickness normal strain and two transverse strains are included. A higher order three-noded isoparametric axisymmetric finite element is used to solve the problem. Numerical experiments with the present element indicate that this element yields accurate vibration results with very few elements. In the present study, the suitability of different theories used for vibration studies has been investigated. Three theories are compared, viz. Love's first approximation shell theory, an improved theory with shear deformation and rotatory inertia, and a shell theory with thickness normal strain and shear deformations. It is found that the shear deformations have an appreciable effect on the vibration characteristics of comparatively thick shells, especially composite shells. A parametric study has been conducted to study the effects of various geometric properties of shell on the free vibration characteristics of conical isotropic and composite shells. The effect of mass distribution on the natural frequencies is also studied in the present work.

ABSTRACT: The Leipholz column which is having the Young modulus and mass per unit length as stochastic processes and also the distributed tangential follower load behaving stochastically is considered. The non self-adjoint differential equation and boundary conditions are considered to have random field coefficients. The standard perturbation method is employed. The non self-adjoint operators are used within the regularity domain. Full covariance structure of the free vibration eigenvalues and critical loads is derived in terms of second order properties of input random fields characterizing the system parameter fluctuations. The mean value of critical load is calculated using the averaged problem and the corresponding eigenvalue statistics are sought. Through the frequency equation a transformation is done to yield load parameter statistics. A numerical study incorporating commonly observed correlation models is reported which illustrates the full potentials of the derived expressions.

ABSTRACT: Due to the asymmetry of the material properties about the middle plane, perfect columns made of functionally graded materials (FGMs) may not remain straight when a compressive axial point load is concentrically applied. This article analytically derives the displacement functions and the buckling load of both
perfect and imperfect Euler–Bernoulli functionally graded columns. The method of derivation is based on the translation of the reference plane to the position at which the coupling between the axial and bending deformations is eliminated, i.e. the physical neutral surface position. Then, all the governing equations and their solutions turn out to have the same form as those of homogeneous columns subjected to an eccentric axial load. The effects of geometric imperfection are studied with the main purpose of finding imperfect shapes that make an imperfect column stronger than a perfect one. Further, the governing equations that are used to find those analytical solutions are expanded so that the equations can deal with large deformation and large strain analysis. These new governing equations are solved by finite element (FE) method based on linear exact shape functions. Then, the FE solutions are used to compare and validate the analytical solutions obtained earlier.

Ganesan (Concordia Center for Composites, Department of Mechanical Engineering, Concordia University, 1455 de Maisonneuve Boulevard West, Montreal, PQ, Canada H3G 1M8), “The study of tapered laminated composite structures: a review”, Composites Science and Technology, Vol. 60, No. 14, November 2000, pp. 2643-2657, doi:10.1016/S0266-3538(00)00138-X

ABSTRACT: Following laminated composite plates and beams, tapered laminated structures, which are formed by dropping off some of the plies at discrete positions over the laminate, have received much attention from researchers because of their structural tailoring capabilities, damage tolerance, and their potential for creating significant weight savings in engineering applications. A review of recent developments in the analysis of tapered laminated composite structures with an emphasis on interlaminar stress analysis, delamination analysis and parametric study is presented. A discussion of various approaches to modelling and analysis of interlaminar response of tapered composites using finite elements and non-finite elements is given. Displacement-based finite elements and hybrid finite elements that are commonly used are also reviewed. A review of various studies on delamination failure mechanisms as a result of drop-off plies in the tapered composites is given next, which mainly encompasses a stress-strength approach and a fracture-mechanics approach. Lastly, a variety of methods that are being used in the parametric studies regarding the structural integrity is presented. Overall remarks drawn from the reviewed works are given in the final section of the paper.

ABSTRACT: Linear formulations are insufficient to take into account the effect of large deflections that occur after initial buckling. This effect can only be considered in the non-linear buckling analysis. In the present work, the non-linear analysis is carried out using the finite element method based on first-order shear deformation shell theories. Two non-linear shell theories, Donnell’s and Sanders’ theories, are used in the analysis. Based on the first-ply failure analysis and non-linear buckling analysis, the critical sizes and parameters of the tapered curved plates that will not fail before global buckling are determined. A parametric study that encompasses the
effects of taper angle, critical length-to-height ratio, radius, radius-to-thickness ratio and geometric parameters of the plates is conducted.

ABSTRACT: A new formulation, based on the semi-analytical finite element method, is proposed for elastic shells conveying fluids. The structural equations are based on the shell element proposed by Ramasamy and Ganesan [Comput Struct 70 (1998) 363] while the fluid model is based on velocity potential. Dynamic pressure acting on the walls is derived from Bernoulli's equation. Imposing the requirement that the normal components of velocity of the solid and fluid be equal, introduces fluid–structure coupling. The proposed technique has been validated using results available in the literature. This study shows that instability occurs at a critical fluid velocity corresponding to the shell circumferential mode with the lowest natural frequency and this phenomenon is also independent of the type of structural boundary conditions imposed.

ABSTRACT: Piezoelectric composite cylindrical shells operating in a steady state axisymmetric temperature are analyzed using a semi-analytical finite element method. Numerical studies are conducted on a clamped–clamped composite cylindrical shell for three typical length to radius ratios. The static thermal buckling analysis is carried out for a single layered composite cylindrical shell with different fiber orientation and hence study its influence on thermal buckling temperature. The influence of axisymmetric temperature on the natural frequencies and active damping ratio of the piezoelectric cylindrical shell is also examined. Two configurations of composite laminates: symmetric and antisymmetric with varying the number of plies is also considered to examine the effect on thermal buckling temperature.

ABSTRACT: Thermoelastic buckling and free vibration analysis of geometrically perfect isotropic hemispherical shells subjected to axisymmetric temperature variation are presented. First order shear deformation theory is used to analyze the moderately thick elastic hemispherical shells. The variations of various field variables are assumed in the circumferential direction and the finite element matrices used in the numerical studies are based on the semi-analytical method. The formulation is validated for thermal buckling strains available in the literature. Thermal buckling temperatures are evaluated for deep shells having a cut-out at the apex. Parameters considered in the study include hemispherical shells with a/h ratios of 100 and 500 and each with cut-out angle at apex equal to 7°, 30° and 45°. Boundary conditions considered are clamped–clamped and clamped–free. A study on the distribution of the stress resultants due to thermal loading is examined in order to relate their influence on the buckling temperature of the shells with respect to above-stated geometric
parameters. The effect of temperature on the free vibration natural frequency of the hemispherical shell is also analyzed.

ABSTRACT: Numerical results on the thermal buckling temperature of geometrically perfect HS-Graphite/Epoxy hemispherical shells with cut-out at apex subjected to uniform temperature distribution is presented. The numerical computation is based on the general shell of revolution semi-analytical finite element applicable to moderately thick shells. Studies are presented considering parameters like ratio of base radius to thickness of shell, size of the cut-out at apex and fibre orientation of the lamina and their effects are examined on the magnitude of the buckling temperature. An in-depth study on the magnitude and distribution of the total effective stress resultants and moment resultants is used to explain the role of these quantities on the magnitude of the lowest thermal buckling temperature. It is found that for a given geometry, uniform temperature rise and edge conditions the lowest buckling temperature of a hemispherical shell is mainly due to the large magnitude of the hoop stress resultant close to the edges of the hemispherical shell and also depends on the distribution of hoop stress resultants.

ABSTRACT: This paper presents the buckling and vibration behavior of a viscoelastic sandwich cylinder in a thermal environment analyzed using the semi analytical finite element method. The analysis is carried out using a decoupled thermo mechanical formulation. The temperature field in the shell domain is evaluated using an eight-noded axisymmetric ring element. Buckling and vibration analyses are carried out using a two-noded sandwich shell element in the semi-analytical finite element method. Buckling temperatures are calculated for sandwich shells with two different core materials. The effect of temperature-dependent core shear modulus on buckling temperature and vibration behavior has been investigated for sandwich shells with different mechanical boundary conditions. Variations of natural frequencies and loss factors with temperature have also been examined for sandwich shells with two different core materials.

ABSTRACT: The purpose of the paper is to investigate the linear thermal buckling and vibration analysis of layered and multiphase magneto-electro-elastic (MEE) cylinders made of piezoelectric/piezomagnetic materials using finite element method. The constitutive equations of MEE materials are used to derive the finite element equations involving the coupling between mechanical, electrical, magnetic and thermal fields. The present study is limited to clamped-clamped boundary conditions. The linear thermal buckling is carried out for an axisymmetric cylinder operating in a steady state axisymmetric uniform temperature rise. The influence of
stacking sequences and volume fraction of multiphase MEE materials on critical buckling temperature and vibration behaviour is investigated. The influence of coupling effects on critical buckling temperature and vibration behaviour is also studied. The critical buckling temperature is higher for MEE axisymmetric cylinder as compared to elastic cylinder.

ABSTRACT: An experimental investigation has been carried out to study the strength and behaviour of Ordinary Portland cement concrete (OPC) and geopolymer concrete (GPC) wall panels. A total of 20 wall panels were tested under uniformly distributed axial load in one-way in-plane action. Out of these, 10 wall panels were made of OPC and the remaining was of GPC. The main variables considered in this study were slenderness ratio (SR) and aspect ratio (AR) of the walls. Also a method was proposed to predict the ultimate load of reinforced GPC wall panels.

ABSTRACT: A new three-node triangular shell element is developed by combining the optimal membrane element and discrete Kirchhoff triangle (DKT) plate bending element, and is modified for laminated composite plates and shells so as to include the membrane-bending coupling effect. Using appropriate shape functions for the bending and membrane modes of the element, the ‘inconsistent’ stress stiffness matrix is formulated and the tangent stiffness matrix is determined. Non-linear analysis of thin-walled structures with geometric non-linearity is conducted using the corotational method. The new element is thoroughly tested by solving few popular benchmark problems. The results of the analysis are compared with those obtained using existing membrane elements.

ABSTRACT: In this study, two optimality criteria are presented for shape optimization of thin-walled structures with geometric nonlinearity modeled by finite elements. The optimization problem considers the thickness and geometry design variables, and aims to maximize the critical load of the structure subject to constant total mass. Results of the optimization with optimality criteria are compared with those found by the gradient-based sequential quadratic programming method. It is shown that the optimum shape can be found using this method without performing the sensitivity analysis, and in less number of iterations compared to the standard gradient-based methods of optimization.

ABSTRACT: In the present work, an efficient facet shell element for the geometrically nonlinear analysis of laminated composite structures using the corotational approach is developed. The facet element is developed by combining the discrete Kirchhoff–Mindlin triangular bending element (DKMT), and the optimal membrane triangular element (OPT). The membrane-bending coupling effect of composite laminates is incorporated in the formulation, and inconsistent stress stiffness matrix is formulated. Using corotational formulation and the proposed facet element, some example laminated composite structures with geometric nonlinearity are analyzed, and the results are compared with those found using other facet elements.

S. Akhlaque-E-Rasul and R. Ganesan (Concordia Center for Composites, Department of Mechanical and Industrial Engineering, Concordia University, 1455 De Maisonneuve W., Montreal, QC, Canada, H3G 1M8), “Finite element global buckling analysis of tapered curved laminates”, (publisher and date not included in the pdf file; most recent reference is 2009)

ABSTRACT: Due to the variety of configurations of tapered curved composite plates the analysis becomes complex. At present no existing work deals with their response to compressive loading except the other works of present authors. The linear and non-linear buckling analyses of tapered curved composite plates are conducted in the present work using SHELL99 element of ANSYS. The results obtained using ANSYS are compared with that of the Finite Element Analysis using a Lagrange element based on First order Shell Theory (FST), and Ritz solution based on Classical Shell Theory (CST) and FST. The strength characteristics and load carrying ability of the tapered curved plates are investigated considering first-ply failure and delamination failure. Based on these analyses, the critical sizes and parameters of the tapered curved plates that will not fail before global buckling are determined. A parametric study is also carried out.

ABSTRACT: Tapered laminated structures have considerable potential for creating significant weight savings in engineering applications. In the present thesis, the ply failure and global buckling failure of internally-tapered curved laminates are considered. For the buckling analysis, four different analytical approaches are employed: (1) classical shell theories using Ritz method, (2) first-order shear deformation shell theories using Ritz method, (3) linear finite element analysis based on first-order shear deformation shell theories, and (4) non-linear finite element analysis. Due to the variety of tapered curved composite plates and the complexity of the analysis, no closed-form analytical solution is available at present regarding their response to compressive loading. Therefore, the Ritz method is used for the global buckling analysis considering uniaxial compressive load. Linear buckling analysis of the plates is carried out based on eight classical shell theories and six first-order shear deformation shell theories. To apply the first-order shear deformation shell theories, an appropriate set of shear correction factors has been determined. The buckling loads obtained using Ritz method are compared with the existing experimental and analytical results, and are also compared with the buckling loads obtained using finite element method. The strength characteristics and load carrying capability of the tapered curved plates are investigated considering the first-ply failure and delamination failure. The commercial software ANSYS® is used to analyze these failures. Based on the ply failure and buckling analyses, the critical sizes and parameters of the tapered curved plates that will not fail before global buckling are determined. Linear buckling analysis is insufficient to take into account the effect of large deflections on the buckling loads. This effect can only be considered in the non-linear buckling analysis. However, very large number of load steps is required to determine the buckling load based on the non-linear analysis in which the stability limit load is calculated from the non-linear load-deflection curve. In the present thesis, a simplified methodology is developed to predict the stability limit load that requires the consideration of only two load steps. The stability limit loads calculated using the present simplified methodology are shown to have good agreement with that calculated from the conventional non-linear load-deflection curve. Parametric studies are carried out using the above mentioned four different types of analytical methods. In these studies, the effects of boundary conditions, stacking sequence, taper configurations, radius, and geometric parameters of the plates are investigated.

ABSTRACT: Tapered composite shells provide considerable weight and energy savings in the engineering applications. Due to the advanced configurations of tapered composite shells and their complex behavior, closed-form analytical solutions are not available at present regarding their response to compressive loading. In the present work, approximate analytical solutions are developed using the Ritz method for the global buckling response of tapered shells considering uni-axial compression. Buckling analysis of the shells is carried out using the Ritz method based on six well-established First-order shear deformation Shell Theories (FST). The failure
strength characteristics and load carrying capability of the above mentioned tapered shells are studied considering the first-ply failure. Based on the failure and buckling analyses, the critical values of size and shape parameters of the shells such that they will fail only in global buckling mode are determined. A comprehensive parametric study is carried out and design guidelines for the tapered shells are established based on this study.

ABSTRACT: The paper describes the application of a curved isoparametric shell element to large displacement analyses including instability phenomena. A total Lagrangian formulation has been adopted using the standard incremental/iterative solution procedure. The linear stability analyses usually performed for the initial position were repeated at several advanced fundamental states on the nonlinear prebuckling path. Thus a current estimate of the final failure load is given. The method has been applied to several perfect and imperfect cylindrical shells under uniform pressure or wind load. Finally the example of a cylindrical panel under one concentrated transverse load is discussed.

ABSTRACT: The stability of a cylindrical shell subjected to wind load is analyzed using numerical solution methods. The multisegment direct integration as well as the finite element method are applied in linear analysis, and a nonlinear finite element algorithm is used to take into account the nonlinear prebuckling effects of the perfect and imperfect structure. The calculated results are compared with measurements, and good agreement is derived with respect to both stability limit and buckling mode.

ABSTRACT: In the paper we are looking at cylindrical shells fixed at the bottom and free at the top. Let us assume that these shells are filled with a viscous, compressible fluid of a mass density, \( p_L \), up to height, \( H \). For definitions see Fig. 1. The shell is accelerated at the bottom, i.e. at position \( x = 0 \), by a horizontal acceleration, \( A(t) \), \( t = \) time.

ABSTRACT: A finite shell element for layered fibre reinforced composite shells has been developed. The degeneration principle is used in combination with specific kinematic assumptions. The thermo-elastic material is either described by the behaviour of the local components, i.e. fibre and matrix material laws and geometrical configuration in each layer, or by the overall orthotropic layer material laws. Thickness integration for obtaining the different contributions to the shell element's stiffness matrix is performed analytically and prior to the numerical in-plane integration. This leads to a considerable saving in computer time during the incremental-iterative analysis. Geometrical non-linearities in terms of large deformations and material non-linearities in
terms of layer cracking are taken into account. Accompanying eigenvalue analyses allow the determination of the—sometimes rather complicated—buckling behaviour with non-linear prebuckling deformations.

ABSTRACT: In this chapter formulations of special finite shell elements for the analysis of composite shell structures (layered fiber-composite and sandwich shells) as well as computational considerations of local effects are described. Nonlinearities due to large deformations and progressive damage as well as local and global loss of stability are treated. Finally, some practical applications of the computational procedures are described.

ABSTRACT: In this section the classical lamination theory is described on the basis of Mindlin-Reissner’s kinematics. Hygrothermal effects are included, and a formulation is achieved which can be simply specified for specific laminates such as symmetric, quasi-orthotropic and quasi-isotropic ones. Furthermore, interlaminar stresses and edge effects as well as some failure criteria and the post-failure behavior with stiffness degradation are considered. Based on antiplane core conditions a sandwich theory is developed, and a procedure is presented for estimating local instability phenomena such as different modes of face layer wrinkling or intracell buckling and failure due to transverse normal stresses.

ABSTRACT: A finite strip (FS) method is presented for the numerical investigation of two design parameters – effective breadth and effective width – of stiffened plates. For the effective breadth, stiffened plates under bending are studied. Due to the transverse bending loads there is shear transmission through the plate from the stiffener which leads to a non-uniform longitudinal stress distribution across the plate width. This phenomenon, termed as shear lag, can be represented by the ‘effective breadth concept’, and has been extensively studied by analytical methods. A linear FS method is presented which utilizes the advantages of decoupling of Fourier terms on the one hand and, on the other hand, allows the treatment of both webs and flanges using a plate model. A definitely different situation exists for estimating the effectiveness of plate breadth (or width) of plates in the postbuckling range. The ‘concept of effective width’ is based on the fact that plates with supported longitudinal edges and/or stiffeners can accept additional load after buckling under longitudinal compression,
and enables the designer to evaluate the postbuckling strength of plate structures simply by using the design parameter ‘effective width’. Several formulae (most of them empirically derived) exist for an approximative calculation of the load dependent value of the effective width. A nonlinear FS method is developed and applied to the investigation of the postcritical strength of locally buckled structures. An incremental successive iterative procedure is introduced for an effective numerical analysis.

ABSTRACT: Introducing beads into thin-walled structures for enhancing bending stiffness is a common practice and has been used for many decades. Typically, forms and patterns of such beads are rather based on experience as well as practical results than on analytical or numerical investigations. Recently computational methods have been developed for designing or optimizing beads. The paper at hand contributes to these attempts. It deals with increasing the buckling resistance as well as the fundamental frequency of thin-walled structures by systematic bead design. The design strategy is based on the idea to disturb the buckling mode and the fundamental vibration mode, respectively, of a structure in an efficient way by laying beads along the direction of the occurring maximum principal curvature of the corresponding mode shape. Since the beads influence this mode shape, an incremental approach is required. Numerical investigations into plate and profile structures are performed by applying this new iterative design procedure in combination with the finite element method.

ABSTRACT: A box-like stringer-stiffened thin-walled CFRP structure was subjected to load cases well beyond the limits of local buckling. The development of the deflection pattern was recorded via optical means and analysed numerically. In addition, the structure was modelled and analysed using the MARC FE program in the nonlinear deflection range. The geometrical imperfections of the test structure were recorded by mechanical
scanning and optical methods and introduced into the mathematical model. For the perfect (‘ideal’) and the geometrically imperfect (‘real’) structural model, the results of the FE analyses were compared and used to judge the effect of geometric imperfections on the postbuckling behaviour of the structure. The effective axial stiffness for the various postbuckling states was evaluated and related to analytical estimates of effective width values for orthotropic sheet-like panels.

ABSTRACT: Computational investigations of the buckling and postbuckling behaviour of a stringer-stiffened composite wing torsion box employing the finite element method are presented. Perfect and imperfect configurations — considering geometrical imperfections as well as initial stresses - are discussed. Two different loadcases are investigated: pure axial loading and axial loading with a superimposed constant torsion moment. The buckling behaviour is determined by tracing the load-deflection curves using Riks' path following method. Additional investigations, such as accompanying eigenvalue analyses and first-ply failure calculations, are performed for the first loadcase. Special attention is put on the modelling of the stiffened regions, where eccentrically placed layers have to be taken into account due to the bonding of the stiffeners to the inner surface of the box. The results show interesting phenomena, such as additional buckling points in the postbuckling region, which, however, can hardly be detected by simply considering the load-axial displacement path.

ABSTRACT: Computational investigations of the buckling and postbuckling behaviour of a stringer-stiffened composite wing torsion box employing the finite element method are presented. Perfect and imperfect configurations considering geometrical imperfections as well as initial stresses are discussed. The determination of load-deflection curves and first-ply-failure calculations for the skin are performed for two different loadcases. In addition, in a global-local approach, the interlaminar stresses, the risk of delamination and first-ply-failure in the stiffener sections in the prebuckled and the postbuckled ranges are examined. This approach combining non-linear global and linear local investigations represents an analysis concept for stiffened composite structures, which considers the stability behaviour of the structure as well as ply failure and onset of delamination in the skin, the stringers and the skin-stringer transitions.

ABSTRACT: Pushing a conical die into a pipe, a forming process also known as “flaring”, is a way of changing the shape of a thin cylindrical tube into that of a conical shell. Interest in predicting the forming limits for this specific process motivated the present study, in which experiments and Finite Element simulations were employed for the identification of two limiting mechanisms: (a) diffuse necking caused by local loss of material stability at the free, expanding end of the pipe, and (b) loss of global stability due to elasto-plastic “Concertina” buckling of the straight pipe part. The former mechanism leads to the formation of periodic necks and subsequent failure by strain localization and rupture, while the latter mechanism is characterized by a periodic buckling pattern that is similar to the one observed in typical crash elements. Whether collapse or rupture is the limiting factor depends on geometrical parameters and material parameters, such as, for example, the hardening exponent in the Ludwik law. There are some publications of analytical considerations of the flaring process, describing the load displacement behavior of the stamp and the development of plastic deformations in the tube. However, the aspect of material and structural instability requires a deeper insight into the problem, which is provided by the experimental results and the numerical studies presented here. It appears to be important to take the tridimensionality of the stress and strain states into account when reliable predictions of necking and rupture limits are to be made.

ABSTRACT: Pushing a conical die into a tube is a forming process that is suitable for changing the shape of a thin cylindrical tube into that of a conical shell. The degree of expansion that is achievable without destroying the tube is limited by two mechanisms: (a) loss of global stability due to elasto-plastic ´Concertina´ buckling of the straight part of the tube, and (b) diffuse necking caused by local loss of material stability in the conical part of the tube. The former mechanism is characterized by a periodic buckling pattern, that is similar to the one observed in typical crash elements, while the latter mechanism leads to the formation of periodic necks and subsequent failure by strain localization and rupture. In this study experimental evidence for both kinds of instabilities is presented along with corresponding simulation results obtained with the finite element method. For long tube specimens ´Concertina´ buckling was found to be the dominant instability mode while for short tube specimens failure by necking and rupture occurred. The critical circumferential strain for the onset of necking at the expanding tube end was markedly higher than the one expected from uniaxial tension results. This finding is attributed to the supporting effect of the tube sections that are subjected to lower strains.

ABSTRACT: Modern materials and material compounds for application in lightweight structures exhibit, in addition to the use of constituents of high specific stiffness and strength, very special micro- and meso-structures. Typical representatives of such material compounds are sandwiches with thin homogeneous or
composite face layers and structured core materials (for instance honeycombs and closed or open cell foams). The load carrying capacity of lightweight structures made of such materials and material compounds, respectively, is limited by a considerable number of rather different but interconnected instability modes occurring at length scales which are several orders of magnitude smaller than the size of the structural part. These non-global instabilities are the subject of the presented keynote paper.

ABSTRACT: Corrugated paper is produced in large volumes for packaging purposes, an application which places high demands on the structural stability of the employed corrugated board containers. This is taken into account in the optimization procedure for reducing the area-specific weight of corrugated board which is presented in this paper. For predicting effective properties of corrugated board designs, the geometry of the board is discretized by finite shell elements, and a periodic unit cell model, which contains a minimum of one full wave of the flute, is generated. By application of appropriate periodicity boundary conditions, the effective mechanical behavior of a theoretically infinite board can be predicted within the limits of linear shell theory. Furthermore, local loss of stability can also be calculated. It is possible to embed this model into an optimization procedure which attempts to reduce the area-specific weight of the board by modifying the governing geometrical parameters while enforcing the stiffness and buckling strength constraints. It has to be noted that the calculation of critical loads with respect to local buckling involves a minimization scheme within this optimization loop in order to find the critical buckling wavelength and adjust the unit cell size accordingly. We apply the proposed optimization scheme to a specific kind of corrugated board in order to determine if there is potential for weight-reduction. The optimization scheme gives a set of parameters which describes a new design of corrugated paper with the same buckling strength, but an area-specific weight that is reduced by more than 18% with respect to the original design. The improved corrugated board shows simultaneous buckling of fluting and liners under a compressive membrane load along the generatrix of the flute.

ABSTRACT: Tensile specimens of metal films on compliant substrates are widely used for determining interfacial properties. These properties are identified by the comparison of experimentally observed delamination buckling and a mathematical model which contains the interface properties as parameters. The current two-dimensional models for delamination buckling are not able to capture the complex stress and deformation states arising in the considered uniaxial tension test in a satisfying way. Therefore, three-dimensional models are developed in a multi-scale approach. It is shown that, for the considered uniaxial tension test, the buckling and associated delamination process are initiated and driven by interfacial shear in addition to compressive stresses in the film. The proposed model is able to reproduce all important experimentally observed phenomena, like cracking stress of the film, film strip curvature and formation of triangular buckles. Combined with experimental data, the developed computational model is found to be effective in determining interface strength properties.

ABSTRACT: The local buckling behavior of perfect/defective and single/multi-walled carbon nanotubes
(CNTs) under axial compressive forces has been investigated by the molecular dynamics approach. Effects of different types of defects including vacancy and Stone–Wales (SW) defects and their configurations on CNTs with different chiralities at room temperature are studied. Results show that defects largely reduce the buckling stress and the ratio of immediate reduction in buckling compressive stress of the defective CNT to the perfect one, but have little influence on their compressive elastic modulus. SW defects usually reduce the mechanical properties more than vacancy defects, and zigzag CNTs are more susceptible to defects than armchairs. In addition, increasing the number of defects leads to higher deterioration in mechanical properties of CNTs. The results of simulations show that in the case of slender single-walled CNTs, the behavior is primarily governed by the Euler buckling law. On the other hand, in the local shell buckling mode, two distinct behaviors are observed, including the primary local shell buckling mode for intermediate CNTs, and the secondary local shell buckling mode for short CNTs. In the local buckling response, CNTs with smaller diameters sustain higher buckling stresses than CNTs with larger diameters.

ABSTRACT: Techniques for the optimization of composite with structures are investigated. The refined optimality criterion technique presented in this paper is an algorithm combining a criterion based on the Kuhn-Tucker conditions and the technique of fully stressed design. The main advantages of this method are the generality of use, the efficiency in computation, and the capability of identifying automatically the set of critical constraints. Sensitivity analysis of constraints is based on the virtual load principle. This method is especially suitable for optimum design of large-scale structures. A modular type computer program, ARS 5 (Automatic Resizing System 5), is developed in accordance with the finite element method, refined optimality criterion, sensitivity analysis and Fortran-77 language for the optimization of composite wing structures subjected to sizes, stresses, displacements, twist and buckling constraints. Numerical results for a triple-spars composite wing structure reveal that the present technique is quite efficient and reliable.

ABSTRACT: This paper presents a two-stage meta-heuristic approach to producing weight-optimised solutions needed prior to the detailed finite element analysis of composite wing. Composite wing covers are assumed to take the form of a group of stiffened sub-panels with varying skin and stiffener geometries according to the wing layout and loads. A population of limited solutions satisfying various design constraints was created using layout (skin and stiffener geometry), selected lay-ups, rule based stacking sequence and various assumed loads. The closed form analytical solutions of flat stiffened orthotropic plates are used for calculating buckling reserve factors and strength margins. For each sub-panel, a meta-heuristic rule was imposed to search for a suitable combination of skin and stiffener geometry. The criterion used was minimum weight satisfying laminate continuity accounting for manufacturability. Later, the optimised solutions for each sub-panel are converted into a format supported by the conventional finite element tool (NASTRAN). The use of meta-heuristic approach and their automation in Visual Basic for Applications resulted in fast convergence and potential time-saving compared to genetic algorithms.

SUMMARY: The paper firstly discusses the fundamental behavior of RC-shells in the ultimate load range which is characterized by a strong interaction of buckling and strength. It reviews current design procedures, few reported structural failures as well as RC model tests and finite element formulations for geometrically and materially nonlinear finite element analyses of RC-shells. Finally a brief description of one specific numerical model is give. It is applied to the ultimate load and stability analyses of conically shaped cooling towers. References listed at the end of the paper: (cannot cut and paste)

ABSTRACT: The paper first classifies various kinds of pressure loads, then linear and nonlinear finite element buckling analyses of cylindrical shells under uniform and nonuniform loads are presented. In particular the influence of displacement dependent loads on the buckling load of cylindrical shells under water and wind loading is discussed. Finally, the paper summarizes the design rules for wind loaded cylindrical tanks recently developed in Austria and Germany. The study has three goals: to clarify the problem and the effect of follower loads, to demonstrate the capability of nonlinear finite element analyses, and to discuss some results for design practice.

doi:10.1016/0956-0521(94)90038-8

ABSTRACT: The optimal design of structures with distinct geometrically non-linear behavior has attracted a great deal of interest in the last years mainly with respect to sizing for prescribed external loads. In the present contribution a method is proposed to maximize the critical load under certain constraints, e.g. for a given volume, allowing varying shape as well as cross-sections. The combination of direct computation of the critical load and path-following methods is integrated into a general optimization procedure consisting of mathematical programming techniques, sensitivity analysis and computer aided geometric design methods. The formulation includes imperfection sensitivity as an important part within the optimization process.

ABSTRACT: The subject of the present study is the optimization of structures with geometrically nonlinear behaviour allowing the inclusion of instability phenomena and imperfection sensitivity in the structural design. The proposed optimization procedure is based on the methods of path following, direct computation of bifurcation and limit points and an accurate and efficient sensitivity analysis. The finite element method is used for the structural analysis. These techniques are used together with mathematical programming schemes and methods of computer-aided geometric, design.

ABSTRACT: In this paper, we have tried to simulate the buckling processes of shells computationally. The two major tasks needed to be carried out in such a simulation, namely (1) tracing of the time history of structural response, and (2) application of appropriate perturbation in initial condition when a deformed state has become unstable in order to trigger the buckling process, are first clarified. We then proceed to the explanation about the tools, namely (1) path-following scheme, and (2) stability criteria, which are necessary in order to carry out the above two tasks. We have omitted the exposition about the path-following scheme and touched only on the stability criteria based on Liapunov's concept of stability. Finally, we show the results of simulation carried out on three examples of shell structures. From the results, it could be concluded that numerical simulation of buckling processes of shells is possible.

ABSTRACT: The postbuckling behavior of an axially compressed circular cylindrical shell is exceedingly complicated due to an infinite number of closely spaced postbuckling branches and bifurcation points. The minimum strength existing in the deep bottom of the postbuckling region may serve as a design limit. The primary concern in this present paper is to compute this stable postbuckling equilibrium solution by two different approaches: One is to repeat the procedures of tracing unstable branches, pinpointing bifurcation points and branch-switching in order to carefully approach to the target. The other is to trigger a static jump to the target by two-parametric loading. As a numerical example, a perfect circular cylindrical panel is analyzed to show that a direct jump from the undeformed state to a stable postbuckling solution is possible with a proper choice of the load perturbation.

ABSTRACT: The analysis of large-scale nonlinear shell problems asks for parallel simulation approaches. One crucial part of efficient and well scalable parallel FE-simulations is the solver for the system of equations. Due to the inherent suitability for parallelization one is very much directed towards preconditioned iterative solvers. However thin-walled-structures discretized by finite elements lead to ill-conditioned system matrices and therefore performance of iterative solvers is generally poor. This situation further deteriorates when the thickness change of the shell is taken into account. A preconditioner for this challenging class of problems is presented combining two approaches in a parallel framework. The first approach is a mechanically motivated improvement called ‘scaled director conditioning’ (SDC) and is able to remove the extra-ill conditioning that appears with three-dimensional shell formulations as compared to formulations that neglect thickness change of
the shell. It is introduced at the element level and harmonizes well with the second approach utilizing a multilevel algorithm. Here a hierarchy of coarse grids is generated in a semi-algebraic sense using an aggregation concept. Thereby the complicated and expensive explicit generation of course triangulations can be avoided. The formulation of this combined preconditioning approach is given and the effects on the performance of iterative solvers is demonstrated via numerical examples.

ABSTRACT: This paper deals with the numerical computation of buckles and wrinkles appearing in membrane structures by means of the total Lagrangian formulation, using genuine membrane finite elements (with zero bending stiffness) and a prestressed hyperelastic constitutive law. The bifurcation analysis is carried out without assuming any imperfections in the structure. The standard arclength method is modified by means of a specific solution procedure to cope with the occurrence of complex roots when solving the quadratic constraint equation. Applying the proposed formulation to a set of typical numerical examples shows its ability to correctly predict the wrinkling and buckling behaviour in membrane structures.

ABSTRACT: This paper deals with the development of a new three-dimensional element with two-dimensional kinematic constraints capable of analysing the mechanical behaviour of the laminated anisotropic shell-type structures. This element, originally developed for the linear analysis of plates, is extended for the linear analysis of laminated composite shells. The element can represent arbitrarily curved shells with variable number of layers and thicknesses, including ply drop-off problems. The element was validated in a previous work by the patch test. All the analytical details necessary to make possible the shell analysis are presented here. Examples are reported to show the capability of the element to predict the behavior of complex structures, and a refined computation of the stresses is carried out by integrating the equilibrium equations.
ABSTRACT: A very simple and practical formulation and procedure to remove the restriction of small rotations between two successive increments for geometrically nonlinear analysis of shells using flat triangular shell elements are presented. The element employed here to implement the present method is the flat triangular element proposed by Bathe and Ho (Comput. Struct. 13, 673–681, 1981). The nonlinear formulation is based on the updated Lagrangian description of motion. The rotation of the coordinate system is assumed to be accomplished by two successive rotations: an out-of-plane rotation followed by an in-plane rotation. The element internal nodal forces are calculated using the total deformational in-plane displacements and nodal rotations. Two methods, referred to as direct method and incremental method, are proposed in this paper to calculate the total deformational rotations. An incremental-iterative method based on the Newton-Raphson method combined with arc length control is adopted. Numerical studies are presented to demonstrate the accuracy and efficiency of the present method.

ABSTRACT: A corotational total Lagrangian (CR-TL) formulation using the Von Kármán assumption is presented for the analysis of nonlinear shell problems. This formulation is applicable for the nonlinear analysis of shell structures with large rotations but moderate deformations. The numerical algorithm used here is an incremental iterative method based on the Newton-Raphson method combined with constant arc length of incremental displacement vector. In order to improve the convergence properties of the equilibrium iterations, special care is taken in the calculation of the geometric stiffness matrix. Numerical examples are presented and compared with the results reported in the literature to demonstrate the accuracy and efficiency of the proposed method.

ABSTRACT: A consistent co-rotational finite element formulation and numerical procedure for the buckling and postbuckling analyses of three-dimensional elastic Euler beam is presented. All coupling among bending, twisting, and stretching deformations for a beam element is considered by consistent second-order linearization of the fully geometrically nonlinear beam theory. However, the third-order terms, which are relevant to the twist rate and curvature of the beam axis, are also considered. An incremental–iterative method based on the
Newton–Raphson method combined with constant arc length of incremental displacement vector is employed for the solution of nonlinear equilibrium equations. The zero value of the tangent stiffness matrix determinant of the structure is used as the criterion of the buckling state. A bisection method of the arc length is proposed to find the buckling load. Numerical examples are presented to demonstrate the accuracy and efficiency of the proposed method and to investigate the effect of third-order terms on the buckling load and postbuckling behavior of three-dimensional beams.

ABSTRACT: A consistent co-rotational total Lagrangian finite element formulation and numerical procedure for the geometric nonlinear buckling and postbuckling analysis of thin-walled beams with monosymmetric open section is presented. The element developed here has two nodes with seven degrees of freedom per node. The element nodes are chosen to be located at the shear centers of the end cross-sections of the beam element and the shear center axis is chosen to be the reference axis. The deformations of the beam element are described in the current element coordinate system, which is constructed at the current configuration of the beam element. In element nodal forces, all coupling among bending, twisting, and stretching deformations of the beam element is considered by consistent second-order linearization of the fully geometrically nonlinear beam theory. However, the third-order term of the twist rate of the beam axis is considered in element nodal forces. An incremental-iterative method based on the Newton–Raphson method combined with constant arc length of incremental displacement vector is employed for the solution of nonlinear equilibrium equations. The zero value of the tangent stiffness matrix determinant of the structure is used as the criterion of the buckling state. A parabolic interpolation method of the arc length is used to find the buckling load. Numerical examples are presented to demonstrate the accuracy and efficiency of the proposed method.

ABSTRACT: This paper aims at describing the buckling behaviour of transversely loaded composite shell structures. Two distinctive glass fabrics, woven and knitted, embedded in the same thermoplastic matrix, polypropylene, were utilised to produce the composites to be used as subject materials. Curved strips with fixed curvature and span, but with different number of plies and orientations, were compressed between two rigid flat platens. Load–displacement responses and deformed shapes were examined using experiments and numerical simulations based on a general finite element code, LUSAS®. As the nonlinear collapse is the buckling mode evident in the experimental tests, a nonlinear stress analysis technique has been adopted to simulate the buckling responses. Single-ply strips, both for woven and knitted, display limit point symmetrical buckling
failure that shows good agreement with the predictions in terms of critical load and buckling mode. In the cases of multi-ply construction, the modes of failure for woven fabric specimens are by means of delaminations while the multi-ply knitted shells still exhibit similar behaviours to that of the single-ply specimens.

ABSTRACT: Buckling analyses of the laminated plates and shells under axial compression are carried out using the finite element method. The formulation of a geometrically non-linear composite shell element based on the updated Lagrangian method is presented to study the buckling behaviour. The element is capable of small strain and large displacement analysis with finite rotations. It has eight nodes with six degrees of freedom per node. Transverse shear deformation effects are included using a first-order (Mindlin-Reissner) theory which allows modelling of relatively thick plates and shells. Results of buckling behaviour show that the present formulation has very good agreement with existing references.

ABSTRACT: This paper presents results for cylindrical shell configurations using the STAGS computer program. Discontinuities have been imposed upon the shell's skin by incorporating symmetrical cutout openings. In addition, the surface is stiffened with both stringer and ring-stringer arrangements. The cutout problem has been shown to be highly nonlinear for smooth surface shells, but the author has found that bifurcation and collapse loads are close when one is considering stiffened skin configurations. In order to arrive at this conclusion, it was necessary to evaluate the following:

—comparison between smeared and discrete stiffener theory for linear solutions
—numerical finite difference convergence as directed toward buckling determination
—collapse load results with the various skin stiffeners.

This paper also includes a linear bifurcation study relating to stiffening effects around cutout areas present within stringer and ring-stringer shell surfaces. Comparisons have been made between a variety of geometric positions considering cutout frame and thickened skin additions. The investigation points toward an optimum positioning.

ABSTRACT: This paper discusses the fabrication process, test methods and analytical procedures used to evaluate the buckling of composite curved panels. A detailed description is given of the panel fabrication steps and the test fixture used to apply axial loading and to achieve a variety of boundary conditions. Results are presented comparing analytical and experimental buckling loads for three-ply orientations.

Mark F. Mulholland and Anthony N. Palazotto (AFIT, School of Engineering Wright-Patterson AFB, OH
ABSTRACT: The buckling loads of eight-ply graphite-epoxy cylindrical panels with midplane delamination were determined experimentally. The study included two different ply orientations, two different aspect ratios, two different delamination sizes, and one set of boundary conditions; clamped along the top and bottom edges and simply supported along the vertical sides. The experimental test results are compared to the linear bifurcation and nonlinear collapse loads of panels with square cutouts obtained from the STAGSC-1 finite-element computer code.

ABSTRACT: Over the past five years the Air Force Institute of Technology has been carrying out an investigation of small and large unreinforced cutout effects on composite cylindrical panels acting under compressive axial loads. Some of the original findings are reviewed and, in addition, new results are presented relating to different loading conditions. In general, not only does a small cutout reduce the panel's collapse load by at least 50%, but the cutout's position and size have further effect.

ABSTRACT: A finite element method, incorporating a modified Riks technique and full Newton-Raphson method (FNR), is investigated in order to trace a highly nonlinear responses such as snap-through, and single and multiple snap-back phenomena of cylindrical shells. A through the thickness parabolic transverse shear strain is considered. An initial load increment or decrement is automatically determined at the beginning of each load step, then the final load increment or decrement and the corresponding displacements are obtained in several iterations by using the modified Riks technique.

ABSTRACT: A modified Riks technique is applied to the finite element method to trace the nonlinear response from the pre-limit point into the post-limit range for a composite cylindrical shell-like structure. Parabolic transverse shear strain is considered through the thickness of the shell. The results are compared with results which did not consider a parabolic shear strain variation through the thickness of the shell.

ABSTRACT: An analytical study is conducted to determine the fundamental frequencies and critical buckling loads for laminated anisotropic circular cylindrical shell panels, including the effects of transverse shear deformation and rotary inertia, by using the Galerkin technique. A linearized form of Sander's shell strain-displacement relations are derived, which include a parabolic distribution of transverse shear strains. The theory is valid for laminate thickness to radius ratios h/R of up to 1/5. Higher order constitutive relations are derived for the laminate. A set of five coupled partial differential equations of motion and boundary conditions are derived and then solved using the modified Galerkin technique. Simply supported and clamped boundary conditions are investigated. Comparisons are made with the Donnell shell solutions. The effects of transverse shear deformation and rotary inertia are examined by comparing the results with classical solutions, where applicable. The radius of curvature is varied to determine the effects of membrane and bending coupling. The theory compares exactly with the Donnell solutions, which are valid up to h/R = 1/50. As expected, as length to thickness ratios are reduced, shear deformation effects significantly lower the natural frequencies and buckling loads. Analysis also shows that rotary inertia effects are very small. Finally, as h/R is varied from 0 (flat plate) to 1/5 (maximum limit), the frequencies and buckling loads increase due to membrane and bending coupling.

ABSTRACT: The large-rotation snap-through characteristics of laminated cylindrical panels are investigated using a finite element method incorporating the “constant arc length” technique and Newton-Raphson method based on the assumption of through-the-thickness parabolic transverse shear strains. Comparisons with solutions obtained from the corotational stags code (i.e., a nonlinear finite element code which can follow large displacement/rotation for plate and shell structures without considering through-the-thickness transverse shear deformation) demonstrate the validity, accuracy and advantage of the present development. The nonlinear response for several laminated cylindrical panels are traced using the present method and the effects of anisotropy, fiber orientation, and stacking sequence, on the significance of large-rotation snap-through buckling are studied.

ABSTRACT: A finite element method, incorporating the modified Riks technique and Newton-Raphson method, is used to trace a highly nonlinear response such as snap-through, single and multiple snap-back phenomenon of cylindrical shells. A through the thickness parabolic transverse shear strain is considered. The
multiple snapping responses of an isotropic panel are investigated, and their results are compared with those not considering the transverse shear deformation. Also comparison differences are noted with respect to a ‘displacement control’ strategy.

PARTIAL INTRODUCTION: The US Air Force Institute of Technology (AFIT) has been carrying out research related to the instability of composite cylindrical panels since 1979. This chapter is a review of the AFIT work and will discuss both its experimental and analytical features. Other organizations have pursued similar research [1,2], and the AFIT work has cited their findings. AFIT is the only organization that has continued to explore many of the intricacies of this interesting area. More than 150 composite graphite/epoxy cylindrical panels have been tested.....

ABSTRACT: Presented here is a new total Lagrangian finite-element formulation for general laminated composite shells undergoing large-displacement, large-rotation, and large-strain motion. The theory fully accounts for geometric nonlinearities (large rotations), large in-plane strains, general initial curvatures, transverse shear deformations, and interlaminar normal stresses by using Jaumann stress and strain measures, an exact coordinate transformation, and a new concept of orthogonal virtual rotations. In addition, with the inclusion of transverse normal and shear stresses, the theory accounts for three-dimensional stress effects and gives accurate effective structural stiffnesses. Because of the inclusion of all possible initial curvatures, the developed strain-displacement expressions can be used for any surface structures and are fully nonlinear, which contain von Kármán strains as a special case. Moreover, the theory accounts for the continuity of interlaminar shear and peeling stresses and the normal and shear stress conditions on the bonding surfaces by using a new layer-wise local displacement field, which results in a higher-order shear theory that contains most shear deformation theories as special cases. In this paper, we develop a fully nonlinear displacement-based finite-element formulation based on the derived shell theory. The verification and accuracy of the theory will be presented in a subsequent paper by comparing obtained numerical results with some exact solutions.

ABSTRACT: The objective of this research is to determine the physical response including material failure of a thin, curved composite panel designed to resist transverse loading. The cause of the material failure, in the form of fiber, matrix and/or delamination failure, will be determined through failure criterion based on nonlinear movement using a finite element analysis technique. The finite element analysis technique known as the simplified large displacement/rotation (SLR) theory allows for large displacements but assumes small to
moderate rotations (A.N. Palazotto, S.T. Dennis, Nonlinear Analysis of Shell Structures, American Institute of Aeronautics and Astronautics, Inc., Washington, DC, 1992). Third-order shell kinematics, defined relative to the shell mid-surface, allow for the characterization of in-plane and transverse shear effects, while neglecting the direct transverse effects. Data generated using the SLR theory both with and without the addition of progressive failure criteria, will be compared with previously published experimental data, noting where the SLR theory diverges from the experimental results. The inclusion of the Hashin failure criterion will provide a more realistic representation of the total physical response of the shell (Z. Hashin, J. Appl. Mech. 47 (1980) 329–334). The criterion will investigate the shell, from initial loading, to further progressive composite failures. As the composite shell fails, the constitutive relations, or shell stiffness will be reduced. Results of the analytic comparison with the experimental data indicate that the SLR theory overpredicts the stiffness of the shell whether considering or not considering failure criteria. Results generated for the case incorporating a progressive failure criterion are closer to the experimental data because of the reduced stiffness due to failure as the deflection increases.

ABSTRACT: The method of multiple scales is used to analyze the non-linear forced response of circular cylindrical shells in the presence of a two-to-one internal (autoparametric) resonance to a harmonic excitation having the frequency OMEGA. If omega_r and a_r denote the frequency and amplitude of a flexural mode and omega_b and a_b denote the frequency and amplitude of the breathing mode, the steady-state response exhibits a saturation phenomenon when omega_b is almost equal to 2omega_r, if the excitation frequency OMEGA is near omega_b. As the amplitude “f” of the excitation increases from zero, a_b increases linearly whereas a_r remains zero until a threshold is reached. This threshold is a function of the damping coefficients and omega_b minus 2omega_r. Beyond this threshold a_b remains constant (i.e. the breathing mode saturates) and the extra energy spills over into the flexural mode. In other words, although the breathing mode is directly excited by the load, it absorbs a small amount of the input energy (responds with a small amplitude) and passes the rest of the input energy into the flexural mode (responds with a large amplitude). For small damping coefficients and depending on the detunings of the internal resonance and the excitation, the response exhibits a Hopf bifurcation and consequently there are no steady state periodic responses. Instead, the responses are amplitude- and phase-modulated motions. When OMEGA is almost equal to omega_b, there is no saturation phenomenon and at close to perfect resonance, the response exhibits a Hopf bifurcation, leading again to amplitude- and phase-modulated or chaotic motions.

ABSTRACT: A general nonlinear theory for the dynamics of elastic anisotropic circular cylindrical shells undergoing small strains and moderate-rotation vibrations is presented. The theory fully accounts for extensionality and geometric nonlinearities by using local stress and strain measures and an exact coordinate
transformation, which result in nonlinear curvatures and strain-displacement expressions that contain the von Karman strains as a special case. Moreover, the linear part of the theory contains, as special cases, most of the classical linear theories when appropriate stress resultants and couples are defined. Parabolic distributions of the transverse shear strains are accounted for by using a third-order theory and hence shear correction factors are not required. Five third-order nonlinear partial differential equations describing the extension, bending, and shear vibrations of shells are obtained using the principle of virtual work and an asymptotic analysis. These equations show that laminated shells display linear elastic and nonlinear geometric couplings among all motions.

ABSTRACT: The objective of this work was to study analytically, numerically, and experimentally the nonlinear dynamic behavior of metallic and composite structural elements to parametric and external excitations. The study was focused on resonance conditions that may produce large and possibly damaging motions. Special attention was given to modal coupling and consequent energy exchanges.

List of Presentations by A.H. Nayfeh, et al given at the end of the report:
ABSTRACT: A general geometrically exact nonlinear theory for the dynamics of laminated plates and shells undergoing large-rotation and small-strain vibrations in three-dimensional space is presented. The theory fully accounts for geometric nonlinearities by using the new concepts of local displacements and local engineering stress and strain measures, a new interpretation and manipulation of the virtual local rotations, an exact coordinate transformation, and the extended Hamilton principle. Moreover, the model accounts for shear coupling effects, continuity of interlaminar shear stresses, free shear-stress conditions on the bonding surfaces, and extensionality. Because the only differences among different plates and shells are the initial curvatures of the coordinates used in the modeling and all possible initial curvatures are included in the formulation, the theory is valid for any plate or shell geometry and contains most of the existing nonlinear and shear-deformable plate and shell theories as special cases. Five fully nonlinear partial-differential equations and corresponding boundary and corner conditions are obtained, which describe the extension-extension-bending-shear-shear vibrations of general laminated two-dimensional structures and display linear elastic and nonlinear geometric coupling among all motions. Moreover, the energy and Newtonian formulations are completely correlated in the theory.

ABSTRACT: An experimental validation of the suitability of reduction methods for studying nonlinear vibrations of distributed-parameter systems is attempted. Nonlinear planar vibrations of a clamped-clamped buckled beam about its first post-buckling configuration are analyzed. The case of primary resonance of the nth mode of the beam, when no internal resonances involving this mode are active, is investigated. Approximate solutions are obtained by applying the method of multiple scales to a single-mode model discretized via the Galerkin procedure and by directly attacking the governing integro-partial-differential equation and boundary conditions with the method of multiple scales. Frequency-response curves for the case of primary resonance of the first mode are generated using both approaches for several buckling levels and are contrasted with experimentally obtained frequency-response curves for two test beams. For high buckling levels above the first crossover point of the beam, the computed frequency-response curves are qualitatively as well as quantitatively different. The experimentally obtained frequency-response curves for the directly excited first mode are in agreement with those obtained with the direct approach and in disagreement with those obtained with the single-mode discretization approach.

ABSTRACT: Introductory concepts such as those of geometric and material nonlinearities are presented through a rich collection of simple yet illuminating examples shedding light on the phenomenological, theoretical and computational aspects. Most of the basic concepts are elucidated, such as the geometric stiffness, the role of nonlinear constitutive laws, the linearization about a natural or prestressed equilibrium state, the critical conditions/limit states due to the loss of elastic stability and the postcritical behaviors beyond the limit states. A major focus is placed on path following techniques for the construction of equilibrium paths or for continuation of periodic solutions. The illustrative examples range from MEMS systems to flutter control of airfoils.

ABSTRACT: This paper, which deals with geometrically nonlinear analysis of multilayered shell structures, presents an evaluation of the approximations made when simplified models are introduced. To this purpose, a transverse shear deformable shell finite element formulation including finite rotations and large displacements is employed and von Karman, as well as moderate and small rotation theories, are obtained as particular cases. Classical shear deformation type-results have been improved in moderately thick shell analysis by using modified multilayered shear stiffnesses. These stiffnesses have been calculated through a variational technique which accounts for parabolic interlaminar continuous transverse shear stress fields and zig-zag form of the in-plane displacements along the shell thickness. Stability problems of several flat and cylindrical thin and thick geometries, different multilayered lay-outs (cross-ply, angle-ply symmetrically and unsymmetrically laminated, including sandwich) and loading conditions are considered in the numerical investigations. It has been concluded that geometrical nonlinear effects are problem dependent, furthermore such effects become more significant in thick shell analysis with respect to thin structures.

SUMMARY: This work is an overview of available theories and finite elements that have been developed for multilayered, anisotropic, composite plates and shells. Although a comprehensive description of several techniques and approaches is given, most of this paper has been devoted to the so called axiomatic theories and related finite element implementations. Most of the theories and finite elements that have been proposed over the last thirty years are in fact based on these types of approaches. The paper has been divided into three parts. Part I, has been devoted to the description of possible approaches to plate and shell structures: 3D approaches, continuum based methods, axiomatic and asymptotic two-dimensional theories, classical and mixed formulations, equivalent single layer and layer wise variable descriptions are considered (the number of the unknown variables is considered to be independent of the number of the constitutive layers in the equivalent
single layer case). Complicating effects that have been introduced by anisotropic behavior and layered constructions, such as high transverse deformability, zig-zag effects and interlaminar continuity, have been discussed and summarized by the acronym C*,0. Requirements.

Two-dimensional theories have been dealt with in Part II. Contributions based on axiomatic, asymptotic and continuum based approaches have been overviewed. Classical theories and their refinements are first considered. Both case of equivalent single-layer and layer-wise variables descriptions are discussed. The so-called zig-zag theories are then discussed. A complete and detailed overview has been conducted for this type of theory which relies on an approach that is entirely originated and devoted to layered constructions. Formulas and contributions related to the three possible zig-zag approaches, i.e. Lekhnitskii-Ren, Ambartsumian-Whitney-Rath-Das, Reissner-Murakami-Carrera ones have been presented and overviewed, taking into account the findings of a recent historical note provided by the author.

Finite Element FE implementations are examined in Part III. The possible developments of finite elements for layered plates and shells are first outlined. FEIs based on the theories considered in Part II are discussed along with those approaches which consist of a specific application of finite element techniques, such as hybrid methods and so-called global/local techniques. The extension of finite elements that were originally developed for isotropic one layered structures to multilayered plates and shells are first discussed. Works based on classical and refined theories as well as on equivalent single layer and layer-wise descriptions have been overviewed. Development of available zig-zag finite elements has been considered for the three cases of zig-zag theories. Finite elements based on other approaches are also discussed. Among these, FEIs based on asymptotic theories, degenerate continuum approaches, stress resultant methods, asymptotic methods, hierarchy-p,_,s global/local techniques as well as mixed and hybrid formulations have been overviewed.

SUMMARY: This work is a sequel of a previous author’s article: “Theories and Finite Elements for Multilayered Anisotropic, Composite Plates and Shell”, Archive of Computational Methods in Engineering Vol 9, no 2, 2002; in which a literature overview of available modelings for layered flat and curved structures was given. The two following topics, which were not addressed in the previous work, are detailed in this review: 1. derivation of governing equations and finite element matrices for some of the most relevant plate/shell theories; 2. to present an extensive numerical evaluations of available results, along with assessment and benchmarking.

The article content has been divided into four parts.

An introduction to this review content is given in Part I.

A unified description of several modelings based on displacements and transverse stress assumptions ins given in Part II. The order of the expansion in the thickness directions has been taken as a free parameter. Two-dimensional modelings which include Zig-Zag effects, Interlaminar Continuity as well as Layer-Wise (LW), and Equivalent Single Layer (ESL) description have been addressed.
Part III quotes governing equations and FE matrices which have been written in a unified manner by making an extensive use of arrays notations. Governing differential equations of double curved shells and finite element matrices of multilayered plates are considered. Principle of Virtual Displacement (PVD) and Reissner’s Mixed Variational Theorem (RMVT), have been employed as statements to drive variationally consistent conditions, e.g. $C_\gamma^0$-Requirements, on the assumed displacements and transverse stress fields. The number of the nodes in the element has been taken as a free parameter. As a results both differential governing equations and finite element matrices have been written in terms of a few $3\times3$ fundamental nuclei which have 9 only terms each.

A vast and detailed numerical investigation has been given in Part IV. Performances of available theories and finite elements have been compared by building about 40 tables and 16 figures. More than fifty available theories and finite elements have been compared to those developed in the framework of the unified notation discussed in Parts II and III. Closed form solutions and and finite element results related to bending and vibration of plates and shells have been addressed. Zig-zag effects and interlaminar continuity have been evaluated for a number of problems. Different possibilities to get transverse normal stresses have been compared. LW results have been systematically compared to ESL ones. Detailed evaluations of transverse normal stress effects are given. Exhaustive assessment has been conducted in the Tables 28–39 which compare more than 40 models to evaluate local and global response of layered structures. A final Meyer-Piening problem is used to assess two-dimensional modelings vs local effects description.

SUMMARY: A state-of-the-art in the development of a series of new finite elements by the addition of non-conforming displacement modes is reviewed in this paper. These new plate finite elements are achieved by the combined use of the addition of non-conforming modes, the application of reduced (or selective) integration scheme, and the construction of substitute shear strain fields. The improvement achieved may be attributable to the fact that the merits of these techniques are merged into the new element in a complementary manner. It is shown that the results obtained by the new elements give reliable solutions without any defects for several benchmark problems.

ABSTRACT: In the present paper two main research areas of computational mechanics, namely the finite element development and the design of time integration algorithms are reviewed and discussed with a special emphasis on their combination. The finite element techniques are designed to prevent locking and the time integration schemes to guarantee numerical stability in non-linear elastodynamics. If classical finite element techniques are used, their combination with time integration schemes allow to avoid any modifications on the element or algorithmic level. It is pointed out, that on the other hand Assumed Stress and Enhanced Assumed Strain elements have to be modified if they are combined with energy conserving or decaying time integration schemes, especially the Energy-Momentum Method in its original and generalized form. The paper focusses on the necessary algorithmic formulation of Enhanced Assumed Strain elements which will be developed by the reformulation of the Generalized Energy-Momentum Method based on a classical one-field functional, the extension to a modified Hu-Washizu three-field functional including enhanced strains and a suitable time discretization of the additional strain terms. The proposed method is applied to non-linear shell dynamics using a shell element which allows for shear deformation and thickness change, and in which the Enhanced Assumed Strain Concept is introduced to avoid artificial thickness locking. Selected examples illustrate the locking free and numerically stable analysis.

ABSTRACT: A survey of effective finite element formulations for the analysis of shell structures is presented. First, the basic requirements for shell elements are discussed, in which it is emphasized that generality and reliability are most important items. A general displacement-based formulation is then briefly reviewed. This formulation is not effective, but it is used as a starting point for developing a general and effective approach using the mixed interpolation of the tensorial components. The formulation of various MITC elements (that is, elements based on Mixed Interpolation of Tensorial Components) are presented. Theoretical results (applicable to plate analysis) and various numerical results of analyses of plates and shells are summarized. These illustrate some current capabilities and the potential for further finite element developments.

ABSTRACT: General criteria of instability in time-independent elastic-plastic solids and the related computational approaches are reviewed. The distinction between instability of equilibrium and instability of a deformation process is discussed with reference to instabilities of dynamic, geometric or material type. Comparison is made between the bifurcation, energy and initial imperfection approaches. The effect of incremental nonlinearity of the constitutive law, associated with formation of a yield-surface vertex, on instability predictions is examined. A survey of the methods of post-critical analysis is presented.

ABSTRACT: This paper concerns the theory and implementation of a numerical procedure that is capable of solving the collapse process of a structure when it is loaded past its ultimate carrying strength. The procedure is a combination of two generally available methods: A path following method for the quasi static part of the solutions and a transient method for the dynamic part. The simulation of a compression test on a thin walled cylindrical shell with a local imperfection is provided to demonstrate the effectiveness of the strategy employed.

ABSTRACT: The present essay contains a general structural stability theory for discretized structural systems. Instabilities are essential constituents of nonlinear structural responses, the computational assessment of which in a modern treatment is exclusively based on incremental-iterative (step-wise) numerical techniques, applied to the tangential equation of motion. The paper derives this fundamental equation as first variation of the nonlinear equation of motion in its standard form and its phase projection. Further, it transforms the principle of virtual work for arbitrary nonlinear (Kelvin-Voigt) continua into its incremental variant and finally into the consistent tangential equation of motion. Its various applications then are demonstrated to classes of time-independent and time-dependent, unstable structural responses, for which suitable numerical instruments are outlined. The derived algorithms are based on the concepts of Lyapunow exponents and Poincaré multipliers which are introduced as universal stability measures. Qualitative and quantitative convergence properties of perturbations in the phase space enable the proper establishment of stability definitions. The validity of the received concepts is illustrated by several examples.

ABSTRACT: This paper presents an innovative device to be used as an impact energy absorber. The absorber consists of a central thin trunk surrounded by a number of triangular webs. The entire assembly is enclosed outside a thin square tube that embodies the energy unit. Energy is dissipated by crumpling forces generated at square tube as well as the side walls of the device when the central trunk is displaced axially which characterizes the device as an innovative energy absorber. The results clearly illustrated the effect of absorption capacity of the absorber, and demonstrated the controllability and stability of the absorption rate. It is considered that this promising new energy absorber would be best suited as a structural fender of automobiles and trains’ compartment.

ABSTRACT: The article traces the important steps of the development of the finite element method from its origins in aircraft structural engineering to the present day, where it provides the essential tool for solution of a great variety of problems in engineering and physics. The emphasis and the choice of the “landmarks” stresses the aspects which are general and essentially of mathematical nature applicable to a wide range of situations. For this reason no mention is made of perhaps equally important developments to new application fields such as metal forming, electromagnetics, geomechanics etc.

ABSTRACT: This article presents a survey of the Core-Congruential Formulation (CCF) for geometrically nonlinear mechanical finite elements based on the Total Lagrangian (TL) kinematic description. Although the key ideas behind the CCF can be traced back to Rajasekaran and Murray in 1973, it has not subsequently received serious attention. The CCF is distinguished by a two-phase development of the finite element stiffness equations. The initial phase develops equations for individual particles. These equations are expressed in terms of displacement gradients as degrees of freedom. The second phase involves congruential-type transformations that eventually bind the element particles of an individual element in terms of its node-displacement degrees of freedom. Two versions of the CCF, labeled Direct and Generalized, are distinguished. The Direct CCF (DCCF) is first described in general form and then applied to the derivation of geometrically nonlinear bar, and plane stress elements using the Green-Lagrange strain measure. The more complex Generalized CCF (GCCF) is described and applied to the derivation of 2D and 3D Timoshenko beam elements. Several advantages of the CCF, notably the physically clean separation of material and geometric stiffnesses, and its independence with respect to the ultimate choice of shape functions and element degrees of freedom, are noted. Application examples involving very large motions solved with the 3D beam element display the range of applicability of this formulation, which transcends the kinematic limitations commonly attributed to the TL description.

ABSTRACT: An exact solution for the postbuckling configurations of composite beams is presented. The equations governing the axial and transverse deformations of a composite laminated beam accounting for the midplane stretching are derived. The inplane inertia and damping are neglected, and hence the two equations are reduced to a single nonlinear fourth-order partial–integral–differential equation governing the transverse deformations. We find out that the governing equation for the postbuckling of symmetric or asymmetric composite beams has the same form as that of beams made of an isotropic material. Composite beams with fixed–fixed, fixed–hinged, and hinged–hinged boundary conditions are considered. A closed-form solution for the postbuckling deformation is obtained as a function of the applied axial load, which is beyond the critical buckling load. To study the vibrations that take place in the vicinity of a buckled equilibrium position, we exactly solved the linear vibration problem around the first buckled configuration. Solving the resulting eigenvalue problem results in the natural frequencies and their associated mode shapes. Both the static response represented by the postbuckling analysis and the dynamic response represented by the free vibration analysis in the postbuckling domain strongly depend on the lay-up of the laminate. Variations of the beam’s midspan rise and the fundamental natural frequency of the postbuckling domain vibrations with the applied axial load are presented for a variety of lay-up laminates. The ratio of the axial stiffness to the bending stiffness was found to be a crucial parameter in the analysis. This control parameter, through the selection of the appropriate lay-up, can be manipulated to help design and optimize the static and dynamic behavior of composite beams.

ABSTRACT: This work presents a geometric nonlinear dynamic analysis of plates and shells using eight-node hexahedral isoparametric elements. The main features of the present formulation are: (a) the element matrices are obtained using reduced integrations with hourglass control; (b) an explicit Taylor-Galerkin scheme is used to carry out the dynamic analysis, solving the corresponding equations of motion in terms of velocity components; (c) the Truesdell stress rate tensor is used; (d) the vector processor facilities existing in modern supercomputers were used. The results obtained are comparable with previous solutions in terms of accuracy and computational performance.

buckling and geometric nonlinear analysis for MSC/NASTRAN’S shell elements”, (publication not given in the pdf file. Most recent reference is dated 1992)

PARTIAL ABSTRACT: This paper presents an improved approach for linear buckling and geometric nonlinear analysis in MSC/NASTRAN. The differential stiffness and the internal forces of the QUAD4 and TRIA3 shell elements have been corrected in MSC/NASTRAN Version 68…

ABSTRACT: An eight-node hexahedral element with uniform reduced integration, which is free of volumetric and shear locking and has no spurious singular modes, is implemented here for geometrically nonlinear static structural analysis. In the element formulation, one-point quadrature is used so that the element tangent stiffness matrix is given explicitly and computational time is substantially reduced in the geometrically nonlinear analysis. In order to avoid shear locking the generalized strain vector is written in a local corotational system and certain non-constant terms in the shear strain components are omitted. The volumetric locking is cured by setting the dilatational part of the normal strain components to be constant. A corotational procedure is employed to obtain the deformation part of the displacement increment in the corotational system and update element stresses and internal force vectors. Numerical examples verify the computational efficiency and the potential of the three-dimensional element in the analysis of shells, plates and beams undergoing large displacements and rotations. Results are compared to those employing classical plate and shell elements.

ABSTRACT: Geometrically nonlinear static and dynamic behaviour of laminate composite shells are analyzed in this work using the Finite Element Method (FEM). Triangular elements with three nodes and six degrees of freedom per node (three displacement and three rotation components) are used. For static analysis the nonlinear equilibrium equations are solved using the Generalized Displacement Control Method (GDCM) while the dynamic solution is performed using the classical Newmark Method with an Updated Lagrangean Formulation (ULF). The system of equations is solved using the Gradient Conjugate Method (GCM) and in nonlinear cases with finite rotations and displacements an iterative-incremental scheme is employed. Numerical examples are presented and compared with results obtained by other authors with different kind of elements and different schemes.

ABSTRACT: The static and dynamic response of geometrically imperfect composite beams is presented. The proposed model accounts for the midplane stretching of the beam that follows the classical beam theory and its curvature is assumed to be shallow. The assumption of a small strain, moderate deformation is used. The governing equations are nonlinear integral partial-differential equations. A unified approach is used to handle
the postbuckling response of composite beams with and without imperfection. As a result, an analytical solution for the beam’s static response in terms of the applied axial load, imperfection, and lay up is obtained. Moreover, the free vibrations in the postbuckling domain are investigated. Having the beam’s imperfection as a control parameter, the beam’s static and dynamic response is investigated and presented. Results show that the imperfection has a significant effect on the static and dynamic response of composite beams.

ABSTRACT: Presented here is a new total-Lagrangian displacement-based finite-element formulation for plates and shells undergoing large displacements and rotations. The theory fully accounts for geometric nonlinearities, general initial curvatures, and extensionality by using Jaumann stress and strain measures, an exact coordinate transformation, and orthogonal virtual rotations. Moreover, transverse shear deformations are accounted for by using a first-order shear deformation theory with shear correction factors obtained by matching the shear strain energy and stress resultants with those of a general layerwise higher-order shear deformation theory. Large static deformations of several different plates and shells under different loading and boundary conditions are obtained. Comparison with available results in the literature reveals that the finite-element model is accurate in predicting large deformations of highly flexible two-dimensional structures.

ABSTRACT: A dynamic finite-element model of a cracked aluminum plate repaired with a composite laminate is presented and the influence of cracks and debond of the repair laminate on the static strength and dynamic characteristics of the repaired structure are investigated. NASTRAN is used to develop a refined two-dimensional finite-element model that accounts for cracks in the aluminum plate, the debond of the repair laminate from the aluminum plate, and transverse shear deformations. The transverse shear effects are accounted for by using an energy-equivalent first-order shear-deformation theory derived from a new layerwise higher-order model of transverse shear deformations. Normal mode analysis shows that debond of the patch significantly reduces natural frequencies and changes the mode shapes of only the higher modes. Frequency response analysis shows that the debond of the patch causes a large change in the magnitudes and shapes of frequency response functions (FRFs) near the patch in the direction of the excitation. Moreover, linear buckling analysis shows that debond reduces the buckling load and may change the buckling mode shape. However, the critical size of debond that reduces the buckling load to a certain percentage of the healthy case is boundary-condition-dependent. Transverse shear deformations also reduce the natural frequencies, move the FRFs to the low-frequency range, and reduce the buckling loads, but they have no significant influence on mode shapes and the shape of the FRFs. This damage characterization study provides information useful for the design of composite repair patches and the development of health-monitoring systems using FRFs.

ABSTRACT: An account is given of the fabrication and proof-testing of a 26 m prototype corrugated GRP hull. In addition to demonstrating the feasibility of corrugated construction and confirming favorable hull cost predictions, a satisfactory outcome was obtained from towing tests to evaluate hull resistance, hull bending tests under hogging and sagging load conditions, and evaluation under a series of underwater explosions. Performance was compared in each case with that of a similar, conventional GRP hull.

ABSTRACT: A nonlinear theoretical analysis for predicting the buckling and postbuckling loads of discretely stiffened composite cylindrical shells is presented in this paper. Geometric and material nonlinearities, the effects of transverse shear and initial imperfection are considered in the analytical model. The composite material formulation is valid with the nonlinear behavior described by the modified Romberg-Osgood relation and Hill's criterion combined in an elastic-plastic model. The prebuckling analysis is obtained using the principle of virtual work, with the postbuckling bifurcation analysis based on Hutchinson's criterion. Some shell examples calculated numerically show that the theoretical analysis is in good agreement with the experimental results and other known solutions. Thus, the nonlinear theory and analysis procedure described herein can be used as an aid in the design process of composite or isotropic cylindrical shells with or without stiffeners and rings.

ABSTRACT: The vibrational response of orthotropic composite cylindrical shells subjected to axial compression is examined, following a refined Love-type theory. Results obtained are compared with those predicted by Donnell-type theory, as found in the literature. Important effects due to shell lay-up, length to radius ratio, radius to thickness ratio and fiber reversal are noted from the calculations performed for a number of double and triple-layered shells.

ABSTRACT: The free vibrations, buckling and the effect of initial prestress upon the frequency spectrum of orthotropic composite cylindrical shells are examined in the context of a theory that includes transverse shear deformation. Results obtained are compared with the predictions of refined Love-type theory and simplified Donnell-type theory that do not consider shear deformation. The calculated examples indicate that transverse shear deformation can be significant not only for short composite shells but even for longer shells possessing low shear moduli.

ABSTRACT: The equations of motion, derived from a Love-type theory, are presented for laminated filament-wound cylindrical shells in which each layer is permitted an arbitrary fixed fiber orientation. A general method of solution is established, based upon the use of a complex finite Fourier transform. The frequency spectra of free natural vibrations are investigated for numerous single, bi- and tri-layered clamped or simply supported generally orthotropic shells. The effect of fiber orientation on the frequency response is found to be quite considerable in certain composite shells; for some shells the frequency is increased by a factor of 3.1 by simply
choosing an optimal combination of the winding angles. Similar important effects are noted due to the combined action of shell heterogeneity and fiber winding angle.

ABSTRACT: The stability of filament-wound composite cylindrical shells under combined torsional/axial loading is considered, for the case in which edge-damage is present at one end of the cylinders. The displacement equilibrium equations, based on Flügge's quasi-linear theory, are solved using a finite complex Fourier transform together with the introduction of a displacement function. The zero of a determinantal equation, arising from nontrivial fulfillment of the boundary conditions, furnishes the value of the critical torque/axial load. The edge-damage is modeled by nonuniform boundary conditions. Results indicated that for isotropic shells the degree of sensitivity to edge-damage decreased the lower the applied axial load, irrespective of the direction of the applied torque. However, for anisotropic shells certain torques can actually enhance the critical axial load sustainable. This effect persists in the presence of edge-damage, and, in addition, can desensitize the shell to edge-damage over a larger section of its circumference.

ABSTRACT: The stability of thin composite layered anisotropic cylindrical shells under axial compression is considered for the case of nonuniform boundary conditions. Such conditions are employed to model the situation where there is edge damage to the shell. The influence of weakening or a crack at an edge on the critical buckling load of a variety of single and multilayered shells is investigated. Results indicate that isotropic shells exhibit a rather sudden steep reduction in the critical buckling load for relatively small edge damage. However, some anisotropic composite shells may not be so sensitive and, in contrast, only a gradual reduction may be brought about by the edge damage. The degree of sensitivity to edge damage appears to be dependent, in some complex fashion, on the various geometric and physical shell parameters.

ABSTRACT: The stability of filament-wound composite cylindrical shells subjected to radial pressure is examined, for the case in which edge-damage is present. The displacement equilibrium equations, based on Flügge's quasi-linear theory, are solved using a finite complex Fourier transform together with the introduction of a displacement function. The zero of a determinantal equation, arising from the nontrivial fulfillment of the boundary conditions, furnishes the value of the critical radial pressure. The edge-damage is modeled by nonuniform boundary conditions. From computed results it is concluded that isotropic shells are capable of withstanding edge-damage up to 50% of their circumference before a reduction in the critical pressure occurs. Anisotropy tends to weaken this sturdiness with all single and bilayered shells considered suffering a fairly sharp drop in the critical pressure sustainable after only up to 20% of the edge is "loosened". This represents a reversal of the roles of isotropy and anisotropy found by the authors for the case when the shells were subjected
to axial compression.

ABSTRACT: The static buckling of orthotropic composite cylindrical shells, under circumferentially non-uniform axial loads is investigated based on Flugge-type field equations. Use of a complex finite Fourier transform provides a simple method for handling any arbitrary non-uniform load but introduces modal coupling between the transformed equations. For simply supported boundaries (conditions SS3) the determination of the critical buckling load reduces to finding the eigenvalues of a finite matrix. Three different non-uniform loads are considered, having forms proportional to (1 + 2costheta), costheta and H(theta* - theta) where H is the Heaviside function, theta is the circumferential coordinate and atheta* is the width of an axially loaded strip of the shell of radius a. Computed results indicate the sensitivity of the critical buckling loads to the type of non-uniform load and the material lay-ups of the cylinders.

ABSTRACT: An experimental investigation to determine the buckling and rupture strength of a fabricated torospherical head under internal pressure loading has recently (1984) been carried out under the sponsorship of several industrial and governmental agencies. Preliminary evaluation of the data indicates a larger than expected factor of safety between initial buckling and failure. An important consideration in the investigation is the elastic stress pattern prior to the initiation of buckling. In this paper, the results of a linear elastic stress analysis are presented in order to demonstrate the resulting stress patterns and to compare several different computer codes. This solution is also thought to be suitable as a benchmark problem for the validation of computer codes for thin shell analysis. The analysis demonstrates several interesting aspects of the significance of bending stresses for a situation where there are neither abrupt geometrical discontinuities nor locally concentrated loads, two classical sources of bending in thin shells.

ABSTRACT: A nonlinear finite element model that is suitable for the static analysis of shells of revolution with local plasticity is developed. Actually, shells of revolution always exhibit local deviations, like a cutout, a junction, and/or an imperfection. The stress concentration caused around a local deviation may make the material plastic in the surrounding region. The analytical model consists of three different types of shell elements: rotational, general, and transitional. The rotational shell elements are used in the region where the shell is axisymmetrical, and the general shell elements are deployed in the region of the deviation. The transitional shell elements are inserted between the two distinctively different types of elements to achieve continuity of displacement fields. Only the general shell element possesses the material nonlinear properties to capture the localized plasticity. A simple description of plastic behavior based on elastic-plastic behavior, the Von Mises criterion, the Prandtl-Reuss flow rule, and a layered structure, developing plastification through the
thickness of the general shell, is used. The stress components at appropriately chosen station points covering the entire volume of the element are stored during the computation. A check is made for initial yielding in the general shell elements at the end of each step of loading. The results of three numerical studies elucidate the localized nonlinear material behavior in a rotational shell structure. In the first example, an axisymmetric junction problem is studied to check the technique against published results. Then, in the last two examples, a cylindrical shell with a circumferential line crack and with a circular cutout are studied. Since the selection of the size of the substructure and the number of harmonics are very important for the localized plasticity problem in the rotational shell, detailed convergence studies are presented. It is shown that the local-global analysis is an attractive alternative to the entirely general element style analysis for axisymmetric shell structures with local imperfections.

ABSTRACT: The mode of collapse in many metallic shells is, oftentimes, one of localized collapse, wherein severe plastic deformation and high displacement gradients are localized within some region. The combined material and geometric non-linearity emanating from this local region is the predominant cause of instability in shells of revolution. In such a situation a local-global strategy is very useful for an efficient analysis. This strategy consists of employing two dimensional degenerated isoparametric shell elements with non-linear capability in a well defined 'local' zone where all the non-linearities are expected to be localized and which also contains some form of local deviation from axisymmetry such as a circumferential imperfection, cutouts, cracks, etc. Linear elastic ring type elements are employed in the remaining axisymmetric zone and the two zones are linked through a transformation between the degrees of freedom involved. The solution of the non-linear problem is achieved by appropriate condensation procedures to reduce the number of active degrees of freedom and the load incrementation is achieved by the well known 'arc length' iterative procedure. Numerical examples are presented to demonstrate that this strategy is very efficient and accurate for problems with well defined non-linear local zones. The capability of this strategy for treating problems with local material discontinuities such as cracks, cutouts, etc. as an efficient alternative to a complete two dimensional discretization is pointed out.

ABSTRACT: A finite element program is developed as a tool to analyse shells of revolution with local non-linearities. In reality, shells of revolution often exhibit local deviations, like a cut-out, a junction and/or an imperfection. The stress concentration around a local deviation may produce plasticity and/or geometric non-linearities in the surrounding region. The analytical model consists of three different types of elements: rotational, transitional and general. The rotational shell elements are used in the region where the shell is axisymmetrical and linear, while the two-dimensional general shell elements are deployed in the deviation region where non-linearities may occur. Transitional shell elements connect the two distinctively different types of elements to achieve displacement field continuities. The solution using the local-global system with
appropriate condensation and a predicted stress incremental procedure is suggested. It is shown that the technique is a very attractive alternative to the entirely general element style analysis for axisymmetric shell structures with local deviations.

ABSTRACT: A local–global finite element model suitable for the analysis of column-supported shells of revolution is presented. The model combines, in a single analysis, axisymmetric shell elements, general shell elements, and column elements. Axisymmetric or rotational shell elements which can accommodate geometric nonlinearities are employed in the axisymmetric portion of the shell. In this region, the nonaxisymmetric behavior in loading and deformation is accounted for by including appropriate Fourier harmonics. The column-supported area is modeled using individual column elements. The local zone is identified as the region consisting of the column elements and the physically and geometrically nonlinear general shell elements inserted between the column-support area and the axisymmetric shell portion. In addition, either deviations from the axisymmetric geometry of the shell, such as imperfections or cut-outs, and/or nonlinear materials can be easily included in the local zone. Examples which illustrate the proposed procedure are presented.

ABSTRACT: A local-global finite element technique suitable for the analysis of shells of revolution with localized non-axisymmetric effects such as cracks, cutouts and column supports is presented. Both material and geometrical nonlinearities are considered. The model combines, in a single analysis, rotational shell elements, general shell elements, and column elements. Rotational shell elements are employed in the axisymmetric portion of the shell, where the nonaxisymmetric behavior in loading and deformation is accounted for by including appropriate Fourier harmonics. In the local zone, where deviations from axisymmetry are contained, a general isoparametric shell element is employed. Continuity of displacements between the rotational and general shell elements is achieved either by a layer of transitional elements or by a direct coordinate transformation. If the shell is supported on a discrete system of columns, a standard 3-D beam element with six degrees-of-freedom per node is deployed. This local-global approach has been applied to a wide variety of shell problems.

ABSTRACT: The first part of the paper presents an extensive literature review of the research done on stability of stiffened plates under uniform compression. The methods developed to predict the overall buckling load are
first presented. The common methods and idealization to predict the local buckling load of stiffened plates are also discussed. The philosophies of the various techniques developed to compute the ultimate strength of the structure are then described. Finally, the optimization approaches developed for minimum weight design of the structure are presented. In the second part of the paper, theoretical formulations for the stability analysis of stiffened plates under uniform compression are presented. As a first stage, the governing differential equations for eccentric stiffening are derived. The transition to the orthotropic plate equation is shown through a simplifying assumption. It will be shown that for eccentric stiffening, three coupled differential equations need to be solved, while for concentric stiffening only Huber differential equation need to be considered. Then, an alternative energy-based approach is described for stability analysis of multi-stiffened plates under uniform compression. The structure is idealized as assembled plate and beam elements and rigidity connected at their junctions. The strain energy components for the plate and the stiffener elements are then derived in terms of the out-of- and in-plane displacement functions and sequential quadratic programming is then used to find the buckling load of the structure for given plate/stiffener geometric proportions. Efficiency of the method is compared with the finite element method. Finally, extensive results are presented to investigate the buckling behavior of multi-stiffened plates. The transition from the various buckling modes is shown by changing the plate/stiffener geometric parameters for various concentric and eccentric stiffening configurations. Influence of stiffener spacing, in-plane boundary condition on the buckling load is also highlighted. Using these results guidelines are proposed for efficient design of stiffened plates.

ABSTRACT: This paper describes the interactive buckling behaviour of thin-walled columns by means of a simple engineering analysis. After a brief review of individual column and plate buckling phenomena, the effect of one upon the other is investigated in the presence of initial imperfections. Estimates of the ultimate load capacity of such columns and the effects of material yielding are obtained. The results are compared with published experimental data, yielding good correspondence. The work clearly demonstrates that the interactive presence of Euler buckling, plate buckling, imperfections, and material yielding in thin-walled columns has a serious detrimental effect on their ultimate strength.

ABSTRACT: A comprehensive mode interaction analysis is presented for thin-walled columns having doubly symmetric cross-sections and carrying axial compression. It is shown that as a result of interaction of overall bending with the primary local mode, a “secondary” local mode having the same wavelength as the primary, is triggered. The problem is therefore viewed as one of interaction of three modes: viz. the overall (Euler) buckling mode and the two local modes. The analysis is based on Koiter's theory of mode interaction and employs finite strips to describe local buckling deformation. The column is treated as being loaded by a prescribed end compression at the centroid and a suitably prescribed end rotation to maintain concentricity of load application. Examples are presented to compare the results of the present theory with the currently available analytical results and to examine the behavior of typical cross-sections. Of particular interest is the considerably reduced imperfection-sensitivity of columns with well-separated critical stresses in comparison to that reported earlier in published literature.

ABSTRACT: A new formulation has been developed to study the interactive buckling of thin-walled columns having arbitrary cross-sections. The emphasis in this paper is, however, on columns with a single axis of symmetry. The formulation is designed to take into account the simultaneous interaction of the purely flexural and flexural-torsional overall modes of buckling with local buckling. The local buckling deformations are described in terms of a primary local mode together with two secondary local modes of the same wavelength. The latter are triggered by the interaction of bending in two perpendicular planes with the primary local mode. The three eigenmodes and the six second-order in-plane displacement fields are all computed using a finite-strip technique. The modulation of the amplitudes of the local modes and the overall displacements are described in terms of a one-dimensional finite element model. Thus a new beam element which has embedded in it the local buckling information is developed. It appears that the present analytical model is very versatile being applicable to members of arbitrary cross-section and end conditions. For columns with a single axis of symmetry, it is seen that there exists a non-linear coupling between the purely flexural and the flexural-torsional modes of buckling via local buckling deformation. Typical examples of channel section columns are presented. It is shown that the channel section columns of commonly used proportions are highly imperfection sensitive in the context of combined interaction of the enumerated modes of buckling. This sensitivity remains even for columns with well separated overall and local critical stresses—a feature which is in stark contrast with the behavior of the Tvergaard panel.

ABSTRACT: The paper reviews the theoretical foundations of a new analytical model developed for the study of nonlinear interaction of local and overall instabilities of axially compressed stiffened plates. It is shown that: the mixed second order field contains within itself all the essential secondary local modes liable to be triggered in the interaction; any such mode having an eigenvalue of the same order of magnitude as the primary local critical stress must be treated as a fundamental mode fully participating in the interaction in order that the analytical procedure is not riddled by singularities in the evaluation of the mixed second order field; and the technique of amplitude modulation is an effective substitute for accounting for a set of local modes of the same transverse description but of slightly differing wave lengths. The computational aspects are briefly touched upon and the form of an explicit potential energy function derived is shown. The results obtained using the present model are then compared with the theoretical results obtained by Koiter and Pignataro and Tvergaard for several cases. The question of optimality is examined. The results confirm the earlier finding of Tvergaard that the optimally designed panels would have the local critical stresses higher than the overall buckling ones. A comparison of the present theory against the experimental results obtained by Thompson et al. for panels with “stocky” and “thin” stiffeners is then presented. In all cases, there is found to be very good agreement between the experimental and theoretical results.

ABSTRACT: A strategy for minimum weight design of axially compressed stiffened panels is presented. It is first noted that the ‘naive’ criterion of simultaneous buckling in the local and overall modes, is not applicable in view of the severe imperfection-sensitivity of such designs. Imperfections are admitted and the required maximum capacity is viewed as the limit point of the nonlinear structure. The interaction of local and overall buckling—the central feature of the behavior of the panels—is accounted for by a well tested analytical model which incorporates amplitude modulation and the influence of secondary local mode(s). The optimization technique employed is based on Powell’s algorithm (VMCON). A systematic approach has been developed for the selection of the trial section. This is based on appropriately ‘beefing up’ and separating the critical stresses of a preliminary section obtained using the ‘naive’ criterion. A reduced model is developed by utilizing the patterns of overall deformation and amplitude modulation obtained from the nonlinear analysis of the trial section. A potential energy expression is developed in terms of the geometric parameters and four degrees of freedom. The algorithm was found to be extremely efficient from the points of view of both computational ease and accuracy. It is found that the configuration of the optimum panel with blade-type stiffeners lies in a transition from ‘thin’ to ‘stocky’ stiffener range. The weight of the optimized panel is sensitive to initial imperfections and can vary over a range of 20% due to moderate level of imperfections commonly assumed in the analyses. The weight of optimal panels with given values of the aspect ratios vary over a wide range and the careful selection of the width of the panel holds the key for successful optimal design.

ABSTRACT: Thick composite-layered shells under hydrostatic pressure are analyzed for buckling and postbuckling response using axisymmetric solid elements. The numerical approach is based on p-version finite elements in conjunction with appropriate trigonometric functions. Particular attention is given to the evaluation of interlaminar stresses in the postbuckling range. The postbuckling response is determined using an asymptotic approach. It is found that layered shells with \( Z \) (the modified Batdorf parameter) < 1000 are imperfection-sensitive with respect to local buckling; shells with relatively small radius to thickness ratios develop significant interlaminar shearing stresses, of the order of 50% of the buckling pressure, for buckling displacements of the order of one-tenth of the shell thickness. Together, the imperfection-sensitivity and the high inter-laminar stresses can precipitate failure before the classical critical pressures are reached. These factors must be considered along with the potential for interaction of local and overall buckling in optimally designed, stiffened shell configurations. Numerical analyses demonstrate the effectiveness of the p-version approach in achieving rapid convergence of the buckling pressures, the imperfection-sensitivity parameter and the magnitude of interlaminar stresses. Wherever possible, comparisons have been made with results available currently in the literature. It is found that for long shells (\( Z > 1000 \)), the Donnell type formulations can seriously underestimate the buckling pressures. The present formulation based on three-dimensional nonlinear elasticity offers an accurate, powerful and yet computationally effective means of analysis of thick shells.

ABSTRACT: In this paper a local–global analysis technique is presented for the non-linear analysis of shells of revolution with a localized material discontinuity in the form of a crack or a cutout. The local zone is modelled using two-dimensional general shell elements. Axisymmetric shell elements with Fourier description in the circumferential direction are used away from this local zone. In contrast to the earlier work of the authors, the geometric non-linearity is taken into account in the axisymmetric zone as well. The harmonic coupling in the axisymmetric zone is efficiently handled through the pseudo-load approach. A special preconditioned conjugate gradient iterative method is employed in conjunction with the arc length method for achieving improved convergence and negotiating the limit points. The attractive features of this methodology are that the tangential stiffness matrix of the structure is never assembled and factorized and that most of the computations are simple matrix–vector multiplications which are carried out efficiently at the element level. Numerical examples are presented to demonstrate the applicability of this method.

ABSTRACT: A novel methodology for the analysis of local and overall instabilities in stiffened plates and shells is proposed. The method consists of embedding the local buckling deformation—the buckling mode together with the associated second order fields—in an appropriate shell element. The local buckling deformation is controlled by a relatively small number of degrees of freedom which also allow for amplitude modulation. Examples of stringer-stiffened plates and shells subjected to axial compression are presented. Excellent agreement is found to exist between the results given by the method and those obtained from full blown nonlinear analysis and experiments. It is shown that the proposed technique offers a simple and considerably less expensive approach to mode interaction problems than conventional nonlinear finite element analysis. Imperfection-sensitivity under coincident buckling of axially compressed stringer-stiffened cylindrical shells is explored and it is shown that there can be an erosion of 50% of the load carrying capacity under imperfections of the kind unavoidable in practice.

ABSTRACT: A novel and computationally effective procedure for the study of the overall and local instabilities in composite ring stiffened shells subjected to hydrostatic pressure is presented. The key feature of the formulation employed is a judicious combination of Koiter's amplitude modulation technique and the Bykov-Hutchinson asymptotic procedure for the interactive buckling analysis. A potential energy function is formulated in terms of a comparatively small number of degrees-of-freedom, viz. the degrees-of-freedom depicting the amplitude modulating function and a scaling factor of the overall buckling mode. As a result of the amplitude modulation, there arise in the potential energy function non-vanishing cubic interactive terms which control the process of mode interaction. Imperfection-sensitivity under coincident buckling is examined. It appears that a 50% reduction of the buckling capacity must probably be allowed for as a result of modal
interaction under near-coincident buckling. The optimality under interactive buckling is also examined with the total volume of the material kept constant and the critical stress ratio varied.

“A structural efficiency study of isogrid-stiffened fiber composite laminate shells: buckling and postbuckling analyses and experiments”, Proceedings of the Tenth International Conference on Composite Materials (ICCM-10), edited by Ken Street, Whistler, B.C., Canada, August 1995

ABSTRACT: Recent advances in fiber composite manufacturing and structural efficiency requirements have led to the consideration of isogrid-stiffened fiber composite laminate shells for various aeronautical and space structural applications. Very little information, if any, on buckling and postbuckling of these grid-stiffened composite shells is currently available in the literature. In this paper, a combined analytical and experimental study is reported on buckling and postbuckling behavior of filament-wound fiber composite laminate cylindrical shells stiffened with isogrid structures made of the same composite. Buckling loads and postbuckling deformation characteristics of isogrid-stiffened composite shells, monocoque shells and pure composite isogrid stiffener structure have been obtained from linear bifurcation and geometric nonlinear postbuckling analyses and experiments.

ABSTRACT: An analytical study is presented in this paper on the effect of material nonlinearity on buckling and postbuckling of fiber composite laminate plates and shells subjected to general mechanical loading. The material nonlinearity of the composite is modelled by power-law type, nonlinear shear constitutive equations for each lamina. The nonlinear effective composite constitutive equations in an incremental form are incorporated into a geometrically nonlinear analysis for studying buckling and postbuckling deformations of composite laminate structures. A modified Riks' solution scheme with an updated Lagrangian formulation is used to construct the equilibrium path during composite postbuckling. Numerical examples are given to illustrate the effect of material nonlinearity on buckling load, postbuckling stiffness, and associated mode shape change of a composite structure under axial and pressure loading. Influences of lamination parameters, geometric imperfection, and loading mode on the postbuckling equilibrium path and load-bearing strength of the composite structure with the nonlinear material properties are also studied.

ABSTRACT: The dynamic instability of interior ring stiffened composite shells under hydrostatic pressure is
investigated. A shell structure such as a submarine vessel can undergo suddenly applied overpressure or successive shocks. In the presence of imperfections, the dynamic instability so triggered leads to a reduction of the load carrying capacity of the shell from that associated with quasi-static loading. Further, the large amplitude vibrations that occur prior to reaching the dynamic limiting pressure can have a damaging effect on the material of the shell. An asymptotic procedure is used in conjunction with p-version finite elements to extract the buckling mode and the associated second-order field. A single differential equation involving cubic nonlinearity is developed to characterize the dynamic behavior of the shell structure. This is solved by the Newmark method for time step integration along with Newton-Raphson iterations. Attention is focused on the reduction of the buckling pressure of the shell under dynamic loading, as well as the shell response at various increasing load levels until the displacements become unbounded.

ABSTRACT: The interaction of local and overall buckling in stiffened plates and cylindrical shells has been analyzed using a novel finite elements in which local buckling deformation has been embedded. Amplitude modulation, a key feature of the interactive buckling has been incorporated in the element formulation. The model has the following additional features: (i) the inclusion of a key secondary local mode where the cross-section has complete or approximate double symmetry; and (ii) the introduction of a simple approach for capturing localization of local buckling; this involves incorporating a single local buckling mode in the analysis, but letting the amplitude modulation function to be different for different elements. Numerical examples of plate and shell structures are presented to throw light on these aspects of the methodology as well as to demonstrate the accuracy and efficiency of the model.

ABSTRACT: This paper presents a summary of the work carried out at Washington University in recent years on the buckling and associated non-linear response and collapse of moderately thick composite cylindrical shells. Ring elements in conjunction with a three-dimensional elasticity formulation are employed in the analysis. The buckling and postbuckling imperfection sensitivity in individual modes is studied first. The problem of interaction between local and overall instabilities is then investigated in detail. Imperfection sensitivity of typical ring-stiffened shells is established by using a simple and effective approach that combines the asymptotic procedure and the amplitude modulation technique. The influence of dynamic application of the hydrostatic pressure is investigated with the simplified model. The results obtained are compared with those produced by a two-dimensional program package which includes full-fledged non-linear analysis with ring elements, and commercial programs wherever possible. The study has thrown light on several issues regarding the modeling and behavioral aspects of thick composite shells which are summarized at the conclusion of the paper.

ABSTRACT: The paper examines the feasibility of piezo-electric control of stiffened plates carrying axial compression and subject to interaction of local and overall buckling. A simple control strategy involving piezo-electric patches along the tips of the stiffeners carrying equal and opposite electric fields to resist bending of the stiffeners was found to effectively counteract the adverse effects of mode interaction and imperfection-sensitivity. For the dynamic problem, this strategy needed to be supplemented with patches attached to the surfaces of the plate in the middle of the panel to damp out local buckling oscillations. Two panels were considered, these being scaled replicas of each other. This enabled an examination of the scaling laws of response with practical applications in view. The results demonstrate that the structural performance of optimally designed stiffened structures can be enhanced with minimal energy consumption by appropriately designed piezo-electric patch configuration.

ABSTRACT: Filament-wound, fiber-reinforced polymer-matrix composite laminate tubes have been used for a wide range of engineering applications, owing to their high specific stiffness, strength and superior corrosion resistance. Leakage failure of composite tubes under multiaxial loading has been an important design concern. Extensive analytical and experimental investigations have recently been reported on leakage failure of composite tubes. These investigations developed deterministic estimates of leakage failure for different combinations of axial load and internal pressure. Effects of uncertainties in material properties and laminate construction on leakage failure need to be studied in detail. In this study; probabilistic analyses are performed to predict first-ply failure of angle-ply composite laminate tubes under combined internal pressure and axial loading. Randomness is considered in (1) elastic moduli along principal lamina directions; (2) uniaxial matrix-dominated strengths of each lamina; and (3) local thickness variation of individual plies. The probabilistic finite element analysis is performed using the ANSYS program and Latin hypercube sampling. Influence of each basic variable on first-ply failure is evaluated. These are compared with experimental results available in the literature.

ABSTRACT: The buckling problem of angle-ply laminated long hollow cylinders under axial compression is investigated on the basis of 3D elasticity considerations. The study is based on a recursive and successive approximation method and the introduction of a periodic complex displacement field. By this approach, the composite cylinders may be composed of a number of anisotropic layers, each of which may have different material properties, thicknesses, and laminate profile. The eigenvalue problem, from which the buckling load is
found, always has a dimension of 3 x 3, regardless of the number of the layers. The buckling of either symmetric or antisymmetric angle-ply laminated cylinders under axial compression is investigated through a parametric study. The results are presented in graphic form for cylinders having various thicknesses and layups.

[10-13] (for external pressure). However, the problem of finding the value of the dynamic load for which the limiting state is reached in a shell has been solved only in [16] from among the papers known to the authors, where the bending and stresses in a steel shell were determined in a geometrically linear formulation upon the action of an axial compressive pulse of rectangular shape. The content of a procedure developed by the authors for the solution by the Bubnov-Galerkin method of the geometrically nonlinear equations of average bending under the action of dynamic axial compression or external pressure on an orthotropic cylindrical shell is briefly outlined in this article. Examples are given of the determination of the critical loads for multilayer shells using the strength surfaces for composites under conditions of a plane stress state…

ABSTRACT: A procedure has been shown for calculating the stress-strain state of cylindrical multilayer shells made from composite materials under the combined action of dynamic axial compression and dynamic external pressure, as well as with different variants of combined loading with static and dynamic forces. An investigation has been made of the effect on the mode of the buckled shell surface of the ratio of the application rate of dynamic loads; ranges of loading rates have been established in which stresses predominate caused either by axial compression or external pressure. It has been shown that, as a result of preliminary static loading, a marked change occurs in the initial imperfections of the shell mode which affects subsequent dynamic buckling. To calculate the time when the first defect occurs and its location in the shell body, a procedure has been devised for layer-by-layer strength analysis employing a tensor-polynomial criterion. It was demonstrated that the level of preliminary static loading noticeably affects the time until the first failure of the layer, not only a reduction of this time being possible with an increase in the static loads, but also an increase in it.

PARTIAL ABSTRACT: The main characteristic feature of the process of buckling of cylindrical shells acted on by both static and dynamic axial compressive loads is its high sensitivity to initial imperfections of the shape of the shell. The assumption that, among the factors which reduce the carrying capacity of a shell, deviations from an ideal cylindrical shape of the surface play a dominant role was first advanced in [1]. It subsequently received convincing confirmation in numerous experimental and theoretical investigations. Two trends have developed in the solution of the problem of static stability…

“Analytical probabilistic modeling of initial failure and reliability of laminated composite structures”,
doi:10.1016/S0020-7683(97)00081-4

ABSTRACT: An analytical approach based on the theory of stochastic processes is developed for the stochastic initial failure analysis and reliability predictions of thin-walled laminated composite structures. The probability of initial failure is calculated using theory of rare passages of the random strain vector field out of the prescribed region of allowable states. The region is limited by the ultimate strain surfaces adopted for each individual layer in the laminate. The surfaces, in their turn, are defined in terms of the scatters in the ultimate strains for the composite layer. Reliability function of a composite layer having random elastic characteristics and loaded with random in-plane tractions is determined through the probability of its initial failure. The reliability function of the laminated composite structure is then calculated through the failure probabilities of individual layers, using the weakest link model. The proposed approach allows one to solve diverse stochastic problems and requires substantially less computational expenses than Monte Carlo simulation technique. The approach may be invaluable for a quick evaluation of various competitive design projects when considering laminated composite structures under the reliability constraint. Applications of the developed approach are illustrated on the examples of reliability predictions of laminated composite cylindrical shells under the effect of random internal pressure and laminated composite plates under random biaxial loading. Numerical results reveal specific probabilistic phenomena related to the effects of ply lay-up, scatters in mechanical and strength characteristics and random loading histories. Results obtained from the developed analytical approach are compared to those calculated with Monte Carlo simulation technique.

V.V. Vendyukov and V.V. Deryushev (Rostov-na-Donu, Russia), “Dynamic short-wave buckling of thin-walled cylindrical shells upon local action of an external pressure pulse”, Scientific and Technical Section,
ABSTRACT: We present the results of experimental investigations of dynamic instability (buckling) of thin-walled cylindrical shells upon local action of an external pressure impulse. In order to create the local short-term loading, we used pulsed radiation from a CO\textsubscript{2} laser. The test pieces were smooth and reinforced shells made from aluminum alloys. The nature of the buckled wave in the treated region and the magnitude of the critical impulse correspond to the short-wave type of buckling in the shell and are determined by the amplitude of the pressure pulse. Axial static compression of the shell leads to a decrease in the critical impulse and an increase in the number of waves in the meridional direction within the treated region.

ABSTRACT: A coupled fluid structure interaction problem is analyzed using semi-analytical finite element method involving composite cylindrical shells conveying hot fluid for free vibration and buckling behavior. The system under study is assumed to have a steady flow of hot fluid and the temperature variation is axisymmetric. First order shear deformation theory is used to model the elastic shells of revolution. Geometric stiffness matrix is evaluated to consider the effects of axisymmetric temperature variation through the shell continuum due to flow of hot fluid. The fluid domain is modeled using the wave equation. Numerical results of the studies on composite cylindrical shells made of HS-Graphite/Epoxy with two different length to radius ratios and clamped–clamped boundary condition conveying hot fluid are presented. The variation of the natural frequency of the coupled system is evaluated with the steady flow of the hot fluid. The influence of the temperature on the mean axial flow velocity through the shell is critically examined. The critical velocity of the hot fluid and cold fluid which leads to shell instability is compared thus establishing the fact that the lowest critical velocity of the hot fluid coincides with the mode corresponding to the lowest critical thermal buckling temperature. Various fibre angles are also considered in the study and its influence is also examined.

ABSTRACT: Linear thermal buckling and free vibration analysis are presented for functionally graded cylindrical shells with clamped–clamped boundary condition based on temperature-dependent material properties. The material properties of functionally graded materials (FGM) shell are assumed to vary smoothly
and continuously across the thickness. With high-temperature specified on the inner surface of the FGM shell and outer surface at ambient temperature, 1D heat conduction equation along the thickness of the shell is applied to determine the temperature distribution; thereby, the material properties based on temperature distribution are made available for thermal buckling and free vibration analysis. First-order shear deformation theory along with Fourier series expansion of the displacement variables in the circumferential direction are used to model the FGM shell. Numerical studies involved the understanding of the influence of the power-law index, r/h and l/r ratios on the critical buckling temperature. Free vibration studies of FGM shells under elevated temperature show that the fall in natural frequency is very drastic for the mode corresponding to the lowest natural frequency when compared to the lowest buckling temperature mode.

ABSTRACT: In this paper, the free vibration analysis of isotropic conical shell panel with all edges clamped carried out by using an integral equation technique is described. Results of a parametric study are presented.

ABSTRACT: The present paper deals with the dynamic response analysis of stiffened conical shell panels using an integral equation method in the space domain. The smearing technique is used for closely spaced stiffeners. The time domain analysis has been done using the mode superposition method. The effect of eccentricity of stiffeners has been studied.

ABSTRACT: In this paper, the application of integral equation technique to dynamic response problem has been illustrated by considering the layered conical shell panel. The method consists of using the integral equation technique in the space domain and direct integration using the Wilson-theta method in the time domain. Since results are not available for layered conical shell panels, the values obtained for the particular case of isotropic cylindrical panel have been compared with the results obtained using a different procedure, viz series solution combined with mode superposition.

ABSTRACT: The theory of nonlinear stability for a truncated shallow conical shell with variable thickness under the action of uniform pressure was presented. The fundamental equations and boundary conditions were derived by means of calculus of variations. An analytic solution for the critical buckling pressure of the shell with a hyperbolically varying thickness is obtained by use of modified iteration method. The results of numerical calculations are presented in diagrams, which show the influence of geometrical and physical parameters on the buckling behavior.

Reimerdes (Department of Aerospace and Lightweight Structures, RWTH Aachen University, 52062 Aachen, Germany), “A strip element with interface layer for the prediction of delamination in buckled composite panels”, The European Commission Project COCOMAT (Improved MATerial Exploitation at Safe Design of COmposite Airframe Structures by Accurate Simulation of COllapse), 2006

ABSTRACT: An element for the prediction of delamination is presented, that is based on the combination of two shells with an interface layer. This interface layer enables the calculation of stresses between the shells, which are the input for a failure criterion indicating the onset of delamination between the shells. The element is implemented into a tool for the postbuckling simulation of composite stiffened panels, which is based on the discretisation of the structure by strip elements, while the buckling and postbuckling behaviour are described by trigonometric functions. As less degrees of freedom are necessary compared to a finite element formulation, the computational effort is reduced. Implementing the strip element with interface layer into this tool enables the prediction of the onset of delamination during the postbuckling analysis. In the following, the approach and its validation are presented.

ABSTRACT: In recent years, structures made up of functionally graded materials (FGMs) have received considerable attention for use in high-temperature applications. In this article, a finite element formulation based on First-Order Shear Deformation Theory (FSDT) is used to study the thermal buckling and vibration behavior of truncated FGM conical shells in a high-temperature environment. A Fourier series expansion for the displacement variable in the circumferential direction is used to model the FGM conical shell. The material properties of the truncated FGM conical shells are functionally graded in the thickness direction according to a volume fraction power law distribution. Temperature-dependent material properties are considered to carry out a linear thermal buckling and free vibration analysis. The conical shell is assumed to be clamped-clamped and has a high temperature specified on the inner surface while the outer surface is at ambient temperature. The one-dimensional heat conduction equation is used across the thickness of the conical shell to determine the temperature distribution and thereby the material properties. In addition, the influence of initial stresses on the frequency behavior of FGM shells has also been investigated. Numerical studies involving the understanding of the role of power law index, r/h ratios, and semi-vertex angle on the thermal buckling temperature as well as on vibration have been carried out.

ABSTRACT: This paper is concerned with the derivation of stiffness matrices for the buckling or vibration analysis of any structure consisting of a series of long, thin, flat plates rigidly connected together at their longitudinal edges. Each plate is assumed to be subjected to a basic state of plane stress which is longitudinally invariant, and it is further assumed that the mode of buckling or vibration varies sinusoidally in the longitudinal direction. During buckling or vibration, the edges of any individual plate are subjected to additional systems of forces and moments which are sinusoidally distributed along the edges, and these give rise to sinusoidally varying edge displacements and rotations. Spatial phase differences between the forces and displacements are accounted for by defining them in terms of complex quantities. The sinusoidal edge forces and displacements are split into two uncoupled systems, corresponding to out-of-plane and in-plane displacements, and two stiffness matrices are defined. The out-of-plane stiffness matrix is shown to be in general complex, and Hermitian in form, but the inplane stiffness matrix is real and symmetrical. Explicit expressions are derived for the elements of the matrices, in which all the essential destabilizing effects of the basic stresses, as well as dynamic effects, are included. Finally, it is shown that buckling and vibration phenomena for any structure of this type are closely interrelated.

ABSTRACT: Many structures consist of a set of thin rectangular flat plates of uniform thickness which are rigidly connected together along their longitudinal edges. Two computer programs which are applicable to such structures are described. They are called gasvip and vipal and they use an exact method of analysis, either to find natural frequencies in the presence of uniform longitudinal stress, or to find the initial buckling stress in uniform longitudinal compression. Gasvip sets up the overall stiffness matrix of the structure, whereas vipal enables substructures to be used. There are some types of problem which cannot be solved by using Vipal, but where it can be used it often takes much less computer time than gasvip. vipal also has the advantage that there is virtually no limit on the number of nodes (i.e., line junctions between component plates) which can be handled within about 4K of core store.

ABSTRACT: This paper describes the underlying theory, and a general-purpose computer program, VIPASA, for determining the critical buckling stresses or natural frequencies of vibration of thin prismatic structures, consisting of a series of plates rigidly connected together along longitudinal edges. Each plate may be either isotropic or anisotropic and may carry a basic stress system consisting of longitudinal and transverse direct stress combined with shear. The structure is assumed to be subjected to a “dead load” system which does not cause buckling; in addition a “live load” system, defined in magnitude by a single load factor, may be applied and the value of the load factor at buckling is determined. Alternatively the natural frequencies of vibration of
the structure when subjected to the dead load system are determined. Any number of critical load factors or natural frequencies can be obtained. The theory is based upon the assumption that all modes are sinusoidal, in the sense that all three components of displacement vary sinusoidally along any longitudinal line, but phase differences are incorporated to allow for the effects of anisotropy and shear. Apart from this assumption no further approximations are made other than those inherent in thin plate theory.

ABSTRACT: The VIPASA computer program accurately treats buckling and vibration of prismatic plate assemblies with a response that varies sinusoidally in the longitudinal direction. In-plane shear loading of component plates produces skewed mode shapes that do not conform to desired support conditions, and this has placed a limitation on the general applicability of VIPASA. This problem is overcome in the present paper by coupling the VIPASA stiffness matrices for different wavelength responses through the method of Lagrangian Multipliers. Supports at arbitrary locations, including support provided by any elastic structure, are included in the theory. Examples illustrate the accuracy and convergence of the method and some of the principal features of the solution. The complete generality and capability of VIPASA have been retained in a computer program VICON that permits constraints and a supporting structure consisting of any number of transverse beam-columns.

ABSTRACT: An existing algorithm enables natural frequencies or critical load factors to be found with certainty when “exact” stiffness matrices are used. This algorithm is extended to permit Lagrangian Multipliers to be used to couple the “exact” stiffness matrices of component structures to represent connections between the structures. The new algorithm also permits coupling of the stiffness matrices for different assumed wavelengths of sinusoidal response of a given structure with the stiffness matrices of other structures to satisfy required constraint conditions. The algorithm applies to problems formulated using real or complex arithmetic.

ABSTRACT: The new computer program VISCAN enables exact modal densities to be computed very
economically for any prismatic assembly of isotropic or anisotropic flat plates which are simply supported at their ends and are rigidly connected together along their longitudinal edges, so long as bending and in-plane displacements are uncoupled for the anisotropic plates. A description of how VISCAN was developed from the well established program VIPASA is followed by results for flat, corrugated and stiffened panels and for a cylindrical shell, a corrugated cylinder and a stiffened cylinder. Comparisons are made with existing experimental results for all these structures except the stiffened panel. The method used to change VIPASA into VISCAN could be applied to other existing computer programs to enable exact modal densities to be found for many additional types of structures.

ABSTRACT: A standard stiffness matrix procedure which permits any combination of rigid, elastic, pinned or sliding connections of the degrees of freedom at the ends of a member to the nodes of its parent structure is described, in order to show how easily it can be extended to allow an existing algorithm to be used to ensure that no eigenvalues of the parent structure can be missed even when “exact” member theory is used. The eigenvalues are the natural frequencies of undamped free vibration analyses or the critical load factors of buckling problems. The method preserves the exactness of the member theory and an efficient method for computer application is indicated. The theory also permits any combination of rigid, elastic, pinned or sliding connections between the freedoms of a substructure and those of its parent structure.

ABSTRACT: This review covers the many applications of the Wittrick-Williams algorithm, which ensures that no critical buckling loads, or natural frequencies of undamped free vibration, are missed even when using the ‘exact’ member equations obtained by solving the appropriate differential equations. The review includes: plane and space frames; prismatic assemblies of isotropic or anisotropic plates, including in-plane plate shear loads; exact multi-level substructuring; design; damping; efficient solution of rotationally or linearly repetitive structures; use of Lagrangian multipliers; programmable pocket calculator methods; program listings for small computers and; references to large computer programs.

“A parametric study of optimum designs for benchmark stiffened wing panels”, Composites Engineering, Vol. 3, Nos. 7-8, 1993, pp. 619-632, Special Issue: Use of Composites in Aircraft
doi:10.1016/0961-9526(93)90086-Y
ABSTRACT: Results are presented for the most heavily and lightly loaded of eight benchmark stiffened laminated wing panels defined from a Dornier wing by a GARTEUR (Group for Aeronautical Research and Technology in Europe) working party. These benchmark panels had three identical and equally spaced blade
stiffeners. The results were chosen to help designers to understand many important aspects of the choice of design variables, and of the effects of changing the sophistication of modelling and theory used, for a wide range of wing panels. The percentage changes of (global) optimum mass are presented, along with the final values of the design variables. Some examples of mass histories and of (rejected) local optimum masses are also given. The principal design variables are skin and blade ply thicknesses and blade height. Additional factors considered include the effects of adding flanges to the blades whose plies either matched those of the blades or were allowed to vary independently, varying the number of stiffeners, allowing the stiffeners to differ from each other, varying stiffener spacing, varying some ply angles, including the stiffening effect of adjacent spars, including the effects of continuity with laterally adjacent panels, including through thickness shear deformation in the panel analysis and analysing the panel with its true skewed shape rather than approximating it as rectangular in plan.

ABSTRACT: The structural efficiency of a range of panels under uniaxial compression is investigated using the optimum buckling design program VICONOPT. The design uses very efficient VIPASA analysis to guard against all possible modes of failure, together with a tailored sizing strategy. The panels all have nine blades, zed or hat stiffeners and between three and fifteen design variables, covering traditional design using one size of stiffener and more sophisticated design with five sizes of stiffener. Results show that using two stiffener sizes or two stiffener types in alternate positions across the panel width can produce mass savings of up to 30% compared with traditional design. Convergence on an optimum normally occurs within six sizing cycles, but up to twelve sizing cycles are required for sophisticated designs when the initial configuration is poorly chosen. Computational efficiency and material strength constraints are also considered.

ABSTRACT: Optimum design of a blade-stiffened panel of composite/honeycomb sandwich construction and a metal T-stiffened panel is considered using the buckling and strength constraint program VICONOPT. Both panels have practical loadings which produce a nonlinear out-of-plane bending moment, calculated using beam-column expressions. Large deflection finite element analysis of the optima shows that modifications to these expressions are necessary when the panels are shear loaded. The use of integrally machined stiffeners, as opposed to a conventional, built-up panel designed using PANDA2, is shown to permit 20% mass saving when the latter has no postbuckling strength and 3% saving when postbuckling strength is allowed for.

EXECUTIVE SUMMARY: This effort is funded by the Aging Aircraft Squadron of the Aeronautical Enterprise Program Office (ASC/AAA, Col P.J. Clark). The prime contractor for the Air Vehicle Health Management program, of which this effort is a part, is S&K Technologies, Inc., Dayton, OH (Mr. Kevin Boyd). Twenty-seven Z-stiffened panels, intended to simulate upper wing skin panels of the Boeing 707, were tested to failure in compression to determine buckling strength. Pristine panels and panels with machined grindouts (with various depths up to 62.6% of the panel skin thickness) were tested to failure. Nine panels each of three configurations were fabricated for testing. The results showed a degradation of buckling strength with grindout depth that could be modeled with a modified Johnson-Euler method and a modified Gerard’s method for long and short panels respectively. The panels with the lower slenderness ratio (short panels) were degraded more by a given grindout depth than were their more slender counterparts. However, it was found that span-wise grindouts along the center stiffener—even deep ones—do not have a severe effect on strength. Even at over 60% grindout depth, the worst degradation was less than a 12% reduction in strength. A small number of panels were tested with deep chord-wise grindouts. These tests showed that the strength of the panel was dramatically reduced by these grindouts, which were transverse to the loading direction.

ABSTRACT: This paper presents axial compression tests on longitudinally stiffened aluminium panels in alloy AA6082 temper T6. A specially designed test facility is presented. The panels are built up with extruded aluminium profiles connected by longitudinal welds. Two panel types are considered, with open section (L-shaped) stiffeners and closed section stiffeners, respectively. The experimental programme comprises tests on single panels supported along all four edges and as a special case panels supported at two edges only. Tests on panels with lengths 1.0 m and 2.0 m are reported. Two deformation modes were observed in the tests: regular flexural buckling of the entire panel towards either the stiffener side or the plating side, and, for the case of the panels with L-shaped stiffeners, collapse initiated by stiffener tripping. The panel resistance is compared with the design resistance obtained from the European standard for aluminium structures, Eurocode 9. For all panels the experimental capacity exceeded the design value.

ABSTRACT: Existing theory and the associated computer program VICONOPT deal with infinitely wide plate assemblies given that boundary conditions on all sides of each panel form a rectangle. They also deal with cases when the four supports form a parallelogram so that the plate is a skew plate. This is true provided the panel is of finite width, i.e. isolated from any adjacent panels, which is the case commonly modelled in practice. It does not represent what happens in the real structure, however, where normally there is continuity with the adjacent panel. The present paper shows how the theory and the computer program VICONOPT can be modified so that skewed plate assemblies that are infinitely wide and repeat at transverse intervals can now be modelled exactly. The paper also shows that the theory can be used, if a small measure of approximation is accepted, to model this situation by analysing only one of the identical stiffeners with associated panel skin in the common situations where the panel has equally spaced, identical, longitudinal stiffeners between each adjacent pair of longitudinal lines of support. Illustrative results are given.
ABSTRACT: A procedure is presented for the buckling analysis of prismatic skew plate assemblies subject to invariant in-plane stresses. Based on the exact solution of the plate differential equations, the method of Lagrangian multipliers is used to enforce the transverse skew boundaries by a sufficient number of point constraints. Analysis assumes that the plate is infinitely long and that supports repeat at bay length intervals, typifying the continuity found in aircraft wing construction. Following a brief derivation of the formulation adopted, results are presented and comparisons are made with other analyses for an unstiffened isotropic skew plate, subject to pure compression loading with both simply supported and clamped boundary conditions. Results for four benchmark stiffened panels, i.e. plate assemblies, incorporating composite material and combined loading are also given for a range of skew angles.

ABSTRACT: This paper provides a Koiter-type initial post-buckling analysis for prismatic plate assemblies made of isotropic materials. The structures are assumed to consist of a series of long flat strips rigidly connected together at their edges, subjected to longitudinal in-plane compressive stress. The transcendental eigenvalue problems, which arise when exact solutions to the member equations are used to form the stiffness matrix of the plate assemblies, are first solved to obtain the buckling load and corresponding buckling mode of the structure. The analysis then obtains exact solutions to the post-buckling member equations and the a-coefficient and b-coefficient which characterize the initial post-buckling behavior. The post-buckling characteristics of the stiffened plate are found to be influenced significantly by the height of the stiffener.

ABSTRACT: The use of substructuring in the buckling and vibration analysis of large structures permits very substantial improvements in computational efficiency. The exact multi-level substructuring capability of the widely used computer program VICONOPT for the analysis and optimum design of prismatic plate assemblies has been extended by the inclusion of new theory, presented in this paper, which permits constraints on any of the internal or external nodes of substructures. The computational savings by using substructuring in this way are shown to be typically 50–70% compared with previous VICONOPT solutions. The theory is applicable to any method or computer code for structures whose buckling or vibration modes combine responses of different half-wavelengths, with VICONOPT being used as an example.
ABSTRACT: A comparison of ‘exact’ and approximate methods for the determination of critical buckling loads of prismatic benchmark metal and composite panels is presented. The panels are stiffened by either J-, blade- or hat-stiffeners and are representative of typical aircraft wing panel configurations, with in-plane shear and compression load combinations. Buckling design curves and modes are illustrated, and associated CPU times are given to demonstrate the accuracy and efficiency of the approximations adopted. Initial results for the benchmarks, which are rectangular in plan-form, are compared with rigorous finite element solutions. Thereafter, attention is focused on results for the same panels but with parallelogram plan-form. Two analysis methods based on Classical Plate Theory are used as follows: an existing, ‘exact’ method, incorporating Lagrangian multipliers to constrain the transverse (or skew) boundary conditions; and a recently developed approximate infinite width technique, based on the previous one but analysing only a repeating portion of the plate assembly.

ABSTRACT: A non-shallow non-linear shell theory is used to analyze the parametric resonance of orthotropic circular cylindrical shells under harmonically varying axial compression. As special cases, post-buckling and non-linear vibration problems are also studied. In the analysis the non-linear terms and the inertias contributed by both normal displacement and circumferential displacement are included. Therefore the final dynamic system includes two equations in w and v. The transverse shear deformation is taken into account by a first order theory. The spatial variables in the governing equations are eliminated by the Galerkin procedure. The final ordinary differential equations are solved by an asymptotic method. Numerical results show the dependence of the post-critical behaviour on the properties of material, geometry and excitation.

ABSTRACT: Buckling, postbuckling, nonlinear vibration and parametric resonance of thick circular cylindrical
shells under axial compression are analyzed in this paper. The theory developed is based on a nonlinear and non-shallow thick shell theory, with its final equations involving two unknowns, the circumferential displacement \( v \) and the radial displacement \( w \). The shell wall is cross-ply laminated. The plies are specially orthotropic, but the lamination can be unsymmetric. The axial load is assumed to be harmonically time dependent, or constant as a special case. The governing nonlinear partial differential equations are reduced to nonlinear ordinary differential equations in terms of time by the Galerkin procedure. Then, an asymptotic method is used to solve the resulting nonlinear ordinary differential equations. The numerical results for buckling loads are shown to compare very well with those of three-dimensional theories in the literature, even for very thick shells. The effects of lay-up and thickness on postbuckling equilibrium, nonlinear vibration and parametric resonance are demonstrated by examples.

ABSTRACT: This paper presents a post-buckling analysis for prismatic plate assemblies made of isotropic materials. The structures are assumed to consist of a series of long flat strips rigidly connected together at their edges, subjected to longitudinal in-plane compressive load. The buckling load and corresponding buckling mode of the structure are first obtained as the results of transcendental eigenvalue problems, which arise when exact solutions to the member differential equations are used to form the stiffness matrix of the plate assemblies. The other post-buckling field functions are also obtained analytically as exact solutions to the member differential equations. Results for the load end-shortening and load–deflection relationships for long prismatic plate assembly examples are obtained and compared with results obtained by other authors.

ABSTRACT: A recently developed reference surface element technique is used to model the behaviour of the buckling and postbuckling of delaminated plates and shells. The technique can be easily incorporated into any finite element analysis programme for which the beam, plate and shell elements etc. satisfy the Reissner–Mindlin assumption. In this paper, the reference surface element formulation of a four-node C0 quadrilateral membrane-shear-bending element (ZQUA24) is presented and numerical investigations are performed for composite plates and shells with various delamination shapes. The numerical results show that the present technique is simple, reliable and able to model delamination buckling and postbuckling behaviour of laminated plates or shells. Observations of practical engineering significance are obtained from the study.

ABSTRACT: An efficient method for the buckling and vibration analysis of plates or stiffened panels with clamped ends is presented. The method uses Lagrangian multipliers to couple sinusoidal modes with appropriate half-wavelengths of response, thereby enforcing the end conditions at discrete point supports. Clamped ends can usually be modelled accurately using only a few point supports, while arguments from symmetry often enable some of the required end conditions to be satisfied without explicitly applying constraints. In such cases few half-wavelengths are needed to obtain excellent accuracy. Solutions obtained for the simple limiting case of single plates are exact or within 1% of the classical or other reported solutions. Solutions obtained for stiffened panels are in close agreement with those obtained using finite element analysis.

ABSTRACT: The problem of the buckling of finite length externally constrained thin circular cylinders is solved to yield a generalized eigenvalue problem with constraint conditions. The solution is based on an inverse iteration procedure in which the non-linear complementary equation is solved by a non-smooth version of Newton's method that saves computer time and space when compared to a linear complementary algorithm. The numerical results show that the method proposed is effective and that the critical buckling load of the constrained cylinder is almost independent of the length of the cylinder, unlike the critical load of free (unconstrained) thin cylinders. In the direction of its axis, the shell is discretized by finite strips which circumferentially use straight bar and beam displacement functions. It is proved that when the widths of the strips approach zero, the geometrical relationships used in this paper approach those of Koiter–Sanders cylindrical shell theory.

ABSTRACT: The current paper outlines recent developments to algorithms and software for critical buckling and natural vibration analysis and optimum design of prismatic plate assemblies, based on the exact strip approach and the Wittrick—Williams algorithm. The current paper acts as a single source document discussing recent progress and planned future explorations in: initial local postbuckling of stiffened panels; discrete optimization of composite structures to satisfy manufacturing requirements; discontinuous cost functions; constraints on fundamental natural frequencies and frequency-free bands; a feasibility study of response surface optimization; and multi-level optimization of composite aircraft wings. The numerous references provide fuller technical details and illustrative examples.

ABSTRACT: A weighted solution for the critical load of a cylindrical shell is presented. To determine the weights, some special known results are applied. The method can be used to solve generally complicated buckling problems by making use of the solutions of special simple problems. Lastly, some numerical solutions for the same problem are obtained by finite elements. Comparison between the solution method in this paper, the finite element solution and cited results in the literature, shows that the weighted solution has good precision.

ABSTRACT: This paper summarized currently available techniques of setting up flexural–torsional buckling theory of thin-walled members. It is found that all the existing methods introduced a nonlinear load potential in their total potentials, while based on the classical variational principle for stability of a solid structure, no such load potential should be included. This situation has led to an inconsistency between some widely referenced monographs in buckling theories of beams with mono-symmetrical cross-sections. This paper provides a new theory for flexural–torsional buckling of thin-walled members based on the classical variational principle and the theory for thin-walled shells. No nonlinear load potential is included, but a new term: nonlinear strain energy from transverse stresses, which has been neglected in previous theories of thin-walled members, is introduced in. It is found that the nonlinear load potential is not equivalent to the contribution of transverse stresses for beams with mono-symmetrical cross-sections, which causes the inconsistency mentioned above. The comparison shows that the proposed theory and the traditional theory are the same for most cases encountered in practice.
ABSTRACT: The elastic-plastic buckling of cylindrical shells under torsion is analysed with a deep thick-shell model under various boundary conditions. The word ‘deep’ means that in the general equations of equilibrium the three non-linear terms that involve the torsional force are all retained for the buckling analysis. In the Donnell-type shallow-shell theory, however, only one of such terms is retained. The word ‘thick’ means that in calculating strains and stress resultants the factor $(1+z/R)$ is retained. This factor results from the trapezoid-like shape of the cross-section and is usually neglected in the thin-shell theory. For boundary conditions, not only the conventional geometrical boundary conditions, which are in terms of displacements and rotations, but also the mechanical boundary conditions, which are in terms of forces and moments, are considered. The numerical results of examples assess the effect of the additional non-linear terms, the effect of the factor $(1+z/R)$, and the effect of the mechanical boundary conditions.

ABSTRACT: Hoo Fatt’s model was modified to obtain analytical solutions of plastic collapse for 3-D damaged cylindrical shells. To assess the effective wall thickness of a damaged pipeline, we used ASME B31G and its burst test results with Hauch and Bai’s approach. The effective thickness represents the corroded region of a pipe; it helps to transfer the response of the undamaged area near the damaged area. We propose solutions for the buckling of a damaged shell subjected to uniform external pressure. In these solutions, we extended Timoshenko’s solutions for the elastic-plastic buckle of linear elastic in a perfectly plastic cylindrical shell. The plastic collapse of a damaged shell is based on a modification of the interaction formula of the fully plastic membrane forces and bending moments in the nonuniform cylinder.

ABSTRACT: The buckling of initially stressed Mindlin plates is considered using a thick finite strip method. The method is compared with a wide variety of published results and for both thin and moderately thick plates
excellent accuracy is obtained. Some further results are obtained for initially stressed rectangular plates with two opposite edges simply supported and various support conditions on the remaining sides. In general, it is found that for moderately thick plates, Mindlin's plate theory gives lower buckling loads than those obtained using classical thin plate theory.

ABSTRACT: A finite strip method is presented for calculating the linear buckling stresses of structural assemblies of long, thin plate components which, in general, are curved and which are rigidly joined together at their longitudinal edges. It is assumed that on buckling under the action of a biaxial direct stress field the perturbation forces and displacements all vary sinusoidally in the longitudinal direction. A stiffness matrix relating the amplitudes of the perturbation forces and displacements is developed for the curved strip on the further assumption of relatively high-order polynomial variations of the displacement components around the plate width. Numerical results are presented of the application of the curved strip in calculating the buckling stresses of plates, cylinders, panels and formed sections.

ABSTRACT: Four finite strip models are developed for the flexural vibration analysis of rectangular plates based on Mindlin theory which takes account of transverse shear deformation and of rotary inertia. The strips are simply supported at their ends and differ one from another in the order of interpolation employed to represent the variation of each of the plate deflection and the two rotations across the strip. The four models are based in turn on quadratic, cubic, quartic and quintic interpolation. Numerical results are presented of applications of the strip models to the calculation of the natural frequencies of both thin and moderately thick plates. The influence that the assumed value of the shear coefficient has on natural frequencies is considered for two particular moderately thick plates.

ABSTRACT: The Rayleigh-Ritz method is applied to the prediction of the natural frequencies of flexural vibration of square plates having general boundary conditions. The analysis is based on the use of Mindlin plate theory so that the effects of shear deformation and rotary inertia are included. The spatial variations of the plate deflection and the two rotations over the plate middle surface are assumed to be series of products of appropriate Timoshenko beam functions. Results are presented for a number of types of plate and these demonstrate the manner of convergence of the method as the number of terms in the assumed series increases.

ABSTRACT: The elastic buckling of rectangular Mindlin plates is considered using two related methods of
analysis. These methods are the Rayleight-Ritz method and one of its piece-wise forms, the finite strip method. Arbitrary combinations of the standard boundary conditions of clamped, simply-supported and free edges are accommodated by the use in the assumed displacement fields of the normal modes of vibration of Timoshenko beams. The applied membrane stress field leading to buckling can comprise biaxial direct stress plus shear stress. A range of numerical applications is described for isotropic and transversely isotropic plates of thin and moderately thick geometry. The results obtained using the two methods compare closely to one another and to other published results where these are available. A direct relationship between unidirectional buckling stress and frequency of vibration is demonstrated for a category of plates having one pair of opposite edges simply supported.

ABSTRACT: In a previous paper [1] the finite strip method was applied to the prediction of the natural frequencies of vibration of longitudinally invariant, rigidly connected assemblies of circularly curved and flat strips having diaphragm end supports. This work is extended here to include the presence of an initial membrane stress field. An individual curved strip may be subjected to a biaxial direct stress field comprising a uniform stress acting in the circumferential direction and a non-uniform stress acting in the longitudinal direction. The presence of the membrane stress field is accommodated in the analysis by the inclusion of an initial stress or geometric stiffness matrix. A further extension included here is a facility to delete in-surface inertia terms. Results are presented for the application of the strip method in predicting the frequencies of vibration of a circular cylinder subjected to a complicated membrane stress system.

ABSTRACT: A previously developed analysis of the flexural vibration of isotropic rectangular plates is extended to include the presence of a membrane stress system. The method of analysis is the Rayleigh-Ritz method and Mindlin plate theory is used which takes into account effects which are disregarded in the classical plate theory. As in the aforementioned earlier analysis the spatial variations of the deflection and two rotations over the plate middle surface are based on the use of Timoshenko beam functions. The membrane stress system comprises biaxial direct stress plus in-plane shearing stress and is uniform throughout the plate. Numerical results are presented for a number of types of plate and of applied stress which show the manner of variation of the frequencies of vibration as the intensity of stress changes. This manner of variation is similar in form to that demonstrated elsewhere by analyses based on the use of the classical plate theory but the magnitudes of the present calculated frequencies are considerably reduced for moderately thick plates.

ABSTRACT: Description is given of a finite strip method for the analysis of the geometrically non-linear behaviour of laterally loaded, rectangular, laminated composite plates. The analysis is based upon the use of a plate theory which includes the effects of transverse shear deformation. For particular end conditions, two types
of finite strip model are presented, one based on linear crosswise interpolation of each of the five fundamental displacement-type quantities (and employing a reduced integration scheme in evaluating strip properties), the other based on cubic crosswise interpolation. Numerical studies reveal the good convergence properties of the strip models and show the importance of including shear deformation effects in the non-linear analysis.

ABSTRACT: Consideration is given to the twin problems of the elastic buckling of rectangular, symmetrically-laminated composite plates and of the vibration in the presence of applied in-plane stress of such laminates. First-order shear deformation plate theory provides the mathematical model of plate behaviour and the Rayleigh-Ritz and finite strip methods are used to generate numerical results for laminates of thin and moderately thick geometry, with various combinations of standard plate edge conditions. The applied stresses include uniform shear stress as well as direct stresses, and anisotropic material properties can be included. The presented results demonstrate the accuracy of the numerical methods and highlight the very significant influence that transverse shear and related thickness effects can have in the subject problems.

ABSTRACT: Free vibration of prismatic plate structures of laminated composite material and having diaphragm end supports is considered using the finite strip method. Description is given of the development of stiffness and mass matrices for both out-of-plane and in-plane deformation of a family of strip models. The former deformation is based on first-order shear deformation plate theory, rather than classical plate theory. Frequency calculations are made using full sets of structure equations and using reduced sets obtained from an economisation procedure. Presented results demonstrate the good convergence characteristics of the finite strip approach and reveal the relative efficiency of particular economisation schemes. Comparison made with results based on the use of classical plate theory in deriving out-of-plane strip properties shows that the effects of through-thickness shear and rotary inertia on a natural frequency are heavily dependent upon the nature of the associated mode shape.

ABSTRACT: A finite strip method is presented for the determination of buckling stresses and natural frequencies of vibration of prismatic plate structures assembled from plate flats, which generally are laminates of fibre-reinforced composite material. The finite strip method is of the single-term type, corresponding to the assumption of sinusoidal longitudinal spatial variation of displacement and force quantities. Anisotropic
material behaviour and applied in-plane shear stress are accommodated by expressing the strip displacement field in terms of complex quantities. The out-of-plane properties of plate flats are based upon the use of first-order shear deformation plate theory. A family of finite strip models is described and a sub-structuring procedure is utilised to reduce the size of the eigenvalue problem. Presented numerical results reveal the high accuracy and good convergence characteristics of the method, as well as indicating the influence of through-thickness shear effects in a range of circumstances.

V. Peshkam, “Linear and geometrically nonlinear analysis of thin rotational shells using the finite element method”, Ph.D. dissertation, Dept. of Civil Engineering and Building, The Polytechnic of Wales, December 1984

SUMMARY: The complete elastic behaviour of rotational shell structures is investigated in the thesis, being presented in two major parts. Energy principles are implemented throughout for the derivation of matrices utilizing the orthotropic strain energy expression developed by Ambartsumyan. Part One concerns the prediction of the small deflection behaviour in seven chapters. Initially it is attempted to analyse various shell structures by examining their deflection patterns, by concentrating on the distribution of stresses and moments in the structure. This is extended further to instability analysis in order to determine the critical load when the structure is subjected to compressive pressures. Economization technique both at the elemental and structural level is deployed based on Irons/Guyan reduction assumption in order to condense the Surplus-Functions and observe their influence on the natural frequencies. The section on dynamic transient response analysis is followed by the latter where the behaviour of structures subjected to forced vibration is studied. Two integration techniques, namely Newmark Beta and Mode Superposition, are used to integrate the second order time dependent differential equations of motion. Finally the linear analysis section is concluded by reformulating the conventional beam element in order to incorporate the Surplus-Functions and to investigate their absolute influence on the convergence of the finite element solution. The performance of the new element has proved to be remarkably superior to its predecessor. The geometrically nonlinear behaviour of shells of revolution subjected to axisymmetric and asymmetric loads are studied in Part Two. Attention is focused on the post-buckling behaviour of structures with particular emphasis given to orthotropic circular plates. The number of numerical examples were restricted due to the limitations of the available literature on the coupled nonlinear behaviour of these structures. However, the problems cited in Part Two with exception of one were found to be in excellent agreement with the other published works.

ABSTRACT: The prediction of the buckling stresses of prismatic plate structures made of composite laminated material is considered. Recent developments which have provided an extended capability in the finite strip analysis of such structures are brought together and discussed. Different analysis procedures are described, dependent upon whether the plate structure is of finite length, with diaphragm ends, or is ‘long’, and on whether first-order shear deformation plate theory or classical plate theory is used in developing out-of-plane strip properties. Features of the analysis include a very general description of laminate material properties, the
presence of applied shear stress, the accommodation of eccentric connections between plate flats and the use of multi-level substructuring techniques, including the so-called superstrip concept. The associated computer software is used to examine the buckling behaviour of two types of panel, with attention paid to the influence of through-thickness shear deformation and of bending-stretching material coupling in unsymmetric laminates.

ABSTRACT: Finite strip methods are presented for the prediction of buckling stresses and natural frequencies of vibration of “long” prismatic plate structures which may be formed of fibre-reinforced, composite, laminated material with very general properties. The finite strip methods are of the single-term type with complex algebra employed to accommodate applied in-plane shear stress and anisotropic material behaviour. The developments, described here follow on very directly from an earlier paper in this Journal ([1] Dawe and Craig, Int. J. Mech. Sci.30, 77, 1988) to which frequent reference is made herein. The first development is the introduction of major improvements and extensions on the earlier work [1] which is based upon the use of first-order shear deformation plate theory to represent the out-of-plane properties of plate flats: the chief advance involves the use of multi-level substructuring procedures, including the introduction of so-called superstrips, but eccentric connections of component plates at their junctions is also included. The second development is the introduction of a new finite strip analysis which is based on the use of classical plate theory and which is complementary to the shear deformation analysis, with similar advanced features. Two computer programs, BAVPAS and BAVPAC, are introduced and description is given of some results of the application of these programs.

ABSTRACT: A description is given of the multi-term, finite strip analysis of the free vibration and buckling, under a system of applied biaxial direct and shear stresses, of thin, prismatic shell structures. The walls of the structure may be composite laminates with a general lay-up. The analysis is based on the use of Koiter-Sanders thin shell theory. Combinations of diaphragm, clamped and free conditions at the two ends of a structure are incorporated. The displacement field of a transversely-curved finite strip utilises Bernoulli-Euler beam functions in the longitudinal direction and quintic polynomial representations in the circumferential direction. The superstrip concept is used in conjunction with the modified Sturm sequence-bisection approach to provide an efficient analysis capability. Several applications involving flat plates, curved plates and complete cylinders are detailed.

ABSTRACT: The finite strip method is developed for the free vibration analysis of prismatic shell structures having diaphragm end supports. In general, the structure is made up of rigidly-connected, circularly-curved and flat plates which are composite laminates with a broad range of material properties, including bending—stretching coupling and anisotropy. The analysis is developed in two ways, based in turn on the use of first-order shear deformation shell theory and of thin shell theory. The finite strip approach is of the multi-term type and the superstrip concept is employed to produce a powerful and efficient solution capability. Results, in the form of calculated natural frequencies, are presented for a number of problems for which accurate alternative solutions exist, and close comparison of results verifies the present approach.

ABSTRACT: A finite strip method is described for the analysis of the geometrically non-linear elastic response of composite laminated, orthotropic prismatic plate structures subjected to progressive uniform end shortening. Attention is restricted to local buckling/post-buckling behaviour so that certain simplifying assumptions related to the insignificance of movements of plate junctions can be invoked. Analyses are based on the use of both classical plate theory and first-order shear deformation plate theory and a range of finite strip models is available for use in the contexts of each of these plate theories. A description is given of a number of applications involving the post-local-buckling behaviour of box sections and top-hat-stiffened and blade-stiffened panels. In one application considering a laminated box section, results are generated using a commercial finite element package and these are seen to compare closely with the predictions of the presented finite strip method.

ABSTRACT: A spline finite strip capability is presented for predicting the buckling stresses and natural frequencies of rectangular laminated plates. The plates may have arbitrary lay-ups and general boundary conditions. The spline finite strip method is first developed in the context of first-order shear deformation plate theory and then, by reduction, the method is also developed in the context of classical plate theory. In both approaches the superstrip concept is incorporated into the solution procedure. A considerable range of types of application is described and it is demonstrated that the spline finite strip method is versatile, with good convergence characteristics and accuracy. In these applications, frequent comparison is made with the results of other approaches which comprise a spline Rayleigh-Ritz method, a finite element method, an analytical Rayleigh-Ritz method and a semi-analytical finite strip method.
ABSTRACT: The finite strip method (FSM) is an effective procedure for the numerical analysis of single rectangular plates and of complicated prismatic plate structures. Figure 4.1 shows examples of such plates and plate structures, each modelled by a number of finite strips which run the whole length of the structure. The finite strips are rigidly joined at longitudinal reference lines at which the requisite compatibility conditions should be satisfied. With regard to Figure 4.1 it should be noted, though, that finite strips may well have reference lines (i.e., lines with which degrees of freedom are associated) in their interior, in addition to their exterior longitudinal edges, and that in some types of analysis the length of the strips which is considered for analysis purposes is less than the full length of the structure.

ABSTRACT: A description is given of the PASSAS finite strip software package for predicting the buckling stresses and natural frequencies of composite laminated prismatic plate and shell structures of complicated cross-section and general lamination. The basic equations underpinning the development of the properties of a transversely curved finite strip are presented in the context of first-order shear-deformation shell theory and, by reduction, in the context of thin shell theory. The B-spline finite strip method is used and this enables the specification of a wide range of end conditions. The major features of the software package are described, and these include a range of strip models, the use of multi-level substructuring techniques across the structure, including superstrips, and the use of an efficient and reliable solution procedure. Results are presented of the application of PASSAS to the solution of a small number of shell buckling and vibration problems.

ABSTRACT: A spline finite strip capability is described for predicting the buckling stresses and natural frequencies of vibration of prismatic plate structures which may be of composite laminated construction with arbitrary lay-ups. The plate structures may have general boundary conditions. The capability embraces analyses based on the use of first-order shear deformation plate theory and of classical plate theory, and utilizes substructuring procedures which include the use of superstrips. The theoretical development is not detailed since the present paper reports a very direct extension of a theoretical study developed for the analysis of single plates in an earlier paper in this Journal. A considerable range of buckling and vibration applications is documented and comparison of spline finite strip numerical values of buckling stresses and frequencies is made with results generated using the semi-analytical finite strip method and, in some cases, the finite element method. Buckled and vibrational mode shapes are presented for some applications.

ABSTRACT: A general spline finite strip capability is presented for predicting the buckling stresses and natural frequencies of prismatic plate and shell structures which are composed of composite laminated plate and/or
shell panels that may have arbitrary lay-ups. The prismatic structures may have general cross-sections and boundary conditions. This method is developed in the context of first-order shear deformation plate and shell theory as well as the classical plate and shell theory and a massive substructuring technique is incorporated into the solution procedure. A considerable range of types of application is described and a particularly interesting one shows that the general spline finite strip capability has great flexibility in matching the boundary conditions specified on the entire structures.

ABSTRACT: The development of an analysis capability for predicting the buckling stresses of composite laminated, prismatic shell structures is described. The basis of the capability is the spline finite strip method, which is presented in the contexts of both first-order shear deformation shell theory and thin shell theory. The structures considered might have arbitrary lamination and general boundary conditions, and the applied stress field in any component flat or curved plate may include shear stress as well as biaxial direct stresses. Multi-level substructuring procedures are used in an efficient solution procedure. The analysis capability is incorporated into a computer software package called PASSAS and selected applications using this package are presented to show the scope and power of the new capability.

ABSTRACT: A description is given of the development of a spline finite strip method for predicting the response of composite laminated, prismatic panels to a progressive uniform end shortening. The response is assumed to be geometrically nonlinear, with the nonlinearity introduced in enhanced strain-displacement equations in a total Lagrangian approach. The set of nonlinear equilibrium equations, obtained by appropriate energy minimization, is solved using the Newton-Raphson method. The development of the properties of a flat finite strip is made in the contexts of both first-order shear deformation plate theory and classical plate theory, and a number of strip models is available corresponding to different displacement fields. Presented applications concern a box section and several longitudinally stiffened panels that include curved panels modeled as faceted shells. Comparison of the finite strip predictions is made, where possible, with results from other sources, and such comparison is shown to be close.

ABSTRACT: Description is given of the development of the spline finite strip method for predicting the critical buckling temperatures of rectangular composite laminated plates. The analysis takes place in two distinct parts, namely an in-plane thermal stress analysis in the pre-buckling stage followed by a buckling analysis using the determined in-plane stress distribution. The buckling analysis takes place in the context of first-order shear
deformation plate theory. The permitted lay-up of the laminates is quite general, within the constraint that the plate remains flat prior to buckling, and the boundary conditions are versatile. The distribution of temperature can be non-uniform in the plane of the plate. A range of applications of the developed procedure is presented and numerous comparisons are made with the results of previous studies. The spline finite strip method is shown to be versatile and accurate, with good convergence characteristics.

ABSTRACT: The semi-analytical finite strip method is developed for the analysis of the geometrically nonlinear response to dynamic loading of rectangular composite laminated plates. The plates have simply supported ends and their properties are evaluated in the context of first-order shear deformation plate theory. The applied loading acts normal to the plate surface but otherwise may be of a general nature with respect to space and time. Solution to the nonlinear dynamic problem is obtained through use of the Newmark time-stepping scheme in association with Newton–Raphson iteration. Applications are described which relate to isotropic and orthotropic plates, and to laminates. In general a close comparison is demonstrated between the predictions of the developed finite strip approach and those of a finite element method.

ABSTRACT: A description is given of the use of the finite strip method (FSM) in determining the behaviour of composite laminated, prismatic plate and shell structures, with emphasis placed on relatively recent work conducted at The University of Birmingham. Both the semi-analytical and the spline variants of the method are described, and some attention is also paid to "exact" strips. Consideration is given to analyses conducted in the contexts of first-order shear deformation theory and of classical, or thin, theory. The calculation of buckling stresses and natural frequencies of vibration is discussed in detail for single span structures and then, using the spline finite strip approach with variable knot spacings, for multi-span structures and stepped structures. An account is given of the use of the FSM in predicting the post-buckling response of plate structures to progressive end-shortening strain. Brief description is given of the use of the method in predicting the thermal buckling and the transient response to dynamic loading of flat plates. Finally, the calculation of buckling stresses and natural frequencies of sandwich plate structures is considered, based on the adoption of a three-zone plate theory. Numerous examples of the application of the FSM are included in the paper.

ABSTRACT: The thermomechanical postbuckling behaviour of composite laminated plates is studied with the aid of the B-spline finite strip method under the combination of temperature load and applied uniaxial
mechanical stress. To account for through-thickness shear deformation effects, the thermal-elastic, first-order shear deformation (Reissner–Mindlin) plate theory is used in this paper. General boundary conditions and laminate lay-ups can be accommodated in the newly developed finite strip approach. A range of applications is described and the results generated by the finite strip procedure are compared with the results of previous studies. The spline finite strip method is shown to be versatile and accurate with good convergence qualities.

ABSTRACT: A finite strip procedure has been developed for the post-buckling analysis of composite laminates when subjected to progressive end shortening. The finite strips are developed based on a higher-order shear deformation plate theory and there are nine variables at each nodal line. Initial imperfection expressed in the form of suitable trigonometric function is allowed. Examples including isotropic plates and laminates with arbitrary lay-up arrangement are presented. Numerical results for laminates with and without initial imperfection are used to illustrate the effect of imperfection.

ABSTRACT: Free vibration analysis of shells of revolution using the spline finite element method is presented in this paper. The spline element, which is based on the classical thin shell theory, employs a set of B-spline shape functions for the interpolation of geometry as well as displacements. It has the merits of both the finite element method and splines interpolation. The efficiency and accuracy of the proposed element are illustrated by examples in the paper.

Philemon Sphiwe Simelane (Department of Mechanical Engineering, Cape Peninsula University of Technology, Cape Town, South Africa), “Thermal buckling of laminated composite plates”, Master’s Thesis, 1998

PARTIAL SUMMARY: A thermal buckling analysis of laminated composite plates is studied using plates with rectangular geometry and antisymmetric lamination with respect to the middle plane. A Dubamel-Neumann type constitutive model is used. The effects of transverse shear deformation are accounted for by the use of the Mindlin first-order shear deformation (FSDT) plate theory. An angle-ply laminated construction was used to generalise the formulation. Since buckling is essentially a non-linear behaviour, the intermediate class of deformation was employed. The buckling analysis was carried out in a series of steps; the derivation of the equilibrium equation, nonlinear prebuckling and linearized buckling analysis, and the evaluation of the critical temperature by solving the resulting eigenproblem. The first variation of the total potential energy establishes the equilibrium equation and the second variation analyses the stability of the laminated composite. A displacement-based finite element 'With five degrees of freedom in each node was used. The effects of
lamination angle, modulus ratio, plate aspect ratio, and boundary constrains upon the critical buckling temperature were investigated and found to be quite significant.

ABSTRACT: In the context of the maturation of finite element methodology this paper reviews solution approaches that combine classical analytical techniques with computer-based numerical methods. Developments in boundary integral equations, asymptotic postbuckling analysis, and limit point analysis are touched upon, as are some aspects of structural modeling. Emphasis is also placed on the importance of understanding both the scope and limitations of a particular structural model. This understanding has implications for the educator as well as for the researcher and the practicing engineer.

ABSTRACT: The spline finite strip method is applied to the buckling analysis of arbitrarily shaped plates. The plate is first mapped into a rectangular domain in the natural coordinate plane by the subparametric transformation, and the mapped plate is discretised into a number of strips. The displacements of each strip are described by interpolation functions which are given as products of piecewise polynomials and B-3 spline functions. The eigenvalue matrix equation for the buckling analysis is then formulated and solved by the same procedure as that of the standard finite element method. Numerical examples are presented to demonstrate the versatility and accuracy of the method.

ABSTRACT: An important phenomenon is presented which has not been given sufficient attention in the stability of shell structures: the buckling of a circular cylinder subjected to a set of equally distributed discrete axial concentrated loads is studied. It is shown that the critical load of a circular cylinder under axial compression is very sensitive to imperfection of the applied loads as well as to initial geometric imperfections and the boundary conditions.

Long-Yuan Li (Shanghai, China), “The criteria for identifying the type of critical points”, Archive of Applied Mechanics, Vol. 61, No. 4, 991, pp. 231-235, doi: 10.1007/BF00794348

ABSTRACT: It is well known that the buckling of a structure includes two kinds of different physical phenomena. One is called snap-through buckling and the other is called bifurcation. In this paper, the criteria to identify the two different unstable types are developed. The analysis in the present paper shows that the type of
critical points can be directly determined by the incremental equilibrium equations in the general finite element analysis and that it only depends on whether or not the load increment does work through the unstable mode associated with the critical load.

ABSTRACT: This paper presents a closed-form solution of critical instability stresses for simply supported rectangular plates with an arbitrary number of stiffeners in longitudinal and/or transverse directions. It is shown that there are only two buckling modes that are coupled to each other for single direction stiffened plates and four for double direction stiffened plates. The coupling of buckling modes represents the feature of interactions of global and local buckling modes. It is also shown that stiffeners have twofold effects on the critical instability stress, one is by enhancing the “stiffness”, the other is by changing the buckling mode. Because of the twofold effects it becomes difficult to apply the conventional optimum method to design the stiffeners and the optimum design of stiffeners still remains a difficult problem. This paper discusses the way by which the stiffeners can effectively enhance the buckling resistance of plates.

ABSTRACT: A new finite strip formulation for the nonlinear analysis of stiffened plate structures subjected to transient pressure loadings is presented. The effects of large deflections, and strain rate sensitive yielding material properties are included. An explicit central difference/diagonal mass matrix time stepping method is adopted. Example results are presented for an I-beam, an isotropic plate and a five-bay stiffened panel and compared with other predictions and/or experimental results. It is observed that design level accuracy can be obtained for practical structures for a fraction of the cost of full finite element analyses.

ABSTRACT: A method of buckling analysis of thin flat-walled structures of finite length subjected to longitudinal compression and bending, transverse compression as well as shear is described. The analysis uses the spline finite strip method and allows for boundary conditions other than simply supported ends as required in the semi-analytical finite strip method of buckling analysis. Convergence studies with increasing numbers of section knots are described for plates in compression, bending and shear, and for long columns with different support conditions subjected to compression. A buckling analysis of a stiffened plate subjected to compression and shear is compared with results from a finite element analysis.

ABSTRACT: This paper describes recent work performed at the University of Sydney to develop buckling and nonlinear analyses of thin-walled structural members undergoing local, distortional and overall buckling. The analyses are based on the finite strip method of structural analysis and include elastic and inelastic buckling and the full nonlinear response with both post-local buckling and plasticity. Two variations of the finite strip method have been used, these being the semi-analytical and spline finite strip methods. A nonlinear beam-column analysis based on the influence coefficient method for including the local buckling behaviour in the overall member response is also described. The analytical methods are compared with tests performed at the University of Sydney on cold-formed rectangular hollow sections, welded I-sections, welded channel sections and cold-formed channel sections. Spatial plastic collapse mechanisms developed for the welded sections described above are also compared with the post-ultimate response of the test sections.

ABSTRACT: The aim of the report is to show that modern methods of verification of steel structures can be used for the structural appraisal of old cast-iron columns. The proposed method of verification takes account of the geometrical imperfections which are typical for cast-iron columns and of the particular behaviour of the material which is distinct from modern structural steel in that the tension strength is significantly lower than the compression strength, the stress-strain curve is non-linear rather than bi-linear and the Young’s modulus is about 2/5 the value for modern steels. The report proposes equations for calculating the strength of cast iron columns by checking failure by yielding in compression and fracture in tension. The proposed strength equations are compared with experimental results obtained by Hodgkinson (1840) and Tetmayer (1901).

ABSTRACT: The main objective of this thesis is to investigate the behaviour of Square (SHS) and Rectangular (RHS) Hollow Sections subject to pure concentrated force, pure moment and combined moment and concentrated force, where the concentrated force is applied to tubular sections either by welding a square hollow section branch member or by a bearing plate. The following experimental and theoretical studies have been performed. An extensive test program on a range of cold-formed SHS and RHS subject to pure concentrated force, pure moment and combined moment and concentrated force is described. The concentrated force was applied by either welding a square hollow section branch member (called T-joint tests) or by a bearing plate (called bearing tests). For the T-joint tests, the ratio ($\beta$) of the width of the branch member to the chord member varied from 0.5 to 1.0 in order to observe different failure mechanisms. For the bearing tests, the ratio ($\gamma$) of the bearing length to the width of the bearing plate varied from 0.5 to 1.0 in order to show the effect of the bearing length on the failure load. For both T-joint tests and bearing tests, the span of the simply supported beam was varied in order to determine the interaction relationship between moment and concentrated force. The slenderness of the member section and the shape of the section (SHS or RHS) were varied to cover a wide range of sections. The results of the bearing tests are compared with the T-joint tests on similar sections to demonstrate the significant reduction in failure loads and the more severe interaction between bending moment and concentrated force. Plastic mechanism analysis (yield line method) is adopted in the thesis, since the failure modes of SHS and RHS involve local collapse mechanisms. The final result of a plastic mechanism analysis largely depends on the plastic moment capacity of yield lines and the mechanism model assumed. For the plastic moment capacity of yield lines, existing formulae are reviewed. The lower bound solutions, which are based on the Tresca yield criterion and the von Mises yield criterion, are derived in the theses to determine the reduced plastic moment capacity of an inclined yield line under axial force. A series of experimental tests on plastic hinges under axial force were performed to verify the formulae. Simplified expressions for the verified formulae are given to permit easy application of the theory. The mechanism models developed in the thesis are based on the experimental observations obtained in the thesis. For T-joints in RHS under concentrated force, a modification of the Kato model is proposed for predicting the yield load. A more refined model is developed to predict the post-yield response and the ultimate load, where plastic hinges in the web, the membrane force in the flange and strain hardening of the material are considered. The virtual work principle is used in the derivation. For RHS under bearing force alone, a mechanism model is developed to predict the web yield load. The eccentric loading of the web where the corner radii meet the flange is considered in the model. For T-joints in RHS subject to combined bending and concentrated force, the mechanism model is approximated by the modified Kato model. The reduction of the plastic moment capacity of yield lines is considered in the derivation. The action in the chord (bending moment) rather than the chord normal stress is used for interaction curves. A proposed interaction formula is given, which includes the variation of capacity with $\beta$. For RHS subject to combined moment and bearing force, interaction formulae are
derived based on the test result. Existing design procedures from Australia, America, Britain and Canada, both for cold-formed members and for hot-rolled members, are reviewed and compared with the test results. Improved design procedures are given for SHS and RHS under concentrated force alone and for SHS and RHS subject to combined moment and concentrated force.

Y.B. Kwon, “Post-buckling behavior of thin-walled channel sections”, Ph.D. dissertation, School of Civil and Mining Engineering, University of Sydney, 1991? (supervisor G.J. Hancock)
ABSTRACT: Thin-walled channel sections may undergo a mode of buckling called distortional in which a lip stiffened flange of the section rotates about the flange-web junction. If the sections are composed of high strength steel, then there may be a significant post-buckling reserve of strength beyond the elastic distortional buckling stress in a similar manner to that which normally occurs for local buckling. A nonlinear elastic analysis based on the spline finite strip method has been developed for studying the post-buckling behaviour of thin-walled sections. The method can handle local, distortional and overall buckling modes in the post-buckling range and the interaction between them. It allows for geometric imperfections, arbitrary loading and non-simple boundary conditions. The accuracy is confirmed by studying several plate, section and shell problems for which solutions are known. The results of compression tests of thin-walled channel section columns formed by brake-pressing are described. Two different section geometries, a simple lipped channel and a lipped channel with an intermediate stiffener in the web, were tested between fixed-ended boundary conditions. The geometries and yield strength were chosen to ensure that a substantial post-buckling strength reserve occurred in the distortional mode and that local buckling might occur simultaneously at a shorter wavelength. The nonlinear spline finite strip method is applied to the prediction of the post-buckling behaviour and the influence of the interaction between buckling modes for the test channel columns. Design curves for the maximum strength of different columns undergoing distortional or mixed modes of buckling are proposed. Two basic design methods to account for the local and distortional buckling or mixed local-distortional buckling mode are also proposed. The test results are compared with the proposed methods and are also compared with the Australian Standard, the American Specification and European Recommendations for the design of cold-formed steel structures.

ABSTRACT: A nonlinear elastic analysis based on the spline finite strip method has been developed for studying the post-buckling behaviour of thin-walled sections. The method can handle local, distortional and overall buckling modes in the post-buckling range and the interaction between them. It allows for geometric imperfections, arbitrary loading and non-simple boundary conditions. By comparison, the semi-analytical finite strip method is restricted to simply supported end boundary conditions and a single buckle half-wavelength. The two incremental-iterative strategies adopted in the nonlinear analysis are the arc-length method and the improved iteration method based on displacement control. Switching between load and displacement control can occur automatically as the need arises in an analysis. Numerical examples are presented for comparison with and verification against solutions for the nonlinear behaviour of plates, plate assemblies and cylindrical shells.

Y.B. Kwon and G.J. Hancock (Centre for Advanced Structural Engineering, School of Civil and Mining Engineering, University of Sydney, N.S.W., Australia), “Post-buckling analysis of thin-walled channel sections

ABSTRACT: A theoretical method for predicting the post-buckling behaviour of thin-walled sections is applied to study the influence of the interaction between local and distortional buckling modes for test channel columns described in an earlier paper. The theoretical predictions are based on a nonlinear elastic spline finite strip method for thin-walled sections which has recently been developed. The method can handle sections buckling simultaneously in local and distortional buckles at different half-wavelengths. The investigation includes convergence studies with different convergence criteria, strip subdivision and longitudinal subsections so as to determine reliable convergence criteria and the required discretizations for use in the nonlinear elastic spline finite strip method.

ABSTRACT: The calculation of the stresses and failure modes in thin-walled structural members is a complex procedure. Structural designers will often need help in analysing these types of structures. A vehicle for providing this help is the computer program developed for the microcomputer. In this paper, a computer procedure is described for the cross-section analysis and elastic buckling analysis of thin-walled structural members. The cross-section analysis calculates the section properties, warping displacements, and the longitudinal and shear stresses for thin-walled open and closed cross-sections of any shape. The longitudinal stresses are used to perform an elastic finite strip buckling analysis of thin-walled structural members. The analysis can be done for a number of different buckle half-wavelengths of the member and the load factor and buckled shape are output for each length. The analysis is performed by the user-friendly computer program THIN-WALL, which is also described in the paper.

ABSTRACT: The paper provides a report on the simulation and computational models of structures prone to interaction buckling. The simulation models are divided into perturbation, cell and discrete models, and all major contribution to the research of interaction buckling are classified using this division. The paper also explores current trends in the development of simulation models and likely future research areas.

ABSTRACT: This paper describes the application of the isoparametric spline finite strip method to the linear elastic analysis of tri-dimensional perforated folded plate structures. The general theory of the isoparametric
spline finite strip method is introduced. Kinematics assumptions and the procedure for combining in-plane (membrane) and bending effects are set out. Particular attention is paid to the procedure for rotating the stiffness matrix and load vector from local to global coordinates. The reliability of the method is demonstrated by comparisons with finely meshed finite element analysis results. Square stiffened perforated plates in compression and bending are analysed.

ABSTRACT: This paper presents the application of the isoparametric spline finite strip method to the elastic buckling analysis of perforated folded-plate structures. The general theory of the isoparametric spline finite strip method is introduced. The kinematics assumptions, strain–displacement and constitutive relations of the Mindlin plate theory are described and applied to the spline finite strip method. The corresponding matrix formulation is utilised in the equilibrium and stability equations to derive the stiffness and stability matrices. A number of numerical examples of flat and folded perforated plate structures illustrate the applicability and accuracy of the proposed method.

ABSTRACT: This paper presents the application of the isoparametric spline finite strip method to the geometric nonlinear analysis of perforated folded-plate structures. The general theory of the isoparametric spline finite strip method is introduced. Kinematics, strain–displacements and constitutive assumptions are described and applied to the spline finite strip method. The derivation of the tangential and secant stiffness matrices is presented by applying the equilibrium condition and its incremental form. The reliability of the method is demonstrated by applying the method to classical nonlinear complex plate and shell problems as well as the geometric nonlinear analysis of perforated flat and stiffened plates.

ABSTRACT: In this study, the finite element method is employed to determine the critical in-plane longitudinal load at which elastic local buckling of the web of cellular beam–column elements occurs. To simplify the simulation of the problem, the interaction between the flanges and perforated web is approximated by modelling the web only as a long plate having aspect ratio (L/hw≥10) with multiple circular perforations. The utilized model incorporates restrained out-of-plane displacements along the four edges of the plate. Analyzed plates are
subjected to linearly varying in-plane loads to simulate various combinations of axial and flexural stresses. The effect of different geometrical parameters on the elastic buckling load of perforated web plate is investigated. These geometrical parameters include the plate’s length and width, and the perforations’ diameter and spacing. Comprehensive finite element analyses are conducted to identify the behaviour of wide spectrum of perforated web plates at buckling under various combinations of axial compressive load and bending moment. Outcomes of the study are expected to enhance the understanding of the elastic local buckling of web plates of cellular beam–column elements.

ABSTRACT: A finite element algorithm for analysis of stiffened plates by normal mode approach under stationary random stochastic loading has been presented. The formulations for both spatially homogeneous and nonhomogeneous loads have been indicated. The isoparametric quadratic stiffened plate bending element employed has a unique feature that the stiffeners can be positioned anywhere within the plate element and they need not necessarily be on the nodal lines. The element, being isoparametric quadratic, can readily accommodate curved boundaries, transverse shear deformation, and laminated materials. The formulation is applicable to thin as well as thick plates. A simple lumped load concept has been used for spatially homogeneous loading; for spatially nonhomogeneous loads, however, the isoparametric shape function and the Gaussian integration technique have been employed to form the generalized nodal cross spectral density matrix from the excitation. Displacement and stress response spectra for plates and stiffened plates under white noise and jet noise excitation have been evaluated. The results have been presented along with those of previous investigators. The performance of the element has been found to be very good under all circumstances.

ABSTRACT: The general spline finite strip method has been extended in this paper to the analysis of stiffened plates having arbitrary shape. The main elegance of the formulation lies in the treatment of stiffeners. It has been shown that the stiffener can be placed anywhere within the plate strip which introduces a considerable amount of flexibility in the analysis. Stiffened plates having various shapes, boundary conditions, loadings and also possessing various disposition of stiffeners as available in the literature, have been analysed by the proposed approach. Comparison obtained with existing theoretical and/or experimental values have indicated good accuracy.

ABSTRACT: The spline finite strip method which has long been applied to the vibration analysis of bare plate has been extended in this paper to stiffened plates having arbitrary shapes. Both concentrically and eccentrically
stiffened plate have been analyzed. The main elegance of the formulation lies in the treatment of the stiffeners. The stiffeners can be placed anywhere within the plate strip, and need not be placed on the nodal lines. Stiffened plates having various shapes, boundary conditions and also possessing various disposition of stiffeners, as available in the literature, have been analyzed by the proposed approach. Comparison with published results indicates excellent agreement.

ABSTRACT: Geometric nonlinear analysis of stiffened plates is investigated by the spline finite strip method. von Karman's nonlinear plate theory is adopted and the formulation is made in total Lagrangian coordinate system. The resulting nonlinear equations are solved by the Newton–Raphson iteration technique. To analyse plates having any arbitrary shapes, the whole plate is mapped into a square domain. The mapped domain is discretised into a number of strips. In this method, the displacement interpolation functions used are: the spline functions in the longitudinal direction of the strip and the finite element shape functions in the other direction. The stiffener is elegantly modelled so that it can be placed anywhere within the plate strip. The arbitrary orientation of the stiffener and its eccentricity are incorporated in the formulation. All these aspects have ultimately made the proposed approach a most versatile tool of analysis. Plates and stiffened plates are analysed and the results are presented along with those of other investigators for necessary comparison and discussion.

ABSTRACT: The spline finite strip method has been applied to linear and nonlinear transient vibration analysis of plates and stiffened plates. In this method, spline functions have been used as the displacement interpolation functions in one direction while finite element shape functions have been used for that in the other direction. The von Karman's large deflection plate theory has been used and the formulation has been done in total Lagrangian coordinate system. The governing equations have been solved by the Newton–Raphson iteration technique where Newmark's method has been used for the time integration. The stiffener has been elegantly modelled so that it may lie anywhere within the plate strip, which helps to increase the flexibility in mesh generation. The formulation has been generalised to cater plates having arbitrary shapes and stiffeners having arbitrary orientation and eccentricity. Examples of stiffened and unstiffened plates under different loading history as available in the literature have been solved to study the performance and range of applicability of the proposed method.

ABSTRACT: Strength of ship plates plays a significant role in the ultimate strength analysis of ship structures. In recent years several authors have proposed simplified analytical methods to calculate the ultimate strength of unstiffened plates. The majority of these investigations deal with plates subjected to longitudinal compression only. For real ship structural plating, the most general loading case is a combination of longitudinal stress, transverse stress, shear stress and lateral pressure. In this paper, the simplified analytical method is generalized to deal with such combined load cases. The obtained results indicate that the simplified analytical method is able to determine the ultimate strength of unstiffened plates with imperfections in the form of welding-induced residual stresses and geometric deflections subjected to combined loads. Comparisons with experimental results show that the procedure has sufficient accuracy for practical applications in design.

ABSTRACT: In spite of the large number of finite elements developed so far, most of these lack in generality, and are found to be inadequate and inefficient in some way or other, when it comes to analyzing plates of arbitrary geometrical configurations. So far the isoparametric element has been the most successful among available elements because of its ability to model a curved boundary successfully. However, the shear-locking problem inherent in the isoparametric element makes it unsuitable for analyzing thin plates of arbitrary shapes. Though research has been conducted using reduced integration and stabilization to overcome the problem, the formulations either do not converge to the correct solution in the thin-plate limit or they make the stiffness matrix a singular one. In this paper, a four-noded stiffened plate element is developed. This has the advantages and elegance of an isoparametric element in modelling arbitrary shaped plates, but without the disadvantage of shear-locking phenomena. Though this element is a high-order element, only the usual degrees of freedom have been considered, and performance is superior to that of the low-order ones. The stiffened plate element has the feature of accommodating the arbitrary shape of the plate geometry, and the stiffener modelling has been done in a general manner, with the stiffener lying anywhere with arbitrary orientation, and not necessarily following the nodal lines. The new element has been successfully used for the static, free vibration and stability analyses of arbitrary bare and stiffened plates. The results are found to agree quite satisfactorily with those of previous investigators.

ABSTRACT: Analysis of plated structures with rectangular cutouts and internal supports by the finite element method is tedious and time consuming. The spline finite strip method has been developed and applied to solve this problem efficiently.

ABSTRACT: In each of the two case studies described in this paper a vessel containing a pressurised fluid failed by the phenomenon of external-pressure buckling. In the first case study a jacketed reactor vessel developed an inward-facing bulge because the heat-transfer oil in the jacket had expanded during a temperature excursion. The second case study involved the “snap-through” of a spherical-cap partition in an oil storage tank. The partition had been subjected to an unacceptably high external pressure because compressed air had been used to propell a fresh supply of oil into the storage tank. The buckling failures were analysed using standard results for the external-pressure buckling of thin-walled tubes and spherical caps, and the critical collapse pressures were found to be of a suitable magnitude to account for the failures.

ABSTRACT: A finite element formulation is presented for the non-symmetric bifurcation analysis of geometrically nonlinear elastic-plastic shells of revolution. The shell may be branched and segmented. The loads are axisymmetric but may include in-plane shears (non-uniform torsion). In place of the widely used relations of Donnell, Novozhilov and Sanders, a new nonlinear shell theory is adopted which includes nonlinear strains arising from in-plane displacements. For the determination of the non-linear prebuckling load deflection path, the J2 flow theory of plasticity is used. For the non-symmetric bifurcation analysis, three theories are provided: J2 flow theory, J2 deformation theory and J2 flow theory with the shear modulus predicted by J2 deformation theory. A new efficient and automatic solution procedure is described to determine the critical buckling mode, and hence the critical buckling stress. Several example problems are analysed and the predictions of the present analysis are compared with available theoretical and experimental results. Very close agreement is achieved. The effect of using different plasticity theories in the stability analysis is also briefly discussed.

ABSTRACT: Elevated steel silos and tanks commonly consist of a cylindrical shell, a conical hopper and a skirt. Much of the total weight of the stored material is supported by the hopper, which is in biaxial tension and may fail by forming a plastic collapse mechanism. This paper examines the plastic collapse of hoppers which are sufficiently restrained by a ring at the hopper/cylinder junction for the collapse mode to be entirely confined to the hopper. The hopper joints are assumed to be stronger than the shell plate. An elastic-plastic finite-element program is used to study the plastic collapse behaviour of these hoppers. It is found that the plastic collapse mode is usually a local mechanism near the top of the hopper. Collapse strengths are determined for hoppers of both uniform thickness and varying thickness subject to internal pressure with and without frictional shear. Most of the calculations are performed using elastic-plastic small deflection theory, because this leads to well-defined collapse strengths and relates to classical limit analysis. Calculations made using large deflection theory
show that the non-linear changes of geometry have a significant stiffening and strengthening effect. The parametric study presented in this paper defines a simple lower bound to the strength of the hopper.

ABSTRACT: Many experiments have been conducted to determine the distribution of pressures and frictional drags on silo walls. Based on this information, design calculations indicate that buckling under vertical compressive stresses is usually the critical consideration for thin-walled steel silos. Many failures of silos in service have occurred by buckling under axial compression and eccentric discharge of the stored solids has been implicated in a number of them. Existing knowledge of the buckling strength of empty, uniformly compressed, cylindrical shells is extensive, and the effects of internal pressurisation are also quite well known. However, little is known about buckling failures in which the wall stresses are directly induced by stored solids, or about the increases in buckling strength which derive from the stiffness of a stored granular solid in contact with the silo wall. This paper describes experiments in which these effects were studied. Model silos were loaded to failure and the wall stresses and consequent buckling failure were caused solely by a stored granular solid. These experiments were designed to explore the buckling strength and behaviour of thin-walled, flat-bottomed silos on initial filling and during discharge. Both concentric and eccentric discharge conditions in funnel flow silos are described. Buckling failures with both stable and unstable characteristics are noted. Finally, conclusions are drawn for the structural design of steel silos.

ABSTRACT: A new finite element formulation for elastic-plastic large deflection analysis of shells of revolution is presented. The new formulation contains most of the best features of nonlinear finite element analyses currently available in the literature, together with some new numerical schemes to improve the capability, accuracy and speed of the computation. It is thoroughly verified using a variety of problems. The doubly curved thin shell finite element used has been widely applied to linear elastic stress analysis and linear stability analysis by the present authors and their co-workers. In place of the widely-used relations of Donnell, Novozhilov or Sanders, more comprehensive nonlinear thin shell strain-displacement relations are used, which account for nonlinear strains caused by in-plane displacements. Unlike most previous nonlinear axisymmetric shell formulations, in-plane shearing is included throughout the treatment. For plastic analysis, a multi-layered approach is adopted, employing the Prandtl-Reuss normal flow rule with isotropic hardening or perfect plasticity. An efficient and accurate state determination algorithm, assuming incremental reversibility for plastic behaviour, is adopted and verified. Implementation of the variable arc-length method provides an efficient iterative procedure for tracing both the pre- and post-critical load-deflection path. Several examples demonstrate the accuracy, efficiency and capability of the present formulation.

J.G. Teng and J.M. Rotter (Department of Civil Engineering and Building Science, University of Edinburgh,

ABSTRACT: Elevated steel bins and tanks typically consist of a cylindrical vessel, a conical hopper and a skirt. The intersection of these three shell segments is termed the transition junction and is subject to a large circumferential compression. A ring is often required at this junction. The high circumferential compression at the intersection may lead to a buckling failure of the ring. Elastic buckling of the ring at the transition junction has been studied recently, but very little is currently known about the plastic buckling of such a ring. This paper presents a theoretical investigation into the plastic buckling of the transition ring using a finite element analysis. Simple annular plate rings are studied first, and the results are compared with the few known predictions from an earlier study. The plastic buckling of T-section rings is then explored.

PARTIAL ABSTRACT: Elevated silos and tanks are often supported on a number of columns. The discrete supports of the columns induce high stresses adjacent to the column terminations. In particular, very high meridional compressive stresses arise above each column termination and these can lead to buckling of the shell at a load much lower than that for a uniformly supported shell. This paper presents a brief summary of recent theoretical work on the elastic buckling strength of column-supported cylinders. Elastic calculations are relevant provided the shell is of typical practical thickness (500 < R/t < 2000).

ABSTRACT: Large elevated silos and tanks are generally supported on a number of columns. The discrete supports of the columns give rise to high stresses adjacent to the column terminations. In particular, very high meridional compressive stresses arise above each column termination and these can lead to buckling of the shell at a load much lower than that for a uniformly supported shell. This paper presents a study of the linear bifurcation buckling behaviour of column-supported thin elastic perfect cylinders using the finite element method. Cylinders on both rigid and flexible column supports are studied, and the effects of varying several shell parameters are examined. The effects of the top and bottom edge boundary conditions are also investigated. It is well recognised that the linear bifurcation load is only an upper bound on the actual elastic buckling load, because the effects of large deflections and initial imperfections are ignored. Nevertheless, our understanding of the buckling behaviour of these structures is so limited that the results obtained here provide a significant starting point from which more elaborate studies may follow.

J.G. Teng and T. Hong (Department of Civil and Structural Engineering, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong, China), “Nonlinear thin shell theories for numerical buckling predictions”, Thin-Walled Structures, Vol. 31, Nos. 1-3, May 1998, pp. 89-115,
ABSTRACT: A basic building block in any numerical (geometrically) nonlinear and buckling analysis is a set of nonlinear strain–displacement relations. A number of such relations have been developed in the past for thin shells. Most of these theories were developed in the pre-computer era for analytical studies when simplicity was emphasized and terms judged to be small relative to other terms were omitted. With the availability of greatly increased computing power in recent years, accuracy rather than simplicity is given more emphasis. Additional complexity in the strain–displacement relations leads to only a small increase in computational effort, but the omission of a term which may be important in only a few complex problems is a major flaw. It is therefore necessary to re-examine classical shell theories in the context of numerical nonlinear and buckling analysis. This paper first describes a set of nonlinear strain–displacement relations for thin shells of general form developed directly from the nonlinear theory of three-dimensional solids. In this new theory, all nonlinear terms, large and small, are retained. When specialized for thin shells of revolution, this theory reduces to that previously derived by Rotter and Jumikis and others. Analytical and numerical comparisons are carried out for thin shells of revolution between Rotter and Jumikis' theory as a special case of the present theory and other commonly used nonlinear theories. The paper concludes with comments on the suitability of the various nonlinear shell theories discussed here for use in numerical buckling analysis of complex branched shells.

ABSTRACT: This paper introduces the NEPAS program which has been developed over a number of years for the nonlinear and buckling analysis of complex branched shells of revolution. Throughout its development, a strong emphasis has been placed on achieving robustness, efficiency, and accuracy. This has led to attempts to identify the best available numerical techniques and the development of new ones for implementation in the program. In this paper, the current capabilities of the NEPAS program are described and the numerical techniques implemented to achieve them are reviewed. A number of numerical examples are included to illustrate these capabilities. Further developments of the program to make it an attractive analysis tool for designers are also discussed.

ABSTRACT: In this paper, the most up-to-date research on the buckling of internally-pressurized cone–cylinder intersections and state-of-the-art finite element analyses are deployed to provide another anatomy of a pressure vessel failure due to mis-operation overpressure recently reported and analyzed by Jones [Jones, DRH. Buckling failures of pressurized vessels: two case studies. Engineering Failure Analysis 1994;1:155–67]. Existing research on these intersections is first outlined, followed by a description of the buckling strength formulae recently developed to approximate finite element buckling loads of the perfect geometry. The validity of these formulae for real vessels with geometric imperfections is next examined through a comparison of theoretical predictions with experimental results, which establishes the limited sensitivity of the buckling load to initial imperfections. The buckling pressure of the cone–cylinder intersection in the failed vessel is then determined using these formulae, while the buckling pressure of the spherical partition in the vessel is evaluated.
using the ECCS rule. These calculations demonstrate that the cone–cylinder intersection buckled first, followed by the buckling of the spherical partition, which also released the vessel from overpressure. The buckling pressure of the spherical partition is therefore also the maximum pressure exerted on the vessel. This proposition is confirmed by postbuckling analyses of the vessel.

ABSTRACT: Cylinders, cones, spheres and tori are some of the common basic shell elements. Steel shell structures such as silos, tanks, pressure vessels, offshore platforms, chimneys and tubular towers generally consist of two or more of these basic shell elements. Axisymmetric intersections featuring meridional slope mismatches between the connected elements are common features in steel shell structures. High bending and circumferential membrane stresses are developed in these intersections, and their buckling and collapse strengths are a key design consideration. This paper presents a summary of recent research on the stress, stability and strength of axisymmetric steel shell intersections. Particular attention is paid to intersections formed from cylindrical and conical segments as these are more common and have been more extensively researched. A simple approximate method for extrapolating the knowledge gained on these intersections to those containing curved shell segments is also suggested.

ABSTRACT: Nonlinear finite-element analysis provides a powerful tool for assessing the buckling strength of shells. Since shells are generally sensitive to initial geometric imperfections, a reliable prediction of their buckling strength is possible only if the effect of geometric imperfections is accurately accounted for. A commonly adopted approach is to assume that the imperfection is in the form of the bifurcation buckling mode (eigenmode-affine imperfection) of a suitable magnitude. For shells of revolution under axisymmetric loads, this approach leads to the analysis of a shell with periodically symmetric imperfections. Consequently, sector models spanning over one or half the circumferential wave of the imperfection may be considered adequate. This paper presents a study which shows that a simple nonlinear analysis of the imperfect shell may not deliver the correct buckling load, due to the tendency of the shell to develop mode changes in the deformation process before reaching the limit point. This inadequacy exists not only with short sector models (half-wave or whole-wave models) but also with more complete models (half-structure or whole-structure models) for different reasons. The paper concludes with recommendations on the proper use of the four different kinds of models mentioned above in determining shell buckling strengths.

ABSTRACT: A new finite element formulation is presented for the non-linear analysis of elastic doubly curved segmented and branched shells of revolution subject to arbitrary loads. The circumferential variations of all quantities are described by truncated Fourier series with an appropriate number of harmonic terms. A coupled
harmonics approach is employed, in which coupling between different harmonics is dealt with directly rather than by the use of pseudo-loads. Key issues in the formulation, such as non-linear coupling and growth of harmonic modes, are carefully and systematically explained. This coupled harmonics approach allows an easy implementation of the arc-length method. As a result, post-buckling load–deflection paths can be traced efficiently and accurately. The formulation also employs a non-linear shell theory more complete than existing classical theories. The results from the present study are independently verified using ABAQUS, while those from other studies are found to be inaccurate in general.

ABSTRACT: This paper presents a ring element for the static analysis of shells of revolution of arbitrary shape under arbitrarily distributed loads, based on a displacement formulation that includes geometric and physical non-linearity. The trial functions for the displacement field in the circumferential direction of the shell involve harmonic series, so that the dependence in the circumferential direction is removed from the formulation. For this element, the derivation of the internal resisting force vector and of the tangent stiffness matrix is presented. Furthermore, the concept of ring elements is extended to a spring ring element for modelling uplift between a shell of revolution and the supporting ground. After the presentation of element theory, the use of these ring elements is demonstrated with two application studies.

ABSTRACT: The paper addresses the buckling of an elastic cylinder under non-uniform axial compression applied at one boundary. It presents a systematic numerical investigation of the nonlinear load carrying behavior and imperfection sensitivity of the shell when a non-uniform axial load is applied to one end in the form of two equal-length uniformly loaded zones, diametrically opposite each other. Four imperfection forms are examined: the linear bifurcation mode, the nonlinear buckling mode, several post-buckling deformed shapes for the perfect shell, and a weld depression. Additional aspects, such as the influence of the weld depression position and its wavelength are also investigated. Special attention is given to the mesh convergence study and the sign of the imperfection amplitude. The numerical results demonstrate that the mode of the lowest linear bifurcation load is not always the ‘worst’ imperfection form. It is also shown that the critical position for a weld depression can be approximately located by examining the nonlinear buckling mode of the perfect shell and that the weld depression generally causes the lowest buckling load for this load case.
PARTIAL INTRODUCTION: Thin-shell structures are widely used in many branches of engineering. Examples include aircraft, spacecraft, cooling towers, nuclear reactors, steel silos and tanks for storage of bulk solids and liquids, pressure vessels, pipelines and offshore platforms, though the latter are largely deemed to be outside the scope of this book. The class of shells covered here is very thin, so failure by buckling is often the controlling design criterion. It is therefore essential that the buckling behavior of these shells is properly understood so that suitable design methods can be established.

ABSTRACT: The design of metal silo structures is dominated by the need to resist shell buckling failures in service. Shell buckling can occur in many different modes, and the strengths are very sensitive to the form and amplitude of very minor deviations of geometry (geometric imperfections) from the ideal shape. Many imperfection forms have been studied in the theoretical literature on shell buckling, but only one study appears to have ever extensively and rigorously measured the imperfections in real full-scale metal silos: this is the study of the 10,000 tonne Port Kembla grain silos in NSW, Australia. The data from this study of three seemingly identical silos are very extensive and cannot be assimilated without considerable processing. In this paper, the first attempt is made to provide a full characterisation of the imperfection set in a manner that permits them to be used in shell buckling analyses of the silo shell that do not rely on simplifying assumptions.

ABSTRACT: Cylindrical shells in large steel silos and tanks are commonly constructed from a large number of curved panels joined by many circumferential and meridional welds (referred to as the panel method hereafter). The extensive use of welding in these shells is a unique feature not previously studied in laboratory buckling experiments due to the great difficulty in fabricating realistic small-scale model shells. This paper presents an innovative technique for the fabrication of small models of such large steel cylindrical shells constructed from many welded panels. The experimental set-ups to implement this technique in the laboratory are also described. The new technique consists of two stages: (a) production of a high quality model by rolling two sheets (or a single sheet) and welding along the meridional seams; and (b) ‘welding’ in the form of controlled heat input in a
required pattern of circumferential and meridional ‘welds’ on the central portion of the shell surface. The imperfections in an example specimen are also examined to show that they have a realistic pattern. The observed buckling behavior of this specimen is presented and discussed. The specimen buckled at a very low load, confirming that the welding-induced imperfections in such shells are severely detrimental to the buckling strength.

ABSTRACT: Steel silos and tanks are commonly constructed by welding together a large number of curved steel panels. The panels are first connected with short meridional welds to form circular strakes (or courses), which are then connected by continuous circumferential welds to form the entire shell wall. Associated with the large number of welds are welding-induced shrinkage deformations and residual stresses, both of which may have a significant effect on the buckling strength of the shell wall. In this paper, a simple method for the simulation of the weld depressions and associated residual stresses is first introduced. The results of a series of finite element buckling analyses of a typical steel cylinder with such simulated welding effects are next presented and discussed, leading to a number of significant conclusions. One of these conclusions is that a weld depression pattern produced using the present weld simulation method can offer a suitable equivalent imperfection form for use in the non-linear analysis of shells for stability design, as it leads to buckling loads in close agreement with predictions by the new European code for steel shell structures.

ABSTRACT: The postbuckling response of shells is known to exhibit complex phenomena including mode switching and interaction, particularly in the advanced postbuckling range. The existing literature contains many initial postbuckling analyses as well as advanced postbuckling analyses for a single buckling mode, but little work is available on the advanced postbuckling analysis of shells of revolution considering mode switching and interaction. In this paper, a numerical method for the advanced postbuckling analysis of thin shells of revolution subject to torsionless axisymmetric loads is presented, in which such mode switching and interaction are properly captured. Numerical results obtained using the present method for several typical problems not only demonstrate the capability of the method, but also lead to significant observations concerning the postbuckling behavior of thin shells of revolution. In particular, the results show that strong interaction between different harmonic modes may exist and the transition of deformation mode from one to another is gradual. Consequently, the conventional approach of finding the postbuckling path of a shell as the lower festoon curve of postbuckling paths of individual harmonic modes is not valid and is at best a convenient approximation.
ABSTRACT: This paper is concerned with the application of different types of analysis in the design of civil engineering shell structures which are required to satisfy national or international standards. It outlines the framework of design in the new Eurocode 3 Part 1.6 Strength and Stability of Shell Structures, discusses the power and breadth of this standard and outlines some of its requirements. It also raises several issues that remain difficult to resolve, but which are worthy of careful discussion amongst the leading experts in the shell analysis and stability community.

ABSTRACT: The imperfection sensitivity of thin shells of revolution has been a topic of great interest to researchers and designers. With the gradual emergence of the new approach of structural design based on advanced numerical simulation, the efficient and accurate prediction of the behaviour of imperfect shells has recently assumed new significance. This paper first presents an efficient semi-analytical finite element formulation for the nonlinear analysis of imperfect shells of revolution subject to general nonsymmetric loads. Both the applied loads and the initial geometric imperfections may take any form and are approximated by Fourier series expansions. Application of the analysis to study the effects of geometric imperfections on the behaviour of shells of revolution is then presented to demonstrate the accuracy and capability of the present method and the imperfection sensitivity of shell structures. As a special case of the present formulation, two different approaches are also presented for the postbuckling analysis of perfect thin shells of revolution under axisymmetric loads. The accuracy and capability of both methods are demonstrated using a number of numerical examples, which also allows some new insight to be gained into the postbuckling behaviour of perfect shells of revolution.

ABSTRACT: The classical buckling problem of the circular cylindrical shell subjected to axial compression is reinvestigated using the intrinsic buckling shell equations. For the purely membrane prebuckling state and relaxed-type boundary conditions complex numerical analysis is performed with the help of Mathematica software. It is found, in particular, that the critical buckling load parameter falls to about half of the classical value following from the simplest Donnell type non-linear shell equations.

doi:10.1016/j.ijsolstr.2009.03.030

ABSTRACT: We present extensive numerical results of bifurcation buckling analysis of the axially compressed circular cylinder. The analysis is based on the modified displacement version of the non-linear theory of thin elastic shells developed by Opoka and Pietraszkiewicz [Opoka, S., Pietraszkiewicz, W., 2009. On modified displacement version of the non-linear theory of thin shells, International Journal of Solids and Structures, 46, 3103-3110]. To solve the buckling problem we apply the separation of variables and expansion of all fields into Fourier series in circumferential direction, with subsequent accurate calculations of eigenvalues of determinants of corresponding $8 \otimes 8$ complicated matrices. The numerical analysis of the buckling load is performed for the cylinders with length-to-diameter ratio in the range $(0.05, 60)$, with eight sets of incremental work-conjugate boundary conditions analogous to those used in the literature and partly summarized in the book by Yamaki [Yamaki, N., 1984. Elastic Stability of Circular Cylindrical Shells. Elsevier, Amsterdam], and additionally with six sets of boundary conditions not discussed in the literature yet. The results allow us to formulate several important conclusions, such as: (a) omission in the non-linear BVP small terms of the order of error introduced by the error of constitutive equations leads to overestimated buckling loads for long cylinders with clamped boundaries; (b) for some relaxed boundary conditions the buckling load decreases for short cylinders with decrease of the cylinder length; (c) the results for additional six sets of boundary conditions reveal existence of several new cases, in which by relaxing geometric boundary conditions the buckling load falls down to about one half of the classical value in a wide range of the cylinder length-to-diameter ratios.

ABSTRACT: We discuss the non-linear theory of thin shells expressed in terms of displacements of the shell reference surface as the only independent field variables. The formulation is based on the principle of virtual work postulated for the reference surface. In our approach: (1) the vector equilibrium equations are represented through components in the deformed contravariant surface base, and using the compatibility conditions the resulting tangential equilibrium equations are additionally simplified, (2) at the shell boundary the new scalar function of displacement derivatives is defined and new sets of four work-conjugate static and geometric boundary conditions are derived, as well as (3) for prescribed shell geometry all non-linear shell relations are generated automatically by two packages set up in Mathematica. The displacement boundary value problem and the associated homogeneous shell buckling problem are generated exactly without using any additional approximations following from errors of the constitutive equations. Both problems are extremely complex and available only in the computer memory. Such an approach allows us to account also for those a few supposedly small terms which may be critical for finding the correct buckling load of shells sensitive to imperfections. This approach is used in the accompanying paper by Opoka and Pietraszkiewicz [Opoka, S., Pietraszkiewicz, W., 2009. On refined analysis of bifurcation buckling for the axially compressed circular cylinder. International Journal of Solids and Structures, 46, 3111–3123.] to perform the refined numerical analysis of bifurcation buckling for the axially compressed circular cylinder.

ABSTRACT: Equations of equilibrium and appropriate four geometric and static boundary conditions are derived for the general nonlinear theory of thin shells. All shell relations are referred to the undeformed shell
middle surface. A modified tensor of change of curvature is used, which is a third-degree polynomial with respect to displacements. A new independent parameter describing the finite rotation of the shell boundary element is introduced, upon which works the boundary couple. All shell equations are consistently simplified in the case of elastic shells undergoing small strains but finite rotations, and the Hu-Washizu variational principle is constructed.

“On modeling and non-linear elasto-plastic analysis of thin shells with deformable junctions”, (publisher and date not given in the “pdf” file. The most recent reference is dated 2006.)

ABSTRACT: The undeformed base surface of the irregular thin shell is modelled by the union of a finite number of regular smooth surface elements joined together along spatial curvilinear surface edges. The equilibrium conditions are formulated by postulating an appropriate form of the principle of virtual work, where also deformability of shell junctions is taken into account. The PVW is then discretised by $C^1$ finite elements and the incremental-iterative procedure is applied to solve the highly non-linear BVP. As an example, the axisymmetric deformation state is calculated in the casing of devise measuring the external pressure and having two pairs of circular welded junctions. The problem is solved within the elasto-plastic range of material behaviour with linear combination of isotropic and kinematic hardening, and deformability of the junctions is taken into account.

ABSTRACT: We construct the unique two-dimensional (2D) kinematics which is work-conjugate to the exact, resultant local equilibrium conditions of the non-linear theory of branching shells. It is shown that the compatible shell displacements consist of the translation vector and rotation tensor fields defined on the regular parts of the shell base surface as well as independently on the singular surface curve modelling the shell branching. Discussing relations between limits of the translation vector and rotation tensor fields when approaching the singular curve, and analogous fields given only along the singular curve itself, several types of the junctions are described. Among them are the stiff, entirely simply connected and partly simply supported junction as well as the elastically and dissipatively deformable junction, and the non-local elastic junction. For each type of junction the explicit form of the principle of virtual work is derived.
ABSTRACT: We carry out further study of the constitutive laws for Cosserat plates developed by Altenbach and Eremeyev. In particular, we examine the problem of choice of the micropolar material coefficients. Requiring that the constitutive matrix is positive definite, we establish some bounds on values of micropolar constants. The constitutive relations for Cosserat plates have been implemented into formulation of shell finite elements developed within the framework of the statically and kinematically exact, nonlinear six-parameter shell theory. By the linear parametric-sensitivity analysis we study the influence of the micropolar material constants on the response of shell structure with orthogonal intersections of branches. Such structures can naturally be analyzed using the six-parameter shell theory. Having established the most influential coefficients, we show how these values affect the behavior of the structure in the nonlinear range of deformations.

ABSTRACT: Contributions of solid mechanics research to the development of composite materials and structures are reviewed. The main topics include the tensile and compressive strength of fibrous composites; transformation and residual fields in composite and laminated microstructures; plasticity and viscoplasticity of composites during processing, under thermomechanical service loads, and in the presence of evolving fatigue damage; delamination, damage and fracture; and future research needs.

ABSTRACT: Free vibration analysis of a through-width multidelaminated beam is performed in the present study. Multiple delaminations are assumed to spread from the top through the thickness direction of the beam. The natural frequencies of the multidelaminated beams are obtained from a recurrent single delaminated beam (RSDB) model, which is the subsingle delaminated beam from the top surface of a global beam. Each frequency equation for the RSDB with unknown boundary conditions is obtained through continuity conditions. Then this result is updated to the next one. With these sequential operations, the final frequency equation of the multidelaminated beams is obtained for both end boundary conditions of the global beam. The numerical results
for the beams are compared with those of finite element analysis to give the reliance on the proposed model and to investigate the effects of the shape, number, and size of multidelaminations on the natural frequency. It was shown that the variations in the natural frequency for the multidelaminated beams were significantly affected by the delamination length.

ABSTRACT: Certain mechanical systems display transitions between two nominally uniform solution states which have certain features in common with the true phase transitions. Three such examples will be discussed here. In order, they are the bulging of a long cylindrical balloon, neck propagation along bars of certain polymeric materials, and buckle propagation along externally pressurized pipes. Most of the results presented here were taken from two earlier papers by the authors and a colleague.
The two references cited in the abstract:

ABSTRACT: Two examples illustrate the propagation of instability modes under quasi-static, steady-state conditions. The first is the inflation of a long cylindrical party balloon in which a bulge propagates down the length of the balloon. The second is the collapse of a long pipe under external pressure as a result of buckle propagation. In each example, there is a substantial barrier to the initiation of the instability mode. Once initiated, however, the mode will not arrest if the pressure is in excess of the quasi-static, steady-state propagation pressure. It is this critical pressure that is determined in this paper for each of the two examples.

ABSTRACT: Conditions for the onset of wrinkling in doubly-curved sheet metal undergoing forming are obtained from a plastic buckling analysis for short-wavelength, shallow modes. The region of the sheet susceptible to wrinkling is assumed to be unconstrained by the die. When the principal axes of the membrane stress state coincide with the principal axes of the curvatures, simple formulas for the stresses or strains at wrinkling are obtained.

ABSTRACT: The property profile exhibited by cellular metals identifies several applications, especially in technologies requiring multifunctionality. Their specific property attributes suggest implementation as:
ultralight panels/shells, energy absorbing structures and heat dissipation media as well as for vibration control. Connections between the properties that govern these performance benefits and the cellular architecture, cell morphology and density have been made. Such structural relations facilitate choices of optimum cell characteristics for defined multifunctional applications.

ABSTRACT: Cellular metals have ranges of thermomechanical properties that suggest their implementation in ultralight structures, as well as for impact/blast amelioration systems, for heat dissipation media and in acoustic isolation. The realization of these applications requires that the properties of cellular metals be understood in terms of their manufacturing constraints and that their thermostructural benefits over competing concepts be firmly established. This overview examines the mechanical and thermal properties of this material class, relative to other cellular and dense materials. It also provides design analyses for prototypical systems which specify implementation opportunities relative to competing concepts.

ABSTRACT: Buckling of cylindrical sandwich shells subject to axial compression is addressed for shells having foamed metal cores. Optimal face sheet thickness, core thickness and core density are obtained which minimize the weight of a geometrically perfect shell with a specified load carrying capacity. Constraints imposed by wrinkling and yielding of the face sheets and yielding of the core are all considered. The range of the structural load index is identified for which the sandwich shells have a competitive weight advantage over stringer stiffened shells. In most of this range, the minimum weight design has elastic buckling simultaneous with face sheet yielding. Imperfection sensitivity of the shells is assessed with special emphasis on the role of plasticity in degrading strength, especially in light of the coincidence of elastic buckling and face sheet yielding in the optimally designed perfect shell. The purpose is to examine the interaction between imperfections and plastic yielding to see if buckling load knockdowns should be larger than those expected for elastic shells.

“The plastic collapse and energy absorption capacity of egg-box panels”, International Journal of Mechanical

ABSTRACT: The plastic collapse response of aluminium egg-box panels subjected to out-of-plane compression
has been measured and modelled. It is observed that the collapse strength and energy absorption are sensitive to
the level of in-plane constraint, with collapse dictated either by plastic buckling or by a travelling plastic
knuckle mechanism. Drop weight tests have been performed at speeds of up to 6 m s\(^{-1}\), and an elevation in
strength with impact velocity is noted. A 3D finite element shell model is needed in order to reproduce the
observed behaviours. Additional calculations using an axisymmetric finite element model give the correct
collapse modes but are less accurate than the more sophisticated 3D model. The finite element simulations
suggest that the observed velocity dependence of strength is primarily due to strain-rate sensitivity of the
aluminium sheet, with material inertia playing a negligible role. Finally, it is shown that the energy absorption
capacity of the egg-box material is comparable to that of metallic foams.

ABSTRACT: Sandwich panels offer high stiffness at low weight. Their cores, commonly, are made of balsa-wood, foamed polymers, glue-bonded aluminum or Nomex (paper) honeycombs. These have the drawbacks that they cannot be used much above room temperature, and that their properties are moisture-dependent. The deficiencies can be overcome by using metal foams as cores. This chapter elaborates the potential of metal-foam-cored sandwich structures.

ABSTRACT: The influence of prototypical imperfections on the nucleation and propagation stages of delamination of compressed thin films has been analyzed. Energy release rates for separations that develop from imperfections have been calculated. These demonstrate two characteristic quantities: a peak that governs nucleation and a minimum that controls propagation and failure. These quantities lead to two separate criteria that both need to be satisfied to cause failure. They involve a critical film thickness for nucleation and a critical imperfection wavelength for buckling. Implications for the avoidance of failure are discussed.

ABSTRACT: Delamination is considered for thin elastic films that are bonded to cylindrical substrates and subject to an equi-biaxial compressive pre-stress. Results for both positive and negative curvatures are obtained. The film buckles or deflects (depending on the sign of the curvature) away from the substrate inducing mixed mode stress intensities at the edge of the delamination. The energy release rate and combination of modal stress intensities at the delamination edges are determined. Steady-state propagation of delamination blisters is analyzed for both axial and circumferential propagation directions. The results depend strongly on the substrate curvature. Circumferential propagation is suppressed when the curvature is negative, but is favored when the curvature is positive. Axial propagation can occur for both positive and negative curvature substrates.

ABSTRACT: Theoretical studies have indicated that truss core panels with a tetragonal topology support bending and compression loads at lower weight than competing concepts. The goal of this study is to validate this prediction by implementing an experimental protocol that probes the key mechanical characteristics while addressing node eccentricity and structural robustness. For this purpose, panels have been fabricated from a beryllium–copper alloy using a rapid prototyping approach and investment casting. Measurements were performed on these panels in flexure, shear and compression. Numerical simulations were conducted for these same configurations. The measurements reveal complete consistency with the stiffness and limit load predictions, as well as providing a vivid illustration of asymmetric structural responses that arises because the bending behavior of optimized panels is dependent on truss orientation.

doi:10.1016/S0020-7683(03)00348-2

ABSTRACT: A class of planar, pin-jointed truss structures based on the ancient Kagome basket weave pattern with exceptional characteristics for actuation has been identified. Its in-plane stiffness is isotropic and has optimal weight among planar trusses for specified stiffness or strength. The version with welded joints resists
plastic yielding and buckling, while storing minimal energy upon truss bending during actuation. Two plate structures are considered which employ the planar Kagome truss as the actuation plane. It is shown that these plates can be actuated with minimal internal resistance to achieve a wide range of shapes, while also sustaining large loads through their isotropic bending/stretching stiffness, and their excellent resistance to yielding/buckling.

References listed at the end of the paper:

ABSTRACT: Kagome truss plates have properties that suggest they should be uniquely effective as an actuation plane for sandwich plates: a Kagome truss plate has in-plane isotropy, optimal stiffness and strength, and its truss members can be actuated with minimal internal resistance. In this paper, sandwich plates are studied that are comprised of one solid face sheet and one actuated Kagome face sheet joined by a pyramidal truss core. Various aspects of the actuation behavior of these plates are investigated, including internal resistance and strains resulting from actuation and efficiency of actuation. Single and double curvature actuation modes are investigated. Contact is made with analytic results for actuation modes with long wavelength.

References listed at the end of the paper:
ABSTRACT: The performance characteristics of a truss core sandwich panel design based on the 3D Kagomé has been measured and compared with earlier simulations. Panels have been fabricated by investment casting and tested in compression, shear and bending. The isotropic nature of this core design has been confirmed. The superior performance relative to truss designs based on the tetrahedron has been demonstrated and attributed to the greater resistance to plastic buckling at the equivalent core density.

ABSTRACT: The performance of metal sandwich plates under impulsive blast loads is compared to that of solid plates made of the same material and having the same weight. Three core geometries are considered: pyramidal truss, square honeycomb and folded plate. Plates of infinite length and clamped along their sides are subject to uniform impulsive load. The momentum impulse is applied to the face sheet towards the blast in the case of the sandwich plate, while it is distributed uniformly through the thickness of the solid plate. Large impulses are considered that are sufficient to produce lateral plate deflections more than 10% of the plate width. Fracture is not considered; the plates are assumed to have sufficient ductility to be able to sustain the deformations. A limited study of weight optimization is carried out for each of the core types with respect to the respective geometric parameters, including core and face sheet thickness, core member aspect ratios and relative density. A well-designed sandwich plate can sustain significantly larger blast impulses than a solid plate of the same weight. If the blast medium is water, fluid–structure interaction can reduce the momentum imparted to a sandwich plate by almost a factor of two relative to that imparted to a solid plate of the same weight, and, consequently, the relative benefit of the sandwich plate is significantly enhanced over its solid counterpart.

ABSTRACT: Explosive tests were performed in air to study the dynamic mechanical response of square honeycomb core sandwich panels made from a super-austenitic stainless steel alloy. Tests were conducted at three levels of impulse load on the sandwich panels and solid plates with the same areal density. Impulse was varied by changing the charge weight of the explosive at a constant standoff distance. At the lowest intensity load, significant front face bending and progressive cell wall buckling were observed at the center of the panel closest to the explosion source. Cell wall buckling and core densification increased as the impulse increased. An air blast simulation code was used to determine the blast loads at the front surfaces of the test panels, and these were used as inputs to finite element calculations of the dynamic response of the sandwich structure. Very good agreement was observed between the finite element model predictions of the sandwich panel front and back face displacements and the experimental observations. The model also captured many of the phenomenological details of the core deformation behavior. The honeycomb sandwich panels suffered significantly smaller back face deflections than solid plates of identical mass even though their design was far from optimal for such an application.

ABSTRACT: In foregoing study, a new phenomenon of the local dent of upper face sheet occurs in the simulation of dynamic response of sandwich plate subjected to blast loading. The reason and the effect of local dent on energy absorption are not ascertained. In this paper, two kind of square honeycomb plate with the cell wall thickness of 1mm and 0.5mm and with the same mass are modeled. And the dynamic response of both plates subjected to blast loading is simulated using LS-DYNA. For the thicker cell wall (1mm), the local dent is obvious while for the thinner cell wall (0.5mm), the local dent is not obvious and can be ignored. In addition, curves of the ratio of the maximum deflection of lower face sheet of sandwich plate to monolithic solid plate vs the mass of TNT charge as well as the ratio of internal energy are obtained. The results indicate that the local dent has the contribution to the energy absorption of sandwich plate especially in early time and the sandwich plate with the core of thinner cell wall has more effective capacity in blast-resistance than that with the core of thicker cell wall.

ABSTRACT: Structural members and components, such as shells and trusses of different geometries, form the intricate and deep seated parts in the manufacturing of missiles submarines, rockets, airplanes, automobiles etc and find applications in civil structures such as bridges. These members are comprised of components like conical frusta, cylindrical panels and shallow trusses. In many cases, the sole purpose of such shell structures is to absorb the energy generated due to impact which means, that these structures are subjected to heavy loads and can experience failure due to buckling. The objective of this work is to study the buckling and post buckling behavior of such members. The study is carried out using finite element analysis. The widely implemented softwares ANSYS APDL and ANSYS Workbench are used to perform the analysis. The components analyzed consist of shell structures such as conical frusta and cylindrical panels, and other structures like the shallow truss, diagonal truss and the shallow arch. These structures are analyzed for their buckling and post buckling behavior when subject to specific loading conditions and geometric, contact and material non-linearity. The
results compare favorably with known solutions.

ABSTRACT: Cellular materials with hollow lattice truss topologies exhibit higher compressive strengths than equivalent structures with solid trusses owing to their greater resistance to plastic buckling. Consequently, hollow trusses have attracted interest as the cores for sandwich panels. Finite-element calculations are used to investigate the elastic–plastic compressive collapse of a metallic sandwich core made from vertical or inclined circular tubes, made from annealed AISI 304 stainless steel. First, the dependence of the axial compressive collapse mode upon tube geometry is determined for vertical tubes with built-in ends and is displayed in the form of a collapse mechanism map. Second, the approach is extended to inclined circular hollow tubes arranged as a pyramidal lattice core; the collapse modes are identified and the peak compressive strength is determined as a function of geometry. For a given relative density of hollow pyramidal core, the inclined tube geometry that maximizes peak strength is identified. The predicted collapse modes and loads for the pyramidal core are in excellent agreement with measurements for the limited set of experimentally investigated geometries.

“Response of metallic pyramidal lattice core sandwich panels to high intensity impulsive loading in air”,

ABSTRACT: Small scale explosive loading of sandwich panels with low relative density pyramidal lattice cores has been used to study the large scale bending and fracture response of a model sandwich panel system in which the core has little stretch resistance. The panels were made from a ductile stainless steel and the practical consequence of reducing the sandwich panel face sheet thickness to induce a recently predicted beneficial fluid–structure interaction (FSI) effect was investigated. The panel responses are compared to those of monolithic solid plates of equivalent areal density. The impulse imparted to the panels was varied from 1.5 to 7.6 kPa s by changing the standoff distance between the center of a spherical explosive charge and the front face of the panels. A decoupled finite element model has been used to computationally investigate the dynamic response of the panels. It predicts panel deformations well and is used to identify the deformation time sequence and the face sheet and core failure mechanisms. The study shows that efforts to use thin face sheets to exploit FSI benefits are constrained by dynamic fracture of the front face and that this failure mode is in part a consequence of the high strength of the inertially stabilized trusses. Even though the pyramidal lattice core offers little in-plane stretch resistance, and the FSI effect is negligible during loading by air, the sandwich panels are found to suffer slightly smaller back face deflections and transmit smaller vertical component forces to the supports compared to equivalent monolithic plates.

ABSTRACT: This paper presents the results of experimental and numerical work on the response of sandwich panels made of thin-walled tubes and mild steel plates to axial loading. The core of the sandwich panels consists of mild-steel square tubes, 20×20×0.9 mm in cross-section, in three different layouts comprising of four or five or nine tubes, (panels A, B and C respectively). Three tube configurations are investigated, as–received tubes, tubes with circular cut-out on opposite sides, and tubes with dents on opposite sides. The imperfections are located at the mid-section of the tube. The outer skin of the sandwich panel is 150×150×10 mm in cross-section and non-deformable. Quasi-static tests carried out on two and three tubes laid out in parallel between the skin indicate that the axial forces is a multiple of the axial force of a single tube, as expected. Consequently, the sandwich panel with the nine tubes deforms less than the sandwich panels with five and four tubes when subjected to similar impact energy. Triggers in the tubes improve the collapse mode of the sandwich panels. The Finite Element package ABAQUS/Explicit v6.7 is used to construct a ¼ symmetry model using shell elements to simulate the response of the sandwich panels to dynamic axial load. The Finite element simulations, validated using high speed photography footage, show good correlations with experiments.

ABSTRACT: According to the classical Alexander solution for the axial collapse of bare metal tubes, a theoretical model is presented to predict the effect of thermal environment on the axial crushing load of a sandwich tubes with an arbitrarily fiber-reinforced layer between the two metal walls, based on a ring collapse mode. The mechanical property of metal walls is considered as a linear function of temperature change. A simple comparison, not considering thermal effect with the experiment previously obtained, is used to prove that the derived mean crushing load and length of the local folding mode are reasonable. The effects of wrapping direction of the reinforcing fibers in sandwich tubes and different thermal environments on the axial crushing load are investigated. The results show that the mean crushing load of a sandwich tubes gradually decreases as the temperature change increases, which must be considered in engineering designs.

John W. Hutchinson, “Comments on the Buckling Assessment of the Oyster Creek Drywell Shell with
Emphasis on the Determination of Capacity Reduction Factors”, pbadupws.nrc.gov, October 2009

ABSTRACT: The approach taken in assessing the integrity of the drywell shell against buckling is sound and in accord with the best practices. However, in reviewing the various studies, it appears to this reviewer that the approach set out in ASME Code Case 2286-1 accounting for transverse stress in the capacity reduction factors for spherical shells should be reviewed with eye to modification in the future. The emphasis of this report will focus on what we believe are possible shortcomings and inconsistencies of Code Case 2286-1. In spite of the concerns that will be spelled out about Code Case 2286-1, the capacity reduction factors generated by the alternative approach suggested here are in close agreement with those used in the assessment. Moreover, it will be argued that the alternative approach provides conservative results for the effect of transverse stress on the capacity reduction factor for the baseline case of large spherical shell segments. Thus, it is not our opinion that any possible shortcomings of Code Case 2286-1 should invalidate the conclusions of the buckling assessments.

This report begins with a brief introduction to the use of the capacity reduction factor to account for the effect of imperfections on buckling of thin spherical shells with emphasis on the stabilizing role of transverse stress. It then reviews several prescriptions for reduction factors for spherical shells highlighting what this reviewer believes are the shortcomings of Code Case 2286-1. Finally, capacity reduction factors from the two approaches as applied to the spherical portion of the drywell shell are presented adding confidence to the conclusions of the drywell assessments reported.

ABSTRACT: We present a basic analysis that establishes the metrics affecting the energy absorbed by multilayer cellular media during irreversible compaction on either a mass or volume basis. The behaviors at low and high impulse levels are distinguished through the energy dissipated in the shock. The overall mass of an energy absorbing system (comprising a cellular medium and a buffer) is minimized by maximizing the non-dimensional dissipation per unit mass parameter for the cellular medium, \( \lambda = \frac{U(m)\rho(s)}{\sigma(y)} \), where \( U(m) \) is the dissipation per unit mass of the cellular medium, ascertained from the area under the quasi-static compressive stress/strain curve, \( \sigma(y) \) is the yield strength of the constituent material and \( \rho(s) \) is the density of the material used in the medium. Plots of \( \lambda \) against the non-dimensional stress transmitted through the medium, \( \sigma(tr)/\sigma(y) \), demonstrate the relative energy absorbing characteristics of foams and prismatic media, such as honeycombs. Comparisons with these benchmark systems are used to demonstrate the superior performance of micro-lattices, especially those with hollow truss members. Numerical calculations demonstrate the relative densities and geometric configurations wherein the lattices offer benefit. Experimental
results obtained for a Ni micro-lattice with hollow members not only affirm the benefits, but also demonstrate energy absorption levels substantially exceeding those predicted by analysis. This assessment highlights the new opportunities that tailored micro-lattices provide for unprecedented levels of energy absorption for protection from impulsive loads.

ABSTRACT: Conical frusta made from leaded gun-metal have been compressed axially. Collapse is either by a travelling plastic hinge or by tearing. An analytical model is developed for the travelling plastic hinge in a rigid, ideally plastic solid; its predictions are compared with the observed response, and with those of an axisymmetric finite element analysis. The travelling hinge mechanism is also observed in the compressive collapse of an egg-box material comprising a square array of conical frusta. Collapse mechanism maps are constructed for the egg-box material, and they show the regimes of dominance of elastic buckling, material tearing and the travelling plastic hinge. The maps are useful for selecting egg-box geometries that maximise the energy absorption per unit mass at any prescribed value of collapse stress. The optimisation indicates that the egg-box material has a similar energy absorption capacity to that of hexagonal honeycombs and is superior to that of metal foams.

ABSTRACT: Corrugated and diamond lattice materials have been manufactured as the cores of sandwich
panels by slotting together stainless steel sheets and then brazing together the assembly. The out-of-plane compressive, transverse shear and longitudinal shear responses of the corrugated cores have been measured at three relative densities 0.03 < \( \text{rhorb} < 0.10 \) and compared with analytical and finite element (FE) predictions. Finite element models are in good agreement with the experimental measurements while the analytical models over-predict the measured strength due to a neglect of manufacturing imperfections. The out-of-plane compressive and transverse shear responses of the diamond cores have also been measured at three relative densities 0.08 < \( \text{rhorb} < 0.25 \). The compressive strengths are sensitive to the aspect ratio of the specimens for \( L/H < 4 \) and again are below the analytical predictions due to imperfections. The longitudinal shear strength and energy absorption compare favorably with competing core topologies but the prismatic corrugated and diamond cores are weaker than the pyramidal and square-honeycomb under compression and transverse shear.

ABSTRACT: Cylindrical shells under uniaxial compression and spherical shells under equi-biaxial compression display the most extreme buckling sensitivity to imperfections. In engineering practice, the reduction of load carrying capacity due to imperfections is usually addressed by use of a knockdown factor to lower the critical buckling stress estimated or computed without accounting for imperfections. For thin elastic cylindrical shells under uniaxial compression and spherical shells under equi-biaxial compression, the knockdown factor is typically as small as 0.2. This paper explores the alleviation of imperfection-sensitivity for loadings with a reduced circumferential (transverse) membrane stress component. The analysis of Koiter (1963) on the effect of an axisymmetric imperfection on the elastic buckling of a cylindrical shell under uniaxial compression is extended to both cylinders and spheres for loadings that produce general combinations of biaxial membrane stresses. Increases in the knockdown factor due to a reduction of the transverse membrane component are remarkably similar for cylindrical and spherical shells.

ABSTRACT: Chromium (Cr) films are widely used as interlayers to promote the adhesion of copper or gold to substrates. However, the Cr interlayer usually fractures at lower strains than the ductile metal films. In this paper, the cracking and buckling behavior of Cr films on polyethylene terephthalate (PET) substrates were studied in situ under tensile loading with the Atomic Force Microscope (AFM) and optical microscope imaging. Cr films with three nominal thicknesses of 15, 70 and 140 nm were studied. The depth and width of the cracks, as well as the height and width of the buckles, were measured from AFM images acquired at incremental loading steps. The buckle shapes at different strain levels were carefully examined using AFM line profile. It was found that at large strain levels the measured buckle shapes usually deviated from the elastic buckling mode shapes. Further in situ AFM imaging of the buckles at a smaller scan area revealed that in some cases the buckles were cracked at the apex. These in situ nanoscale measurements provided experimental observations and data for further model development and more accurate measurement of the interfacial fracture energy at the Cr-PET interface.

ABSTRACT: We take a fresh look at diatoms, and find a reasonable visual match of some valve and girdle contours to various kinds of buckling phenomena, describable as corrugations, pleats and folds, and Bessel functions, such as describe the vibrations of a round musical drum. Buckling of raphes and costae, considered as buckling of columns, may account for some of their features. The matches we find will have to be tested by finite element method, computer simulation, time sequence microscopy, micromanipulation, and direct measurement of the physical (constitutive) properties of the materials from which a diatom constructs itself. The genome may set up boundary conditions that lead to mechanical instabilities and buckling, rather than controlling these diatom patterns in any direct way. This investigation also led us to propose that there is an electric potential in the silicalemma that may account for the generally straight course of growth of costae.

ABSTRACT: Thin stiff films on compliant elastic substrates subject to equi-biaxial compressive stress states are observed to buckle into various periodic mode patterns including checkerboard, hexagonal and herringbone. An experimental setting in which these modes are observed and evolve is described. The modes are characterized and ranked by the extent to which they reduce the elastic energy of the film–substrate system relative to that of the unbuckled state over a wide range of overstress. A new mode is identified and analyzed having nodal lines coincident with an equilateral triangular pattern. Two methods are employed to ascertain the energy in the buckled state: an analytical upper-bound method and a full numerical analysis. The upper-bound
is shown to be reasonably accurate to large levels of overstress. For flat films, except at small states of overstress where the checkerboard is preferred, the herringbone mode has the lowest energy, followed by the checkerboard, with the hexagonal, triangular, and one-dimensional modes lowering the energy the least. At low overstress, the hexagonal mode is observed in the experiments not the square mode. It is proposed that a slight initial curvature of the film may play a role in selecting the hexagonal pattern accompanied by a detailed analysis. An intriguing finding is that the hexagonal and triangular modes have the same energy in the buckled state and, moreover, a continuous transition between these modes exists involving a linear combination of the two modes with no change in energy. Experimental observations of various periodic modes are discussed with reference to the energy landscape. Discrepancies between observations and theory are highlighted and open issues are highlighted.

Von Kármán, T., Tsien, H.S., 1941. The buckling of cylindrical shells under axial compression. J. Aerosci. 8, 303–312.

ABSTRACT: Wrinkles in thin films on soft substrates have been shown to self-organize into topological patterns, providing a possible route towards inexpensive generation of surface microstructure. However, the effect of the magnitude of applied stress in relation to the critical buckling stress, or overstress, on the observed patterns has until this point been neglected experimentally. In this paper, we investigate the effect of overstress using poly(dimethylsiloxane) which has been surface-oxidized with a UV-ozone oxidation technique. Using a swelling-based stress application technique, where the applied swelling stress in the thin film is controlled by changing the concentration of vapor-phase swelling agent (ethanol) in a sealed swelling chamber, we are able to impart swelling stresses below, at, and well above the critical stress. We observe a transition from hexagonally packed dimples at low overstress to ridge-based morphologies (herringbone and labyrinth) at high overstress. The observed dimple structures are remarkably widespread, and the hexagonal arrangement of these dimples is confirmed using Fourier analysis. Although analytical results predict that a square arrangement of dimples is preferred to hexagonal for flat wrinkling surfaces, hexagonal arrays are nonetheless unilaterally observed at low overstress. We attribute this observation to an inherent curvature that develops in the swelling film. The overstress is quantified by measuring the radius of curvature of swelling bilayer beams, both confirming the preferential swelling of the surface oxide layer by ethanol and quantifying the swelling extent. Effects of non-equi-biaxial stress are investigated by inducing a compressive prestress prior to swelling, and “trapped” non-equilibrium morphologies are discussed briefly.

ABSTRACT: The most common solutions for in-situ connections of steel tubular tower segments of onshore wind turbines are ring flange connections. These have certain drawbacks, such as e.g. costly production, long delivery time and rather low fatigue endurance. Friction connections with long open slotted holes have previously been proven to be a competitive alternative. In this work, the new type of connection is investigated in various scales: segment tests, down-scaled experiments and full-scale models. The influence of tower cross-section shape, execution tolerance (horizontal gap between the tower segments) and length of the connection on the bending resistance is thoroughly studied. In addition, buckling behaviour of the shell in the vicinity of the friction connection in towers with circular and polygonal cross-sections is analysed in order to check possible advantages of either cross-section. The influence of two types of the execution tolerances on the connection strength is investigated: inwards bent “fingers”, leading to inclined gaps, and a parallel gap created by different diameters of the tower segments. Based on validated finite element analyses recommendations for execution tolerances are proposed. A closer look is taken at the level of bolt forces under load application for the new friction connections as well as for the ring flange connection. For the former case, the influence of slotted holes on the joint resistance is checked. For both types of connections, comparison is drawn to hand calculation models used in engineering practice. Additionally, the distribution of meridional stresses in the shell in the vicinity of the connection is studied. Based on the findings from the above described investigations, recommendations for the design of friction connections with open slotted holes in steel tubular towers for onshore wind turbines are given.

ABSTRACT: An arch structure offers an effective load carrying system for large span structures. Environmental and economical considerations makes glulam a good material of choice for the arch members. However, asymmetric loading of an arch cause bending moment that implies use of deep and narrow arch cross-sections. Such slender section shape increases the risk of instability.

The purpose of this master’s thesis is to gain knowledge of instability phenomena of timber arches. Identification and evaluation of influencing variables by non-linear numerical analysis are compared to the rules for structural design used in EU: Eurocode.

Eurocode considers instability of straight beams and columns with respect to boundary conditions and cross-section properties, while initial imperfections are considered only implicitly. For instability of curved members no analytical approach is provided in the code, thus some numerical method is needed.

In structural design the load carrying capacity of arches is commonly evaluated by finite element (FE) method. Typically used today is linear instability FE analysis. However, this thesis also includes non-linear FE analysis which considers large deformations with redistribution of stresses and a material fail criterion.

Our findings conclude that the linear analysis overestimates the critical load due to instability typically by 20-40% for a parabolic arch. The analysis further indicates that the lateral arch support setup is a fundamental design aspect for the buckling behaviour for which both extrados and intrados lateral support is needed to obtain an effective structure.

The variations in timber material properties and the influence of moisture and long duration of loading are effectively regarded in Eurocode using reduction coefficients. Non-linear FE calculations with respect to influence of moisture and load duration indicated reasonably good agreement with Eurocode. Reduction of material strength due to moisture and load duration effects does not affect the critical load as much as the corresponding reduction of material stiffness. Moisture induced stiffness reduction can give 20% reduction of critical load.

The difficulty in Eurocode is to determine a feasible capacity reduction with respect to the risk of instability for an arch. The authors conclude that structural design of a parabolic arch should be conducted using critical loads from a non-linear FE analysis to be implemented in the Eurocode design calculations.

ABSTRACT: Recognition of the positive features of elastic instabilities for use in smart and adaptive materials and structures has increased in recent years. Among many unstable events, buckling is one of the oldest and most well-understood types of response and yet this critical condition has been mainly regarded as a failure limit and the afterward response (postbuckling) as a safeguard. However, research on smart/adaptive devices has identified buckling and postbuckling as a favorable behavior. This dissertation explores the potential of cylindrical shells under axial compression, for which mode transitions during the postbuckling response lead to sudden and high-rate deformations from generally smaller changes in the controlling load or displacement input to the system. Such geometric nonlinear responses allow cylindrical shells to be considered as a viable structural prototype for purposes such as energy harvesting, sensing, actuation, etc.

Experimental and numerical studies evaluated three avenues for modifying and controlling the postbuckling response of cylindrical shells: (1) by introducing seeded geometric imperfections (SGI); (2) by introducing non-uniform stiffness distributions (NSD); and (3) by providing lateral constraints and interactions (LCI). An SGI cylinder is obtained by superposing a single mode shape from the eigenvalue analyses on a uniform cylinder to provide a governing role over other initial random imperfections. An NSD cylinder follows a similar concept of introducing artificial imperfections but by strategically placing patterned thickened regions (which alter the stiffness distribution) on the shell surface with the aim of triggering localized buckling events in non-thickened regions. Finally, an LCI cylinder is driven by the desire to gain further control of the postbuckling response through the interaction of multiple cylinders in nested assemblies. The numerical simulations were conducted through extensions on established methods for simulating nonlinear geometric response in slender structures. Prototyped cylinder were fabricated, first by using laminated composite materials and later through 3D printing and tested under cyclic loading. Further extension of these concepts was explored through a design optimization process.

Numerical and experimental results suggest that SGI and NSD cylinders can attain a controllable postbuckling response due to the governing role of artificial imperfections. For both cases, the localized buckling events can be triggered in predefined regions; and careful selection of the geometry and stiffness distribution can lead to elastic postbuckling responses with tailorable features, which implies diverse design opportunities. Further, simulations and test results demonstrated that the elastic postbuckling response of SGI and NSD shells was less sensitive to initial (manufacturing) imperfections as well as loading variations compared to that of uniform cylinders. Studies on LCI cylinders showed that this concept allows the attainment of a higher number of mode transitions in the elastic postbuckling regime and the post-buckling stiffening behavior increases to levels that surpass the initial buckling load. Optimization results showcased that postbuckling response can be tailored into three types (softening, sustaining and stiffening) and design guidelines were developed to achieve a targeted behavior.

The study has led to knowledge on the possibilities, extent and means to control (and thus design) the elastic far postbuckling response of cylindrical shells with the noted variations in geometry, stiffness and boundary conditions. Full characterization and understanding of these variables in the attainment and control of postbuckling response with desirable features can promote the use of the presented cylindrical shell concepts for a variety of purposes of emerging interest and across scales for various applications.

ABSTRACT: The present thesis addresses some of the problems dealing with the static and dynamic analyses of functionally graded plates and shells subjected to aero-thermo-mechanical loads using field-consistent and high precision plate/shell finite elements. The formulation is based on the first-order shear deformation theory and developed with reference to both the neutral and the mid-surfaces. The material properties vary through the thickness according to a power-law distribution and the locally effective material properties are evaluated using the Voigt rule of mixture or the Mori-Tanaka homogenization method. The geometric nonlinearity is incorporated using von Karman's theory. The solutions are obtained using the Newton-Raphson iterative method/eigenvalue approach for the static problems and using the direct time integration procedure/eigenvalue formulation for the dynamic cases. The methodologies employed here are assessed, wherever possible, by studying the problems for which the solutions are available.

Firstly, as the position of neutral surface for FGM plates/shells varies depending on the material gradation, the effect of in-plane fixity and the approach of neutral/mid-surface based formulation are clearly brought out by investigating the bending behavior of FGM plates. Then, the post-buckling behavior of FGM plates and the appropriate solution procedures to obtain its characteristics depending on the boundary and loading conditions are discussed. The occurrence of secondary instability in the primary post-buckling path of FGM plate at higher load level is also established. Later, the nonlinear free and flutter vibration of FGM plates are examined under aero-thermal loads. The onset of change in equilibrium position, where a sudden drop occurs in the frequency value at higher amplitude of vibration, is also predicted. The flexural vibration of plates changing from limit cycle oscillation to chaotic motion with the increase in aerodynamic load is also examined using a time-response analysis. Here, the aerodynamic force is evaluated based on the third-order piston theory. Finally, the nonlinear axi-symmetric dynamic buckling of shallow spherical caps is analyzed using an axi-symmetric shell element with a semi-analytical approach. Different loading profiles in the form of step load or triangular pulse of various durations are considered. In addition to the above nonlinear studies, the linear asymmetric vibration and buckling of FGM circular plates are also investigated as a special case by deducing the formulation of spherical shells. In all these problems, the parametric studies are performed considering various geometric material parameters, and different types of loading and boundary conditions.
Derek Breid (University of Massachusetts, Amherst), “Controlling morphology in swelling-induced wrinkled surfaces”, Ph.D dissertation, Polymer Science and Engineering, University of Massachusetts – Amherst, February 2012

ABSTRACT: Wrinkles represent a pathway towards the spontaneous generation of ordered surface microstructure for applications in numerous fields. Examples of highly complex ordered wrinkle structures abound in Nature, but the ability to harness this potential for advanced material applications remains limited. This work focuses on understanding the relationship between the patterns on a wrinkled surface and the experimental conditions under which they form. Because wrinkles form in response to applied stresses, particular attention is given to the nature of the stresses in a wrinkling surface. The fundamental insight gained was then utilized to account for observed wrinkle formation phenomena within more complex geometric and kinetic settings. In order to carefully control and measure the applied stresses on a wrinkling film, a swelling-based system was developed using poly(dimethylsiloxane) (PDMS), surface-oxidized with a UV-ozone treatment. The swelling of the oxidized surface upon exposure to an ethanol vapor atmosphere was characterized using beam-bending experiments, allowing quantitative measurements of the applied stress. The wrinkle morphologies were characterized as a function of the overstress, defined as the ratio of the applied swelling stress to the critical buckling stress of the material. A transition in the dominant morphology of the wrinkled surfaces from dimple patterns to ridge patterns was observed at an overstress value of ~2. The pattern dependence of wrinkles on the ratio of the principal stresses was examined by fabricating samples with a gradient prestress. When swollen, these samples exhibited a smooth morphological transition from non-equibiaxial to equibiaxial patterns, with prestrains as low as 2.5% exhibiting non-equibiaxial characteristics. This transition was seen both in samples with low and high overstresses. To explore the impact of these stress states in more complex geometries, wrinkling hemispherical surfaces with radii of curvature ranging from 50-1000 mm were fabricated using the same material system. Upon wrinkling, the hemispheres formed complex hierarchical assemblies reminiscent of naturally occurring structures. The curvature of a surface exhibited a correlation with its critical buckling stress, independent of other factors. This enables the surface curvature to be used as an independent control over the dimple-to-ridge transition which occurs as a function of overstress. As in the flat buckling surfaces, this transition was shown to occur at an overstress value of ~2. Surface curvature was also shown to improve the observed hexagonal ordering of the dimple arrays, resulting in the formation of regular "golf ball" structures. Geometric effects in finite flat plates were also examined. Using circular masks during the oxidation process, plates with radii ranging from 0.4-8.6 mm were created. Upon wrinkling, a dimple-to-ridge transition was observed with increasing plate size, with the morphological switch occurring at a radius of ~2 mm. This observed transition was not found to be due to the inherent mechanics of plates of different sizes, but instead to a reduction in the oxide conversion due to shadowing or stagnation caused by the masking process, which lowered the applied overstress. The shape of the finite plate was found to have little impact on the resulting wrinkle morphologies. Kinetic aspects of wrinkling were qualitatively characterized by observing the wrinkling process over the course of swelling. Wrinkling was observed to frontally propagate across the surface, and the ordering of the patterns which developed showed a qualitative correlation with the degree of uniformity in the advancing wrinkle front. Swelling with different solvents was found to lead to the formation of different patterns, based on the swelling kinetics of the UVO-treated PDMS upon exposure to each solvent.

ABSTRACT: Three-dimensional topological insulators host linearly dispersing states with unique properties and a strong potential for applications. An important ingredient in realizing some of the more exotic states in topological insulators is the ability to manipulate local electronic properties. Direct analogy to the Dirac material graphene suggests that a possible avenue for controlling local properties is via a controlled structural deformation such as the formation of ripples. However, the influence of such ripples on topological insulators is yet to be explored. Here we use scanning tunnelling microscopy to determine the effects of one-dimensional buckling on the electronic properties of Bi$_2$Te$_3$. By tracking spatial variations of the interference patterns generated by the Dirac electrons we show that buckling imposes a periodic potential, which locally modulates the surface-state dispersion. This suggests that forming one- and two-dimensional ripples is a viable method for creating nanoscale potential landscapes that can be used to control the properties of Dirac electrons in topological insulators.

ABSTRACT: Differential growth in elastic materials can produce stress either through incompatibility of growth or by interaction with the surrounding medium. In many situations, this stress can be sufficient to induce shape instability in the growing medium. To gain better insight in growth-induced instabilities, the growth of an elastic shell loaded with hydrostatic pressure or embedded in an elastic medium is studied. The residual stress arising from the incompatibility of growth and the contact stress arising from the interaction with the surrounding medium are computed with respect to growth and geometric parameters and critical values for instability are obtained. Depending on these parameters, different modes of instability can be obtained. References listed at the end of the paper:

ABSTRACT: The buckling of hyperelastic incompressible cylindrical tubes of arbitrary length and thickness
under compressive axial load is considered within the framework of nonlinear elasticity. Analytical and
numerical methods for bifurcation are developed using the exact solution of Wilkes for the linearized problem
within the Stroh formalism. Using these methods, the range of validity of the Euler buckling formula and its
first nonlinear corrections are obtained for third-order elasticity. The values of the geometric parameters (tube
thickness and slenderness) where a transition between buckling and barrelling is observed are also identified.

ABSTRACT: In many cylindrical structures in biology, residual stress fields are created through differential growth. In particular, if the outer and inner layers of a cylinder grow differentially, parts of the cylinder will be in a state of axial compression and other parts will be in tension. These tissue tensions change the overall material properties of the structure. Here, we study the role of tissue tension in the overall rigidity and stability of the cylinder. A detailed analysis, based on nonlinear elasticity, of the effect of tissue tension on the mechanical properties of growing cylinders reveal a subtle interplay between geometry, growth, and nonlinear elastic responses that help understand some of the remarkable properties of stems and other biological tissues.

ABSTRACT: Incremental equilibrium equations and corresponding boundary conditions for an isotropic, hyperelastic and incompressible material are summarized and then specialized to a form suitable for the analysis of a spherical shell subject to an internal or an external pressure. A thick-walled spherical shell during inflation is analyzed using four different material models. Specifically, one and two terms in the Ogden energy formulation, the Gent model and an I1 formulation recently proposed by Lopez-Pamies. We investigate the existence of local pressure maxima and minima and the dependence of the corresponding stretches on the material model and on shell thickness. These results are then used to investigate axisymmetric bifurcations of the inflated shell. The analysis is extended to determine the behavior of a thick-walled spherical shell subject to an external pressure. We find that the results of the two terms Ogden formulation, the Gent and the Lopez-Pamies models are very similar, for the one term Ogden material we identify additional critical stretches, which have not been reported in the literature before.

Coda (Department of Structural Engineering, São Carlos School of Engineering, University of São Paulo, São Carlos, São Paulo, Brazil), “A shell finite element formulation to analyze highly deformable rubber-like materials”, Latin American Journal of Solids and Structures, Vol. 10, No. 6, 2013

ABSTRACT: In this paper, a shell finite element formulation to analyze highly deformable shell structures composed of homogeneous rubber-like materials is presented. The element is a triangular shell of any order with seven nodal parameters. The shell kinematics is based on geometrically exact Lagrangian description and on the Reissner-Mindlin hypothesis. The finite element can represent thickness stretch and, due to the seventh nodal parameter, linear strain through the thickness direction, which avoids Poisson locking. Other types of locking are eliminated via high-order approximations and mesh refinement. To deal with high-order approximations, a numerical strategy is developed to automatically calculate the shape functions. In the present study, the positional version of the Finite Element Method (FEM) is employed. In this case, nodal positions and unconstrained vectors are the current kinematic variables, instead of displacements and rotations. To model near-incompressible materials under finite elastic strains, which is the case of rubber-like materials, three nonlinear and isotropic hyperelastic laws are adopted. In order to validate the proposed finite element formulation, some benchmark problems with materials under large deformations have been numerically analyzed, as the Cook’s membrane, the spherical shell and the pinched cylinder. The results show that the mesh refinement increases the accuracy of solutions, high-order Lagrangian interpolation functions mitigate general locking problems, and the seventh nodal parameter must be used in bending-dominated problems in order to avoid Poisson locking.

ABSTRACT: The nonlinear kinematics of thin shells is developed in full generality according to a duality approach in which kinematics plays the basic role in the definition of the model. The Kirchhoff–Love shell model is the central issue and is discussed in detail but shear deformable and polar models are also considered and critically reviewed. The analysis is developed with a coordinate-free approach which provides a direct geometrical picture of the shell model. The finite and tangent Green strains of the foliated continuum are explicitly expressed in terms of middle surface kinematics. The new expressions contributed here do not require the splitting of the velocity into parallel and normal components to the middle surface, and provide a computationally convenient context. Finite strain measures for the shell and their tangent and secant rates are analyzed and consistency and nonredundancy properties are discussed. The relations between the finite Green strain, its tangent and secant rates and the corresponding shell strains, are provided. The differential and boundary equilibrium equations of the shell are given in variational terms, both in unsplit and split form. A new expression of the boundary equilibrium equations is contributed and its mechanical soundness with respect to the classical one is emphasized. Equilibrium in a reference placement for the shell model is briefly discussed.

ABSTRACT: Based on first-principles calculations, we present various properties of single- and double-layered boron sheets, along with single- and double-walled boron nanotubes. Single-layered boron sheets, made of hexagons and triangles, have buckled ground-state geometries if the ratio of triangles to hexagons is large and stay flat otherwise. We demonstrate that this asymmetric behavior of buckling cannot be explained by a simple chemical picture based on $\sigma-\pi$ mixing. Instead, reduction in the electronic kinetic energy is the driving force for buckling. In addition, we show that double-layered boron sheets can form strong interlayer bonds between two layers only if the precursor single-layered sheet itself prefers a buckled ground-state structure. The optimal double-layered boron sheet in our library is semiconducting and is more stable than any single-layered sheet. Next, we discuss the curvature energies, buckling behavior and soliton structural fluctuations for single-walled boron nanotubes and the implications for the electronic properties of these nanotubes: our main finding is that the semiconducting nature of small-diameter single-walled nanotubes is robust under various perturbations and fluctuations. We end by showing that due to strong bonds forming between walls, the optimal double-walled boron nanotubes have different wall structures from single-walled ones. Such double-walled nanotubes are always more stable than any single-walled nanotube and are furthermore metallic for the likely experimentally relevant diameter range. We conclude with the implications of these results for fabricated nanotube systems.

“Hyperelastic axial buckling of single wall carbon nanotubes”, Physica E, Bol. 44, pp 525-529, 2011
DOI: 10.1016/j.physe.2011.10.006

ABSTRACT: This paper proposes a hyperelastic finite element-based lattice approach for the description of buckling behaviour in single wall carbon nanotubes (SWCNTs). A one-term incompressible Ogden-type hyperelastic model is adopted to describe the equivalent mechanical response of C–C bonds in SWCNTs under axial compression. The material constants of the model are chosen by matching the linearised response with the elastic constants adopted in the AMBER force field and by establishing equivalence between the Ogden strain energy and the variation of the interatomic strain energy obtained from molecular mechanics simulations. Numerical experiments are carried out and the results are compared to atomistic simulations, demonstrating the predictive capabilities of the present model in capturing initial buckling strain, deformation mechanisms and
post-buckling behaviour under very large compressive deformations.

ABSTRACT: A new structural mechanics model is developed to closely duplicate the atomic configuration and behaviours of single-walled carbon nanotubes (SWCNTs). The SWCNTs are effectively represented by a space frame, where primary and secondary beams are used to bridge the nearest and next-nearest carbon atoms, to mimic energies associated with bond stretching and angle variation, respectively. The elastic properties of the frame components are generalized from molecular dynamics (MD) simulation based on an accurate ab initio force field, and numerical analyses of tension, bending, and torsion are carried out on nine different SWCNTs. The space-frame model also closely duplicates the buckling behaviours of SWCNTs in torsion and bending. In addition, by repeating the same process with continuum shell and beam models, new elastic and section
parameters are fitted from the MD benchmark experiments. As an application, all three models are employed to study the thermal vibration behaviours of SWCNTs, and excellent agreements with MD analyses are found. The present analysis is a systematic structural mechanics attempt to fit SWCNT properties for several basic deformation modes and applicable to a variety of SWCNTs. The continuum models and fitted parameters may be used to effectively simulate the overall deformation behaviours of SWCNTs at much larger length- and timescales than pure MD analysis.

ABSTRACT: A nonlocal continuum mechanics model is developed and applied to study the vibration of both single-walled nanotubes (SWNTs) and double-walled nanotubes (DWNTs) via elastic beam theories. The small-scale effects on vibration characteristics of carbon nanotubes are explicitly derived through a complete mechanics analysis. A qualitative validation study shows that the results based on nonlocal continuum mechanics are in agreement with the published experimental reports in this field. Numerical simulations are conducted to quantitatively show the small-scale effect on vibrations of both SWNTs and DWNTs with different lengths and diameters.

ABSTRACT: Capsules of micron and sub-micron dimensions are abundant in nature in the form of bacterial or viral capsids and play an increasing role in modern technology for encapsulation and release of agents. The capsules’ mechanical properties are of great importance in this context not only for stability but as well for transport properties in flow, rheology or adhesion. Thus, techniques that allow for single-capsule mechanical characterization have caught much attention recently and we summarize experimental developments in this field as well as theoretical background of capsule deformation with special attention to small deformation measurements. Deformation studies on polyelectrolyte multilayer capsules are introduced as a case study, since they can be tailored in their geometry and composition and are thus well-suited as a model system.

ABSTRACT: This paper studies the vibrational characteristics of double-walled carbon nanotubes (DWNTs) with initial stress using a nonlocal Euler–Bernoulli beam model. Both the effect of initial stress and the effect of small length scale are discussed in detail. The effect of van der Waals forces is incorporated in the formulation. The corresponding resonant vibrational characteristics are presented in detail; they are shown to be very different from those predicted by classical elasticity theory when nonlocal effects are significant. The influence of initial stress in carbon nanotubes on their flexural vibration modes is dependent on the tension or compression form of the initial stress. The investigation of the effects of initial stress on transverse wave propagation in carbon nanotubes may be used as a useful reference for the application and the design of nanoelectronic and nanodrive devices, nano-oscillators, and nanosensors, in which carbon nanotubes act as basic elements.

ABSTRACT: In this paper, we propose a lattice dynamic treatment for the total potential energy of single-walled carbon nanotubes (SWCNTs) which is, apart from a parameter for the nonlinear effects, extracted from the vibrational energy of the planar graphene sheet. The energetics, elasticity and lattice dynamics are treated in terms of the same set of force constants, independently of the tube structures. Based upon this proposal, we have investigated systematically the relaxed lattice configuration for narrow SWCNTs, the strain energy, the Young's modulus and Poisson ratio, and the lattice vibrational properties with respect to the relaxed equilibrium tubule structure. Our calculated results for various physical quantities are nicely in consistency with existing experimental measurements. In particular, we verified that the relaxation effect makes the bond length longer and the frequencies of various optical vibrational modes softer. Our calculation provides evidence that the Young's modulus of an armchair tube exceeds that of the planar graphene sheet, and that the large diameter limits of the Young's modulus and Poisson ratio are in agreement with the experimental values of graphite; the calculated radial breathing modes for ultra-narrow tubes with diameters ranging between 2 and 5 Å coincide with the experimental results and the existing ab initio calculations with satisfaction. For narrow tubes with a diameter of 20 Å, the calculated frequencies of optical modes in the tubule's tangential plane, as well as those of radial breathing modes, are also in good agreement with the experimental measurements. In addition, our calculation shows that various physical quantities of relaxed SWCNTs can actually be expanded in terms of the chiral angle defined for the corresponding ideal SWCNTs.

C.Y. Wang and L.C. Zhang (The School of Aerospace, Mechanical and Mechatronic Engineering, University of Sydney, Sydney 2006, Australia), “A critical assessment of the elastic properties and effective wall thickness of
ABSTRACT: This paper discusses the fundamental issues of the elastic properties and effective wall thickness of single-walled carbon nanotubes (SWCNTs). It provides an in-depth analysis based on the rationale of the nanoscale-to-macroascale deformation relationship of SWCNTs and carries out a critical assessment of the diverse theoretical predictions in the literature. It was found that the in-plane stiffness of SWCNTs is a mechanics quantity that has been consistently reflected by the majority of the existing models. However, a further systematic study is necessary to clarify the dilemma of the wall thickness of SWCNTs.

ABSTRACT: This paper proposes a two-dimensional elastic shell model to characterize the deformation of single-walled carbon nanotubes using the in-plane rigidity, Poisson ratio, bending rigidity and off-plane torsion rigidity as independent elastic constants. It was found that the off-plane torsion rigidity of a single-walled carbon nanotube is not zero due to the off-plane change in the π-orbital electron density on both sides of the nanotube. It was concluded that a three-dimensional elastic shell model of single-walled carbon nanotubes can be established with well-defined effective thickness.

ABSTRACT: This paper is concerned with the use of the nonlocal Timoshenko beam model for free vibration analysis of single-walled carbon nanotubes (CNTs) including the thermal effect. Unlike the Euler beam model, the Timoshenko beam model allows for the effects of transverse shear deformation and rotary inertia. These effects become significant for CNTs with small length-to-diameter ratios that are normally encountered in applications such as nanoprobes. The elastic Timoshenko beam model is reformulated using the nonlocal differential constitutive relations of Eringen (1972 Int. J. Eng. Sci. 10 1–16). The study focuses on the wave dispersion caused not only by the rotary inertia and the shear deformation in the traditional Timoshenko beam model but also by the nonlocal elasticity characterizing the microstructure of CNTs in a wide frequency range up to terahertz. Numerical results are presented using the nonlocal beam theory to bring out the effect of both the nonlocal parameter and the temperature change on the properties of transverse vibrations of CNTs. The exact nonlocal Timoshenko beam solution presented here should be useful to engineers who are designing microelectromechanical and nanoelectromechanical devices.

ABSTRACT: A second-order strain gradient nonlocal shell model is established to study the mode
transformation in single-walled carbon nanotubes (SWCNTs). Nonlocal length is calibrated carefully for SWCNTs in reference to molecular dynamics (MD) simulations through analysis of nonlocal length effects on the frequencies of the radial breathing mode (RBM) and circumferential flexural modes (CFMs) and its effects on mode transformation. All analyses show that only a negative second-order nonlocal shell model is appropriate to SWCNTs. Nonlocal length is evidently related to vibration modes and the radius-to-thickness ratio. It is found that a nonlocal length is approximately 0.1 nm in an average sense when RBM frequency is concerned. A nonlocal length of 0.122–0.259 nm is indicated for the mode transformation in a selected group of armchair SWCNTs. 2:1 and 1:1 internal resonances are found for the same SWCNT based on different models, which implies that the internal resonance mechanism depends on the model employed. Furthermore, it is shown that an effective thickness of approximately 0.1 nm is more appropriate to SWCNTs than 0.066 nm.

ABSTRACT: The unique features of axial, torsional, transverse and radial breathing vibrations are captured for armchair and zigzag singlewalled boron nitride nanotubes (BNNTs) based on molecular mechanics simulations and continuum mechanics theories. Equivalent Young's modulus 1 TPa and shear modulus 0.4 TPa are obtained independent of the chirality of BNNTs. In particular, a distorted optimized structure is observed for the first time for BNNTs with sufficiently large diameter and length. It is found that the deformed structures result in behaviours of BNNTs deviating from those of classical columns/beams. Such symmetry-breaking could also exert significant impacts on the structural instability (buckling) and electronic properties of BNNTs that are sensitive to the structural symmetry.

ABSTRACT: The unceasing upgrading of techniques and processes to fabricate high purity carbon nanotubes (CNTs) and the improvement of the available techniques to produce high performance matrix materials, have fostered the way to enhance composite materials and their properties, either mechanical, thermal, electrical or magnetic. CNTs reinforcements have been introduced into polymers, ceramics, cement-based materials and metals. Polymers were the first material to be exploited as matrix material being reinforced by CNTs. Up to
now other materials have tentatively been investigated for that purpose, including metals. Today, many applications of CNT reinforced composites exist but CNT reinforced metals are still scarce and only found in very specific applications. Several reasons can be identified but the still growing demand for lighter and stronger metals paved the way to more fundamental research on the topic of CNT reinforced metal matrix composites (MMCs). This review describes the state-of-the art in this field and highlights the excellent and promising mechanical, thermal, electrical properties of CNT reinforced MMCs.

ABSTRACT: This paper is concerned with numerical simulations of three-dimensional finite deformation of a thick-walled circular elastic tube subject to internal or external pressure and zero displacement on its ends. We formulate the system of equations that can accommodate large strain and displacement for the incompressible isotropic neo-Hookean material. The fully non-linear governing equations are solved using the Cþþ based object-oriented finite element library libMesh. A Lagrangian mesh is used to discretize the governing equations, and a weighted residual Galerkin method and Newton iteration solver are used in the numerical scheme. To overcome the sensitivity of the fully non-linear system to small changes in the iterations, the analytical form of the Jacobian matrix is derived, which ensures a fast and better numerical convergence than using a numerically approximated Jacobian matrix. Results are presented for different parameters in terms of wall thickness/radius ratio, and length/ radius ratio, as well as internal/external pressure. Validation of the model is achieved by the excellent agreement with the results obtained using the commercial package Abaqus. Comparison is also made with the previous work on axisymmetric version of the same system (Zhu et al., 2008 [34]; Zhu et al. 2010 [43]), and interesting fully three-dimensional post-buckling deformations are highlighted. The success of the current approach paves the way for fluid–structure interaction studies with potential application to collapsible tube flows and modeling of complex physiological systems.

ABSTRACT: Venous tortuosity is associated with multiple disease states and is often thought to be a consequence of venous hypertension and chronic venous disease. However, the underlying mechanisms of vein tortuosity are unclear. We hypothesized that increased pressure causes vein buckling that leads to a tortuous appearance. The specific aim of this study was to determine the critical buckling pressure of veins. We determined the buckling pressure of porcine jugular veins and measured the mechanical properties of these veins. Our results showed that the veins buckle when the transmural pressure exceeds a critical pressure that is strongly related to the axial stretch ratio in the veins. The critical pressures of the eight veins tested were 14.2 ± 5.4 and 26.4 ± 9.0 mmHg at axial stretch ratio 1.5 and 1.7, respectively. In conclusion, veins buckle into a tortuous shape at high lumen pressures or reduced axial stretch ratios. Our results are useful in understanding the development of venous tortuosity associated with varicose veins, venous valvular insufficiency, diabetic retinopathy, and vein grafts.

ABSTRACT: The stability of blood vessels under lumen blood pressure is essential to the maintenance of normal vascular function. Differential buckling equations have been established recently for linear and nonlinear elastic artery models. However, the strain energy in bent buckling and the corresponding energy method have not been investigated for blood vessels under lumen pressure. The purpose of this study was to establish the energy equation for blood vessel buckling under internal pressure. A buckling equation was established to determine the critical pressure based on the potential energy. The critical pressures of blood vessels with small tapering along their axis were estimated using the energy approach. It was demonstrated that the energy approach yields both the same differential equation and critical pressure for cylindrical blood vessels as obtained previously using the adjacent equilibrium approach. Tapering reduced the critical pressure of blood vessels compared to the cylindrical ones. This energy approach provides a useful tool for studying blood vessel buckling and will be useful in dealing with various imperfections of the vessel wall.

ABSTRACT: Tortuous arteries are often associated with aging, hypertension, atherosclerosis, and degenerative vascular diseases, but the mechanisms are poorly understood. Our recent theoretical analysis suggested that
mechanical instability (buckling) may lead to tortuous blood vessels. The objectives of this study were to determine the critical pressure of artery buckling and the effects of elastin degradation and surrounding matrix support on the mechanical stability of arteries. The mechanical properties and critical buckling pressures, at which arteries become unstable and deform into tortuous shapes, were determined for a group of five normal arteries using pressurized inflation and buckling tests. Another group of nine porcine arteries were treated with elastase (8 U/ml), and the mechanical stiffness and critical pressure were obtained before and after treatment. The effect of surrounding tissue support was simulated using a gelatin gel. The critical pressures of the five normal arteries were 9.52 kPa (SD 1.53) and 17.10 kPa (SD 5.11) at axial stretch ratios of 1.3 and 1.5, respectively, while model predicted critical pressures were 10.11 kPa (SD 3.12) and 17.86 kPa (SD 5.21), respectively. Elastase treatment significantly reduced the critical buckling pressure ($P < 0.01$). Arteries with surrounding matrix support buckled into multiple waves at a higher critical pressure. We concluded that artery buckling under luminal pressure can be predicted by a buckling equation. Elastin degradation weakens the arterial wall and reduces the critical pressure, which thus leads to tortuous vessels. These results shed light on the mechanisms of the development of tortuous vessels due to elastin deficiency.

ABSTRACT: Arteries are under significant mechanical loads from blood pressure, flow, tissue tethering, and body movement. It is critical that arteries remain patent and stable under these loads. This review summarizes the common forms of buckling that occur in blood vessels including cross-sectional collapse, longitudinal twist buckling, and bent buckling. The phenomena, model analyses, experimental measurements, effects on blood flow, and clinical relevance are discussed. It is concluded that mechanical buckling is an important issue for vasculature, in addition to wall stiffness and strength, and requires further studies to address the challenges. Studies of vessel buckling not only enrich vascular biomechanics but also have important clinical applications. References listed at the end of the paper:

“Study on tracheal collapsibility, compliance, and stress by considering nonlinear mechanical property of cartilage”, Annals of Biomedical Engineering, Vol. 37, No. 11, pp 2380-2389, November 2009
DOI: 10.1007/s10439-009-9765-3

ABSTRACT: Tracheal cartilage has been widely regarded as a linear elastic material either in experimental studies or in analytic and numerical models. However, it has been recently demonstrated that, like other fiber-oriented biological tissues, tracheal cartilage is a nonlinear material, which displays higher strength in compression than in extension. Considering the nonlinearity requires a more complex theoretical framework and costs more to simulate. This study aims to quantify the deviation due to the simplified treatment of the tracheal cartilage as a linear material. It also evaluates the improved accuracy gained by considering the nonlinearity. Pig tracheal rings were used to examine the mechanical properties of cartilage and muscular membrane. By taking into account the asymmetric shape of tracheal cartilage, the collapse behavior of complete rings was simulated, and the compliance of airway and stress in the muscular membrane were discussed. The results obtained were compared with those assuming linear mechanical properties. The following results were found: (1) Models based on both types of material properties give a small difference in representing collapse behavior; (2) Regarding compliance, the relative difference is big, ranging from 10 to 40% under negative
pressure conditions; and (3) the difference in determining stress in the muscular membrane is small too: <5%. In conclusion, treating tracheal cartilage as a linear material will not cause big deviations in representing the collapse behavior, and mechanical stress in the muscular part, but it will induce a big deviation in predicting the compliance, particularly when the transmural pressure is lower than −0.5 kPa. The results obtained in this study may be useful in both understanding the collapse behavior of trachea and in evaluating the error induced by the simplification of treating the tracheal cartilage as a linear elastic material.

ABSTRACT: A novel large self-expanding endovascular stent was designed with strut thickness of 70 μm × 70 μm width. The method was developed and investigated to identify a novel simpler technique in aortic aneurysm therapy. Stage 1 analysis was performed after deploying it in a virtual aneurysm model of 6 cm wide × 6 cm long fusiform hyper-elastic anisotropic design. At cell width of 9 mm, there was no buckling or migration of the stent at 180 Hg. Radial force of the stents was estimated after parametric variations. In stage 2 analysis, a prototype 300 μm × 150 μm stent with a cell width of 9 mm was chosen, and it was evaluated similarly after embedding in the aortic wall, and also with a tissue overgrowth of 1 mm over the stent. The 300/150 μm stent reduced the peak wall stress by 70% in the aneurysm and 50% reduction in compliance after embedding. Stage 3 analysis was performed to study the efficacy of stents with struts (thickness/width) 70/70, 180/100 and 300/150 μm after embedding and tissue overgrowth. The adjacent wall stresses were very minimal in stents with 180/100 and 70/70 μm struts after embedding. There is potential for a novel stent method in aortic aneurysm therapy.

ABSTRACT: (none given)
ABSTRACT: Euler’s celebrated buckling formula gives the critical load $N$ for the buckling of a slender cylindrical column with radius $B$ and length $L$ as

$$N/(\pi^3 B^{-2}) = (E/4)(B/L)^2,$$

where $E$ is Young’s modulus. Its derivation relies on the assumptions that linear elasticity applies to this problem, and that the slenderness $(B/L)$ is an infinitesimal quantity. Here we ask the following question: What is the first nonlinear correction in the right hand-side of this equation when terms up to $(B/L)^4$ are kept? To answer this question, we specialize the exact solution of incremental nonlinear elasticity for the homogeneous compression of a thick compressible cylinder with lubricated ends to the theory of third-order elasticity. In particular, we highlight the way second- and third-order constants —including Poisson’s ratio— all appear in the coefficient of $(B/L)^4$.

ABSTRACT: Gels are used to design bilayered structures with high residual stresses. The swelling of a thin layer on a compliant substrate leads to compressive stresses. The postbuckling of this layer is investigated experimentally; the wavelengths and amplitudes of the resulting modes are measured. A simplified model with a self-avoiding rod on a Winkler foundation is in semiquantitative agreement with experiments and reproduces the observed cusplike folds.

References listed at the end of the paper:

ABSTRACT: We study the buckling of thin elastic plates caused by residual strains concentrated near a free edge. This is a model for plant leaves and torn plastic sheets morphologies. We derive new governing equations explaining self-similar patterns reported earlier in experiments. We reveal the cascade mechanism, determine the bounds for its wavelengths and predict a similarity factor of 3 in agreement with experiments. This is confirmed by numerical solutions with up to five generations of wrinkles.

References listed at the end of the paper:

ABSTRACT: The patterns arising from the differential swelling of gels are investigated experimentally and theoretically as a model for the differential growth of living tissues. Two geometries are considered: a thin strip of soft gel clamped to a stiff gel, and a thin corona of soft gel clamped to a disk of stiff gel. When the structure is immersed in water, the soft gel swells and bends out of plane leading to a wavy periodic pattern whose wavelength is measured. The linear stability of the flat state is studied in the framework of linear elasticity using the equations for thin plates. The flat state is shown to become unstable to oscillations above a critical swelling rate and the computed wavelengths are in quantitative agreement with the experiment.

ABSTRACT: The buckling of a thin elastic film bound to a compliant substrate is studied: we analyze the different patterns that arise as a function of the biaxial residual compressive stress in the film. We first clarify the boundary conditions to be used at the interface between film and substrate. We carry out the linear stability analysis of the classical pattern made of straight stripes, and point out secondary instabilities leading to the formation of undulating stripes, varicose, checkerboard or hexagonal patterns. Straight stripes are found to be stable in a narrow window of load parameters only. We present a weakly nonlinear post-buckling analysis of these patterns: for equi-biaxial residual compression, straight wrinkles are never stable and square checkerboard patterns are found to be optimal just above threshold; for anisotropic residual compression, straight wrinkles are present above a primary threshold and soon become unstable with respect to undulating stripes. These results account for many of the previously published experimental or numerical results on this geometry.

ABSTRACT: We study the buckling of a thin compressed elastic film bonded to a compliant substrate. We focus on a family of buckling patterns, such that the film profile is generated by two functions of a single variable. This family includes the unbuckled configuration, the classical primary mode made of straight stripes, as well the pattern with undulating stripes obtained by a secondary instability investigated in the first companion paper, and the herringbone pattern studied in last companion paper. A simplified buckling model relevant for the analysis of these patterns is introduced. It is solved analytically for moderate or for large residual compressive stress in the film. Numerical simulations are presented, based on an efficient implementation. Overall, the analysis provides a global picture for the formation of herringbone patterns under increasing residual stress. The film shape is shown to converge at large load to a developable shape with ridges. The wavelength of the pattern, selected in a first place by the primary buckling bifurcation, is frozen during the subsequent increase of loading.

ABSTRACT: We study the buckling of a compressed thin elastic film bonded to a compliant substrate. An
asymptotic solution of the equations for a plate on an elastic foundation is obtained in the limit of large residual stress in the film. In this limit, the film's shape is given by a popular origami folding, the Miura-ori, and is composed of parallelograms connected by dihedral folds. This asymptotic solution corresponds to the herringbone patterns reported previously in experiments: the crests and valleys of the pattern define a set of parallel, sawtooth-like curves. The kink angle obtained when observing these crests and valleys from above are shown to be right angles under equi-biaxial loading, in agreement with the experiments. The absolute minimum of energy corresponds to a pattern with very slender parallelograms; in the experiments, the wavelength is instead selected by the history of applied load.

ABSTRACT: We consider the deformation of a thin elastic film bonded to a thick compliant substrate, when the (compressive) misfit is far beyond critical. We take a variational viewpoint – focusing on the total elastic energy, i.e. the membrane and bending energy of the film plus the elastic energy of the substrate – viewing the buckling of the film as a problem of energy-driven pattern formation. We identify the scaling law of the minimum energy with respect to the physical parameters of the problem, and we prove that a herringbone pattern achieves the optimal scaling. These results complement previous numerical studies, which have shown that an optimized herringbone pattern has lower energy than a number of other patterns. Our results are different because (i) we make the scaling law achieved by the herringbone pattern explicit, and (ii) we give an elementary, ansatz-free proof that no pattern can achieve a better law.

ABSTRACT: The wrinkling and delamination of stiff thin films adhered to a polymer substrate have important applications in “flexible electronics.” The resulting periodic structures, when used for circuitry, have remarkable mechanical properties because stretching or twisting of the substrate is mostly accommodated through bending of the film, which minimizes fatigue or fracture. To date, applications in this context have used substrate patterning to create an anisotropic substrate-film adhesion energy, thereby producing a controlled...
array of delamination “blisters.” However, even in the absence of such patterning, blisters appear spontaneously, with a characteristic size. Here, we perform well-controlled experiments at macroscopic scales to study what sets the dimensions of these blisters in terms of the material properties and explain our results by using a combination of scaling and analytical methods. Besides pointing to a method for determining the interfacial toughness, our analysis suggests a number of design guidelines for the thin films used in flexible electronic applications. Crucially, we show that, to avoid the possibility that delamination may cause fatigue damage, the thin film thickness must be greater than a critical value, which we determine.

ABSTRACT: Many ship accidents and casualties are caused by large freak ocean waves. Traditionally, the strength of ships against freak waves is assessed by means of ultimate strength evaluation, assuming quasi-static conditions, but the nonlinear dynamic structural response of ships to freak waves should be considered as well. This paper describes how the strength of a ship can be evaluated in terms of its nonlinear vertical bending moment (VBM). Linear dynamic VBM of a ship, which is derived from hydrodynamics, is calculated using a time-domain strip theory code under freak wave conditions, and the nonlinear dynamic VBM, which is dependent on structural nonlinearity, is calculated using a combination of quasi-static and dynamic nonlinear analyses based on the finite element method (FEM). The nonlinear and linear VBMs are then compared to assess how they differ. Then, the influence of freak wave height and wave speed on the VBMs and deformation is studied.

ABSTRACT: The topology of the telephone cord buckling of compressed diamond-like carbon films (DLC) on glass substrates has been characterized with atomic force microscopy (AFM) and with the focused ion beam (FIB) imaging system. The profiles of the several buckles have been measured by AFM to establish the symmetry of each repeat unit, revealing similarity with a circular buckle pinned at its center. By making parallel cuts through the buckle in small, defined locations, straight-sided buckles have been created on the identical films, enabling the residual stress in the film to be determined from the profile. It has been shown that the telephone cord topology can be effectively modeled as a series of pinned circular buckles along its length, with an unpinned circular buckle at its front. The unit segment comprises a section of a full circular buckle, pinned to the substrate at its center. The model is validated by comparing radial profiles measured for the telephone cord with those calculated for the pinned buckle, upon using the residual stress in the film, determined as above. Once validated, the model has been used to determine the energy release rate and mode mixity, G(psi). The results for G(psi) indicate that the telephone cord configuration is preferred when the residual stress in the DLC is large, consistent with observations that straight-sided buckles are rarely observed, and, when they occur, are generally narrower than telephone cords. Telephone cords are observed in many systems, and can be regarded as the generic morphology. Nevertheless, they exist subject to a limited set of conditions, residing within the margin between complete adherence and complete delamination, provided that the interface has a mode II
toughness low enough to ensure that the buckle crack does not kink into the substrate.

INTRODUCTION: Residually compressed thin films on thick substrates may buckle. The buckles propagate beneath the film if the induced energy release rate exceeds the interface fracture toughness. The associated mechanics has been documented (Evans and Hutchinson, 1984; Hutchinson et al., 1992; Hutchinson and Suo, 1992; Thouless et al., 1992; Jensen and Thouless, 1995; Evans et al., 1997; Chai, 1998; Hutchinson et al., 2000; Audoly, 2000; Hutchinson, 2001). The buckles exhibit several configurations: ranging from circular, to linear to telephone cord (Fig. 1) (Matuda et al., 1981; Gille and Rau, 1984; Lee et al., 1993; Colín et al., 2000; Moon et al., 2002). Straight buckles propagate with a curved front. The conditions at the stationary side and the circular front have been modeled and rationalized in terms of mode mixity and energy release rate (Hutchinson and Suo, 1992; Hutchinson, 2001; Jensen and Sheinman, 2001). The corresponding mechanics for telephone cord buckles are less well developed. The purpose of this study is to gain some insight by performing measurements on thin films of diamond-like carbon (DLC) deposited onto nominally flat glass substrates and conducting a corresponding mechanics assessment. Such systems are typically subject to high residual compression (1–4 GPa) and modest adhesion, causing them to be susceptible to telephone cord buckles. The profiles of telephone cord buckles are characterized along different chords, by using the atomic force microscope (AFM). To make a direct comparison between telephone cord and (the more completely understood) straight-sided buckles, the focused ion beam (FIB) imaging system has been used to create two parallel (damage free) cuts, converting a section of the former into the latter. Changes in the profile before and after cutting can be used to correlate the two configurations, with all other variables fixed. The ensuing measurements provide a direct assessment of the mechanics of telephone cord buckling.

ABSTRACT: The buckling and wrinkling of thin films has recently seen a surge of interest among physicists, biologists, mathematicians, and engineers. This activity has been triggered by the growing interest in developing technologies at ever-decreasing scales and the resulting necessity to control the mechanics of tiny structures, as well as by the realization that morphogenetic processes, such as the tissue-shaping instabilities occurring in animal epithelia or plant leaves, often emerge from mechanical instabilities of cell sheets. Although the most basic buckling instability of uniaxially compressed plates was understood by Euler more than two centuries ago, recent experiments on nanometrically thin (ultrathin) films have shown significant deviations from predictions of standard buckling theory. Motivated by this puzzle, we introduce here a theoretical model that allows for a systematic analysis of wrinkling in sheets far from their instability threshold. We focus on the simplest extension of Euler buckling that exhibits wrinkles of finite length—a sheet under axisymmetric tensile loads. The first study of this geometry, which is attributed to Lamé, allows us to construct a phase diagram that demonstrates the dramatic variation of wrinkling patterns from near-threshold to far-from-threshold conditions. Theoretical arguments and comparison to experiments show that the thinner the sheet is, the smaller is the compressive load above which the far-from-threshold regime emerges. This observation emphasizes the relevance of our analysis for nanomechanics applications.

“Multiple-length-scale elastic instability mimics parametric resonance of nonlinear oscillators”, Nature Physics, Vol. 7, pp 56-60, 2011, DOI: 10.1038/nphys1806

ABSTRACT: Spatially confined rigid membranes reorganize their morphology in response to the imposed constraints. A crumpled elastic sheet presents a complex pattern of random folds focusing the deformation energy¹, whereas compressing a membrane resting on a soft foundation creates a regular pattern of sinusoidal wrinkles with a broad distribution of energy²,³,⁴,⁵,⁶,⁷,⁸. Here, we study the energy distribution for highly confined membranes and show the emergence of a new morphological instability triggered by a period-doubling bifurcation. A periodic self-organized focalization of the deformation energy is observed provided that an up-down symmetry breaking, induced by the intrinsic nonlinearity of the elasticity equations, occurs. The physical model, exhibiting an analogy with parametric resonance in a nonlinear oscillator, is a new theoretical toolkit to understand the morphology of various confined systems, such as coated materials or living tissues, for example wrinkled skin¹, internal structure of lungs⁶, internal elastica of an artery¹⁰, brain convolutions¹¹,¹² or formation of fingerprints¹³. Moreover, it opens the way to a new kind of microfabrication design of multiperiodic or chaotic (aperiodic) surface topography through self-organization.

ABSTRACT: Most previous studies on spontaneous buckling pattern formations in thin films on compliant substrates were limited to elastic deformation, where the herringbone mode is the most often observed under equi-biaxial compression. In practice, plastic deformation is often encountered in ductile metal and polymer films. The effect of plasticity on buckling patterns is explored in this paper using extensive finite element simulations, where the film is assumed to be elastic—perfectly plastic. It is found that upon equi-biaxial compression, depending on the competition among the yield strain, critical buckling strain and applied strain, three new types of patterns may emerge: the plastic diamond-like pattern, the elastoplastic square lattice pattern and the elastoplastic sharp herringbone pattern, and their characteristics are compared with the elastic
herringbone mode. Moreover, unique features including the asymmetry in crests and troughs, the sharp saw-like undulation profile and varying wavelengths with applied strain are observed for some types of the new patterns. The study may find its potential applications in the design of stretchable electronics, fabrication of micro/nanofluid channels or channel networks, and morphogenesis of tissues and plants, among others.

ABSTRACT: The static postbuckling of flat and doubly-curved shallow panels under the combined action of a system of uniaxial/biaxial compressive edge loads and a lateral pressure field is investigated, and the effects of transverse shear, initial geometric imperfections and tangential edge constraints upon load carrying capacity of curved panels are emphasized. Comparisons of the classical and shear deformable theories are made and issues related to the sensitivity to the snap-through behaviour are discussed. A variety of loading systems and panel geometries are considered in the numerical illustrations and pertinent conclusions related to the postbuckling response are outlined.

ABSTRACT: An analysis and comparison of several shear deformable bending theories of composite laminated anisotropic plates currently encountered in the field literature are given in this paper. Although apparently different, it is shown in a unitary way, that these theories constitute in fact only different formulations of a single theory, generically designated to as the moderately thick plate theory. Their connection with the first order transverse shear deformation theory is also emphasized and some conclusions concerning its shortcomings and field applicability are presented.

ABSTRACT: This paper deals with the substantiation of a shear deformable theory of cross-ply laminated composite shallow shells. While the developed theory preserves all the advantages of the first order transverse shear deformation theory it succeeds in eliminating some of its basic shortcomings. The theory is further employed in the analysis of the eigenvibration and static buckling problems of doubly curved shallow panels. In this context, the state space concept is used in conjunction with the Lévy method, allowing one to analyze these problems in a unified manner, for a variety of boundary conditions. Numerical results are presented and some pertinent conclusions are formulated.

ABSTRACT: The static postbuckling of simply-supported single and multilayered composite doublecurved shallow panels subjected to a system of in-plane compressive edge loads is studied. The effects caused by transverse shear deformation, lamination, the character of in-plane boundary conditions and transverse normal stress, are considered and a series of pertinent conclusions are outlined. Comparisons are made of the obtained results with their classical counterparts and conclusions related to their range of applicability arc presented. Moreover, by incorporating the initial geometric imperfections, their influence on the load carrying capacity of curved composite panels is discussed and the peculiarities of their effect as compared to the case of flat panels arc emphasized.

ABSTRACT: This study deals with the postbuckling and vibration behavior of flat and shallow curved panels resting on a Winkler linear/non-linear elastic foundation. The considered plate/shell structural model is based on a higher-order shear deformable theory and encompasses a number of effects such as transverse shear, geometric non-linearities and the initial geometric imperfection. Special emphasis is given to the influence played by Winkler's foundation moduli as well as by the previously mentioned effects upon the postbuckling and vibrational response in the pre/postbuckling ranges and a number of pertinent conclusions are outlined.

ABSTRACT: The postbuckling behavior of flat/curved panels resting on a Winkler linear/nonlinear foundation,
subjected to compressive edge loads and exposed to a nonuniform temperature field is investigated. Effects played by transverse shear, initial geometric imperfections, panel curvature and Winkler's foundation moduli are highlighted and a number of pertinent conclusions are outlined.

ABSTRACT: A study of the postbuckling behavior of geometrically imperfect anisotropic sandwich doubly-curved and flat panels subjected to a system of compressive edge loads and a lateral pressure is presented. The study is carried out in the context of the weak core sandwich shell model whose superior structural performance as compared to those of the strong core sandwich or standard laminated structures has resulted in its increased use in the design of advanced flight vehicles. A detailed investigation of the influence played by a number of kinematical and physical parameters as well as by the character of tangential boundary conditions on the load carrying capacity of sandwich structures is performed and pertinent conclusions are outlined.

ABSTRACT: In the present paper, an advanced geometrically nonlinear shell theory of doubly curved structural sandwich panels with transversely compressible core is presented. The model is based on the adoption of the Kirchhoff theory for the face sheets and a second/third order power series expansion for the core displacements. The theory accounts for dynamic effects as well as for initial geometric imperfections. In the v. Kármán sense, large displacement theory is employed with respect to the transverse direction while the displacement gradients with respect to the tangential directions are assumed to be small. The equations of motion are derived by means of Hamilton’s principle and hold valid for all types of elastic and elastic–plastic material models. The theory is illustrated by an analysis of the elastic buckling and postbuckling behavior of flat and curved sandwich panels using an extended Galerkin scheme. Owing to the assumed transverse flexibility of the core, both the global and the local (face wrinkling) instability modes can be addressed.

ABSTRACT: The present study is concerned with the analysis of the transient response of softcore sandwich structures in the postbuckling range using a higher-order geometrically nonlinear shell model including the
transverse core compressibility. The transverse compressibility results in the development of a chaotic vibration with unpredictable wrinkling amplitudes and has significant effects on the eigenfrequency.

ABSTRACT: In the present study, the effect of the transverse compressibility of the core on the transient dynamic response of structural sandwich panels under rapid loading conditions is investigated. The analysis is based on a higher-order sandwich shell theory in an effective multilayer formulation. The model is based on the standard Kirchhoff–Love hypothesis for the face sheets whereas a first/second order power series expansion is employed for the core. Consistent equations of motion and boundary conditions are derived by means of Hamilton’s principle. An analytical solution is obtained by an extended Galerkin procedure. The theory is applied to the dynamic buckling and postbuckling analyses of plane and curved sandwich panels subjected to rapidly applied tangential and transverse loads. It is observed that the transverse compressibility of the core can have distinct effects on both, the frequency and the amplitudes of the resulting free oscillations. Due to interactions between the overall oscillation and a local oscillation in the presence of a face wrinkling instability mode, the dynamic response can be chaotic, resulting in oscillating face wrinkling instability modes with unpredictable amplitudes.

ABSTRACT: This paper is devoted to a study of the effects played by transverse core compressibility of sandwich plates and shells on their static and dynamic behavior. The analysis is based on a higher-order structural model using the standard Kirchhoff–Love assumption for the face sheets and a higher order displacement representation for the core layer. The model accounts for the geometrical nonlinearities that are considered in the von Kármán sense and for initial geometric imperfections. Transverse shear effects are included in the soft-core layer. Consistent equations of motion and boundary conditions are derived via the application of Hamilton’s principle. In the cases that are analyzed and presented in this paper, it was revealed that the static and dynamic buckling/response and postbuckling of flat and curved sandwich structures, are strongly affected by transverse compressibility of the core. It is also shown that in the context of this structural model, the wrinkling instability and response are captured directly from the derived governing equations, and not, as customarily, via a post-processing analysis.

ABSTRACT: Buckling loads of sandwich panels obtained by analytical calculations and FE-analysis are compared. Approximate buckling loads for panels with different boundary conditions have been derived using an energy method with deflection functions satisfying the boundary conditions. The comparison shows good agreement for panels with simply supported edges. In other cases the agreement is acceptable for panels with a length/ breadth ratio of 1 or greater. The approximate solutions can thus be used to estimate buckling loads of panels when designing sandwich structures.

ABSTRACT: This paper presents a method for calculating the critical buckling load of sandwich panels. Based on earlier ‘zig-zag’ models for through-thickness displacements, the transverse shear deformation of the faces is included, thus allowing the analysis of thick sandwich plates. Where possible, predictions have been compared with other workers. Also, the influence of face lay-up and plate aspect ratio are investigated.

ABSTRACT: The wrinkling analysis of anisotropic sandwich panels is found by developing Benson–Mayers unified theory for isotropic sandwich panels into general anisotropic sandwich panels. Both symmetrical and antisymmetrical wrinkling are analyzed and calculated simultaneously. The present method has been applied to orthotropic and antisymmetric cross-ply sandwich plates and the results are in good agreement with the published analytical and experimental results.

ABSTRACT: Solid unstiffened, sandwich and hat-stiffened rectangular orthotropic fiber reinforced plastic (FRP) plates were tested for buckling by in-plane compression and for stresses and deflections under uniform out-of-plane pressure. The solid unstiffened and hat-stiffened plates were 154 x 77 cm (1 x w) (72 x 36 in), while the sandwich plates were 102 x 77 cm (1 x w) (48 x 36 in). Balsa core was used in the sandwich plates and in the hat-stiffeners. The two short edges of the unstiffened and sandwich plates were clamped, while the two long edges were simply supported. The two long edges of the hat-stiffened plates were free, while the short edges were clamped. The buckling load, as well as stresses and deflections from the tests, were then compared to those from finite element analysis (FEA) and analytic solutions. There was reasonably good agreement between FEA, analytic, and experimental buckling stresses for the unstiffened solid plates. There was reasonable agreement in buckling stresses between FEA and experimental results for the hat-stiffened plate. There was poor agreement between FEA, analytic, and experimental elastic buckling results for the sandwich plates because they failed in local buckling prior to global buckling. Under out-of-plane uniform pressure, FEA and analytic solutions of the stresses and deflections for the unstiffened solid plates agreed well with experimental results. There was poor agreement between FEA and experimental results for stresses and deflections of the hat-stiffened or sandwich plates. Experimental error could be traced, in part, to plate fabrication, the method of applying out-of-plane pressure, edge support, and instrumentation accuracy.

ABSTRACT: Rectangular orthotropic sandwich fiber reinforced plastic (FRP) panels were tested for buckling
in uniaxial compression. The panels, with either balsa or linear PVC foam cores, were tested in two sizes: 183 cm x 92 cm (72 in. x 36 in.) and 122 cm x 92 cm (48 in. x 36 in.) for aspect ratios of 2.0 and 1.3, respectively. The sandwich panels were fabricated using the vacuum-assisted resin transfer molding (VARTM) technique. The two short edges of the sandwich panels were clamped, while the two long edges were simply supported. The experimental elastic buckling loads of panels with an aspect ratio of 1.3 were 400 kN (90 klb) for balsa core panels and 267 kN (60 klb) for foam core panels. For balsa and foam core panels with an aspect ratio 2.0, the experimental buckling loads were 334 kN (75 klb) and 240 kN (54 klb), respectively. Experimental buckling results for balsa core panels of both sizes differed by 5 _8% from numerical and analytical results. Differences in experimental and predicted buckling loads for foam core panels ranged between 15% and 23%. Post-buckling collapse of balsa and foam core panels with an aspect ratio of 1.3 were 694 kN (156 klb) and 347 kN (78 klb), respectively. For balsa and foam core panels with an aspect ratio of 2.0, post-buckling collapse occurred at 592 kN (133 klb) and 334 kN (75 klb), respectively. A numerical post-buckling analysis qualitatively followed that of the experimental results.

ABSTRACT: Rectangular orthotropic fiber-reinforced plastic (FRP) sandwich panels were tested for buckling in uni-axial compression. The panels, with 0.32 cm (0.125 in.) face sheets and a 1.27 cm (0.5 in.) core of either balsa or linear poly(vinyl chloride) (PVC) foam, were tested in two sizes: 154x77 cm2 (72x36 in.2) and 102x77 cm2 (48x36 in.2). The sandwich panels were fabricated using the vacuum-assisted resin transfer molding process. The two short edges of the sandwich panels were clamped, while the two long edges were simply supported for testing. The clamped panel ends were potted into a steel frame. The experimental elastic buckling loads were then measured using strain gauges fixed to both sides of the panels. A total of 12 panels were tested under uni-axial compression. Bifurcation in the load versus engineering strain curve was noted in all cases. For all six sandwich panels tested using balsa core, the type of failure was easily identified as face sheet delamination followed by core shear failure. For all six PVC foam core sandwich panels tested, the type of failure consisted of core shear failure with little or no face sheet delamination. In the failed balsa core panels there was little or no evidence of balsa remaining on the FRP face sheet, however, in the PVC foam core panels there were ample amounts of foam left on the FRP face sheet. It was concluded that although the buckling loads for the foam core panels were not as high as those for the balsa core panels, PVC foam core bonding to the FRP face sheets was superior to balsa core bonding.

ABSTRACT: Metallic sandwich panels with textile cores have been analyzed subject to combined bending and shear and then designed for minimum weight. Basic results for the weight benefits relative to solid plates are
presented, with emphasis on restricted optimizations that assure robustness (non-catastrophic failure) and acceptable thinness. Select numerical simulations are used to check the analytical results and to explore the role of strain hardening beyond failure initiation. Comparisons are made with competing concepts, especially honeycomb and truss core systems. It is demonstrated that all three systems have essentially equivalent performance. The influence on the design of a concentrated compressive stress that might crush the core has been explored and found to produce relatively small effect over the stress range of practical interest. “Angle ply” cores with members in the ±45° orientation are found to be near optimal for all combinations of bending, shear and compression.

ABSTRACT: Metallic sandwich panels with periodic, open-cell cores are important new structures, enabled by novel fabrication and topology design tools. Fabrication protocols based on the sheet forming of trusses and shell elements (egg-boxes) as well as textile assembly have allowed the manufacture of robust structures by inexpensive routes. Topology optimization enables control of failure mechanisms at the truss length scale, leading to superior structural performance. Analysis, testing and optimization have demonstrated that sandwich panels constructed with these cores sustain loads at much lower relative densities than stochastic foams. Moreover, the peak strengths of truss and textile cores are superior to honeycombs at low relative densities, because of their superior buckling resistance. Additional benefits of the truss/textile cores over honeycombs reside in their potentially lower manufacturing cost as well as in their multifunctionality.

ABSTRACT: The buckling behavior of sandwich panels with a core that is flexible in the out-of-plane direction, also denoted as “soft” core including high-order effects, is presented. The buckling analysis consists of the formulation of the linear and the nonlinear governing equations along with the boundary conditions. The sandwich panel construction is general and consists of two skin-panels, metallic or composite laminated symmetric that may be unidentical and a flexible isotropic or orthotropic core made of foam or a low strength honeycomb. The analysis uses a high-order theory formulation, which permits nonlinear distortions of the cross-section plane of the core as well as changes in its height. The analysis determines the bifurcation loads along with the associated mode shapes, local or overall buckling modes, as well as deformations, internal resultants and stresses at skin-core interface layers due to imperfections. Numerical results using closed form solutions for simply-supported panels, with identical and non-identical skin-panels subjected to compressive inplane loads as well as imperfection analysis results, are presented. The results reveal that, under some structural configurations, the local buckling mode is a critical, rather than a global one as a result of the out-of-plane flexibility of the core.
ABSTRACT: The classical and the high-order computational models of unidirectional sandwich panels with incompressible and compressible cores are presented. The significant theoretical and practical differences are discussed and elaborated through some numerical examples of typical sandwich panels. The classical models considered for the incompressible panel consists of two variants of the well-known splitted rigidity approach. The first one, due to Allen and Plantema and many others, assumes that the plane section of the shear substructure takes a specific ‘zigzag’ pattern with no in-plane deformation in the face sheets and a vertical one when the flexural rigidity of the faces is ignored. The second model, due to Frostig, assumes that the plane section of the core in the shear substructure remains vertical and the face sheets are subjected to in-plane deformation as well as flexural ones. They are compared with the accurate incompressible model, denoted as ordinary sandwich panel theory (OSPT) and with the high-order sandwich panel theory (HSAPT) based on a variational approach. In case of a sandwich panel with a compressible core the elastic foundation models based are compared with the high-order one. The governing equations and the appropriate boundary conditions of the classical models have been rederived to clarify the ambiguity involved in the definition of the boundary conditions of the various computational models. The cases of simply supported panel, cantilevered and a two-span panel are used to demonstrate numerically the differences in the overall response of the panel as well as in the near vicinity of the localized loads and supports.

ABSTRACT: When a laminated composite is subjected to compressive loads a delaminated region may buckle. This causes high interlaminar stresses at the delamination front and the delamination may grow. In this study, the effect of multiple delaminations on the postbuckling behavior of laminated rectangular plates is studied experimentally. In the experimental study extensive strain gauging is involved to obtain a thorough investigation of the behavior of the distribution of the surface strains on the plate. Results of the experimental investigation are compared with the theory developed by Chai.

ABSTRACT: The method of reliable solutions alias the worst scenario method is applied to the problem of von Karman equations with uncertain initial deflection. Assuming two-mode initial and total deflections and using Galerkin approximations, the analysis leads to a system of two nonlinear algebraic equations with one or two uncertain parameters-amplitudes of initial deflections. Numerical examples involve (i) minimization of lower buckling loads and (ii) maximization of the maximal mean reduced stress.

ABSTRACT: Local instability in the form of “intra-cell buckling” or “dimpling” is a well-known failure mode in honeycomb-cored sandwich panels with very thin faces. Most work reported on the subject suggests relatively simple design formulæ for the estimation of the intra-cell buckling load. It is however widely known that these classical design formulæ in some cases considerably underpredict the intra-cell buckling load. In this paper a series of experimental results obtained for different CFRP/honeycomb sandwich panel configurations loaded in compression are presented. The results confirm that the “classical” design formulæ provide overly conservative results. During the tests the intra-cell buckling patterns were monitored carefully, and it was observed that the hitherto assumed buckling patterns did not correspond to the experimental observations. Based on these findings a new simplified design formulæ is suggested, which for the investigated CFRP/honeycomb sandwich panels provides significantly more accurate predictions than the “classical” design formulæ.

ABSTRACT: The paper presents the results of an investigation of the non-linear behavior of delaminated sandwich panels with a compressible core. The delaminated zone, at one of the face-core interfaces, consists of through-the-width crack, which is free of shear stresses but is capable of accommodating partial contact with compressive stresses only within the debonded zone. The governing non-linear equations along with the appropriate boundary conditions and the continuity conditions are derived through variational principles. The governing equations include moderate deformations type of kinematic relations, and include the high-order effects due to the transverse flexibility of the core. The governing equations along with the stress and displacements fields for the core and the appropriate continuity conditions are presented. The effects of the non-
linear response and the partial contact are described through some numerical cases of three points bending typical sandwich panels with inner delaminations in the vicinity of a concentrated load, in the vicinity of a stiffened core and, finally, far from the load. Numerical results in the form of displacements, bending moments, shear stresses in the core and vertical interfacial normal stresses at the upper and lower face-core interfaces along the panel length and at the delamination crack tips are presented. Buckling curves of load versus various extreme structural parameters are included. The analyses show that a full contact type of delamination transforms into a partial contact area with buckling of the compressed face sheet, as the load is increased and it is associated with extreme large displacements and stresses.

ABSTRACT: Wind turbine blades are being manufactured using polymer matrix composite materials, in a combination of monolithic (single skin) and sandwich composites. Present day designs are mainly based on glass fiber-reinforced composites (GFRP), but for very large blades carbon fiber-reinforced composites are being used increasingly, in addition to GFRP by several manufacturers to reduce the weight. The size of wind turbines have increased significantly over the last 25 years, and this trend is expected to continue in the future. Thus, it is anticipated that wind turbines with a rated power output in the range of 8—10 MW and a rotor diameter about 170—180 m will be developed and installed within the next 10—15 years. The article presents an overview of current day design principles and materials technology applied for wind turbine blades, and it highlights the limitations and important design issues to be addressed for up-scaling of wind turbine blades from the current maximum length in excess of 61 m to blade lengths in the vicinity of 90 m as envisaged for future very large wind turbines. In particular, the article discusses the potential advantages and challenges of applying sandwich type construction to a larger extent than is currently being practiced for the load-carrying parts of wind turbine blades.

doi: 10.1002/nme.1100

ABSTRACT: A homogenization method is proposed for sandwich structures consisting of two plates interlaced with beams and shells in a periodic, lattice structure. The proposed method is a quasi-continuum approach where the constitutive response is obtained from the generalized forces of the interlacing elements. Buckling is studied as part of this model. Comparison of the homogenized model with fully discrete models show reasonable to very good agreement.

ABSTRACT: Multifunctional sandwich panels with corrugated and prismatic diamond cores have been analyzed and their behavior compared with panels designed using truss and honeycomb cores. Failure mechanism maps have been devised that account for interactions between core and face members during buckling. The optimal dimensions and the minimum weight have been evaluated. The load capacities predicted for near-optimal designs have been validated by conducting selected finite element calculations. Designs that use diamond prismatic cores (with corrugation order 4) are slightly more weight efficient than trusses, when optimized for a specific loading direction. Honeycomb cores, while somewhat more weight efficient, especially at lower load capacities, are not amenable to the fluid flows needed for cooling. We conclude that the diamond prismatic topology is the most weight efficient among designs amenable to simultaneous load bearing and active cooling.

ABSTRACT: An experimental and computational study of the bending response of steel sandwich panels with corrugated cores in both transverse and longitudinal loading orientations has been performed. Panel designs were chosen on the basis of failure mechanism maps, constructed using analytic models for failure initiation. The assessment affirms that the analytic models provide accurate predictions when failure initiation is controlled by yielding. However, discrepancies arise when failure initiation is governed by other mechanisms. One difficulty is related to the sensitivity of the buckling loads to the rotational constraints of the nodes, as well as to fabrication imperfections. The second relates to the compressive stresses beneath the loading platen. To address these deficiencies, existing models for core failure have been expanded. The new results have been validated by experimental measurements and finite element simulations. Limit loads have also been examined and found to be sensitive to the failure mechanism. When face yielding predominates, appreciable hardening follows the initial non-linearity, rendering robustness. Conversely, for designs controlled by buckling (either elastic or plastic) failure initiation is immediately followed by softening. The implication is that, when robustness is a key requirement, designs within the face failure domain are preferred.

ABSTRACT: A general methodology for the design of strong, lightweight sandwich panels is described and implemented. Several core topologies are considered, including square-section truss members in pyramidal and tetrahedral configurations, square honeycombs, and corrugated sheets. When the number of independent design parameters is restricted to three, closed-form analytical solutions for the optimal design are obtained. Alternatively, when a fourth parameter is added (as needed to fully characterize the panel geometry), numerical routes are required. The results demonstrate that the three parameter optimizations yield design weights that are only slightly heavier than those of the fully optimized panels, provided the value of the fourth parameter is selected judiciously. The weight rankings of the various core topologies change with load capacity, although the differences between them are generally small, particularly upon comparison with the weight of a solid panel.

ABSTRACT: In an effort to improve structural design of corrugated board packages under compression load, buckling analysis of simply-supported corrugated board panels, which constitute the main load-bearing components of a compression-loaded box, has been performed. This paper focuses on prediction of effective
(homogenised) properties of the corrugated core and the critical buckling load of a simply-supported board panel. An improved buckling load prediction has been obtained by incorporation of the additional moments produced by transverse shear deformation in the governing differential equation for equilibrium. The buckling load predictions are compared to previous analytical formulations, finite element analysis and experiments.

ABSTRACT: This study focuses on the mode dependence of delamination growth under cyclic compressive loads in cross-ply composite plates. The model proposed makes use of an initial postbuckling solution derived from a perturbation procedure. A mode-dependent crack growth criterion is introduced. Expressions describing the fatigue crack growth are derived in terms of the distribution of the mode adjusted energy release rate. The resulting crack growth laws are numerically integrated to produce delamination growth versus number of cycles diagrams. The model does not impose any restrictive assumptions on the relative thickness of the delaminated and the base plates, although transverse shear stress effects are not considered. Experimental results are presented for cross-ply graphite/epoxy specimens, and the results are compared with experimental results for unidirectional specimens. The test data are obtained for different delamination locations and for different values of applied compressive strain.

“Buckling response of sandwich composites: Effect of core density and implanted interface cracks”, Paper ID 1452, (Publisher and date not given in the “pdf” file; the most recent reference is dated 1998.)

ABSTRACT: Buckling response of foam core sandwich composites with various core densities and implanted delaminations have been investigated. Klegcell foams with densities ranging from 75-300 kg/m$^3$ were used in the analysis. Various lengths of delaminations were introduced between the face sheets by implanting non-porous Teflon during the construction of the sandwich. The idea was to determine the influence of $a/L$ (Crack length over the length of specimen) on the critical strain. The study further investigated the effect of interface crack in controlling/accelerating the core shear and local buckling of the face sheet. Buckling tests were carried out with simple support end conditions on a newly designed test fixture. Both in- and out-of-plane displacements were recorded and were utilized in determining the critical buckling loads. Both FEM and analytical calculations were carried out to determine the initial and post-buckling responses. They were later compared with the experimental data. Failure modes with various core densities have also been identified, and their relationship with interface crack propagation has been determined. Details of the experimental, finite element and analytical work are presented in this paper.

ABSTRACT: A three-dimensional (3D) finite element analysis has been conducted to examine the local buckling behavior of foam-cored composite sandwich panels containing a face-core debond. The influences of core stiffness and debond size and shape are examined. The core stiffness was found to have a profound influence on the local buckling load, especially for low modulus cores and smaller debonds. Panels with square debonds buckled at lower loads than those with circular debonds of the same dimension, and buckling loads for both circular and square debonds decreased with increased debond size. The results of the analysis were compared to local buckling loads determined experimentally. Reasonable agreement was found between the predicted and experimentally measured local buckling loads for both circular and square debonds.

ABSTRACT: Nonlinear finite element analysis is conducted to predict initiation of debond propagation in compression loaded foam cored sandwich panels containing a circular face/core debond embedded at the panel center. A three-dimensional geometrically nonlinear finite element model of the debonded sandwich panel combined with linear elastic fracture mechanics is used to determine the stress intensity factors $K_I$ and $K_{II}$ and energy release rate at the debond (crack) front parallel and perpendicular to the applied load. A range of core densities and debond sizes are analyzed. The opening mode (mode I) was found to dominate the fracture process. The critical load for crack propagation predicted using fracture mechanics concepts was found to agree with measured collapse loads for smaller debonds, but fell below measured debond propagation loads for larger debonds. In all cases the predicted direction of crack propagation was perpendicular to the loading direction, in agreement with experimental observations.

ABSTRACT: Failure of compression loaded sandwich columns with an implanted through-width face/core debond is examined. Compression tests were conducted on sandwich columns containing implemented face/core debonds. The strains and out-of-plane displacements of the debonded region were monitored using the digital image correlation technique. Finite element analysis and linear elastic fracture mechanics were employed to predict the critical instability load and compression strength of the columns. Energy release rate and mode mixity were determined and compared to fracture toughness data obtained from TSD (tilted sandwich debond) tests, predicting propagation loads. Instability loads of the columns were determined from the out-of-plane displacements using the Southwell method. The finite element estimates of debond propagation and instability loads are in overall agreement with experimental results. The proximity of the debond propagation loads and the instability loads shows the importance of instability in connection with the debond propagation of sandwich columns.

ABSTRACT: The object of the study was to optimize the shear buckling load of laminated composite plates. The laminates lacked coupling between bending and extension ($B_{ij} = 0$) but had otherwise arbitrary selection of the ply angle variation through the thickness. The plates were rectangular and either simply supported or clamped on all edges. For orthotropic plates, it was seen that there is only one parameter necessary for finding the optimal design for different materials and plate aspect ratios. This parameter can be interpreted as the layup angle $\theta$ in a (+/−$\theta$) orthotropic laminate. When bending-twisting coupling is present, the buckling strength depends on the direction of the applied load. A laminate with non-zero bending-twisting coupling stiffnesses can be described with four lamination parameters. The allowable region of these parameters was investigated, and an optimization of the buckling load within this region was performed. It was seen that even this is a one parameter problem. This parameter can be interpreted as the layup angle $\theta$ in an off-axis unidirectional laminate ($\theta$).

ABSTRACT: In this paper, the influence of initial imperfection and coupling between bending and extension on vibration, buckling and nonlinear dynamic stability of laminated plates is studied. The governing equation is derived. It is a nonlinear modified Mathieu Equation. Numerical solutions of 5 typical composite materials namely, Glass-epoxy Scotch-1002, Aramid-epoxy Kevlar-49, Boron-epoxy B4-5505, Graphite-epoxy T300-5208 and AS-3501 are computed. Results reveal that the existence of initial imperfection, and also coupling effect, make the plates much more sensitive to entering parametric resonance with amplitude greater than that of perfect plates. Coupling effect for different composite laminates, especially, for that with few layers, is different. If coupling effect is neglected, the design of plate structures for buckling and dynamic stability would unconservatively be for more than 10%.

ABSTRACT: Compression wrinkling of composite sandwich panels with corrugated skins was investigated numerically, analytically and experimentally. Semi-circular and sine-wave shaped corrugations were studied.
The corrugations significantly increased wrinkling strength when compared with equal mass flat panels. Semi-circular corrugations proved to be highly preferable to sine-wave shaped corrugations due to localized buckling in the latter. Over 40 fiberglass and foam core sandwich specimens were manufactured with semi-circular skin corrugations. These specimens were tested to failure, providing confirmation of the numerical and analytical results.

ABSTRACT: The non-classical problem of buckling of a simply-supported rectangular plate due to various types of non-uniform compressive edge loads is analysed here. For each case, the elasticity solution for the internal in-plane stress field is obtained rigorously using a superposition of Airy’s stress functions and also approximately using extended Kantorovich method. Subsequently, the convergent buckling loads are obtained using Galerkin’s method. Results are presented to highlight the dependence of the total buckling load and the corresponding buckled shape on the edge load distribution, as well as to illustrate the applicability of the approximate plane stress solutions.

ABSTRACT: Here, the elastic stability behavior of simply supported anisotropic sandwich flat panels subjected to mechanical in-plane loads is investigated using an analytical approach. The formulation is based on first-order shear deformation theory and the shear correction factors employed are based on energy consideration that depends on the lay-up as well as material properties. The governing equations are obtained using the Raleigh–Ritz method assuming a combination of sine and cosine functions in the form of double Fourier series for the displacement fields. The effectiveness of the integrated formulation is tested for global characteristics considering examples related to multi-layered laminates and sandwich panels for which solutions are available.

ABSTRACT: This study treats the elasto-plastic deformation and buckling behavior of thin cylindrical shell subjected to multi-directional excitations. A steel cylindrical pier is modeled as a thin cylindrical structure with an attached mass on its tip. Numerical simulations are carried out, where the horizontal and the vertical seismic loads are applied simultaneously. The effects of the horizontal and vertical input frequencies and input accelerations on the dynamic behaviors are studied, under both the elastic shell assumption and the elasto-plastic shell assumption. It is found that flattening phenomena will occur for the elastic shell and the buckling phenomena similar to that found in Hyogo Ken Nambu Earthquake occurs for the elasto-plastic shell.

ABSTRACT: When thin cylindrical shells having freely supported end such as heat-shielding shells of after-burners, labyrinth air seals and annular structures in large diameter pipings are subjected to axial annular flow, an unstable vibration and a fatigue failure are apt to be occurred. In this paper, the unstable vibration of thin cylindrical shells is investigated considering the fluid structure interaction between shells and fluid flowing through a narrow passage. The coupled equation of motion between shells and fluid is derived using Flügge's shell theory and Navier-Stokes equation. Especially, focusing on the higher circumferential vibrations, the unstable phenomenon of thin cylindrical shells is clarified by using root locus based on the complex eigenvalue analysis by using the mode functions obtained by the exact solution. The influence of shell-dimensions and so forth on the threshold of the instability of the coupled vibration of shells and flowing fluid are investigated and discussed.

ABSTRACT: Structural pipe-in-pipe cross sections have significant potential for application in offshore oil and gas production systems because they combine thermal insulation performance with structural strength and self weight in an integrated way. Such cross sections comprise inner and outer thin-walled pipes with the annulus between them fully filled by a selectable filler material to impart an appropriate combination of properties. Structural pipe-in-pipe cross sections can exhibit several different collapse mechanisms, and the basis of the preferential occurrence of one over the others is of interest. This article presents an exact analysis for predicting the elastic buckling behaviours of a structural pipe-in-pipe cross section when subjected to external hydrostatic pressure. Simplified approximations are also investigated for elastic buckling pressure and mode when the outer pipe and its contact with the filler material is considered as a pipe on an elastic foundation. Results are presented to show the variation of elastic buckling pressure with the relative elastic modulus of the filler and pipe materials, the filler thickness, and the thicknesses of the inner and outer pipes. Case studies based on realistic application scenarios are used to show that the simplified approximations are sufficiently accurate for practical structural design purposes.

ABSTRACT: For isotropic incompressible hyperelastic materials the problem of determining the critical pressure at which a thick-walled spherical shell buckles when subjected to a uniform external pressure involves solving a fourth-order system of highly non-homogeneous ordinary differential equations. Closed-form solutions of this system are derived here for a particular hyperelastic material which has not been studied previously. These solutions are used to derive the buckling criterion, and numerical values are obtained for the resulting critical pressures. For thin shells these values are in agreement with classical thin-shell theory while for thicker shells close agreement is obtained with existing results for the neo-Hookean material. However for thin shells the predicted buckling mode is different from that given by previous authors. It can be shown from previously published experimental results on simple extension and simple compression that the new strain-energy function is a valid prototype for vulcanized rubber over a limited range of deformation and moreover that it agrees with the neo-Hookean theory for small strains.

ABSTRACT: General instability is one of the important collapse modes of cylindrical shells reinforced by ring stiffeners under uniform pressure. Few research, however, has appeared in this field because of difficulties and complexity of the problem. Pressure hulls of deep diving submersibles have been designed on the basis of research works which were developed under idealized conditions for boundaries, stress-strain relations, and geometries. Recently, the development of high strength materials and the increase of operating pressure and diameter of pressure hulls have brought a change in proportion of primary structural members of cylindrical ring-reinforced shells, which leads to the review of the design procedure. In order to satisfy the above-mentioned requirements, pressure hulls should be designed on a reasonable basis. In the present paper, the elasto-plastic analysis of the general instability of ring reinforced cylindrical shells is performed on the basis of the finite element method, and results obtained are compared with collapse tests using two machined models and one welded model, which shows good coincidence with the theory. On the basis of a series of calculation, the authors propose a design criteria for the pressure hulls of deep diving submersibles. Furthermore, they investigate the influence of boundary conditions and initial imperfections on the general instability theoretically.

ABSTRACT: A computationally effective method is described to evaluate the non-deterministic dynamic instability (probabilistic dynamic buckling) of thin composite shells. The method is a judicious combination of available computer codes for finite element, composite mechanics, and probabilistic structural analysis. The solution method is incrementally updated Lagrangian. It is illustrated by applying it to thin composite cylindrical shell subjected to dynamic loads. Both deterministic and probabilistic buckling loads are evaluated to demonstrate the effectiveness of the method. A universal plot is obtained for the specific shell that can be used to approximate buckling loads for different load rates and different probability levels. Results from this plot show that the faster the rate, the higher the buckling load and the shorter the time. The lower the probability, the lower is the buckling load for a specific time. Probabilistic sensitivity results show that the ply thickness, the fiber volume ratio and the fiber longitudinal modulus, dynamic load and loading rate are the dominant uncertainties, in that order.

ABSTRACT: Composite pipe has been used in transporting corrosive fluid in many chemical processes in the petrochemical and pulp and paper industries. It is often subjected to external pressures due to process conditions (vacuum), water hammer, pump suction, and differences in elevation head. Most composite pipe designers are currently using traditional metallic pipe standards which do not take into account the anisotropic nature of composite materials. An analytical model for the buckling of orthotropic composite pipe under external pressure has been developed in this study. In this study, first-order laminated anisotropic plate theory was used to construct models of the kinematic and constitutive behavior of the composite cylinders. The Ritz Method was then applied to determine the buckling load under external pressure. Results obtained from the developed model were compared with the theory derived by Flügge for the case of metallic pipe. Due to the inclusion of shear deformation, the new model gave lower buckling loads than Flügge's results especially for the case of thick-walled pipe. Good agreement was found when comparing the developed model with experimental results provided by Fibercast Company following ASTM D 2924 for centrifugally cast composite pipe.

ABSTRACT: The buckling behavior of $[0/+\theta/-\theta, 90]$$_S$ laminated cylindrical panels under axial compression is investigated by a parametric study on fiber angles and panel widths. The shape of the buckled panel and the buckling mode are influenced by the change of fiber angles. When the fiber angle is not 0 or 90°, panels are deformed into the twisted shape due to the bending-twisting coupling even for symmetric laminates. The fiber angle for the maximum buckling stress of the laminated cylindrical panel depends upon the panel width.

ABSTRACT: A new technology known as asymmetric sandwich structures is now used for the design of lightweight structures. Static failure tests demonstrate the high performance of this technology and show its original mechanical behavior. Due to this complex mechanical behavior, the use of non-linear finite element models in the pre-project phase is a long, expensive process. This paper presents a specific theory which enables faster design loops. The theory is first validated by comparison to numerical models and is then used to correlate structural tests on asymmetric sandwich plate under combined compression/shear loadings. The tests were conducted on original test equipment designed to investigate the capabilities of this technology.

ABSTRACT: Finite element analysis is conducted to investigate the effect of coupling between the stiff facesheets and the flexible core on the stability of sandwich plates. The facesheets and the core are treated separately as three-dimensional solids. Initially, linear buckling analysis was carried out to determine the buckling loads for a wide range of the facesheet stiffness and core stiffness. Numerical results indicate that, for sandwich plates with a soft core such as PVC foam, the model that smears the facesheets and core overestimates the initial buckling load, demonstrating the importance of treating the facesheets and the core separately. Subsequently, postbuckling analysis was carried out. Numerical results show that, for sandwich plates with a soft core, the postbuckling behavior is unstable in that static equilibrium cannot be maintained once the buckling initiates.

ABSTRACT: The paper presents a finite element formulation for the geometrically non-linear analysis of shells. The formulation is based on the Hellinger—Reissner approach and uses internal transverse shear stress unknowns to alleviate the problem of shear locking. A ring and a quadrilateral element are presented, together with three examples which demonstrate the accuracy of the elements.
ABSTRACT: The work’s aim has been to verify the suitability of commercial engineering software for geometrically non-linear analysis of shell structures. The paper deals with static, geometrically non-linear analysis of shells made of isotropic materials. The Finite Element Method (FEM) has been chosen to solve the problem. The results of the ROBOBAT Robot Millennium v. 19.0 and MSC.Marc v. 2005r2 commercial software are compared with the literature results.

ABSTRACT: A geometrically nonlinear formulation is presented for the axisymmetric plate and shell structures. The formulation is based on the total Lagrangian approach. The nonlinear equilibrium equations are solved using the Newton-Raphson method. Different numerical examples are performed to obtain the geometrically non-linear behaviour of axisymmetric plates and shells.

ABSTRACT: This paper deals with buckling and vibration analysis of initially stressed damped composite sandwich plates using assumed strain finite elements. A family of plate bending elements containing nine degrees of freedom per node are developed based on a refined higher-order shear deformation theory. The...
higher-order theory contains in-plane displacements that are expanded to include the higher-order terms in the Taylor series expansion as a result of which there is no need for shear correction factors. The popular assumed strain concept is used to ensure that the developed four- and nine-node elements pass the patch test and show no signs of shear locking and spurious zero energy modes in the present finite element formulations. Parametric studies are carried out to study the behavior of length to thickness ratios, boundary conditions, fiber orientations on vibration, and buckling of damped composite sandwich plates.

ABSTRACT: A simple isoparametric assumed strain finite element formulation incorporating a third-order polynomial displacement model for the buckling and vibration analysis of initially stressed composite sandwich laminates is presented. The displacement model involves a nonlinear distribution of in-plane displacements through the plate thickness; the theory does not require shear correction coefficients. A nine-noded quadratic Lagrangian two-dimensional element is used with three displacements, two rotations of the normals about the plate midplane, and two warps of the normals. Full integration is carried out to evaluate various terms in the energy formulation. A consistent mass matrix is employed to preserve the total kinetic energy of the system. The accuracy of the present formulation is verified with the existing results in the literature. Numerical results are presented for the stability and free vibration of initially stressed composite sandwich plates.

ABSTRACT: Top-hat stiffened plates provide an efficient structure for engineering applications. During service debonding between the stiffener and the plate is often observed and parametric studies of open section stiffeners have shown that debond size and location have a significant effect on the damage mode of the panel. However, these studies do not consider the interaction of failure modes and do not assess the ultimate failure of the structure. In this paper top-hat stiffened composite structures are assessed considering debond damage between the stiffener and plate. A non-linear finite element model is used to perform a parametric study on the effect of both damage and the panel’s geometry on the failure modes, ultimate strength and its damage tolerance. Results show that top-hat stiffened panels exhibit a trend between ultimate strength and the debond size with crack initiation not necessarily propagating. Geometric imperfections accelerate buckling but can provide an arrest point for crack propagation.

“The application of reliability methods in the design of tophat stiffened composite panels under in-plane loading”, (publisher and date not given in the pdf file. The latest citation is 2009. Perhaps November 2013?)

ABSTRACT: Composite materials have been widely used in modern engineering fields such as aircraft, space and marine structures due to their high strength-to-weight and stiffness-to-weight ratios. However, structural
efficiency gained through the adoption of composite materials can only be guaranteed by understanding the influence of production upon as-designed performance. In particular, topologies that are challenging to production including panels stiffened with pi or tophat stiffeners dominate many engineering applications and often observe complex loading. The design of stiffened composite panels against buckling is a key point of composite structures. While a growing number of studies are related to the reliability analysis of composites few of these relate to the local analysis of more complicated structures. Furthermore for the assessment of these structures in a design environment it is important to have models that allow the rapid assessment of the reliability of these local structures. This paper explores the use of a stochastic approach to the design of stiffened composite panels for which typical applications can be found in composite ship structures. A parametric study is conducted using Navier grillage theory and First-order Reliability Methods to investigate any detectable trend in the safety index with various design parameters. Finally, recommendations are made to provide guidance on applications.

ABSTRACT: Stiffened composite panels are used within many applications, from aerospace to marine applications. Stiffened panels are utilized for their high strength to weight ratio and flexibility of layups while counteracting the low stiffness exhibited by composites. Complications arise when attempting to utilize the full variability of layups in conjunction with reliability constraints creating a complex design problem when constrained by both buckling and material strength. To aid the process of optimizing the design of composite structures and layups, while ensuring a low mass, this paper presents a bi-level optimization scheme for minimization of the weight of tophat stiffened composite panels with probabilistic deflection constraints. To improve the computational efficiency, an energy based grillage method is formulated and applied for the investigation of buckling problems under bi-directional in-plane loads. The method is validated by comparing the results obtained from FE model calculations. The variables that have a large impact on the structural safety have been identified by both safety index and COV based reliability analysis. A parametric study of plate dimensions and loading ratios is conducted to investigate the coupling effects on critical buckling load. The method presented in this paper, makes it possible for engineers to improve their designs, at an early stage, with an integrated consideration between product performance and design parameters.

ABSTRACT: Finite element analysis and the optimization problem of sandwich constructions are treated. The thicknesses of the face plates and the core are used as design variables. The hybrid approximation technique in combination with the dual method from mathematical programming is used. Three examples are solved using six-nodal triangular and eight-nodal quadrilateral sandwich shell elements.

ABSTRACT: General buckling analysis of composite sandwich constructions is treated in this paper. Two modes of buckling exist in an elastic structure under certain loading cases, that is, bifurcation point buckling
and extreme point buckling. This paper is concerned with bifurcation point buckling. The energy criterion is used for deriving the theoretical formulae. According to the energy criterion, the positive two-order variation of the general potential energy, $\pi$, for an elastic mechanics system is necessary and sufficient condition to ensure a stable static balance state. The sandwich construction would not support loads and would suffer failure if general instability occurred on it. In the general buckling analysis, the formulae are based on the finite element method of linearity theory. The critical stress control equations corresponding to the bifurcation point buckling can be obtained by commanding two-order variation of the general potential energy, $\pi$, to equal zero. The critical load corresponding to structural general instability can be given by solving the generalized eigenvalue problem. It is shown by four numerical examples that the calculated results and accuracy are satisfied under a set of computation equations derived in this paper.

ABSTRACT: This paper presents buckling of unstiffened/stiffened orthotropic foam sandwich cylindrical shells simply supported at both ends. For the unstiffened cylinders, five equations of equilibrium are derived in terms of the mid-surface displacements and cross-section rotations according to the thick shell theory. Critical buckling loads are obtained by modal expansion under the loading conditions of axial compression, lateral pressure and torsional load with reasonable results. The stiffened cases are investigated by using the principle of minimum potential energy and smear-out technique typical of the fewer discrete and closely spaced small stiffeners. Critical buckling loads and mode shapes are obtained for cylinders with 4 and 20 stiffeners respectively.

ABSTRACT: This paper is concerned with the semi-analytical solution for the axisymmetric buckling for perfect complete thick orthotropic spherical shells and hemispherical shells under various edge conditions,
subjected to uniform full external pressures. The meridional and radial mid-surface displacements and the circumferential cross-sectional rotation are expressed as an expansion in Legendre polynomials respectively in the meridional coordinate. Transverse shear strain effects are included in the energy formulation of small strains. The solutions are achieved directly by use of the Ritz method without considering the force and moment equilibrium and solving the complicated governing equations. Critical buckling loads and the various modes are found from the equations by use of orthogonality and some integral relations.

ABSTRACT: A three-dimensional vibration study is presented using the three-dimensional theory developed by Chao et al. [34–39] for a variety of simply supported shallow spherical, cylindrical, plate, and saddle (hyperbolic) panels in rectangular planform. A complete survey and comparison of existing literature have been made with excellent lowest frequencies via a 3-D augmented energy variational approach. In all of these shell configurations, natural frequencies are noted to decrease in the above-mentioned order according to minimum total potential energy in the natural state.

ABSTRACT: A simple C0 isoparametric finite element formulation based on a shear deformable model of higher-order theory using a higher-order facet shell element is presented for the free vibration analysis of isotropic, orthotropic and layered anisotropic composite and sandwich laminates. This theory incorporates a realistic non-linear variation of displacements through the shell thickness, and eliminates the use of shear correction coefficients. The validity and efficiency of the present formulation is established by obtaining solutions to a wide range of problems and comparing them with the available three-dimensional closed-form and finite element solutions. In addition, other plate and shell solutions of different kind and available in the literature are also compiled and tabulated for the sake of completeness. The parametric effects of degree of orthotropy, length-to-thickness ratio, plate aspect ratio, number of layers and fibre orientation upon the frequencies and mode shapes are discussed.

ABSTRACT: This paper begins by presenting a Generalized Beam Theory (GBT) formulation for analyzing the vibration behavior of loaded composite thin-walled members, which accounts for the effects of (i) cross-section in-plane deformation, (ii) shear deformation, (iii) geometric and material coupling, (iv) primary, secondary and non-linear warping, and (v) rotary inertia. This formulation is then used to investigate the local and global vibration behavior of lipped channel columns and beams displaying cross-ply orthotropy, focusing on issues dealing with the variation of the fundamental frequency and vibration mode nature with the member length and applied stress level. For validation purposes, some GBT-based results are also compared with values obtained by means of 4-node shell finite element analyses using ABAQUS. Some relevant conclusions are drawn concerning the dependence of the member vibration mode shape (wave number) on the compression/bending level (applied-to-critical ratio).

ABSTRACT: On the basis of Flügge's approximations and with account taken of the transverse shear deformation (SDT) and all rotatory inertias, the equations of in-plane buckling and free vibrations of multilayered, anisotropic, doubly curved shells are presented. As a particular case, the equations relative to Love's approximations and Donnell's approximations and as well as of the corresponding classical theories (CLT) are derived. Analytical exact solutions are presented for buckling under axial compression and free vibrations of cross-ply laminated, simply supported, circular cylindrical and spherical composite shells. Depending on geometric parameters of the shell (length to radius ratio a/R, length to thickness ratio a/h and radius to thickness ratio R/h), numerical results (in tables and figures) are quoted to compare the different theories, and some trends are singled out about the effects of both transverse shear deformations and curvatures of the shell. Particular attention is given to the application of Flügge's approximations in which are presented solutions of the equilibrium equations containing terms of the same order in h/R. Finally, the effects of coupled out-of-plane stiffnesses on the theories is investigated.

ABSTRACT: This paper deals with the non-linear analysis of multilayered axially compressed plates in the static elastic conservative cases. A finite element model based on a Reissner-Mindlin theory involving von Kármán nonlinearity is developed. Results related to the classical Kirchhoff plate approximations are obtained via application of a penalty technique to the shear correction factor. The numerical investigations have concerned the large deflections and postbuckling behaviour of symmetrically and non-symmetrically anisotropic flat panels. The main conclusions are: (1) the non-linear effects very much depend on lay-up and boundary conditions, moreover for the asymmetric laminated long plates the snapping-type instability occurs; (2) the shear deformation effects are very much subordinate to both multilayered lay-up and load levels,
furthermore they are greater in the large deflections field; (3) it has been observed that in the neighbourhood of a singularity (of buckling point type) of the tangent stiffness matrix, the use of an arc-length type algorithm could lead to a new buckled path and that happens without employing an appropriate turning bifurcation algorithm with an accompanying eigenvalues calculation, but via a non-convergent iteration in the loadstep.

ABSTRACT: This paper evaluates transverse normal stress effect on vibration of multilayered structures. To this purpose a mixed plate model initially introduced by Toledano and Murakami has been extended to dynamics analysis of double curved shells. These models allow both continuous interlaminar transverse shear and normal stresses as well as the zigzag form of the displacement distribution in the shell thickness directions to be modelled. Governing equations have been derived by employing a Reissner's mixed theorem. Classical models on the basis of standard displacement formulations have been considered for comparison purposes. The evaluations of transverse stress effects have been conducted by comparing constant, linear and higher order distributions of transverse displacement components in the plate thickness directions. Free vibrational response of layered, simply supported plates, cylindrical and spherical shells made of isotropic as well as orthotropic layers has been analyzed. The numerical investigation carried out and comparison with earlier results has concluded that:
1. The possibility of describing interlaminar continuous transverse normal stress makes the mixed theories more attractive with respect to other available modelling.
2. Any refinements of classical models are meaningless, unless the effects of interlaminar continuous transverse shear and normal stresses are both taken into account in a multilayered shell theory.

ABSTRACT: Beam models are widely used to investigate the mechanical behavior of slender bodies such as aircraft wings, wind turbines, and slender bridges. Classical beam theories are those by Euler-Bernoulli and Timoshenko [1] which are particularly effective in analyzing the bending of compact slender structure made of isotropic materials. As the structure becomes thin-walled, short, or composite materials are used, classical model validity ceases since a number of non-classical effects has to be taken into account: warping, cross-section distortion, shear effects, etc.. The overcome of these limitations can be obtained by adopting refined beam models. Interesting papers on this topic are those by Kapania and Raciti [2, 3], and Yu and Hodges [4].

ABSTRACT: The present work evaluates the effect of thickness stretching in plate/shell structures made by materials which are functionally graded (FGM) in the thickness directions. That is done by removing or retaining the transverse normal strain in the kinematics assumptions of various refined plate/shell theories. Variable plate/shell models are implemented according to Carrera’s Unified Formulation. Plate/shell theories with constant transverse displacement are compared with the corresponding linear to fourth order of expansion in the thickness direction ones. Single-layered and multilayered FGM structures have been analyzed. A large numerical investigation, encompassing various plate/shell geometries as well as various grading rates for FGMs, has been conducted. It is mainly concluded that a refinements of classical theories that include additional in-plane variables could results meaningless unless transverse normal strain effects are taken into account.

ABSTRACT: The free vibration analysis of thin- and thick-walled layered structures via a refined one-dimensional (1D) approach is addressed in this paper. Carrera unified formulation (CUF) is employed to introduce higher-order 1D models with a variable order of expansion for the displacement unknowns over the cross section. Classical Euler–Bernoulli (EBBM) and Timoshenko (TBM) beam theories are obtained as particular cases. Different kinds of vibrational modes with increasing half-wave numbers are investigated for short and relatively short cylindrical shells with different cross section geometries and laminations. Numerical results of natural frequencies and modal shapes are provided by using the finite element method (FEM), which permits various boundary conditions to be handled with ease. The analyses highlight that the refinement of the displacement field by means of higher-order terms is fundamental especially to capture vibrational modes that require warping and in-plane deformation to be detected. Classical beam models are not able to predict the
realistic dynamic behavior of shells. Comparisons with three-dimensional elasticity solutions and solid finite element solutions prove that CUF provides accuracy in the free vibration analysis of even short, nonhomogeneous thin- and thick-walled shell structures, despite its 1D approach. The results clearly show that bending, radial, axial, and also shell lobe-type modes can be accurately evaluated by variable kinematic 1D CUF models with a remarkably lower computational effort compared to solid FE models.

M. Cinefra, E. Carrera and S. Valvano (Dept. of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Italy), “Free-vibration analysis of delaminated shells via unified formulation”, (publisher and date not given in the pdf file. The most recent citation is dated 2014.)
ABSTRACT: The present work deals with the free-vibration analysis of multilayered composite shells affected by localised delaminations. The delamination in composite structures may occur either during the manufacturing process or during service period of the structure. Delaminations can be distinguished into two types, one delamination at the free edges caused by high free edge stresses, and the other embedded within the body of the structure which may be due to manufacturing defects or voids, or due to impact loads. To facilitate the understanding of the effect of the delamination on the structures, and to analyze possible algorithms for structural health monitoring of delaminated structures, delamination models are required. Several authors have studied delaminated shells, like Nanda and Sahu have carried out free vibration analysis of delaminated composite shells [1] using different shell theories. Dynamic instability of delaminated skew plates subjected to static and dynamic loads based on higher order shear deformation theory was studied out by Noh and Lee [2]. These works used a single theory or couple of theories to carry out their studies. The proposed investigation tries to comprehensively carry out free vibration analysis of delaminated composite shells using refined and advanced shell models, contained in the Carrera’s Unified Formulation (CUF). One of the most interesting features of the CUF consists in the possibility to keep the order of the expansion of the state variables along the thickness of the plate as a parameter of the model. Finite elements with layer-wise capabilities are employed to ensure an accurate description of the mechanical fields in the layers. It is essential to take into account the discontinuity of the mechanical properties at the layer interfaces. For these reasons, the use of classical plate theories based on Kirchhoff and Reissner-Mindlin hypotheses can lead to inaccurate results. The Mixed Interpolated Tensorial Components (MITC) method is employed to contrast the membrane-shear locking phenomenon that usually affects shell finite elements. This formulation has already shown all its potentiality as a base for finite elements in the mechanical analysis of multilayered shells [3]. Some results from the free-vibration analysis of shells will be provided, in order to show the efficiency of models presented.

ABSTRACT: Linearized buckling analysis of laminated plates subjected to combined bi-axial/shear loading is described in this work. Isotropic, orthotropic and anisotropic plates are referred to. Two-dimensional plate
modelling is considered. The Principle of Virtual Displacement (PVD) is applied. The Finite Element Method (FEM) is adopted in order to approximate the solution. The same cases-study are handled using different kinds of plate Finite Elements (FEs), with the purpose of providing some guidelines/benchmarks useful for identifying the most appropriate modelling for each class of buckling problem. The considered set of FEs is hierarchical in the sense that a variable kinematics approach is employed: both Equivalent Single Layer (ESL) and Layer-Wise (LW) variable descriptions are implemented, keeping the expansion order for thickness variables generic. FE matrices are obtained in compact form by referring to Carrera’s Unified Formulation (CUF). When available, exact solutions are referred to in order to assess the FEM results.

ABSTRACT: Buckling is one of the characteristic failure modes of slender laminated and sandwich structures like plates and shells. It is well known that a rational design of composite structures demands dedicated models in order to cope with their complex behavior due to the heterogeneous multilayered cross-section, the characteristic transverse shear deformability and the coupled membrane-bending-twisting response. These peculiarities increase the complexity of the buckling behavior of composite shells [1]. This paper presents a rigorous assessment of various 2D approximations against buckling of laminated and sandwich plate/shell models. For this, the established variable kinematics modeling technique known as Carrera’s Unified Formulation (CUF) is employed. CUF permits a systematic assessment of a large number of plate/shell models, whose accuracy has been demonstrated to range from classical 2D models to quasi-3D descriptions [2]. By referring to the closed-form solution of Navier, the attention is restricted to simply-supported, orthotropic laminates and sandwich plates and cylindrical shells under axial load. Two different pre-buckling states are addressed, i.e., a uniform initial stress and a uniform initial strain load.

ABSTRACT: The buckling of thin-walled structures is presented using the 1D finite element based refined beam theory formulation that permits us to obtain N-order expansions for the three displacement fields over the section domain. These higher-order models are obtained in the framework of the Carrera unified formulation (CUF). CUF is a hierarchical formulation in which the refined models are obtained with no need for ad hoc
formulations. Beam theories are obtained on the basis of Taylor-type and Lagrange polynomial expansions. Assessments of these theories have been carried out by their applications to studies related to the buckling of various beam structures, like the beams with square cross section, I-section, thin rectangular cross section, and annular beams. The results obtained match very well with those from commercial finite element softwares with a significantly less computational cost. Further, various types of modes like the bending modes, axial modes, torsional modes, and circumferential shell-type modes are observed.

De Xie and Sherrill B. Biggers, Jr. (Department of Mechanical Engineering, Clemson University, Clemson, SC 29634, USA), “Postbuckling analysis with progressive damage modeling in tailored laminated plates and shells with a cutout”, Composite Structures, Vol. 59, No. 2, February 2003, pp. 199-216, doi:10.1016/S0263-8223(02)00233-7

ABSTRACT: An approach to modeling inplane damage progression in postbuckled laminated composite panels is shown to be accurate by comparison to experimental test data from other sources. A simple tailoring concept is shown to be very effective in increasing compressive buckling loads and ultimate loads for flat plates and curved panels with a central cutout. Effects of cutout size, the degree of tailoring, and inplane restraint on the unloaded edges are investigated. Optimal tailoring produces relative improvements in the flat plates ranging from 40% to 175% in buckling load and 190–240% in ultimate load capacity when compared to uniform plates with the same cutout sizes. In the curved panels, tailoring lowers the imperfection sensitivity and in some cases produces ultimate loads greater than the theoretical undamaged buckling loads. To the contrary, the ultimate load for the uniform curved panel is much lower than the undamaged buckling load. Relative improvements in ultimate loads range from a low of about 40% to a high of about 155% compared to uniform curved panels. Large differences in the damage initiation locations and damage progression patterns are shown between the flat and the curved panels. In summary, the tailoring concept investigated here can provide excellent improvements in ultimate load capacity in flat and curved panels with the largest benefits occurring in thin flat panels that are loaded far into the compressive postbuckling regime.

ABSTRACT: This paper discusses the development and application of two alternative strategies, in the form of global and sequential local response surface (RS) techniques, for the solution of reliability-based optimization (RBO) problems. The problem of a thin-walled composite circular cylinder under axial buckling instability is used as a demonstrative example. In this case, the global technique uses a single second-order RS model to estimate the axial buckling load over the entire feasible design space (FDS), whereas the local technique uses multiple first-order RS models, with each applied to a small subregion of the FDS. Alternative methods for the calculation of unknown coefficients in each RS model are explored prior to the solution of the optimization problem. The example RBO problem is formulated as a function of 23 uncorrelated random variables that include material properties, the thickness and orientation angle of each ply, the diameter and length of the cylinder, as well as the applied load. The mean values of the 8 ply thicknesses are treated as independent design variables. While the coefficients of variation of all random variables are held fixed, the standard deviations of the ply thicknesses can vary during the optimization process as a result of changes in the design variables. The structural reliability analysis is based on the first-order reliability method with the reliability index treated as the design constraint. In addition to the probabilistic sensitivity analysis of the reliability index, the results of the RBO problem are presented for different combinations of cylinder length and diameter and laminate ply patterns. The two strategies are found to produce similar results in terms of accuracy, with the sequential local RS technique having a considerably better computational efficiency.

ABSTRACT: Postbuckling analysis of composite laminates representative of wind turbine blade substructures, utilizing the commercial finite element software ANSYS, is presented in this paper. The procedure was validated against an existing postbuckling analysis. Three shell element formulations, SHELL91, SHELL99,
and SHELL181, were examined. It was found that the SHELL181 element with reduced integration should be used to avoid shear locking. The validated procedure was used to examine the variation of the buckling behavior, including postbuckling, with lamination schedule of a laminate representative of a wind turbine blade shear web. This analysis was correlated with data from a static test. A 100% postbuckling reserve in a composite structure representative of a shear web was quantified through test and analysis. The buckling behavior of the shear web was improved by modifying the lamination schedule to increase the web bending stiffness. Modifications that improved the buckling load of the structure did not always equate to improvements in the postbuckling reserve.

ABSTRACT: This paper deals with development of triangular finite element for buckling and vibration analysis of laminated composite stiffened shells. For the laminated shell, an equivalent layer shell theory is employed. The first-order shear deformation theory including extension of the normal line is used. In order to take into account a non-homogeneous distribution of the transverse shear stresses a correction of transverse shear stiffness is employed. Based on the equivalent layer theory with six degrees of freedom (three displacements and three rotations), a finite element that ensures C0 continuity of the displacement and rotation fields across inter-element boundaries has been developed. Numerical examples are presented to show the accuracy and convergence characteristics of the element. Results of vibration and buckling analysis of stiffened plates and shells are discussed.

R. Rikards, K. Kalnins & O. Ozolinsh (Institute of Materials and Structures, Riga Technical University, Riga 1658, Latvia), “Skin-Stringer Debonding and Delamination Analysis in Composite Stiffened Shells”, (no publisher or date given in the pdf file; most recent reference is 2002)

ABSTRACT: In the present paper the skin-stringer delamination problem for composite stiffened shells is solved. The skin-stringer delamination is analyzed employing linear fracture mechanics approach. Energy release rates (ERR) are calculated by Modified Virtual Crack Closure Integral (MVCCI) method. The problem is solved not using the 3D solid finite elements, but employing the 2D shell elements. Employment of the 2D shell elements instead of 3D elements significantly reduces computational efforts in the case when whole composite stiffened structure is analyzed for post-buckling. Mode I, mode II and mixed mode I/II fracture properties are obtained for the fracture criterion of the carbon/epoxy composite laminate. The fracture criterion is used for prediction of debonding at the skin-stringer interface.

ABSTRACT: The development of an optimization design procedure for stiffened composite shells has emerged as an essential component in overcoming the challenge of deriving design guidelines with a reasonable amount of tested structures. The optimization procedure is based on the building of surrogate models employing the experimental design and response surface methodology. Surrogate models are built using continuous and discrete quantitative parameters and approximated with global and local nonparametric approximations. The numerical data obtained from finite element simulations of composite stiffened shells subjected to buckling and post-buckling is used for the building of surrogate models. Additionally a data set of natural experiments has been implemented into surrogate models showing high efficiency in the estimation of the post-buckling behavior of the stiffened composite shells (panels). The resulting design procedure provides an effective optimal design tool for the preliminary study of composite stiffened shells.

ABSTRACT: The intense interest coming from the aerospace industry indicates the need of safe exploitation of composite materials within post-buckling region. Since stiffened curved panels are by far the most consumed...
structural component, it is important to study the behavior of structural degradation to evaluate the safe design guidelines. An assessment of structural degradation in terms of stiffness reduction in the skin stringer zone is carried out to estimate the degradation influence on the postbuckling stiffness of the axially loaded stiffened panels. The presented procedure is based on the building of metamodels employing experimental design and response surface methodology. Metamodels are built using stiffened shell geometrical variables adding structural degradation variables such as degradation region length ratio and material elastic property reduction coefficient. The numerical responses, obtained from explicit FEM simulations of composite stiffened shells subjected to buckling and post-buckling, are used for the building of metamodels. The resulting design procedure provides an effective analysis tool for the safe exploitation of composite stiffened panels under axial compression.

“Overview of Slow Computational and Fast Simulation Tools”, (COCOMAT project, publisher and date not given in the pdf file; most recent reference is September 2008)

ABSTRACT: The paper overviews the progress achieved by the European Commission funded project COCOMAT [1] work package devoted to the development of improved simulation procedures for collapse of composite airframe structures, which take degradation into account. It has been identified by industrial applications that very accurate, but necessarily slow tools are required for the final certification, whereas reliable fast tools reducing design and analysis time by an order of magnitude, will allow for an economic design process. Twelve industrial and academic partners have been involved in the extension of commercial analysis software such as SAMCEF, B2000, ABAQUS, MSC.MARC, MSC.NASTRAN and improvement of in-house tools. In general, structural degradation has been implemented as growth of skin-stringer separation and delamination in the stiffened composite structures. Interlaminar fracture growth criteria have been implemented by means of Virtual Crack Closure Technique (VCCT) and Virtual Crack Extension (VCE) Method. Furthermore stress/strain based failure criteria such as Hashin, Puck and Maximum Stress have been introduced to model initiation and progression of the ply damage. Finally, all developed tools have been validated by means of the experimental results obtained from the other work packages within the COOCMAT project. Among the validation experiments were: double cantilever beam, end-notched flexure and mixed mode stiffener specimens together with stiffened panel and box structures with pre-existing and industrially pre-selected damage.

ABSTRACT: The structural behaviour of composite stiffened flat panels under axial compression is here investigated up to collapse. The panel configuration is designed to buckle once the limit load is reached and to work in post-buckling until the ultimate load. The design phase is based on the use of four different kinds of finite element analyses: eigenvalue, non-linear static with modified Riks’ method and both implicit and explicit dynamic analyses. Once the final configuration is identified, two specimens are manufactured. The initial geometrical imperfections are measured and analyzed, then axial compression tests are performed until collapse. As foreseen by the numerical analyses, experimental results prove the ability of the panels designed to work in the post-buckling field until collapse which takes place due to the failure of the stiffener blades. Finally, the measured initial imperfections are included in the model significantly increasing the numerical–experimental correlation

ABSTRACT: A multi-objective optimization procedure for the design of composite stiffened panels capable to operate in post-buckling is presented. The procedure is based on Genetic Algorithms and three different methods of global optimization: Neural Networks, Radial Basis Functions and Kriging approximation. Response surfaces are used to approximate the post-buckling behaviour of the panels using a limited number of sample points. Optimization results underline the significance of non-dominated solutions, as the best panel configurations inside the domain of interest. Finally, one of the non-dominated solutions is selected, manufactured and tested up to collapse. The analyses, performed a priori without considering any kind of imperfection, are closed and in good agreement with the tests in terms of pre-buckling and post-buckling stiffness, as well as in terms of collapse loads. The introduction of imperfections reduced the percentage errors between computations and tests within 5% in so far as buckling and collapse loads are concerned. The obtained results prove the influence of the initial imperfections not only on the first-buckling load but also in the post-buckling range up to collapse.

Carlos A. Coello Coello (Laboratorio Nacional de Informática Avanzada, Rébsamen 80, Xalapa, Veracruz 91090, México), “Constraint-handling using an evolutionary multiobjective optimization technique”, (publisher and date not given in the pdf file)

ABSTRACT: In this paper we introduce the concept of non-dominance (commonly used in multiobjective optimization) as a way to incorporate constraints into the fitness function of a genetic algorithm. Each individual is assigned a rank based on its degree of dominance over the rest of the population. Feasible individuals are always ranked higher than infeasible ones, and the degree of constraint violation determines the rank among infeasible individuals. The proposed technique does not require fine tuning of factors like the traditional penalty function and uses a self-adaptation mechanism that avoids the traditional empirical adjustment of the main genetic operators (e.g., crossover and mutation).

ABSTRACT: In order to improve confidence in composite structure design, a better description of the failure of laminates is necessary. In this paper the buckling and postbuckling behaviour of axially compressed layered composite panels is studied by means of Finite Element Method (FEM). A series of experiments was conducted to verify the FEA-results, but also to address the stability and strength of the composite structure. Combining a geometric nonlinear finite element analysis (FEA) based on the von Kármán theory and High Order Shear Deformation Theory (HOST) are used to study the first-ply failure behavior as well as the postbuckling behavior of laminated type composite structures. For this purpose and for the investigation of the failure responses, the improved 4-node layered shell finite elements are used. The finite element formulation is based on the third order shear deformation theory with four-node shell finite elements having eight degrees of freedom per node. A simple method is proposed to predict buckling loads and the post-buckling behaviour. The comparisons between the numerical and the experimental results show quite a good agreement.

ABSTRACT: This paper deals with the formulation of beam elements for the numerical analysis of instability phenomena in frame-type structures. Total versus co-rotational approaches are discussed comparatively, for both two-dimensional and three-dimensional problems, and the similarities between the two types are outlined.

In the context of 3D beam elements, special attention is given to the parameterisation of the orthogonal transformation used to define the rotational field of the beam. The technique advocated in the paper is based on the so-called rotational vector. This leads to symmetric stiffness matrices and avoids the need for special updating procedures for the rotational variables. A set of test problems, for which the critical behaviour is governed by fold, cusp and butterfly catastrophes, is used to assess the performances of the considered element types. It is shown that analytically verified identities in element formulation, also hold in numerical application. The examples also show how complex instability behaviour can be reproduced by all elements, where sufficient accuracy is introduced into the kinematic expressions. The analytical derivation of element expressions, with symbolic manipulations from stated basic assumptions, is consistently used in the paper.

ABSTRACT: This paper investigates the formulation of co-rotational flat facet triangular elements for the numerical analysis of instability phenomena in shell structures. The elements have three nodes with six degrees of freedom at each node. The term ‘co-rotational’ relates here to the provision of a local system that continuously rotates and translates with the element. Following mainly Nour-Omid and Rankin [B. Nour-Omid and C.C. Rankin, Finite rotation analysis and consistent linearization using projectors, Comput. Methods Appl. Mech. Engrg. 93 (1991) 353–384], the definition of an element resorts to a change of variables from the local frame to the global one. This is done through the use of a projector matrix which relates the variations of the local displacements to the variations of the global ones, by extracting the rigid body modes from the latter. The main difference from the original formulation lies in the parameterization of 3D finite rotations. In contrast to the paper by Nour-Omid and Rankin, a parameterization based on the rotational vector is here adopted and thus, an additional change of variables has to be performed. As a result, the rotational variables become additive and the necessity of a special updating procedure is avoided. The main feature of the adopted formulation is its independence of the local assumptions used to derive the internal forces and tangent stiffness in local coordinates. For a certain class of elements (i.e. elements with the same number of nodes and degrees of freedom) the main co-rotational framework is the same. Using this property, three types of local formulations are considered. A set of carefully chosen test problems is used in order to assess the performances of the three element types.

ABSTRACT: The paper describes how quasi-static, conservative instability problems can be analysed in a multi-parametric space, using generalised path-following procedures for augmented equilibrium problems. The general formulation of such augmented equilibrium problems is discussed in some detail. The focus is set on two classes of generalised 1D paths: basic equilibrium paths and fold lines, i.e. critical subset paths. The solution methods are seen as extensions to common incremental-iterative strategies, allowing the computation of subsets of equilibrium states which also fulfil some auxiliary conditions, e.g. criticality. In this context, some emphasis is also given to the evaluation of the properties of the problem, at a certain state; the tangential stiffness is here used to evaluate – possibly multidimensional – tangent spaces, and in the isolation of special states, i.e. vanishing variables, turning points and exchanges of stability, being important aspects of instability analyses. A set of carefully chosen numerical examples demonstrate on one hand the ability of the numerical procedures to deal with complex instability phenomena, including coincident or near coincident buckling modes, modal interaction, secondary bifurcations, and, on the other hand, their versatility in performing parameter sensitivity analyses. Finally, comparisons with alternative techniques, based on asymptotic strategies, are also put forth.

ABSTRACT: This paper discusses some aspects of FEM based shell instability analyses. The primary focus is on the properties of different element formulations. A co-rotational setting is used for the large-displacement, small-strain form. Three core elements are briefly described. Numerical examples show that, although the elements show very similar behaviours in the linear regime, the differences in results for non-linear and instability problems may be considerably larger.

ABSTRACT: We show that mode jumping in the buckling of a rectangular plate may be explained by a secondary bifurcation — as suggested by Bauer et al. [1] — when “clamped” boundary conditions on the vertical displacement function are assumed. In our analysis we use the singularity theory of mappings in the presence of a symmetry group to analyse the bifurcation equation obtained by the Lyapunov-Schmidt reduction applied to the Von Kármán equations. Noteworthy is the fact that this explanation fails when the assumed boundary conditions are “simply supported”. Mode jumping in the presence of “clamped” boundary conditions was observed experimentally by Stein [9]; “simply supported” boundary conditions are frequently studied but are difficult — if not impossible — to realize physically. Thus, it is important to observe that the qualitative post-buckling behavior depends on which idealization for the boundary conditions one chooses.

ABSTRACT: The buckling of thin elastic rectangular plates due to two arrays of edge dislocations symmetrically placed with respect to the longitudinal axis of the plate is studied for two different dislocation orientations. The analysis is based on the governing equation of plate buckling. Through a standard eigenvalue analysis the buckling criterion is analytically-numerically computed and numerical results are presented pertaining to cases of practical engineering interest such as welding.

ABSTRACT: This work is concerned with the numerical study of unsymmetrical buckling of clamped orthotropic plates under uniform pressure. The effect of material heterogeneity on the buckling load is examined. The refined 2D shell theory is employed to obtain the governing equations for buckling of a clamped circular shell. The unsymmetric part of the solution is sought in terms of multiples of the harmonics of the angular coordinate. A numerical method is employed to obtain the lowest load value, which leads to the appearance of waves in the circumferential direction. It is shown that if the elasticity modulus decreases away from the center of a plate, the critical pressure for unsymmetric buckling is sufficiently lower than for a plate with constant mechanical properties.

ABSTRACT: The qualitative behavior of buckled states of two different models of elastic beams is studied. It is assumed that random imperfections affect the governing nonlinear equations. It is shown that near the first critical value of the buckling load the stochastic bifurcation is described asymptotically by an algebraic equation whose coefficients are Gaussian random variables. The corresponding asymptotic expansion for the displacement is to lowest order a Gaussian stochastic process.

third beam model based on the second-order approximation of finite rotations is also discussed along with its application to constructing a consistent formulation of the linear eigenvalue problem for computing an estimate of the critical load. Exact linearized forms, which are crucial for facilitating the buckling load computation and assuring a robust performance of a Newton-method-based continuation strategy, are presented for all three beam models. An elaborate set of numerical simulations of buckling and post-buckling analysis of beam structures is given in order to illustrate the performance of each of the presented models. Finally, some conclusions are drawn.

**ABSTRACT:** The paper deals with the formulation of plate and shell elements based on the discrete Kirchhoff technique. In the first part we review the flat facet shell elements which have been formulated during the last 30 years. In the second part, we present the formulation of a new family of discrete Kirchhoff plate/shell elements based on the free formulation. The triangular, quadrilateral, pentagonal and hexagonal elements belong also to the family of semi-Loof elements having only displacements at the corner nodes and one tangential rotation along each side.

**ABSTRACT:** The mixed degenerate shell finite element DDSE, incorporating drilling degrees of freedom, is dedicated to solve some engineering applications directly and without any numerical tricks. This finite element has shown good performances in the linear and nonlinear, isotropic and anisotropic, static problems. Thanks to the application of shear and membrane substituted strain fields; it is also free from any locking. The very satisfactory results obtained by its previous application to the nonlinear dynamic regime have suggested the present work. The formulation of the problem, the derivation of the time integration scheme and the mass matrix were conducted in the most appropriate way to deal with the dynamic buckling load prediction. Both geometrical and material nonlinearities are considered in this study. The general stability criterion of Budiansky-Ruth is used, together with the phase plane control to detect the critical dynamic buckling load. In order to evaluate the accuracy of the element and the effect of the plasticity on the critical dynamic buckling value, two selected and documented examples of the critical dynamic buckling load determination were treated.

**ABSTRACT:** An improved arc-length method based on the nonlinear finite element approach is applied to the postbuckling analysis of composite laminated cylindrical panels under axial compression. In the non-linear finite element analysis, the updated Lagrangian formulation and the eight-node degenerated shell element are used. The composite cylindrical panels considered as numerical examples are unidirectional, cross-ply, angle-ply, and quasi-isotropic laminates. Experiments are conducted to verify the validity of the present analysis for a cross-ply laminate. Present finite element results show good agreement with experiments on buckling and
postbuckling behaviour. There exist some differences between the initial buckling loads and the postbuckling load-carrying capacities of composite cylindrical panels.

ABSTRACT: Based on the conventional arc-length method, an improved arc-length method with high-efficiency is proposed. The weighted modifications with respect to the variation of structural stiffness and extra-interpolation modification by using the information of known equilibrium points are introduced to improve the incremental arc-length. An approximate expansion method for the accumulated and expected arc-length is used to ensure the convergence at given load levels in large range of applications. Numerical results show that the improved arc-length method has well adaptability and higher efficiency in the post-buckling analysis of plates and shells structures for tracing whole load-deflection path and obtaining the convergence values at any specified load levels.

ABSTRACT: A combined experimental and analytical study of a hat-stiffened carbon-fibre composite panel loaded in uniaxial compression was investigated. A buckling mode transition was observed in the panel’s skin bay which was not captured using non-linear finite-element analysis. Good correlation between experimental and numerical strain and displacement results was achieved in the prebuckling and initial postbuckling region of the loading history. A Marguerre-type Rayleigh-Ritz energy method was applied to the skin bay using representative displacement functions of permissible mode shapes to explain the mode transition phenomenon. The central criterion of this method was based on the assumption that a change in mode shape occurred such that the total potential energy of the structure was maintained at a minimum. The ultimate strength of the panel was limited by the column buckling strength of the hat-stiffeners.

ABSTRACT: The postbuckling behaviour of a panel with blade-stiffeners incorporating tapered flanges was experimentally investigated. A new failure mechanism was identified for this particular type of stiffener. Failure was initiated by mid-plane delamination at the free edge of the postbuckled stiffener web at a node-line. This was consistent with an interlaminar shear stress failure and was calculated from strain gauge measurements using an approximate analysis based on lamination theory and incorporating edge effects. The critical shear stress was found to agree well with the shear strength obtained from a three-point bending test of the web laminate.

ABSTRACT: Damage tolerant hat-stiffened thin-skinned composite panels with and without a centrally located circular cutout, under uniaxial compression loading, were investigated experimentally and analytically. These panels incorporated a highly postbuckling design characterised by two integral stiffeners separated by a large skin bay with a high width to skin-thickness ratio. In both configurations, the skin initially buckled into three half-wavelengths and underwent two mode-shape changes; the first a gradual mode change characterised by a central deformation with double curvature and the second a dynamic snap to five half-wavelengths. The use of standard path-following non-linear finite element analysis did not consistently capture the dynamic mode change and an approximate solution for the prediction of mode-changes using a Marguerre-type Rayleigh-Ritz energy method is presented. Shortcomings with both methods of analysis are discussed and improvements suggested. The panels failed catastrophically and their strength was limited by the local buckling strength of the hat stiffeners.

ABSTRACT: A postbuckling blade-stiffened composite panel was loaded in uniaxial compression, until failure. During loading beyond initial buckling, this panel was observed to undergo a secondary instability characterised by a dynamic mode shape change. These abrupt changes cause considerable numerical difficulties using standard path-following quasi-static solution procedures in finite element analysis. Improved methods such as the arc-length-related procedures do better at traversing certain critical points along an equilibrium path but these procedures may also encounter difficulties in highly non-linear problems. This paper presents a robust, modified explicit dynamic analysis for the modelling of postbuckling structures. This method was shown to predict the mode-switch with good accuracy and is more efficient than standard explicit dynamic analysis.

ABSTRACT: This paper presents a robust finite element procedure for modelling the behaviour of postbuckling structures undergoing mode-jumping. Current non-linear implicit finite element solution schemes, found in most finite element codes, are discussed and their shortcomings highlighted. A more effective strategy is presented which combines a quasi-static and a pseudo-transient routine for modelling this behaviour. The switching between these two schemes is fully automated and therefore eliminates the need for user intervention during the solution process. The quasi-static response is modelled using the arc-length constraint while the pseudo-transient routine uses a modified explicit dynamic routine, which is more computationally efficient than standard implicit and explicit dynamic schemes. The strategies for switching between the quasi-static and pseudo-transient routines are presented.

ABSTRACT: The phenomenon of secondary instabilities in stiffened composite panels loaded in uniaxial compression is studied through a number of experimental investigations. This behavior is shown to manifest itself as a ‘mode-jump’ – a sudden change in the out-of-plane deformation of a buckled panel. Use of high-speed digital speckle photogrammetry is made to gain further insight into an I-stiffened panel’s response during the transient phase associated with mode-jumping. At high loading, this sudden dissipation of energy will be shown to be able to cause failure in vulnerable structures. Predicting this structural response reliably, using the finite element method, poses considerable numerical challenges and the shortcomings of current non-linear solution schemes are discussed. A robust and efficient strategy, which utilizes an automated quasi-static/pseudo-transient hybrid scheme, is presented and validated using a number of experimental tests. This approach is shown to be able to predict mode-jumping with good accuracy.

ABSTRACT: A theoretical analysis is presented for determining the free vibrational characteristics of thin-walled, circular cylindrical shells with layers of anisotropic elastic material arbitrarily laminated either symmetrically or unsymmetrically about the shell middle surface. An arbitrarily laminated, anisotropic version of Love's first-approximation shell theory is used to formulate the coupled equations of motion. An exact solution with a classical checkerboard nodal pattern is found for the case of a shell with specially orthotropic layers arbitrarily laminated and with freely supported ends. For a boron/epoxy composite cylinder, the significant effect of omitting bending-stretching coupling is demonstrated and various lamination arrangements are investigated. Also, a general solution is presented for the axisymmetric modes of an arbitrarily laminated anisotropic shell. Finally, an approximate solution, using a combination of two helical-nodal-pattern modes, is obtained for the unsymmetric modes of the same general class of shell with a supported boundary condition.

ABSTRACT: The plate theory recently developed by Levinson is extended to laminates. Closed-form solutions of this theory, as well as those of Reissner-Mindlin plate theory with appropriate shear correction, Seide's discrete-layer plate theory, and the higher-order theory of Lo et al. are all compared with Pagano's elasticity-theory solution for the cases of cylindrical bending of a single orthotropic layer and a symmetric cross-ply (0°/90°/0°) laminate consisting of three equal-thickness layers. Quantities compared are maximum plate deflection, bending stress distribution and transverse shear stress distribution.

ABSTRACT: The dynamic instability of simply supported, finite-length, circular cylindrical shells subjected to parametric excitation by axial loading, is investigated analytically. The shell is taken to be orthotropic, due to closely spaced longitudinal and/or circumferential stiffeners or to many layers of fiber-reinforced composite material either oriented at angles of 0° and 90° (cross-ply) or at +theta and –theta (angle-ply) with respect to the shell axis. The theory used is a general first-order shear deformable shell theory introduced by Hsu, Reddy, and Bert; it can be considered to be the thick-shell version of the popular Sanders-Koiter thin-shell theory. By means of tracers, this theory can be reduced to thick-shell versions of the theories of Love (and Loo) and of Donnell (and Morley). Quantitative results are presented to show the effects of shell geometry, materials, and fiber orientation on the stability boundaries.

ABSTRACT: Initial buckling of an elastic coating perfectly bonded to a circular-section prismatic bar subjected to axial extension is investigated analytically. The phenomenon is associated with the substrate Poisson contraction. Two different models of the coating are used: the first is based on classical thin-shell theory and the other is based on first-order shear-deformation shell theory. The results for typical examples are compared and used to explain cracking of the coating previously observed experimentally.

ABSTRACT: The dynamic stability of thin, multi-layered composite shells reinforced by axial and ring stiffeners and subjected to pulsating loads acting in the axial direction is considered. The presence of a thermal field is shown to affect the location of dynamic instability regions in the load amplitude-frequency plane. The boundaries of these regions can be evaluated as functions of static critical loads, natural frequencies, and thermal terms; the latter can be easily calculated. This permits straightforward conclusions to be drawn regarding dynamic stability of shells for which the buckling and free vibration problems have already been solved.
References listed at the end of the paper:

ABSTRACT: Effects of temperature on buckling and post-buckling behavior of reinforced and unstiffened composite plates or cylindrical shells are considered. First, equilibrium equations are formulated for a shell subjected to the simultaneous action of a thermal field and an axial loading. These equations are used to predict a general form of the algebraic equations describing the post-buckling response of a shell. Conditions for the snap-through of a shell subjected to thermomechanical loading are formulated. As an example, the theory is applied to prediction of post-buckling response of flat large-aspect-ratio panels reinforced in the direction of their short edges.

ABSTRACT: A new approach to apply the differential quadrature method to the deflection, buckling, and free vibration analysis of beams and plates with various boundary conditions is presented. A different method for application of the beam boundary conditions, proposed earlier by Wang and Bert, is extended to clamped-fixed, simply supported-fixed, and fixed-fixed beams and excellent results are obtained. It is found that the differential quadrature method gives less accurate results for the buckling load when the plate aspect ratio a/b exceeds 2.45
for the cases considered and possible reasons for this are discussed.

ABSTRACT: Laminated composite, circular cylindrical hollow shafts are used extensively as primary load-carrying structures in many applications under various loading configurations. Advanced composite materials also seem ideally suited for long, power drive-shaft applications. At the same time, from a design point of view, local and general instability arising from the action of torsional loads often represents the limiting load condition. In the present study, a theoretical analysis is presented for determining the buckling torque of a circular cylindrical hollow shaft with layers of arbitrarily laminated composite materials by means of various thin-shell theories. Comparisons with previous investigations are listed for isotropic and arbitrarily laminated composite material drive shafts. Consideration is also given to the various shell theories, such as those of Flügge, Sanders, Love (first approximation), Loo, Morley, and Donnell. The effect of the off-axis stiffnesses and the bending moment on buckling torque is considered.

ABSTRACT: Modeling the complex deformations of cylindrical tubes under external pressure is of interest in engineering and physiological applications. The highly nonlinear post buckling behavior of cross section of the tube during collapse attracted researchers for years. Major efforts were concentrated on studying the behavior of thin wall tubes. Unfortunately, the knowledge on post buckling of thick wall tubes is still incomplete, although many experimental and several theoretical studies have been performed. In this study we systematically studied the effect of the wall thickness on post buckling behavior of the tube. For this purpose, we utilized a computational model for evaluation of the real geometry of the deformed cross sectional area due to negative transmural (internal minus external) pressure. We also developed an experimental method to validate the
computational results. Based on the computed cross sections of tubes with different wall thicknesses, we developed a general tube law that accounts for thin or thick wall tubes and fits the numerical data of computed cross sectional areas versus transmural pressures.

ABSTRACT: In this research the torsional stability of a composite drive shaft torsion is studied. Composite materials are considered as the suitable choice for manufacturing long drive shafts. The applications of this kind of drive shafts are developed in various products such as cars, helicopters, cooling towers, etc. From the design point of view, local and global torsional instability of drive shafts limits the capability for them to transfer torque. After reviewing the closed form solution methods to calculate the buckling torque of composite drive shafts, a finite element analysis is performed to study their behavior. Furthermore, to evaluate the results obtained by the finite element method, a comparison with experimental and analytical results is presented. A case study of the effects of boundary conditions, fiber orientation and stacking sequence on the mechanical behavior of composite drive shafts is also performed. Finally, the reduction of the torsional natural frequency of a composite drive shaft due to an increase of applied torque is studied.

DOI: 10.5829/idosi.wasj.2015.33.03.14573
ABSTRACT: One interesting application of composite materials is the composite drive shafts as power transmission tubing which are used in many mechanical and structural systems; such as automobiles, marine and flight vehicles, gas and wind turbines...etc. In this paper, a composite drive shaft for an automotive application is optimized for maximizing the torsional buckling torque under mass constraint. Other constraints include bending natural frequency as well as interlaminar shear failure criterion. The selected design variables are the fiber volume fraction, fiber orientation angle and thickness of each composite layer. A case study for a simply supported drive shaft made of carbon/epoxy composite material is considered through the work of this paper. The attained optimum solutions are compared with a known baseline design having the same length, same cross section and same material properties. The optimization problem is built in a nondimensional form; and Global Optimization Toolbox in MATLAB program has been implemented for modeling the optimization problem. It was found that the cross-ply layup gives the best results for maximum buckling torque and bending natural frequency without mass penalty.

ABSTRACT: One of the challenges facing the designers of aeroengine drive shafts is to transmit higher torques while at the same time reducing the overall diameter of the engine in order to reduce drag. The resulting high performance drive shafts are smaller, lighter and have thinner walls, and it is essential that the factors affecting instability are known and understood. Torque is the principal load carried by these shafts, and most of the analytical methods for predicting torsional stability are either analytical or semi-empirical and tend not to cover the relevant range of geometries of interest here in terms of shaft geometry. Also, they give only limited information about the failure mode involved. A finite element analysis (FEA) approach has been developed to
address this need, and this paper presents results for plain shaft sections subjected to torque loading. Geometries leading to elastic buckling and plastic collapse are identified, along with appropriate formulae for calculating the torque capacity.

ABSTRACT: The measured torsional buckling load of Graphite/Epoxy shafts is found in good agreement with theoretical predictions based on a general shell theory that includes elastic coupling effects and transverse shearing deformations. The direction of the applied torque and the lay-up stacking sequence drastically affects the buckling load (up to 80%). Transverse shearing deformations are found significant when the number of circumferential waves in the buckling pattern is larger than 3. The residual strength of shafts with holes is also measured, and the dominant failure mode remains torsional buckling. The buckling mode patterns are seemingly unaffected by damage but buckling loads are lower compared to undamaged specimens. Material failure concentrated around the hole does not occur until the hole size is approximately one-third of the shaft's diameter. Teflon disks inserted between plies to simulate delaminations decrease the buckling load, but not significantly. In conclusion, stiffness characteristics, rather than strength characteristics dominate the behavior of thin-walled, undamaged shafts under torsional load, and this appears to remain true for shafts with sizable damage (up to about one-third of the shaft's diameter).

ABSTRACT: Optimization is one of the important stages in the design process. In this paper the genetic algorithms method is applied for weight and transient dynamic response and two constraints including critical buckling loads and principle strains optimization of laminated composite cylindrical shells. The multi-objective function seeks the minimum structural weight and transient dynamic response. Nine design variables including material properties (fibre and matrix), volume fraction of fibre, fibre orientation and thickness of each layer are considered. In analytical solution, vibration of composite circular cylindrical shells are investigated based on the first-order shear deformation shell theory. The boundary conditions are assumed to be fully simply support. The dynamic response of the composite shells is studied under transverse impulse and axial compressive loads. The modal technique is used to develop the analytical solution of the composite cylindrical shell. The solution for the shell under the given loading conditions can be found using the convolution integrals. An example of simply supported laminated composite cylindrical shells is given to demonstrate the optimality of the solution obtained by the genetic algorithms technique. Results are shown that the weight coefficient of multi-objective function and the type of the constraints have considerable effect on the optimum weight and dynamic response.

ABSTRACT: In this paper, a refined model of interlocked composite grid stiffened structure and an equivalent model based on simplified ICG panel are built. Buckling and dynamic response of the composite panel are then analyzed using the models. The result is the accuracy of buckling and mode analysis of refined model is greatly improved compared with the equivalent model. Simulation for impact response under different impactors is considered. The coefficients such as material properties and structure dimension of the slot are discussed.

Faruk Elaldi (University of Baskent, Faculty of Engineering, Mechanical Engineering Department, 06530 Ankara, Turkey), “Buckling, Post-Buckling And Failure Analysis Of Hat Stiffened Composite Panel”, Proceedings of 8th International Fracture Conference 7 – 9 November 2007 Istanbul/TURKEY

ABSTRACT: Current use of advanced composites in aircraft structures has demonstrated the potential for decreasing structural weight. But, the inherent complexities associated with the design and analysis of carbonfiber composite structures has restricted its use in post-buckling designs. In conventional aircraft application, it is common practice to design stiffened metallic plate and shell structures to buckle below design ultimate limit. The buckling and failure characteristics of a thin composite skin reinforced by stiffeners, such as fuselage shell or wing components, have to be determined explicitly. Post-buckled design allows buckling before design limit is reached and the buckled structure can carry design ultimate load. Closed-sectioned hat stiffened panels were studied by several researchers in order to show significant post-buckling strength. Usually, the post-buckled design also results in significant weight savings when compared to buckling-resistant design. In the present study, the aim was to explore technologies for manufacturing integral composite structures to evaluate the manufacturing concepts by determining the structural behavior of hat-stiffened composite panels under compression loading. The experimental results of hat-stiffened panels for initial buckling and post-buckled response under compression loading were compared with numerical results obtained using linear and non-linear finite element analysis.

ABSTRACT: The aim of this study was to explore post-buckling behaviors of hat-stiffened composite panels under compression loading. A shadow Moiré technique was used to monitor the out-of-plane displacement of the skin panel. The experimental results of hat-stiffened panels for initial buckling and post-buckled response of the panels were compared with numerical results obtained from linear and non-linear finite element methods. It was found to be in reasonably good agreement with each other. The panels showed good post-buckling strength and total failure began with the local buckling of the hat stiffeners.

References listed at the end of the paper:

ABSTRACT: The aim of this study was to explore post-buckling strength potential of two different stiffener types and evaluate structural efficiencies of those by making a comparison. This has been done by first determining the buckling and post-buckling behavior of J- and hat-stiffened composite panels under compression loading. By making a structural efficiency definition, the experimental results of J- and hat-stiffened panels for initial buckling and post-buckled responses of the panels were compared with predicted and analytical results.

References listed at the end of the paper:

ABSTRACT: Donnel type stability equations for buckling of stringer stiffened cylindrical panels under combined axial compression and hydrostatic pressure are solved by the displacement approach of [6]. The solution is employed for a parametric study over a wide range of panel and stringer geometries to evaluate the combined influence of panel configurations and boundary conditions along the straight edges on the buckling behavior of the panel relative to a complete “counter” cylinder (i.e. a cylinder with identical skin and stiffener parameters). The parametric studies reveal a “sensitivity” to the “weak in shear”, Nx = Nxphi= 0, along the straight edges, SS1 boundary conditions type where the panel buckling loads are always smaller than those predicted for a complete “counter” cylinder. In the case of “classical”, SS3 B.Cs., there always exist values of panel width, 2phi0, for which rho = 1, i.e. the panel buckling load equals that of the complete “counter” cylinder. For SS2 and SS4 B.Cs. types, the nature by which the panel critical load approaches that of the complete cylinder appears to be panel configuration dependent. Utilization of panels for the experimental determination of a complete cylinder buckling load is found to be satisfactory for relatively very lightly and heavily stiffened panels, as well as for short panels, (L/R) = 0.2 and 0.5. Panels of moderate length and stiffening have to be debarred, since they lead to nonconservative buckling load predictions.

ABSTRACT: Results are presented for impact tests conducted on postbuckled, thin, orthotropic carbon/epoxy laminates manufactured by the RTM process from preforms of uniweave fabric, some of which were stitched with Kevlar sewing thread. They were impacted by a 13 mm diameter 8.9 g steel projectile at velocities ranging to 90 m/s on their convex and concave faces. For impact velocities above a critical value, either penetration occurred or the specimens failed catastrophically. Their corresponding critical velocity boundaries were established. Their projected impact damage area increased with increased impact velocity, however, it was independent of preload. Their postimpact properties remained largely unchanged. Stitching reduced significantly the projected damage area, however none of their other impact damage resistance and tolerance characteristics were effected, including their critical velocities for penetration and catastrophic damage. Impacting on the concave face, compared to impacting on the convex face, reduced the projected damage area and the penetration critical velocity boundary. No catastrophic damage was observed for these specimens.

ABSTRACT: Damage tolerance of stitched stiffened composite panels with clearly visible impact damage to a stiffener was investigated. Two-blade stiffened composites panels were fabricated using resin film infiltration technique. The effects of stitching are assessed using unstitched, selectively stitched and fully stitched panels. Impact damage was induced using a drop weight impact of 30 J from the skin side over the stiffener. The experimental results indicate that selectively stitched panels showed 14.4% improvement in compression after impact strength compared to both the unstitched and fully stitched panels. Post-buckling finite element analysis was performed to predict the buckling and failure strengths of these stiffened panels.

ABSTRACT: Delamination as a result of low-velocity impact loading is a major cause of fibre-reinforced composite failure. Through-thickness reinforcement in the form of transverse stitching is an effective way to suppress delamination in these composite laminates. In this paper, the effect of stitching on Mode II delamination toughness is analysed by using two specimen geometries, namely, the end-notch flexure (ENF) specimen geometry and the end-notch cantilever (ENC) specimen geometry. The ENC specimen geometry allows larger crack propagation lengths which may be necessary to develop fully the stitch-thread bridging zone in the case of compliant stitch threads. Initially the energy release rate, $G_{II(\Delta a)}$, is determined by the contour
integral method and then the use and equivalence of the stress intensity factor approach is demonstrated. The effect of stitching on both specimen geometries is found to be the same, and identical closed-form analytical expressions are obtained for the potential energy release rate, GIIR(_ia), required for crack propagation. The effect of stitching is expressed in terms of the stitching parameters _± and _≤. The influence of friction between the crack surfaces is also included in the analysis. A simple design study for sizing the ENF and ENC specimens to minimise geometric non-linear response is presented. The effects of the stitching parameters and various geometric and material properties are examined.

ABSTRACT: We analyze the steady-state response of a functionally graded thick cylindrical shell subjected to thermal and mechanical loads. The functionally graded shell is simply supported at the edges and it is assumed to have an arbitrary variation of material properties in the radial direction. The three-dimensional steady-state heat conduction and thermoelasticity equations, simplified to the case of generalized plane strain deformations in the axial direction, are solved analytically. Suitable temperature and displacement functions that identically satisfy the boundary conditions at the simply supported edges are used to reduce the thermoelastic equilibrium equations to a set of coupled ordinary differential equations with variable coefficients, which are then solved by the power series method. In the present formulation, the cylindrical shell is assumed to be made of an orthotropic material, although the analytical solution is also valid for isotropic materials. Results are presented for two-constituent isotropic and fiber-reinforced functionally graded shells that have a smooth variation of material volume fractions, and/or in-plane fiber orientations, through the radial direction. The cylindrical shells are also analyzed using the Flügge and the Donnell shell theories. Displacements and stresses from the shell theories are compared with the three-dimensional exact solution to delineate the effects of transverse shear deformation, shell thickness and angular span.

Vel (Mechanical Engineering Department, University of Maine, 5711 Boardman Hall, Orono, ME 04469, USA), “Multi-objective optimization of fiber reinforced composite laminates for strength, stiffness and minimal mass”, Computers & Structures, Vol. 84, Nos. 29-30, November 2006, pp. 2065-2080, doi:10.1016/j.compstruc.2006.06.001

ABSTRACT: We present a methodology for the multi-objective optimization of laminated composite materials that is based on an integer-coded genetic algorithm. The fiber orientations and fiber volume fractions of the laminae are chosen as the primary optimization variables. Simplified micromechanics equations are used to estimate the stiffnesses and strength of each lamina using the fiber volume fraction and material properties of the matrix and fibers. The lamina stresses for thin composite coupons subjected to force and/or moment resultants are determined using the classical lamination theory and the first-ply failure strength is computed using the Tsai–Wu failure criterion. A multi-objective genetic algorithm is used to obtain Pareto-optimal designs for two model problems having multiple, conflicting, objectives. The objectives of the first model problem are to maximize the load carrying capacity and minimize the mass of a graphite/epoxy laminate that is subjected to biaxial moments. In the second model problem, the objectives are to maximize the axial and hoop rigidities and minimize the mass of a graphite/epoxy cylindrical pressure vessel subject to the constraint that the failure pressure be greater than a prescribed value.

ABSTRACT: In this paper, optimization of a spherical shell under various dynamic loads is investigated. The aim of this optimization problem is to minimize the volume of the shell. Design variables are corner thicknesses of each finite element. Constraints are stresses obtained from von Mises stress criterion not to exceed the yield stress in corner nodal points of each finite element at the top and bottom surfaces of shell and thicknesses are restricted not to be less than 2.5 mm. In addition to shell's own weight, the vertical loads with equal intensity are applied at the nodal points on the upper edge of spherical shell, varying with respect to time function P(t). Time varying load vector is considered three different cases such as step, step after ramp and impulse functions. A program is coded with MapleV for optimization of spherical shell and finite element package program ANSYS is used for structural analysis. Obtained results are presented in graphical and tabular form. Finally, concluded remarks are given.

ABSTRACT: A C0 (penalty) finite element is developed for the equations governing the heterogeneous laminated plate theory of Yang, Norris and Stavsky. The YNS theory is a generalization of Mindlin's theory for homogeneous, isotropic plates to arbitrarily laminated anisotropic plates and includes shear deformation and rotary inertia effects. The present element can also be used in the analysis of thin plates by appropriately specifying the penalty parameter. A variety of problems are solved, including those for which solutions are not available in the literature, to show the material effects and the parametric effects of plate aspect ratio, length-to-thickness ratio, lamination scheme, number of layers and lamination angle on the deflections, stresses, and vibration frequencies. Despite its simplicity, the present element gives very accurate results.

ABSTRACT: Closed-form and finite-element solutions are presented for the free vibration of axially compressed, thick, circular cylindrical shells laminated of bimodulus composite materials, which have different elastic properties depending upon whether the fiber-direction normal strain is tensile or compressive. The theory used is a dynamic, shear deformable theory, which is the moderately-thick-shell analog of the Sanders 'best' first-approximation thin-shell theory. By means of certain tracers introduced in the paper, the analysis can be reduced to the thick-shell analog of simpler shell theories, namely Love's first-approximation and Donnell's shallow-shell theory. The buckling load is found by determining the lowest value of axial compressive load for which the lowest natural frequency vanishes. To validate the analysis, numerical results obtained by the two solutions are compared with each other and with existing results (for ordinary, not bimodulus, materials) for special cases. The effects of shell theory, secondary buckling effects, aspect ratio, and bending-stretching coupling are investigated parametrically.

ABSTRACT: A special three-dimensional element based on the total Lagrangian description of the motion of a layered anisotropic composite medium is developed, validated and employed to analyse laminated anisotropic composite shells. The element contains the following features: geometric nonlinearity, dynamic (transient) behaviour and arbitrary lamination scheme and lamina properties. Numerical results of nonlinear bending, natural vibration and transient response are presented to illustrate the capabilities of the element.

ABSTRACT: An extension of the Sanders shell theory for doubly curved shells to a shear deformation theory of laminated shells is presented. The theory accounts for transverse shear strains and rotation about the normal to the shell midsurface. Exact solutions of the equations are presented for simply supported, doubly curved, cross-ply laminated shells under sinusoidal, uniformly distributed, and concentrated point load at the center. Fundamental frequencies of cross-ply laminated shells are also presented. The exact solutions presented herein for laminated composite shells should serve as benchmark solutions for future comparisons.
ABSTRACT: A dynamic, shear deformation theory of a doubly curved shell is used to develop a finite element for geometrically non-linear (in the von Karman sense) transient analysis of laminated composite shells. The element is employed to determine the transient response of spherical and cylindrical shells with various boundary conditions and loading. The effect of shear deformation and geometric non-linearity on the transient response is investigated. The numerical results presented here for transient analysis of laminated composite shells should serve as references for future investigations.

ABSTRACT: A finite-element computational procedure is developed for the first-ply failure analysis of laminated composite plates. The procedure is based on the first-order shear deformation theory and a tensor polynomial failure criterion that contains the maximum stress, maximum strain, the Hill, Tsai-Wu and Hoffman failure criteria as special cases. By specifying the desired criterion, a first-ply failure analysis of composite laminates subjected to in-plane and/or bending loads can be achieved. A number of problems are presented to evaluate these failure criteria when applied to laminates subjected to in-plane and or bending loads.

ABSTRACT: A review of two-dimensional (e.g., equivalent single-layer) kinematic models of laminated composite plates and constitutive models of fiber-reinforced composites for failure is presented. The recent research work of the author in the formulation of refined theories of laminated composite plates is also included.

ABSTRACT: The present paper deals with a novel approach to the derivation of constrained geometrically nonlinear shell theories which has been given in recent years by Pietraszkiewicz [1–4]. This approach has a distinct advantage over others in that it is theoretically well founded on exact polar decomposition of the shell deformation into rigid-body translation, pure stretch along the principal directions of strain and rigid-body rotation. Pietraszkiewicz [1–4] developed an exact theory of finite rotations in shells which allows for the derivation of appropriate kinematic shell relations for restricted strains and rotations of clearly defined order of magnitude. This approach has led already to a significant number of related publications [5–36] which cover various aspects of nonlinear shell theory: the derivation of first approximation theories for shells and beams undergoing small strains accompanied by moderate, large, or unrestricted rotations, associated variational
principles, stability and post-buckling equations, and finite element computations. Furthermore, a similar approach to the derivation of a moderate rotation shell theory via the polar decomposition theorem has been given just recently by Naghdi and Vongsarnpiboon [37] in terms of Cosserat surface theory. Therefore, it seems to be justified to term these recent advances [1–37] based on exact polar decomposition of shell deformation with subsequent restriction of strains and rotations a new, current trend in shell theory. First, the present paper reviews briefly the progress obtained in Refs. [1–36]. Then, we present some foundations of large rotation shell theory, especially some new results which allow for the construction of variationally derivable theories. The general large rotation shell theory is simplified for problems in which the in-surface rotations remain moderate or even small. The latter variant is compared with two theories given recently by Nolte and Stumpf [9] and Pietraszkiewicz [14]. Then, for all these variants a set of basic variational principles is derived in a unified operator notation. Finally, as contribution towards the numerical justification of the present approach we present solutions for a spherical shell stability problem obtained together with ChróImage cielewski [63] by three-dimensional finite element analysis and compare this reference solution with those obtained by Nolte [8] on the basis of large rotation shell theories.

ABSTRACT: A general refined shell theory that accounts for the transverse deformation, small strains, and moderate rotations is presented. The theory can be reduced to various existing shell theories including: the classical (i.e., linear Kirchhoff-Love) shell theory, the Donnell-Mushtari-Vlasov shell theory, the Leonard-Koiter-Sanders moderate rotations shell theory, the von Kármán type shear-deformation shell theory and the moderate-rotation shear-deformation plate theory developed by Reddy. The present theory is developed from an assumed displacement field, nonlinear strain-displacement equations that contain small strain and moderate rotation terms, and the principle of virtual displacements. The governing equations exhibit strong coupling between the membrane and bending deformations, which should alter the bending, stability, and post-buckling behavior of certain shell structures predicted using the presently available theories.

ABSTRACT: A general two-dimensional shear deformation theory of laminated composite plates is presented. The theory account for a desired degree of approximation of the displacements through the laminate thickness. As special cases, the classical, first-order (Reissner–Mindlin) and other shear deformation theories available in the literature can be deduced from the present theory.

ABSTRACT: An exact mathematical tool to analyze the free vibration and buckling of symmetric cross-ply laminated plates is developed. The procedure, based on a generalized Lévy type solution considered in conjunction with the state space concept, enables one to solve exactly the equations governing the laminated anisotropic plate theory as considered by Reddy [3,4]. Combinations of simply supported, clamped and free boundary conditions are considered. Comparisons with other higher order, first order and classical plate theories are made.

ABSTRACT: Analytical solutions for displacements, natural frequencies and buckling loads of cross-ply circular cylindrical shells under various boundary conditions are developed using the classical, first-order and third-order shell theories and the state-space technique. The third-order theory of shells of Reddy accounts for cubic variation of surface displacements through the thickness of the laminate and there is no need for shear correction factors. Analytical solutions are developed for simply-supported, clamped and free boundary conditions, and the effect of boundary conditions, lamination schemes and shear deformation on the deflections, stresses, natural frequencies and buckling loads is investigated.

ABSTRACT: Analytical and finite-element solutions of the classical, first-order, and third-order laminate theories are developed to study the buckling and free-vibration behavior of cross-ply rectangular composite laminates under various boundary conditions. The effects of side-to-thickness ratio, aspect ratio, and lamination schemes on the fundamental frequencies and critical buckling loads are investigated. The study concludes that shear deformation laminate theories accurately predict the behavior of composite laminates, whereas the classical laminate theory overpredicts natural frequencies and buckling loads.

ABSTRACT: Thermal deformations and stresses in cross-ply laminated circular cylindrical shells are investigated. The state space approach is used to solve exactly the thermoelastic governing equations of the third-order, first-order and classical theories for arbitrary boundary conditions. To illustrate the thermoelastic behavior, exact analytical solutions for deflections and stresses are obtained for laminated circular cylindrical shells undergoing uniform and linearly varying temperature fields through the thickness while having sinusoidal distribution of thermal loading.

A.M. Zenkour (Department of Mathematics, Faculty of Science, Kafir El-Sheikh University, Kafir El-Sheikh, 33516, Egypt and Department of Mathematics, Faculty of Science, King Abdul Aziz University, P.O. Box 80203, Jeddah, 21589, Saudi Arabia), “Stresses in cross-ply laminated circular cylinders of axially variable thickness”, Acta Mechanica, Vol. 187, No. 1, pp 85-102, November 2006
ABSTRACT: This paper presents the results from an analytical investigation of the behavior of composite circular cylinders subjected to internal and external surface loading. The present cylinder consists of a number of homogeneous ply groups of axially variable thickness. Each ply group forming a layer is treated as an individual thin elastic cylinder of generally orthotropic material with interfacial stresses on the inner and outer surfaces of the layer as boundary loading. The deformation and stresses in each layer can be expressed in terms of interfacial stresses along the exterior surfaces of each layer. All displacement and stresses throughout the composite cylinder can be determined subsequently after satisfying boundary conditions at the inside and outside surfaces of the cylinder in conjunction with the recurrence relationship among interfacial stresses. Numerical results are presented for different values of the inner-to-outer ratio, number of layers, stacking sequence, axially-variable-thickness parameter, and load factor. Based on the presented results, conclusions can be drawn concerning the cylinder behavior and its sensitivity to different parameter variations.

ABSTRACT: Finite element models of the continuum-based theories and two-dimensional plate/shell theories used in the analysis of composite laminates are reviewed. The classical and shear deformation theories up to the third-order are presented in a single theory. Results of linear and non-linear bending, natural vibration and stability of composite laminates are presented for various boundary conditions and lamination schemes. Computational modelling issues related to composite laminates, such as locking, symmetry considerations, boundary conditions, and geometric non-linearity effects on displacements, buckling loads and frequencies are discussed. It is shown that the use of quarter plate models can introduce significant errors into the solution of certain laminates, the non-linear effects are important even at small ratio of the transverse deflection to the thickness of antisymmetric laminates with pinned edges, and that the conventional eigenvalue approach for the determination of buckling loads of composite laminates can be overly conservative.

ABSTRACT: The instability of composite laminated plates under uniaxial, harmonically-varying, in-plane loads is investigated. Both symmetric cross-ply laminates and antisymmetric angle-ply laminates are analyzed. The first-order shear deformation plate theory is used to model composite laminates. The resulting linear equations of motion are transformed into small, uncoupled sets of equations, and instability regions in the plane of load amplitude versus load frequency are determined using the finite element method. The effects of damping, ratio of edge length to thickness of the plate, orthotropy, boundary conditions, number of layers and lamination angles on instability regions are examined.

ABSTRACT: The incremental equations of motion based on the principle of virtual displacements of a continuous medium are formulated using the total Lagrangian description. A degenerate shell element with a degenerate curved beam element as a stiffener is developed for the geometric nonlinear analysis of laminated, anisotropic, stiffened shells. Compatibility and completeness requirements are stressed in modeling the general shell-type structures in order to assure the convergence of the finite-element solution. An iterative solution procedure, either Newton-Raphson method or modified Riks method, is employed to trace the nonlinear equilibrium path. A variety of numerical examples are presented to demonstrate the validity and efficiency of the stiffened shell element. The effects of boundary conditions, lamination scheme and geometric nonlinearity on deflections are also investigated.

ABSTRACT: The dynamic and static behavior of cross-ply laminated shells are investigated using the third-order shear deformation shell theory of Reddy. The theory is a modification of the Sanders shell theory and accounts for parabolic distribution of the transverse shear strains through the thickness of the shell and does not require shear correction coefficients. The Lévy-type exact solutions for bending, buckling and natural vibration are presented for doubly curved, cylindrical and spherical shells under various boundary conditions.

ABSTRACT: Transient response of simply-supported circular cylindrical shells is investigated using a higher-order shear deformation theory (HSDT). The theory is a modification of the Sanders' shell theory and accounts for parabolic distribution of the transverse shear strains through thickness of the shell and tangential stress-free boundary conditions on the bounding surfaces of the shell. The results obtained using the classical shell theory (CST) and the first-order shear deformation theory (FSDT) are compared with those obtained using the higher-order theory. The state-space approach is used to develop the analytical solutions to the equations of motion of the three theories.

ABSTRACT: A moderate rotation theory of laminated anisotropic shells, proposed by Schmidt and Reddy [J. appl. Mech. 55, 611–617.1988], is developed and its application is presented. All aspects of the derivations are explicitly developed and specific forms of the equations are derived in this part. The finite-element formulation and its applications are presented in Part 2 of the paper.

ABSTRACT: The finite element model of the moderate rotation theory (MRT) is developed and its application to composite plates and shells is presented. Comparison of results obtained by the moderate rotation theory with the von Kármán non-linear theory and continuum 2D theory is made.

ABSTRACT: Analytical solutions of the Reddy layer-wise laminate theory for buckling of composite cylindrical shells are presented. The layer-wise shell theory accounts for varying degrees of displacement expansion through the thickness of the shell. The Navier solution procedure is used to obtain exact buckling loads of cross-ply laminated cylindrical shells.

ABSTRACT: The static response of cross-ply laminated shallow shells subjected to thermal loadings is investigated. An exact analytical solution using the state space approach is presented in conjunction with the Lévy method, for doubly curved, cylindrical and spherical shells under various boundary conditions. Numerical results of the higher-order theory of Reddy and Liu (1985, 1987) for center deflection of cross-ply laminated shallow shells are compared with those obtained using classical and first-order shell theories.

A. A. Khdeir (Department of Civil Engineering, Division of Structural Mechanics, Middle East Technical University, 06531, Ankara, Turkey), “A remark on the state-space concept applied to bending, buckling and free vibration of composite laminates”, Computers & Structures, Vol. 59, No. 5, June 1996, pp. 813-817, doi:10.1016/0045-7949(95)00330-4
ABSTRACT: The present study shows that the state-space concept used to generate exact solutions for various boundary conditions for bending, buckling and free vibration of composite laminates, can be modified easily and exactly and has no drawback when the laminate thickness is reduced. Numerical results for central deflections, axial stresses, transverse shear stresses, critical buckling loads and natural frequencies of cross-ply laminated plates are obtained using the classical, first- and third-order theories for large side to thickness ratios.

ABSTRACT: Generalized Levy-type solutions are obtained for the problems of linear vibration and stability of cross-ply laminated plates. The governing equations, which are derived by using the principle of virtual displacement and a third-order shear-deformation plate theory, are transformed into a set of first-order linear ordinary differential equations with constant coefficients. The general solution of these equations can be obtained by using the state-space concept. Then, application of the boundary conditions yields equations for the natural frequencies and buckling loads. Unfortunately, a straightforward application of the state-space concept yields numerically ill-conditioned problems as the plate thickness is reduced. Various methods for overcoming this problem are discussed. A combination of an initial-value method and the modified Gram-Schmidt orthonormalization procedure is used to overcome this problem. It is shown that this method not only yields results that are in excellent agreement with the results in the literature, but also it converges fast and gives all the frequencies and buckling loads regardless of the plate thickness.

ABSTRACT: The layer-wise shell theory of Reddy is used to study the postbuckling response of circular
cylindrical shells. The Rayleigh-Ritz method is used to solve the equations by assuming a double Fourier expansion of the displacements with trigonometric coordinate functions.

ABSTRACT: An improved analytical procedure is introduced in the context of free vibration and stability problems of cross-ply laminated circular cylindrical shells. The Donnell shear-deformation type theory and Donnell's classical theory are used to illustrate the procedure. Numerical results are presented for shells with a variety of boundary conditions. Special attention is given to the axisymmetric problems and new results, not yet found in the literature, for stability and vibration are reported. It is recommended that the new technique be used for generating the Lévy-type solutions in vibration and stability problems of laminated shell panels and plates when the number and order of equations are higher than those of the classical theories.

ABSTRACT: Plate finite elements based on the generalized third-order theory of Reddy and the first-order shear deformation theory are analysed and compared on the basis of thick and thin plate modelling behaviour, distortion sensitivity, overall accuracy, reliability and efficiency. In particular, several four-noded Reddy-type elements and the nine-noded Lagrangian and heterosis (Mindlin-type) plate elements are analysed to assess their behaviour in bending, vibration and stability of isotropic and laminated composite plates. A four-noded Reddy-type element is identified which is free of all spurious stiffness and zero energy modes, computationally efficient, and suitable for use in any general-purpose finite element program.

ABSTRACT: The nonlinear response of laminated composite structures subjected to thermal loads is investigated. Analysis is performed using a refined theory and an associated finite element model for geometrically nonlinear analysis of laminated composite shell structures. The model is based on a third-order displacement field which accounts for both transverse shear and transverse normal deformations. Numerical studies of simply-supported plates and cylindrical panels indicate that when the panels are free to expand or contract in the transverse direction, the predicted critical buckling temperatures do not depend significantly upon whether or not transverse normal deformations are explicitly accounted for in the analysis model. However, the critical buckling temperatures are strongly dependent upon whether or not the transverse normal deformations are restrained along the boundaries of the panels.

ABSTRACT: The buckling and postbuckling of stiffened laminated cylinders under uniform axial compression is investigated to determine the effects of shell lamination scheme and stiffeners on the reduced load-carrying capacity. The effect of geometric imperfection is also included. The analysis is based on the layerwise shell theory of Reddy for simply-supported, cross-ply laminated circular cylinders, and the smeared stiffener technique is used to account for the stiffener stiffness. The Rayleigh-Ritz method is used to reduce the continuum problem to a set of nonlinear algebraic equations, which are then solved using the Riks-Wempner iterative technique. Numerical results for stiffened and unstiffened, cross-ply laminated, simply-supported graphite-epoxy cylinders are to the number of nearly simultaneous buckling modes.

ABSTRACT: A new displacement-based two-dimensional theory for the analysis of multilayered plates is presented. The theory is based on the only kinematic constraint of transverse inextensibility, whereas no restrictions are imposed on the representation of the in-plane displacement components. A governing system of integral-differential equations is obtained which can be given a closed-form solution for a number of problems where no boundary layer are present. It is also shown that most of the 2-D plate models can be directly derived from the presented theory. The possibility of developing asymptotic solutions in the boundary layers is discussed with reference to the problem of a plate in cylindrical bending. Finally some numerical solutions are compared with those given by the plate model by Lo et al. (1977) and with F.E.M. solutions.

ABSTRACT: Analytical solutions for buckling loads of composite cylindrical shells with axial and circumferential stiffeners are presented using a layerwise shell theory. The layerwise shell theory accounts for displacement variations through the thickness of the shell. The effect of stiffeners is averaged over the domain of the shell, and the effect of stiffener eccentricity is taken into account. The Navier solution procedure is used to develop analytical solutions for buckling of stiffened cylindrical shells. Numerical results are presented to illustrate the accuracy of the layerwise shell theory in comparison to single-layer shell theories.

ABSTRACT: The post-buckling of stiffened, cross-ply laminated, circular determine the effects of shell lamination scheme and stiffeners on the reduced load-carrying capacity. The effect of geometric imperfection is also included. The analysis is based on the layerwise shell theory of Reddy, and the “smeared stiffener”
technique is used to account for the stiffener stiffness. Nu cylinders under uniform axial compression is investigated to numerical results for stiffened and unstiffened cylinders are presented, showing that imperfection-sensitivity is strictly related to the number of nearly simultaneous buckling modes.

ABSTRACT: The first-order shear deformation moderate rotation shell theory of Schmidt and Reddy [R. Schmidt and J. N. Reddy, J. Appl. Mech. 55, 611–617 (1988)] is used as a basis for the development of finite element models for the analysis of the static, geometrically non-linear response of anisotropic and laminated structures. The incremental, total Lagrangian formulation of the theory is developed, and numerical solutions are obtained by using the isoparametric Lagrangian 9-node and Serendipity 8-node shell finite elements. Various integration schemes (full, selective reduced, and uniformly reduced integration) are applied in order to detect and to overcome the effects of shear and membrane locking on the predicted structural response. A number of sample problems of isotropic, orthotropic, and multi-layered structures are presented to show the accuracy of the present theory. The von Kármán-type first-order shear deformation shell theory and continuum 2D theory are used for comparative analyses.

ABSTRACT: The response of functionally graded ceramic metal plates is investigated using a plate finite element that accounts for the transverse shear strains, rotary inertia and moderately large rotations in the von Kármán sense. The static and dynamic response of the functionally graded material (fgm) plates are investigated by varying the volume fraction of the ceramic and metallic constituents using a simple power law distribution. Numerical results for the deflection and stresses are presented. The effect of the imposed temperature field on the response of the fgm plate is discussed. It is found that in general, the response of the plates with material properties between those of the ceramic and metal is not intermediate to the responses of the ceramic and metal plates.

PARTIAL ABSTRACT: The Layerwise Shell Theory is used to model discretely stiffened laminated composite cylindrical shells for stress, vibration, pre-buckling and post-buckling analysis. The layerwise theory reduces a three-dimensional problem to a two-dimensional problem by expanding the three-dimensional displacement field as a function of a surface-wise two dimensional displacement field and a one-dimensional interpolation through the shell thickness. Any required degree of accuracy can be obtained by an appropriate, independent selection of the one-dimensional interpolation functions through the thickness and the two-dimensional interpolation of the variable on the surface…

ABSTRACT: The layerwise shell theory is used to model discretely stiffened laminated composite plates and cylindrical shells for stress, vibration, pre-buckling and post-buckling analyses. The layerwise theory reduces a three-dimensional (3-D) problem to a two-dimensional (2-D) problem by expanding the 3-D displacement field as a function of a surface-wise 2-D displacement field and a one-dimensional (1-D) interpolation polynomial through the shell thickness. Using a layerwise format, discrete axial and circumferential stiffeners are modeled as 2-D beam elements. Similar displacement fields are prescribed for both the stiffener and shell elements. The contribution of the stiffeners to the membrane stretching, bending and twisting stiffnesses of the laminated shell or plate, is accounted by forcing compatibility of strains and equilibrium of forces between the stiffeners and the skin.

ABSTRACT: Fiber-reinforced composite materials continue to experience increased adoption in aerospace, marine, automobile, and civil structures due to their high specific strength, high stiffness, and light weight. This increased use has been accompanied by applications involving non-traditional configurations such as compression members with elliptical cross-sections. To model such shapes, we develop and report an improved generalized shell element called 4EAS-FS through a combination of enhanced assumed strain and the substitute shear strain fields. A flat shell element has been developed by combining a membrane element with drilling degree-of-freedom and a plate bending element. We use the element developed to determine specifically buckling loads and mode shapes of composite laminates with elliptical cross-section including transverse shear deformations. The combined influence of shell geometry and elliptical cross-sectional parameters, fiber angle, and lay-up on the buckling loads of an elliptical cylinder is examined. It is hoped that the critical buckling loads and mode shapes presented here will serve as a benchmark for future investigations.

ABSTRACT: The dynamic stability of thin, laminated cylindrical shells under combined static and periodic axial forces is studied using Love’s classical theory of thin shells. A normal-mode expansion of the equations of motion yields a system of Mathieu–Hill equations. Bolotin’s method is then employed to obtain the dynamic instability regions. The present study examines the dynamic stability of antisymmetric cross-ply circular, cylindrical shells of different lamination schemes. The effect of the magnitude of the axial load on the instability regions is also examined.

ABSTRACT: In this paper, a formulation for the dynamic stability analysis of functionally graded shells under
harmonic axial loading is presented. A profile for the volume fraction is assumed and a normal-mode expansion of the equations of motion yields a system of Mathieu–Hill equations the stability of which is analyzed by the Bolotin’s method. The present study examines the effects of the volume fraction of the material constituents and their distribution on the parametric response, in particular the positions and sizes of the instability regions.

ABSTRACT: A flat-shell element is presented for the active control of functionally graded material (FGM) shells through integrated piezoelectric sensor/actuator layers. The finite element formulation based on first-order shear deformation theory (FSDT) can be applied to shells ranging from relatively thin to moderately thick dimensions. A constant gain displacement and velocity feedback control algorithm coupling the direct and inverse piezoelectric effects is applied to provide active control of the integrated FGM shell in a self-monitoring and self-controlling system. Frequency response characteristics of the FGM shell containing the piezoelectric sensors/actuators are analyzed in the frequency domain. The effects of constituent volume fraction and the influence of feedback control gain values on the dynamic responses of the FGM shell system are examined in detail.

ABSTRACT: An exact solution is obtained for three-dimensional deformations of a simply supported functionally graded rectangular plate subjected to mechanical and thermal loads on its top and/or bottom surfaces. Suitable temperature and displacement functions that identically satisfy boundary conditions at the edges are used to reduce the partial differential equations governing the thermomechanical deformations to a set of coupled ordinary differential equations in the thickness coordinate, which are then solved by employing the power series method. The exact solution is applicable to both thick and thin plates. Results are presented for two-constituent metal–ceramic functionally graded rectangular plates that have a power law through-the-thickness variation of the volume fractions of the constituents. The effective material properties at a point are estimated by either the Mori–Tanaka or the self-consistent schemes. Exact displacements and stresses at several locations for mechanical and thermal loads are used to assess the accuracy of the classical plate theory, the first-order shear deformation theory, and a third-order shear deformation theory for functionally graded plates. Results are also computed for a functionally graded plate with material properties derived by the Mori–Tanaka method, the self-consistent scheme, and a combination of these two methods.

ABSTRACT: The nonlinear response of functionally graded ceramic–metal shell panels under mechanical and thermal loading is studied. The nonlinear formulation is based on a modified version of Sander's nonlinear shell theory, in which the geometric nonlinearity takes the form of von Kármán strains. It is assumed that the material properties vary through the thickness according to a power-law distribution of the volume fraction of the constituents. The displacement field is expressed in terms of a set of mesh-free kernel particle functions. The bending stiffness is evaluated using a stabilized conforming nodal integration technique, and the shear and membrane terms are computed using a direct nodal integration to eliminate shear and membrane locking. The arc-length method, combined with the modified Newton–Raphson approach, is employed to trace the full load–displacement path. The characteristic of the displacement and the axial stress in panels under thermal and mechanical loading is investigated, and the effects of the volume fraction exponent, boundary conditions, and material properties on the nonlinear response of shell panels are also examined.

ABSTRACT: Three-dimensional thermomechanical deformations of simply supported, functionally graded rectangular plates are studied by using an asymptotic method. The locally effective material properties are estimated by the Mori–Tanaka scheme. The temperature, displacements and stresses of the plate are computed for different volume fractions of the ceramic and metallic constituents, and they could serve as benchmark results to assess two-dimensional approximate plate theories.

J. N. Reddy and Zhen-Qiang Cheng (Department of Mechanical Engineering, Texas A&M University, College Station, TX 77843-3123, USA), “Frequency correspondence between membranes and functionally graded spherical shallow shells of polygonal planform”, International Journal of Mechanical Sciences, Vo. 44, No. 5, May 2002, pp. 967-985, doi:10.1016/S0020-7403(02)00023-1
ABSTRACT: The present work presents further development of the linking relationships between vibration frequencies predicted by different theories, and they are extended from a flat plate to a spherical shallow shell. In analogy with the membrane vibration problem, exact correspondences are found for vibration frequencies of a functionally graded spherical shallow shell using the classical theory and the first-order and third-order shear deformation theories. Only the predominantly stretching and thickness-shear vibration of dilatational type and predominantly flexural vibration are considered in this work. They are decoupled from the predominantly stretching and thickness-shear vibration of rotational type. These results apply to a simply supported functionally graded spherical shallow shell of polygonal planform with arbitrarily varying material properties in the thickness direction. A Winkler–Pasternak elastic foundation and rotary inertias are incorporated. It is proved that the mathematical analogy warrants positive free vibration frequencies for the shallow shell. Mori–Tanaka's scheme is used to estimate the material properties in the numerical results.

ABSTRACT: In this paper, a review of the shear deformation plate and shell theories is presented and a consistent third-order theory for composite shells is proposed. The discussion of plate and shell theories from Stavsky to the present is largely a review of various theories for modeling laminated shells, including shear effects and some analytical studies. Following this discussion, a finite element formulation of the proposed theory is developed. The formulation has seven displacement functions satisfying the tangential traction-free conditions on the inner and outer surfaces of the shell. Exact computations of stress resultants are carried out
through numerical integration of material stiffness coefficients of the laminate. Numerical examples are presented for typical benchmark problems involving isotropic and composite plates, and cylindrical and spherical shells.

ABSTRACT: In the present work the buckling and postbuckling behavior of laminated cylindrical shells under axial compression and lateral pressure loading are investigated. A nonlinear theory for thin cylinders incorporating the effects of transverse shear deformation is employed. A modal solution based on the Koiter theory is utilized to derive the nonlinear equilibrium equations for the postcritical behavior of the shell. The Rayleigh–Ritz method is used to obtain analytical solutions for the critical load through algebraic routines written in Maple. Prebuckling and postbuckling equations are also solved by using symbolic computation. The influence played by geometrical parameters of the cylinder and physical parameters of the laminate (i.e. fiber orientation of each lamina, material properties and number of layers) on the critical and postcritical behavior of the shell is examined. It is noticed that the stability of shells is highly dependent on laminate characteristics and, from these observations, it is concluded that specific configurations of laminates should be designed for each kind of application.

ABSTRACT: A geometrically nonlinear analysis of functionally graded shells is presented. The two-constituent functionally graded shell consists of ceramic and metal that are graded through the thickness, from one surface of the shell to the other. A tensor-based finite element formulation with curvilinear coordinates and first-order shear deformation theory are used to develop the functionally graded shell finite element. The first-order shell theory consists of seven parameters and exact nonlinear deformations and under the framework of the Lagrangian description. High-order Lagrangian interpolation functions are used to approximate the field variables to avoid membrane, shear, and thickness locking. Numerical results obtained using the present shell element for typical benchmark problem geometries with functionally graded material compositions are presented.

ABSTRACT: Various available beam theories, including the Euler–Bernoulli, Timoshenko, Reddy, and
Levinson beam theories are reformulated using the nonlocal differential constitutive relations of Eringen. The equations of motion of the nonlocal theories are derived, and variational statements in terms of the generalized displacements are presented. Analytical solutions of bending, vibration, and buckling are presented using the nonlocal theories to bring out the effect of the nonlocal behavior on deflections, buckling loads, and natural frequencies. The theoretical development as well as numerical solutions presented herein should serve as references for nonlocal theories of beams, plates, and shells.

ABSTRACT: The equations of motion of the Euler–Bernoulli and Timoshenko beam theories are reformulated using the nonlocal differential constitutive relations of Eringen [International Journal of Engineering Science 10, 1–16 (1972)]. The equations of motion are then used to evaluate the static bending, vibration, and buckling responses of beams with various boundary conditions. Numerical results are presented using the nonlocal theories to bring out the effect of the nonlocal behavior on deflections, buckling loads, and natural frequencies of carbon nanotubes.

ABSTRACT: The accuracy of widely employed classical shell-theory-based formulae to calculate the buckling strain of single- and double-walled carbon nanotubes is assessed here. It is noted that some simplifications have been made in deriving these widely employed formulae. As a result critical buckling strains calculated from these formulae are independent of aspect ratio (length/diameter). However, molecular dynamics simulation results in the literature show an aspect ratio dependence of buckling strain. Therefore, analytical expressions are derived in this paper to calculate buckling strains of single- and double-walled carbon nanotubes based on classical shell theory without simplifications. Applicability of these expressions is further verified through molecular dynamics simulations based on the COMPASS force field. In addition, improvement in results achieved through a refinement of classical shell theory is assessed by calculating buckling strains based on first-order shell theory. Results show that simplified formulae introduce a significant error at higher aspect ratios and smaller diameters. The formulae derived here show reasonable agreement with the molecular dynamics results at all aspect ratios and diameters. First-order shell theory is found to produce a slight improvement in results for CNTs with smaller diameters and lower aspect ratios.

ABSTRACT: Owing to their remarkable mechanical properties, carbon nanotubes have been employed in many diverse areas of applications. However, similar to any of the many man-made materials used today, carbon nanotubes (CNTs) are also susceptible to various kinds of defects. Understanding the effect of defects on the mechanical properties and behavior of CNTs is essential in the design of nanotube-based devices and composites. It has been found in various past studies that these defects can considerably affect the tensile strength and fracture of CNTs. Comprehensive studies on the effect of defects on the buckling and vibration of nanotubes is however lacking in the literature. In this paper, the effects of various configurations of atomic vacancy defects, on axial buckling of single-walled carbon nanotubes (SWCNTs), in different thermal environments, is investigated using molecular dynamics simulations (MDS), based on a COMPASS force field. Our findings revealed that even a single missing atom can cause a significant reduction in the critical buckling strain and load of SWCNTs. In general, increasing the number of missing atoms, asymmetry of vacancy configurations and asymmetric distribution of vacancy clusters seemed to lead to higher deterioration in buckling properties. Further, SWCNTs with a single vacancy cluster, compared to SWCNTs with two or more vacancy clusters having the same number of missing atoms, appeared to cause higher deterioration of buckling properties. However, exceptions from the above mentioned trends could be expected due to chemical instabilities of defects. Temperature appeared to have less effect on defective CNTs compared to pristine CNTs.

ABSTRACT: Postbuckling analysis of functionally graded ceramic–metal plates under edge compression and temperature field conditions is presented using the element-free kp-Ritz method. The first-order shear deformation plate theory is employed to account for the transverse shear strains, and the von Kármán-type nonlinear strain–displacement relationship is adopted. The effective material properties of the functionally graded plates are assumed to vary through their thickness direction according to the power-law distribution of the volume fractions of the constituents. The displacement fields are approximated in terms of a set of mesh-free kernel particle functions. Bending stiffness is estimated using a stabilised conforming nodal integration approach, and, to eliminate the membrane and shear locking effects for thin plates, the shear and membrane terms are evaluated using a direct nodal integration technique. The solutions are obtained using the arc–length iterative algorithm in combination with the modified Newton–Raphson method. The effects of the volume fraction exponent, boundary conditions and temperature distribution on postbuckling behaviour are examined.

ABSTRACT: A three-dimensional degenerated isoparametric multilayer finite element is described in conjunction with an automatic incremental/iterative method to find the complete non-linear response of arbitrarily laminated composite panels under destabilizing loads. In the prebuckling range of the structural
response, incremental bifurcation analyses are combined with an arclength algorithm to control the step size; for the postbuckling path, the increment size is determined automatically by a new recurrence formula. The good behaviour of this proposed procedure is illustrated on two structural applications, namely a thick hinged multilayer cylindrical shell subjected to a transverse load and a highly curved cylindrical composite panel under in-plane compression.

ABSTRACT: This paper describes some of the current global/local testing and analysis approaches to evaluating the design of composite structure. A case study for the local, fracture mechanics analysis of failure in a 4-stringer compression panel is described in detail. The analysis investigates the variation of strain energy release rate G with debond length using a 2-D plane strain finite element analysis (FEA) of one of the stringers. The boundary conditions on the local model were determined from a global shell element model of the panel. Delamination was also modelled in the cap of the stringer using FEA and a closed form solution. The values of G for these two damage modes were compared with the material's fracture toughness. Using this analysis, the load to initiate the stringer debond and to cause edge delamination of the cap may be determined.

ABSTRACT: A finite element methodology for postbuckling failure analysis of composite stringer/skin panels is presented. The methodology employs a global two-dimensional plate finite element model for representing overall panel deformation and a local three-dimensional solid finite element model for representing stress within a critical panel region. Global and local models are connected with a two-dimensional/three-dimensional coupling methodology that is based on multipoint constraints. Analyses are carried out for two different panel designs utilizing both linear and nonlinear material models. Computational results for failure load, failure location, and failure mode compare favorably with results from earlier experimental test programs. The findings suggest that failure initiation in postbuckled composite stringer//skin panels can be effectively modeled with the developed finite element methodology.

ABSTRACT: This paper presents experimental and numerical investigations on the performance of repaired thin-skinned, blade-stiffened composite panels in the post-buckling range. The results show that under the present repair scheme the strength of the panel can be recovered satisfactorily. Further, the repair scheme is seen capable of restoring the general load path in the panels as well as the general post-buckling behaviour.

K. Swaminathan and Govind R. Sangwai (National Institute of Technology Karnataka, Surathkal, Mangalore –
ABSTRACT: In the present work two higher order computational models with 9 and 12 DOF already available in the literature for which analytical formulations and solutions for the stress analysis not yet reported are considered. In addition to these models, few higher order models and the first order model developed by other investigators are also considered for the evaluation. A simply supported plate subjected to sinusoidal transverse load with SS-2 boundary conditions is considered for the analysis. Solutions are obtained using Navier's technique. Transverse stresses are computed by post processing technique and the accuracy of models in predicting the stresses is evaluated.

Nemi Sharan (Master’s Thesis, Department of Civil Engineering, National Institute of Technology, Rourkela, Odisha-769008), “Vibration and stability of laminated composite doubly curved shells by a higher order shear deformation theory”, May 2011

ABSTRACT: The present study deals with a higher order shear deformation theory of laminated shells as suggested by Reddy and Liu. The theory is based on a displacement field in which the displacements of the middle surface are expanded as cubic functions of the thickness coordinate, and the transverse displacement is assumed to be constant through the thickness. This displacement field leads to the parabolic distribution of the transverse shear stresses (and zero transverse normal strain) and therefore no shear correction factors are used. The theory is also based on the assumption that the thickness to radius ratio of shell is small compared to unity and hence negligible. The governing equations are derived in orthogonal curvilinear coordinates. These equations are then reduced to those of doubly curved shell. All the quantities are suitably non-dimensionalised. The Navier solution has been used which gives rise to a generalized eigenvalue problem in matrix formulation. The natural frequencies for vibration and buckling loads of laminated orthotropic doubly curved shells and panels with simply supported ends are obtained. The eigenvalues, and hence the frequency parameters are calculated by using a standard computer program. To check the derivation and computer program, the frequencies in HZ for different layer are compared with earlier results. The lowest value of frequency parameter and buckling load are computed for the laminated composite doubly curved shell. The effects of various parameters such as number of layers, aspect ratio, modular ratio, etc on the above are studied. Frequency also increases as number of layers of the shell increases for symmetric cross-ply layout. But when there is unsymmetrical cross-ply layout, then frequency decreases. With the increasing of modular ratio, non-dimensional frequency is also increasing.

ABSTRACT: The present study discusses buckling of multilayered composite plates from the standpoint of a natural shear deformation theory (NSDT) which is developed and shaped by means of matrix language on a model facet three-node triangular finite element. Isotropic, sandwich, and hybrid plates can also be treated. It is
shown that by invoking a physical decomposition and lumping concept, evolved through the adoption of a natural coordinate system in harmony with the given element geometry, an assembly of three edge-beams is created and is solely responsible for the carrying of the transverse shear forces. Thus, three correction factors can directly adjust the element's transverse shear stiffness for thicker plates while retaining a direct linear strain distribution across the element thickness. Subsequently, the geometric stiffness, which arises mostly from the rigid body movements of the element is derived, and the corresponding buckling eigenvalue problem is stated. The complete derivation of the geometrical stiffness matrix is in principle reduced to a simple transformation of the nodal freedoms. The matrix formulation, as well as convergence of the triangular element are completely natural, and numerical experiments for simply supported plates reveal that the obtained buckling loads conform very well at the thin limit with results from classical plate theory, and for moderately thick plates from a higher order shear deformation theory, as well as from theory of elasticity.

ABSTRACT: In the present study, the behaviour of laminated composite plates under thermally induced loads is examined. A natural thermoelastic theory is developed, based on a linear through-the-thickness temperature variation. The material properties are assumed independent of temperature, but this assumption in no way restricts the generality of the formulation and the developed computer program. The theory is implemented on a model three-node triangular facet finite element which accounts for transverse shear deformation. The underlying principles of the developed methodology lie in the Natural Mode method which is a physically inspired and mathematically consistent method which was conceived with the intention of analyzing large and complex structures. The triangular element necessitates the computation of a $12 \times 12$ natural stiffness matrix, and a $12 \times 1$ thermal (initial) load vector, which makes it probably one of the most inexpensive shell elements available. The effects of large displacements are included in our theory through the geometrical stiffness. In this regard, an Eulerian scheme conceived for the solution of geometrically nonlinear thermoelastic deformation is discussed. The methodology is validated with numerical examples which show the response of multilayered composite plates on thermally or thermomechanically induced bending, buckling, and postbuckling. All composite plates examined have shown remarkable resistance against high-temperature.

ABSTRACT: The evolution of the Natural Mode Method (NMM) for finite element analysis of complex composite structures continues in the present study by applying its principles and formulating the kinematically consistent matrix of a model three-node multilayered triangular element. Both translational and rotational inertia are included in the mass matrix which is conceived using kinematical and geometrical arguments consistent with the assumed natural rigid-body and straining modes of the element. Linear eigenfrequencies are validated with experimental and finite element solutions. Subsequently the large-amplitude nonlinear undamped free vibration of composite plates is investigated. A computational scheme is conceived, whereby the structure is initially displaced by conducting a full geometrically nonlinear static analysis, and subsequently set to transient nonlinear free oscillations by removing the static loading. In this regard, we discuss the two structured Eulerian (convective) computational schemes employed namely, the ARIBAN scheme (accumulation of rigid-body and
natural modes) for static nonlinear analysis, and the cubic Hermitian scheme (CUHERM) for large-displacement transient deformation. Numerical examples demonstrate the efficiency of the formulation and the potential of the Natural Mode Method to deal vigorously with intricate nonlinear time-dependent phenomena, as well as its potential to provide answers for larger and more complex structures. The study also indicates the efficiency and tailoring flexibility offered by advanced composite structural systems.

ABSTRACT: A novel approach to the art of optimal design of modern flying vehicles including the application of multiple objective functions and constraints is presented and should hopefully advance the art of modern aircraft design. First, the concept of system identification is used to characterize non-linear systems in terms of generalized state space coordinates. Next, modern optimal control theory is applied to design concurrently, the functional elements of an aircraft system. Furthermore, modal coordinates are used to formulate the equations of motion of the total system so that the computational effort is minimized. The proposed analytical concept is validated using simple test cases.

ABSTRACT: Here we study the thermo-mechanical postbuckling response of fibrous composite laminates. This study is based on the Natural Mode Method and invokes rigid-body and straining modes of deformation that are assigned to the edges of flat and shallow shell laminated triangular finite elements. Some new ideas on the subject are introduced and implemented in the conceived nonlinear algorithm, most notably the incorporation of temperature-dependent material properties (cubic variation), the decomposition of the total strain energy into its invariant natural components, assessing also their effect on failure initiation, the combined effect of load and temperature and the influence of initial imperfections on the overall behaviour, and finally comments on some of the intricate differences revealed for some problems by using the flat and shallow shell triangular elements. Comparisons with reported analytical and experimental results is attempted where available. Overall, the computational experiments substantiate the developed methodology and show its potential to treat larger and more complex panels and also contribute to their design.

ABSTRACT: We present the computational performance and the achieved accuracy of the TRIC flat triangular shell element for nonlinear postbuckling analysis of arbitrary isotropic and composite shells. The element is based on the natural mode finite element method, which allows a convenient description of the current position of the structure. These natural modes are assigned to a convective coordinate system which follows the element during deformation within the framework of an Eulerian motion. With respect to this coordinate system the natural modes are additive. Numerical examples verify the accuracy, computational efficiency and the potential of the TRIC element in predicting the postbuckling behaviour of shells. Natural energy measures inform us about the energy allocation during nonlinear deformation and the interplay of the separate energy components.

ABSTRACT: TRIC is a facet triangular shell element, which is based on the natural mode method. It has been shown that the TRIC shell element satisfies the individual element test and in the framework of the nonconsistent formulation the convergence requirements are fulfilled, while it has been proved to be very efficient in linear and nonlinear static problems. Moreover, another major advantage in the formulation of this element is the incorporation of the transverse shear deformations in a way that defies the shear-locking phenomenon. In this work the derivation of the consistent and lumped mass matrices of the TRIC element is presented so that it can be used in linear and nonlinear dynamic problems. Both translational and rotational inertia are included in the consistent mass matrix, which is conceived, using kinematical and geometrical arguments consistent with the assumed natural rigid body and straining modes of the element. All the kinematical and geometrical arguments that are invoked for the derivation of the consistent mass matrix are briefly presented. Moreover, two formulations of the lumped mass matrix of TRIC are derived. The first formulation is based entirely on geometrical considerations whereas the second is based on lumping the consistent mass matrix of TRIC. Finally, the element’s robustness and accuracy will be shown by applying it to properly selected benchmark examples of nonlinear shell dynamics, while its computational efficiency will be demonstrated by comparing the CPU performance of the element with the other available shell elements.

ABSTRACT: In the present study, a generalization of the Energy–Momentum Method, denoted by Generalized Energy–Momentum Method, applied to the non-linear dynamics of shells will be developed within the framework of the Generalized-α Method. This algorithmic environment contains the unconditionally stable Energy–Momentum Method and its numerically damped version as well as the classical Newmark and α-methods as special cases. In order to control the size of the time steps of the integration scheme with respect to accuracy and efficiency, an adaptive time stepping procedure based on local a posteriori error estimation will be improved for non-linear dynamical systems and applied to the proposed class of algorithms. The spatial discretization is realized by an eight noded finite shell element of Reissner/Mindlin type including an extensible shell director field permitting the application of three-dimensional material laws. The original formulation of this finite element will be developed for non-linear dynamic analysis and adapted for the employment within the introduced energy conserving/decaying time integration scheme.

ABSTRACT: A novel integration scheme for nonlinear dynamics of geometrically exact shells is developed based on the inextensible director assumption. The new algorithm is designed so as to imply the strict decay of the system total mechanical energy at each time step, and consequently unconditional stability is achieved in the nonlinear regime. Furthermore, the scheme features tunable high frequency numerical damping and it is therefore stiffly accurate. The method is tested for a finite element spatial formulation of shells based on mixed interpolations of strain tensorial components and on a two-parameter representation of director rotations. The robustness of the scheme is illustrated with the help of numerical examples.

ABSTRACT: A modified time-integration method is developed for non-linear structural dynamics combining controllable algorithmic dissipation of higher modes and, at the same time, conservation of energy as well as linear and angular momentum. Although these features seem to be actually inconsistent, numerical stability with...
large time steps for dynamic buckling and snap-through problems as well as for dynamical systems with smooth solutions is guaranteed. Arbitrary implicit, one-step time-integration schemes with Newmark approximations are suitable for use as basic algorithms for the proposed method. The desired conservation attributes are obtained if the basic algorithm is augmented by energy and momentum constraints. The potential of the suggested algorithm is demonstrated by selected applications to non-linear dynamics of shell structures.

ABSTRACT: The present study is concerned with the application of two vector iteration methods in the investigation of the large deflection behavior of spatial structures. The dynamic relaxation and the first order conjugate gradient belong to this category of methods which do not require the computation or formulation of any tangent stiffness matrix. The convergence to the solution is achieved by using only vectorial quantities and no stiffness matrix is required in its overall assembled form. In an effort to evaluate the merits of the methods, extensive numerical studies were carried out on a number of selected structural systems. The advantages of using these vector iteration methods, in tracing the post-buckling behavior of spatial structures, are demonstrated.

ABSTRACT: A review of conventional testing methods for applying external hydrostatic pressure to buckling-critical shells is presented. A new “volume-control” pressure testing method, aimed at preventing catastrophic specimen failures and improving control of specimen deformation near the critical load, is also introduced. The implementation of conventional and volume-control systems in an experimental program involving the destructive pressure testing of ring-stiffened cylinders is described. The volume control method was found to improve control of the specimen deformations, especially near the critical load, and catastrophic failures observed while using a conventional setup were avoided. The quasi-static tracking of post-collapse load-deformation relationships for snap-through buckling behaviour was possible while using a volume-control system, but precise control of dynamic shell deformations during buckling was not achieved for specimens failing with large buckling lobes. Expressions for estimating the available control over specimen deformations for pressure testing systems are presented.

ABSTRACT: In this study, the buckling behavior of optimum laminated composite cylindrical shells subjected to axial compression and external pressure are studied. The cylindrical shells are composed of multi orthotropic layers that the principal axis gets along with the shell axis (x). The number of layers and the fiber orientation of layers are selected as optimization design variables with the aim to find the optimal laminated composite cylindrical shells. The optimization procedure was formulated with the objective of finding the highest buckling pressure. The Genetic Algorithm (GA) and Imperialist Competitive Algorithm (ICA) are two optimization algorithms that are used in this optimization procedure and the results were compared. Also, the effect of materials properties on buckling behavior was analyzed and studied.

ABSTRACT: Thin walled cylinders under external pressure may be affected by instability phenomena particularly dangerous when taking place in the elastic domain. Geometric imperfections caused by fabrication processes heavily influence the critical pressure. In order to investigate the relationship between the collapse mechanism and the various types of imperfections affecting this kind of structures a series of experimental tests on scale models has been carried out. The dimensional parameters of the specimens have been selected in order to keep the instability phenomenon in the elastic range. At the same time numerical calculations simulating the experimental tests have been performed by finite element method. The geometrical defects measured on the specimens were introduced in the correspondent numerical models. A good agreement was found in the comparison between experimental and numerical results.

ABSTRACT: Theoretical and experimental research on the ultimate strength of rigid pipelines for deepwater applications conducted at the Laboratory for Submarine Technology—COPPE has been reviewed. Small scale laboratory tests included intact pipes under external pressure combined with longitudinal bending as well as damaged pipes under external pressure. Results obtained from specialist computer programmes and analytical formulations have been correlated with experimental results in order to propose ultimate strength equations to be used in the design procedures. Aspects related to the pipeline installation by reeling method are considered.

ABSTRACT: A theoretical explicit formulation for numerical simulation of the buckle propagation in deepwater pipelines is proposed. It is based on thin shell theory incorporating large rotations and material elastic–plastic behavior for infinitesimal strains. The equilibrium equations are solved numerically through a computer program using the finite difference method associated to the dynamic relaxation technique. The pipe post-buckling behavior is determined by the arc-length method used in convolute regions of the load–displacement curve. The numerical results are correlated with experimental data from small scale laboratory tests.

ABSTRACT: The Hobbs equations have been used for years to evaluate the susceptibility of flowlines to lateral buckling. However these equations are sometimes used without a clear understanding of the driving mechanism and for some flowlines configurations care shall be taken for a direct application of these formulas. In particular, the infinite mode buckle shape, although widely considered in the industry, does not reflect the lateral buckling mechanism. Through a thorough review of the assumptions and validity of the Hobbs equations, this paper presents adequate formulations to evaluate the susceptibility to lateral buckling for specific flowlines configurations. The cases of short flowlines, medium flowlines and unbounded pipe in pipe systems...
are presented. The methodology described in Hobbs paper is analyzed in detail and the bases of the equations are rewritten for short and medium flowlines. The pipe length in the feed-in zone before and after buckle is calculated based on the strain profiles in the pipes. Then the critical buckling force is deduced by the application of an equation of continuity of displacements. For unbounded pipe in pipe the same principle is used with the addition of an uncoupled behaviour between the axial and lateral components and the share of axial force at the bulkhead location. The contribution of the centralizers is also incorporated in the formulation. Eventually, the criteria presented in the paper are compared with a more realistic probabilistic approach to evaluate their degree of conservatism.

ABSTRACT: Concern for structural design methods for naval ships and submarines including uncertainties in modeling techniques. Particular attention shall be given to those aspects that characterise naval ship and submarine design such as blast loading, vulnerability analysis and others, as appropriate.

IN PARTICULAR WE ARE INTERESTED IN SECTION 6.2: Ring-Stiffened Cylinder Subject to Hydrostatic Pressure Load: This case study consisted of a round robin whereby the participants generated collapse predictions for two experimental models (Mackay and Pegg, 2010). Those models were tested under a joint project of Defence Research and Development Canada and the Netherlands Ministry of Defence that examined the effect of corrosion thinning on pressure hull strength and stability (Mackay, Smith et al., In Press). The test models are small-scale aluminium ring-stiffened cylinders, their nominal dimensions are shown in Figure 8. The two models chosen for the case study are nominally identical, except for a patch of artificial corrosion on one of the specimens that was introduced by machining away some of the shell material (Figure 9). The participants were allowed to use any method to predict the strength of the cylinders, including analytical, empirical or numerical methods, or some combination thereof. Each participant reported the predicted collapse pressure and yield pressure of each specimen, as well as predicted pressure-strain histories. The experimental results were withheld until after the participants submitted their results.

ABSTRACT: The ultimate longitudinal bending strength of thin plated steel structures such as box girder bridges and ship hulls can be determined using an incremental-iterative procedure known as the Smith progressive collapse method. The Smith method first calculates the response of stiffened panel sub-structures in the girder and then integrates over the cross section of interest to calculate a moment–curvature response curve. A suitable technique to determine the strength behaviour of stiffened panels within the Smith method is therefore of critical importance. A fundamental assumption of the established progressive collapse method is that the buckling and collapse behaviour of the compressed panels within the girder occurs between adjacent transverse frames. However, interframe buckling may not always be the dominant collapse mode, especially for lightweight stiffened panels such as are found in naval ships and aluminium high speed craft. In these cases overall failure modes, where the buckling mode extends over several frame spaces, may dominate the buckling and collapse response. To account for this possibility, an adaptation to large deflection orthotropic plate theory
is presented. The adapted orthotropic method is able to calculate panel stress-strain response curves accounting for both interframe and overall collapse. The method is validated with equivalent nonlinear finite element analyses for a range of regular stiffened panel geometries. It is shown how the adapted orthotropic method is implemented into an extended progressive collapse method, which enhances the capability for determining the ultimate strength of a lightweight stiffened box girder.

ABSTRACT: Results are described of a numerical study of the initial compressive buckling and post-buckling behaviour of GRP panels reinforced by longitudinal hat-section stiffeners. Particular reference is made to the effects of interaction between local buckling of the panel laminate and overall column-like buckling involving bending of the stiffeners. Conclusions are reached regarding the influence of interactive effects on collapse strength and recommendations are made on allowance for these effects in design.

ABSTRACT: This paper presents extensive non-linear finite element (FE) analysis and formulation development work carried out on the ultimate compressive strength of plates and stiffened panels of ship structures. A review of contemporary designs for large ships was carried out. The existing formulae for plate ultimate compressive strength were reviewed and compared with non-linear FE analysis results. A semi-analytical formula for ultimate compressive strength assessments of stiffened panels was proposed and is described. The developed formula was verified against results using ABAQUS non-linear FE software for a series of 61 stiffened panels and a good agreement between the proposed formula and FE results were achieved. The method was verified against a large number of published FE results and was also compared with 58 experimental results. The developed method was also applied to the deck and bottom structures for a range of various sizes oil tankers and bulk carriers.

ABSTRACT: An overview of current design practices for submarine pressure hulls is presented, along with the results of a survey of the literature that was conducted to determine standard nonlinear numerical modelling practices for those structures. The accuracies of the conventional submarine design formulae (SDF) and nonlinear numerical analyses for predicting pressure hull collapse are estimated by comparing predicted and experimental collapse loads from the literature. The conventional SDF are found to be accurate within approximately 20%, with 95% confidence, for intact pressure hulls. The accuracy of a wide range of nonlinear numerical methods, including axisymmetric finite difference and general shell finite element (FE) models, is found to be within approximately 16% with 95% confidence. The accuracy is found to be within 9% when only higher fidelity general shell FE models are considered. It is shown how the observations taken from the survey could serve as a starting point for establishing modelling guidelines, quantifying the accuracy of nonlinear FE analysis in pressure hull collapse calculations, and introducing this method into a design procedure by way of a partial safety factor.

ABSTRACT: Pressure hulls are the main load bearing structures of naval submarines, commercial and research submersibles, and autonomous underwater vehicles (AUVs). The many similarities between pressure hull, offshore, aerospace and some civil engineering structures mean that advances in one group are often applicable to the others, and thus this document is sometimes concerned with the entire collection of thin-walled curved structures designed for instability, referred to hereafter as “buckling-critical shells.” The state-of-the-art of pressure hull structural analysis and design is established in this document by: 1) explaining the nature of structural strength, and associated weaknesses, in pressure hulls; 2) summarizing traditional and contemporary structural analysis and design methods for pressure hulls; 3) identifying trends with respect to numerical modeling of buckling-critical shell structures; and 4) reviewing novel design procedures for buckling-critical shell structures. It is suggested that the layered conservatism of the traditional design approach could be improved by the use of nonlinear numerical methods for strength predictions, and a way forward is suggested that would allow pressure hull design procedures to incorporate these methods.

ABSTRACT: An energy method is developed for analyzing the flexural-torsional and lateral-torsional buckling (“tripping”) behavior of flanged stiffeners subjected to axial force, end moment, lateral pressure and any combination of these. A strain distribution is assumed and the total potential energy functional is then derived. The strain assumptions coincide with van der Neut’s assumption. However, unlike the somewhat obscure differential equation approach given by van der Neut, this study provides a simple, clear, energy approach. Both the rigid web case and the flexible web case are studied. The study explores the effect of plate rotational restraint, and a previously unresolved question regarding plate mode shape is answered. The method requires only four degrees of freedom and therefore the solution process is rapid. A number of sample stiffened panels are analyzed using the ABAQUS finite-element program; the results are in quite good agreement. The method has also been extended to inelastic tripping, and this generalized form shows excellent agreement with experimental tests on typical steel panels. This work will be presented in a second paper, to avoid an overly long publication.

ABSTRACT: A previous paper [1] proposed an elastic tripping model using a Rayleigh-Ritz approach with 4 d.f. This paper extends the elastic model into the inelastic range, using deformation theory and an iterative and incremental formulation. Nonetheless, because of the efficiency of the Rayleigh-Ritz formulation, the solution is very rapid, even for ordinary PCs. The method can be used for analyzing the flexural-torsional and lateral-torsional buckling (“tripping”) behavior of flanged stiffeners subjected to axial compression, end moment, uniform lateral pressure and any combination of these. The effects of cross-sectional distortion, postbuckling behavior of the plate (incorporated by considering the plate effective width) and plasticity are included. Results obtained using the method are shown to be in good agreement with experimental results, and to be more accurate than other methods.

ABSTRACT: A non-linear finite element (FE) package has been used to investigate the torsional behaviour of flat-bar stiffeners in longitudinally stiffened panels subject to axial loading. The effects of plate slenderness, stiffener slenderness and boundary conditions have been studied including the modelling of the outstand both as part of a stiffened panel and in isolation. A simple analytical approach is proposed by using a theoretical mechanism model developed by Murray combined with a simple elastic loading line to give an upper bound to the tripping failure load. The results are compared with existing design guidance.

“Tripping of thin-walled stiffeners in the axially compressed stiffened panel with lateral pressure”, Thin-Walled Structures, Vol. 37, No. 1, pp 1-26, May 2000, DOI: 10.1016/S0263-8231(00)00010-0

ABSTRACT: Tripping of stiffeners in stiffened panels under combined loads of axial force and lateral pressure is studied. Firstly, on the basis of the Vlasov's differential equation for torsional buckling of thin-walled bars, a generalized eigenvalue problem for tripping of stiffeners is derived by using the Galerkin's Method. Then the effect of the lateral pressure (dead load) to the critical axial stress (live load) upon tripping is investigated by solving the eigenvalue problem. The rotational restraint provided by the plate is taken into account. The effects of the compressive stress in the plate and the plate buckling mode are also discussed. Finally, an approximate equation to estimate the critical tripping stress with the effect of the lateral pressure is proposed. After some modifications, it can be applied in design rules for the purpose of checking the tripping strength of the stiffeners.

ABSTRACT: Tripping of stiffeners under combined loads of axial force, lateral pressure and end moment is studied. First, the neutral balance differential equation under the three combined loads is deduced. The equation is solved with Galerkin's method and a general eigenvalue problem is got. Second, the rotational restraint provided by the plate is studied. Based on the result of FEM, existing formula is modified and comparison of results according to different spring stiffness shows that the modified formula is more reasonable. A program based on the method is developed and its result has a very good coincidence with the result of FEM program MARC. Last, a series of calculation is conducted with above program to study the relation of the three kinds of loads. Regression of the results of the calculation gives out a correlativity formula of the three kinds of loads.

ABSTRACT: The subject of this research is the buckling behavior of a rectangular plate, with a bulb flat stiffener attached to one side of the plate. The stiffener cross section has a thin web and a bulb flat flange that extends to one side of the web. The stiffened plate structure is subjected to axial compression that increases to
the buckling load. Results of the investigation include planar property formulas for the asymmetric flange geometry, an analytic expression for the Saint-Venant torsional constant of the flange cross section, and an analytic expression for the buckling stress corresponding to a tripping mode of the structure. The torsional constant for the bulb flat stiffener is 15–23% higher than understood previously. The analytic expression for the buckling stress of a bulb flat stiffened plate differs by less than 4% from finite element and experimental results.

ABSTRACT: An increasingly popular approximate method for assessing ship hull girder ultimate strength is to combine the individual elasto-plastic load-carrying characteristics of each single stiffened-plate unit comprising the ship hull cross section. In order to evaluate methods (numerical and experimental) for developing the load-carrying characteristics (load–shortening curves), a full-scale testing system was designed and constructed to provide data for stiffened steel plate units under combined axial and lateral loads. The system included an assembly of discrete plate edge restraints that were developed to represent symmetric boundary conditions within a grillage system. Twelve full-scale panels including ‘as-built’, ‘deformed’ and ‘damaged’ specimens were tested in this set-up. The specimens failed by combined plate and flexural buckling, stiffener tripping or local collapse, depending on the magnitude of lateral loads and local damage. Load-shortening curves associated with different failure modes were found to be distinctly different and it was found that a small lateral load could change the failure mode from flexural buckling to tripping. Current design criteria should directly consider effects of the lateral loads on the failure modes and the collapse loads of stiffened plates.

ABSTRACT: A series of elastoplastic large deflection analyses are performed on stiffened plates with flat-bar and angle-bar stiffeners subjected to thrust, and the influences of sectional geometries of stiffeners on the buckling/plastic collapse behaviours are investigated. It has been found that: (1) Local panel buckling strength among stiffeners, post-buckling inplane rigidity and ultimate strength is increased owing to the stiffener; (2) stiffened plates undergo elastoelastic secondary buckling after local panel buckling; (3) higher ultimate strength is attained by stiffeners with lower depth-to-thickness ratio of a web, but, the reduction in capacity after the ultimate strength is more rapid for stiffened plates with such stiffeners; (4) when stiffeners with relatively high depth-to-thickness ratio are provided, the ultimate strength is lower than with a lower depth-to-thickness ratio, but the capacity reduction after the ultimate strength is rather moderate.

ABSTRACT: An analytical formula for estimating elastic local buckling strength of a continuous stiffened plate subjected to biaxial thrust is derived considering the influence of plate/stiffener interaction and welding residual stresses. Through a comparison of calculated results with those by FEM eigenvalue analysis, high accuracy of the proposed formula is demonstrated. A series of buckling strength analyses is performed on the deck and bottom plating of actual ships.

ABSTRACT: A new simplified model for collapse analysis of stiffened plates is developed in the framework of the idealized structural unit method (ISUM). By idealizing material and geometrical nonlinearities, larger structural units are defined as an element in ISUM than in conventional finite element analysis (FEA). The proposed stiffened plate model consists of ISUM plate elements and beam-column elements. The formulation of the plate element is performed by introducing accurate shape functions to simulate the buckling/plastic collapse behaviour of plate panels. Combining plate and beam-column elements allows for both local buckling of the plate panel and overall buckling of the stiffener. Fundamental collapse modes of plate panels and stiffened plates are investigated by conventional FEA. According to the observed characteristics, the new simplified model is formulated. Comparisons with FEA demonstrate the accuracy of the simplified model and its high applicability to typical stiffened plates in marine structures.

ABSTRACT: This paper shows that the application of pre-determined failure equations, derived from nonlinear finite element analyses, is effective in determining failure of structural components in a simpler linear finite element analysis. An analysis method is presented which is called simplified failure analysis. The first step of this method is the nonlinear determination of a component's failure limit. Next, a linear coarse-meshed finite element model of the component is analyzed under the failure load determined in the previous step. The resulting linear stress distribution is a ’representative failure stress’ for the component because it is in equilibrium with the applied failure load. This ‘failure stress’ is then used in simpler linear analysis to provide a representative failure limit. This method is verified by an analysis of a structural grillage.

ABSTRACT: In this paper, simplified formulas to calculate the ultimate strength of corrugated bulkheads are derived using the beam–column theory. The formulas can take account of the influences of shear force and
adjoining structures. By comparing the results from present formulas with those of other numerical analyses, it is shown that the formulas derived in this paper are accurate and reliable for engineering purposes. Thus, a more powerful design tool is provided. Finally the effects of the shear force and rigidities of adjoining structures on the ultimate strength of corrugated bulkheads are also studied.

ABSTRACT: The ultimate longitudinal strength of a typical bulk carrier is analyzed by using a simplified method. The moment–curvature curve, the ultimate bending moment and the location of the instantaneous neutral axis at ultimate state are calculated for both hogging and sagging conditions of the ship under vertical bending. The stress distribution over the hull cross-section at ultimate state is also obtained. The ultimate strength of the ship hull under combined vertical and horizontal bending moments is further investigated. An interaction curve is obtained according to the results of a series of calculation for the hull subjected to bending conditions with different angles of curvature. It is found that the interaction curve is asymmetrical because the hull cross-section is not symmetrical about the horizontal axis and the behavior of the structural members under compression is different from that under tension due to the non-linearity caused by buckling. The angle of the resultant bending moment vector and that of the curvature vector are different in general cases. An interaction equation suitable for bulk carriers is proposed based on the results of the analyzed ship.

Yufeng Zha and Torgeir Moan (Department of Marine Structures, Faculty of Marine Technology, Norwegian University of Science and Technology, N-7491 Trondheim, Norway), “Ultimate strength of stiffened aluminium panels with predominantly torsional failure modes”, Thin-Walled Structures, Vol. 39, No. 8, pp 631-648, August 2001, DOI: 10.1016/S0263-8231(01)00027-1

ABSTRACT: The aim of this paper is to investigate the ultimate strength of aluminium plates with flatbar stiffeners with a torsional buckling or tripping failure mode. The formulations for torsional buckling of stiffeners in steel plating are still debated. Compared with steel structures, the ultimate strength of aluminium structures is sensitive not only to residual stresses and initial deformations, but also to the deterioration of mechanical strength in heat-affected zones (HAZ). In the present paper, the ultimate strength of stiffened aluminium panels with predominantly torsional failure modes is investigated by experimental and theoretical analysis. Stiffened panels made of the aluminium alloy AA5083-H116 and AA6082-T6 are considered. Various height of flatbar and various thickness of plate and stiffener were studied. The test results are compared with numerical predictions by using the finite element code ABAQUS (ABAQUS Version 5.7 (1997)), considering the influence of initial deflections, welding residual stresses and HAZ. The influence of HAZ and residual stresses on the ultimate strength of stiffened aluminium panels with the actual failure mode is discussed in detail. The numerical predictions are also compared with strength of material formulations used in DNV Rules for Classification of High Speed and Light Craft (Rules for classification of high speed and light craft, Hull structural design (1996)), NORSOK (Design of steel structures (1998)) all for steel, using the relevant values of the modulus elasticity and yield strength of aluminium, as well as EUROCODE 9 (Eurocode 9, Part 1-1: General rules (1998)).
ABSTRACT: This is the first of two companion papers dealing with nonlinear finite element modelling and analysis of the ultimate strength of a bulk carrier hull girder under alternate hold loading condition (AHL) condition. The purpose is to contribute to establishing rational ultimate longitudinal strength criteria for the hull girder under combined loading. The focus is on the hogging condition. An important issue is the significant double bottom bending in empty holds in AHL due to combined global hull girder bending moment and local loads. The local loads may substantially reduce the strength of the hull girder. Different AHL conditions, i.e. fully loaded cargo and (partially) heavy cargo are considered. A critical review of external and internal design pressures for different AHL conditions is accomplished using both CSR-BC rules and DNV rules. A methodology for nonlinear finite element modelling of hold tanks of a bulk carrier under AHL is presented by use of ABAQUS. A mesh convergence study is carried out in order to find the appropriate mesh for the model. The implication of using different design pressures on the hull girder strength is assessed. The FE results can be used as a basis for establishing simplified methods applicable to practical design of ship hulls under combined loadings. This issue is discussed in the companion paper.

ABSTRACT: This is the second of two companion papers dealing with nonlinear finite element modelling and ultimate strength analysis of the hull girder of a bulk carrier under Alternate Hold Loading (AHL) condition. The methodology for nonlinear finite element modelling as well as the ultimate strength results from the nonlinear FE analyses was discussed in the companion paper (Part 1). The purpose of the present paper is to use the FE results to contribute towards developing simplified methods applicable to practical design of ship hulls under combined global and local loads. An important issue is the significant double bottom bending in the empty hold in AHL due to combined global hull girder bending moment and local loads. Therefore, the stress distributions in the double bottom area at different load levels i.e. rule load level and ultimate failure load level are presented in detail. The implication of different design pressures obtained by different rules (CSR-BC rules and DNV rules) on the stress distribution is investigated. Both (partially) heavy cargo AHL and fully loaded cargo AHL are considered. Factors of influence of double bottom bending such as initial imperfections, local loads, stress distribution and failure modes on the hull girder strength are discussed. Simplified procedures for determination of the hull girder strength for bulk carriers under AHL conditions are also discussed in light of
the FE analyses.

Lars Brubak and Jostein Hellesland (Mechanics Division, Department of Mathematics, University of Oslo, P.O. Box 1053, NO-0316 Oslo, Norway), “Strength criteria in semi-analytical, large deflection analysis of stiffened plates in local and global bending”, Thin-Walled Structures, Vol. 46, No. 12, pp 1382-1390, December 2008 DOI: 10.1016/j.tws.2008.03.013

ABSTRACT: Various strength criteria that may be used in semi-analytical methods for ultimate strength prediction of arbitrarily stiffened plates are studied. The main objective is to evaluate the applicability of the criteria in ultimate strength predictions of in-plane loaded plates, both in local and global bending. The equilibrium path is traced using large deflection theory and the Rayleigh–Ritz approach on an incremental form. The approach is able to account for the reserve strength of slender plates in the postbuckling region. Results are compared with fully nonlinear finite element analyses for a variety of plate dimensions and stiffeners with regular and irregular arrangements. Good agreement is obtained with a combination of a plate and a stiffener criterion. With the considered criteria included, the method is computationally very efficient and gives rather high numerical accuracy.

ABSTRACT: In this paper, the optimal stiffener design of moderately thick plates under uniaxial and biaxial compression is investigated on the premise that the plate thickness and the required ultimate strength are given. As the theoretical basis of stiffener design, the ultimate strength formulations of weak stiffened thick panels under in-plane biaxial compression are first developed on the basis of large deflection orthotropic plate theory, in which the post-weld initial deflection is taken into account. The von Mises yield criterion is employed to determine the limit state of the panel, and the Nelder–Mead simplex algorithm is used to obtain the efficient solution of nonlinear differential equations. The optimization method presented is based on the stiffener design principles of the overall instability stress and of the working stress. In the optimization formulation, the numbers and geometric sizes of the stiffeners are defined as design variables; the weight ratio of stiffeners to plate is taken as a single objective function; requirements against overall buckling of the panel, local buckling of the plates between the stiffeners and local buckling of the stiffeners themselves are set as constraint functions. Results of both design examples and parameter studies show that, for moderately thick plates, the stiffener weight given by the proposed optimization method is much lower than the weight determined by the current stiffener design method on the premise of the same requirement of structural safety. Using the present optimization method to obtain the lightest and the most effective stiffener layout for moderately thick plates is proposed.

ABSTRACT: In order to perform a detailed analysis of large deflection behavior of a rectangular plate or stiffened plate, an efficient semi-analytical method is developed. First, incremental forms of the governing differential equations of plates and stiffened plates with initial deflection are derived. These equations are linearized and may be easily solved. Secondly, these equations are solved for each load increment by the Galerkin method with a special consideration of simply supported boundaries. A procedure of equilibrium correction at intermediate load steps is presented such that good accuracy of the solution may be maintained with larger load steps. This method is successfully applied to plates with initial deflection subjected to in-plane as well as out-of-plane loads to obtain the whole histories of the behavior of these plates. Application of this method to stiffened plates with initial deflection is also presented. Comparisons of results obtained by this method with those obtained by other methods are made and the validity of the method is demonstrated. This incremental version of the Galerkin method is found to be extremely advantageous in certain types of plate and stiffened plate problems. These types are identified and the efficiency of the method is demonstrated.

ABSTRACT: A method for analysis of the structural damage due to ship collisions is developed. The method is based on the idealized structural unit method (ISUM). Longitudinal/transverse webs which connect the outer and the inner hulls are modelled by rectangular plate units. The responses are determined by taking into account yielding, crushing, and rupture. Some plates of the outer and the inner shell subjected to large membrane tensions are modelled by membrane tension triangular/rectangular plate units, while the remaining shell panels are modelled by the usual plate units. The effect of stiffeners on the stiffness and the strength is considered as well. In order to include the coupling effects between local and global failure of the structure, the usual nonlinear finite-element technique is applied. In order to deal with the gap and contact conditions between the striking and the struck ships, gap/contact elements are employed. Dynamic effects are considered by inclusion of the influence of strain-rate sensitivity in the material model. On the basis of the theory a computer program has been written. The procedure is verified by a comparison of experimental results obtained from test models of double-skin plated structures in collision/grounding situations with the present solutions. As an illustrative example the procedure has been used for analyses of a side collision of a double-hull tanker. Several factors affecting ship collision response, namely the collision speed and the scantlings/arrangements of strength members, are discussed.

“A numerical investigation of tripping”, Marine Structures, Vol. 11, Nos 4-5, pp 159-183, May 1998
DOI: 10.1016/S0951-8339(98)00010-0
ABSTRACT: The twin aims of the present study are to investigate numerically the characteristics of tripping failure of flat-bar stiffened panels subject to uniaxial compressive loads and also to study the accuracy of two available design formulations. A special-purpose nonlinear finite element method capable of efficiently analyzing the elasto-plastic large deflection behavior of stiffened panels is developed and used in the study. A benefit of the application of the nonlinear finite element method is that it makes possible a rigorous accounting of the interacting effects of stiffener tripping and plating collapse and also the inclusion of the influence of elasto-plastic rotational restraint at the plate-stiffener intersection prior to and during failure. A parametric series of elasto-plastic large deflection analyses for stiffened panels with flat-bar type of stiffeners under uniaxial compressive loads are carried out varying member proportions and structural parameters. Based on the computed results, a basic investigation of tripping behavior of flat-bars is made, and the accuracy of design formulations is studied. The calculations and comparisons of this paper are for flat-bar stiffened panels under uniaxial compression, but the special-purpose finite element method implemented is considerably more general.

ABSTRACT: Aluminum sandwich construction has been recognized as a promising concept for structural design of lightweight transportation systems such as aircraft, high-speed trains and fast ships. The aim of the present study is to investigate the strength characteristics of aluminum sandwich panels with aluminum honeycomb core theoretically and experimentally. A series of strength tests are carried out on aluminum honeycomb-cored sandwich panel specimen in three point bending, axial compression and lateral crushing loads. Simplified theories are applied to analyze bending deformation, buckling/ultimate strength and crushing strength of honeycomb sandwich panels subject to the corresponding load component. The structural failure characteristics of aluminum sandwich panels are discussed. The test data developed are documented.

“Large deflection orthotropic plate approach to develop ultimate strength formulations for stiffened panels under combined biaxial compression / tension and lateral pressure”, Thin-Walled Structures, Vol.39, No.3, pp.215-246, 2001, DOI: 10.1016/S0263-8231(00)00059-8
ABSTRACT: This paper uses the large deflection orthotropic plate approach to develop the ultimate strength formulations for steel stiffened panels under combined biaxial compression/tension and lateral pressure loads, considering the overall (grillage) buckling collapse mode. The object panel has a number of one-sided small stiffeners in either one or both orthogonal directions. The stiffened panel is then modeled as an equivalent orthotropic plate, for which the various elastic constants characterizing structural orthotropy are determined in a consistent systematic manner using classical theory of elasticity. The panel edges are considered to be simply supported. The influence of initial deflections is taken into account. The membrane stress distribution inside the panel under combined uniaxial loading (in either longitudinal or transverse direction) and lateral pressure is
analyzed by solving the nonlinear governing differential equations of large deflection orthotropic plate theory. It is presumed that the panel collapses when the most highly stressed boundary location yields, resulting in closed-form expressions for the ultimate strength of the stiffened panel. Based on the insights previously developed through numerical studies, the panel ultimate strength interaction formulation between biaxial loads, with lateral pressure regarded as a secondary load component is then proposed as a relevant combination of the two sets of panel ultimate strength formulations, i.e. one for combined longitudinal axial load and lateral pressure and the other for combined transverse axial load and lateral pressure. The validity of the proposed ultimate strength formulations is verified by a comparison with nonlinear finite element and other numerical solutions.

“Ultimate strength of ship hulls under torsion”, Ocean Engineering, Vol. 28, No. 8, pp 1097-1133, August 2001
DOI: 10.1016/S0029-8018(01)00015-4

ABSTRACT: For a ship hull with large deck openings such as container vessels and some large bulk carriers, the analysis of warping stresses and hatch opening deformations is an essential part of ship structural analyses. It is thus of importance to better understand the ultimate torsional strength characteristics of ships with large hatch openings. The primary aim of the present study is to investigate the ultimate strength characteristics of ship hulls with large hatch openings under torsion. Axial (warping) as well as shear stresses are normally developed for thin-walled beams with open cross sections subjected to torsion. A procedure for calculating these stresses is briefly described. As an illustrative example, the distribution and magnitude of warping and shear stresses for a typical container vessel hull cross section under unit torsion is calculated by the procedure. By theoretical and numerical analyses, it is shown that the influence of torsion induced warping stresses on the ultimate hull girder bending strength is small for ductile hull materials while torsion induced shear stresses will of course reduce the ship hull ultimate bending moment.

ABSTRACT: This paper develops advanced, yet design-oriented ultimate strength expressions for stiffened panels subject to combined axial load, in-plane bending and lateral pressure. The collapse patterns of a stiffened panel are classified into six groups. It is considered that the collapse of the stiffened panel occurs at the lowest value among the various ultimate loads calculated for each of the collapse patterns. The panel ultimate strengths for all potential collapse modes are calculated separately, and are then compared to find the minimum value which is then taken to correspond to the real panel ultimate strength. The post-weld initial imperfections (initial deflection and residual stress) are included in the developed panel ultimate strength formulations as parameters of influence. The validity of the developed formula is confirmed by comparing with the mechanical collapse tests and nonlinear FEA. A comparison of the present method is also made with theoretical solutions from the Det Norske Veritas classification society design guideline. Important insights developed are summarized.

ABSTRACT: In this paper the ultimate strength characteristics of dented steel plates under axial compressive loads are investigated using the ANSYS nonlinear finite element code. The effects of shape, size (depth, diameter), and location of the dent on the ultimate strength behavior of simply supported steel plates under axial thrust are studied. A closed-form formula for predicting the ultimate compressive strength of dented steel plates are empirically derived by curve fitting based on the computed results. The results and insights developed in the present study will be useful for damage tolerant design of steel plated structures with local denting.

“A concise introduction to the idealized structural unit method for nonlinear analysis of large plated structures and its application”, Thin-Walled Structures, Vol. 41, No. 4, pp 329-355, April 2003

DOI: 10.1016/S0263-8231(02)00113-1

ABSTRACT: The idealized structural unit method (ISUM) has now been widely recognized by researchers as an efficient and accurate methodology to perform nonlinear analysis of large plated structures such as ships, offshore platforms, box girder bridges or other steel structures. This paper presents a summary of pertinent ISUM theory and its application to nonlinear analysis of steel plated structures. Important concepts for development of various ISUM units which are needed to analyze nonlinear behavior of steel plated structures are described. Some application examples are shown, wherein comparisons of ISUM analysis predictions are made with numerical or experimental results for progressive collapse analysis of general types of steel plated structures and ship hulls, to illustrate the possible accuracy and versatility of the ISUM method. The use of ISUM for the analysis of internal collision/grounding mechanics of ships is also illustrated. This paper is in part an attempt to demystify ISUM and its applications for the benefit of a designer of steel plates structures (Paik and Thayambali, Ultimate limit state design of steel plated structures; 2002).
ABSTRACT: The aim of the present study is to obtain experimental data on the ultimate strength of steel plates under dynamically applied axial compressive loads. A series of dynamic collapse tests were carried out on steel plate models under axial compressive loads, varying the loading speed. Based on the test results, the effect of loading speed (or strain rate) on the ultimate strength of steel plates is investigated. Relevant useful formulations for assessing the dynamic ultimate compressive strength of steel plates are also derived as a function of the strain rate by curve fitting. The test data developed are documented.

ABSTRACT: The present paper deals with the estimation of buckling loads of plates with cracking damages. The hierarchical trigonometric functions are used to define the displacement function of the cracked plate. Selective choosing of the trigonometric functions satisfies the various boundary conditions of a plate bounded by support members in a continuous plated structure. Moreover, the analysis of the cracked plate can be carried out with a minimum number of equations accurately. In the present paper, the buckling loads of plates with various types of cracks, such as edge crack and central crack, are estimated under uniaxial compressive load, biaxial compressive load and in-plane shear load. The results are found to correlate well with those obtained using a finite element method.

ABSTRACT: The present study was undertaken by the support from Ship Structure Committee (http://www.shipstructure.org), a North American-based interagency research and development committee, in association with SR-1446 project, and also from Alcan Marine, France. Empirical expressions are developed for predicting the ultimate compressive strength of welded aluminum stiffened panels used for marine applications. Existing data of the ultimate compressive strength for aluminum stiffened panels experimentally and numerically obtained by the SR-1446 project is used for deriving the formulations which are expressed as functions of two parameters, namely the plate slenderness ratio and the column (stiffener) slenderness ratio. The formulae implicitly include the effects of weld induced initial imperfections, and softening in the heat affected zone.

ABSTRACT: The aim of the present study is to investigate the ultimate strength characteristics of perforated steel plates under edge shear loading, which is a primary action type arising from cargo weight and water pressure in ships and ship-shaped offshore structures. The plates are considered to be simply supported along all (four) edges and kept straight. The cutout is circular and located at the center of the plate. A series of ANSYS nonlinear finite element analyses (FEA) are undertaken with varying the cutout size (diameter) as well as plate dimensions (plate aspect ratio and thickness). By the regression analysis of the FEA results obtained, a closed-form empirical formula for predicting the ultimate shear strength of perforated plates, which can be useful for first-cut strength estimations in reliability analyses or code calibrations, is derived. The accuracy of the ultimate strength formula developed is verified by a comparison with more refined nonlinear FEA results.

ABSTRACT: The present paper is a sequel to the author’s papers [Paik JK, Ultimate strength of perforated steel plates under edge shear loading. Thin-Walled Structures 2007; 45: 301–6, Paik JK Ultimate strength of perforated steel plates under axial compressive loading along short edges. Ships Offshore Struct, 2007; 2(3): (in press)]. In contrast to the previous papers with the focus on edge shear or uniaxial compressive loads, the aim of the present study is to investigate the ultimate strength characteristics of perforated steel plates under combined biaxial compression and edge shear loads, which is a typical action pattern of steel plates arising from cargo weight and water pressure together with hull girder motions in ships and ship-shaped offshore structures. The plates are considered to be simply supported along all (four) edges, keeping them straight. The cutout is circular and located at the center of the plate. A series of ANSYS nonlinear finite element analyses (FEA) are undertaken with varying the plate dimension (thickness). Based on the FEA results obtained, closed-form empirical formulae of the ultimate strength interaction relationships of perforated plates between combined loads, which can be useful for first-cut estimations of the ultimate strength in reliability analyses or code calibrations, are derived.

ABSTRACT: It is well known that welding-induced initial deflections, among other factors, significantly affect the ultimate strength behavior of welded plate structures. This means that it is of vital importance to identify the features of plate initial deflections prior to the plate ultimate strength computations. The aim of the present paper is to investigate the characteristics of initial deflections that occur during welding fabrication of aluminum plates used for marine applications. A total of 78 single and multi-bay stiffened plate prototype aluminum structures which are full scale equivalent to sub-structures of an 80 m long all aluminum high speed vessel are constructed by metal inert gas (MIG) welding. Initial deflections of plating between stiffeners are then measured. A statistical analysis of the measured database is performed to determine mean and coefficient of variation (COV) of the plate initial deflection. The insights developed from the present study will be very useful for reliability analyses and code calibrations of ultimate limit state strength and fabrication quality control for welded aluminum plate structures.

Jeom Kee Paik, Bong Ju Kim and Jung Kwan Seo (Department of Naval Architecture and Ocean Engineering,
ABSTRACT: The present paper is Part I of a series of three papers prepared by the authors on the methods useful for ultimate limit state assessment of marine structures, that have been developed in the literature during the last few decades. It is considered that such methods are now mature enough to enter day-by-day design and strength assessment practice. The aims of the three papers are to conduct some benchmark studies of such methods on ultimate limit state assessment of (unstiffened) plates, stiffened panels, and hull girders of ships and ship-shaped offshore structures, using some candidate methods such as ANSYS nonlinear finite element analysis (FEA), DNV PULS, ALPS/ULSAP, ALPS/HULL, and IACS common structural rules (CSR) methods. As an illustrative example, an AFRAMAX-class hypothetical double hull oil tanker structure designed by CSR method is studied. In the present paper (Part I), the ultimate limit state assessment of unstiffened plates under combined biaxial compression and lateral pressure loads is emphasized using ANSYS, DNV PULS, and ALPS/ULSAP methods, and their resulting computations are compared. Part II will deal with methods for the ultimate limit state assessment of stiffened panels under combined biaxial compression and lateral pressure using ANSYS, DNV PULS, and ALPS/ULSAP methods, and Part III will treat methods for the progressive collapse analysis of the hull structure using ANSYS, ALPS/HULL, and IACS CSR methods.

ABSTRACT: The present paper is Part II of a series of three papers on methods useful for the ultimate limit state assessment of ships and ship-shaped offshore structures. In contrast to Part I [Paik et al., 2007a. Methods for ultimate limit state assessment of ships and ship-shaped offshore structures: Part I unstiffened plates, Ocean Engineering, doi:10.1016/j.oceaneng.2007.08.004] that deals with unstiffened plates, the present paper (Part II) is focused on methods for the ultimate limit state assessment of stiffened plate structures under combined biaxial compression and lateral pressure actions. The object structure is the bottom part of an AFRAMAX-class hypothetical double-hull oil tanker structure designed by IACS common structural rules (CSR) method, that is the same ship studied in Part I. Three candidate methods, namely ANSYS nonlinear finite element method, DNV PULS method, and ALPS/ULSAP method, are employed for the present study. The results and insights developed from the present study are summarized in terms of ultimate strength characteristics of bottom-stiffened plate structures.

ABSTRACT: Box columns are often used as main strength members of various types of thin-walled structures such as ships, ship-shaped offshore structures, and aerospace structures. Until and after the ultimate limit state is reached, box columns exhibit highly nonlinear structural behavior in terms of geometrical and material aspects. In particular, the effects of local buckling, global buckling, and their interaction play a significant role in the resulting consequences of box columns under extreme actions. In order to calculate the maximum load-carrying capacity of box columns, it is thus highly required to perform the progressive collapse analysis to take into
account progressive failures of individual components and their interacting effects. The aim of the present study is to demonstrate a method that is useful for the progressive collapse analysis of thin-walled box columns in terms of computational efficiency and accuracy. Theoretical outline of the method is addressed. Short, medium and long box columns in length are studied in terms of interacting effects between local component failure modes and global system failure modes. The effect of unloaded edge conditions of individual plate elements is also studied. A comparison of the method with more refined nonlinear finite element method computations is made.

“Numerical method for predicting the elastic lateral distortional buckling moment of a mono-symmetric beam with web openings”, Thin-Walled Structures, Vol. 49, No. 6, pp 713-723, June 2011
DOI: 10.1016/j.tws.2011.01.003

ABSTRACT: When used as floor joists, the new mono-symmetric LiteSteel beam (LSB) sections require web openings to provide access for inspections and various services. The LSBs consist of two rectangular hollow flanges connected by a slender web, and are subjected to lateral distortional buckling effects in the intermediate span range. Their member capacity design formulae developed to date are based on their elastic lateral buckling moments, and only limited research has been undertaken to predict the elastic lateral buckling moments of LSBs with web openings. This paper addresses this research gap by reporting the development of web opening modelling techniques based on an equivalent reduced web thickness concept and a numerical method for predicting the elastic buckling moments of LSBs with circular web openings. The proposed numerical method was based on a formulation of the total potential energy of LSBs with circular web openings. The accuracy of the proposed method's use with the aforementioned modelling techniques was verified through comparison of its results with those of finite strip and finite element analyses of various LSBs.

ABSTRACT: The primary objective of the present paper is to experimentally examine the buckling collapse characteristics of fusion welded aluminum-stiffened plate structures under axial compression until and after the ultimate limit state is reached. The secondary objective of the paper is to study a nonlinear finite element method modeling technique for computing the ultimate strength behavior of welded aluminum structures. A set of aluminum-stiffened plate structures fabricated via gas metal arc welding is studied. The test structure is equivalent to a full scale deck structure of an 80 m long high speed vessel. The plate part of the structures is made of 5383-H116 aluminum alloy, and extruded stiffeners are made of 5083-H112 aluminum alloy. Welding induced initial imperfections such as plate initial deflection, column type global initial deflection of stiffeners,
sideways initial distortion of stiffeners, welding residual stresses, and softening in the heat-affected zone are measured. The ANSYS nonlinear finite element method is employed for the numerical computations of the test structure’s ultimate strength behavior by means of a comparison with experimental data. Insights and conclusions developed from the present study are documented.

ABSTRACT: The formulation of a nonlinear composite shell element is presented for the solution of stability problems of composite plates and shells. The formulation of the geometrical stiffness presented here is exactly defined on the midsurface and is efficient for analyzing stability problems of thin and thick laminated plates and shells by incorporating bending moment and transverse shear resultant forces. The composite element is free of both membrane and shear locking behavior by using the assumed natural strain method such that the element performs very well as thin shells. The transverse shear stiffness is defined by an equilibrium approach instead of using the shear correction factor. The proposed formulation is computationally efficient and the test results showed good agreement. In addition the effect of the viscoelastic material is investigated on the postbuckling behaviour of laminated composite shells.

ABSTRACT: A co-rotational, quasi-conforming formulation of a 4-node stress resultant shell element is presented for non-linear analysis of plate and shell structures. The tangent stiffness matrix in this quasi-conforming formulation is explicitly integrated. This makes the element computationally efficient in incremental, non-linear analysis. It includes drilling degrees of freedom, which improves membrane behavior and allows the modeling of stiffened plates and shells. It is also free of shear locking behavior. The formulation of the geometrical stiffness is derived using the full definition of Green strain tensor. The inclusion of the bending moment and transverse shear resultant forces in the geometric stiffness allows effective analysis of stability problems of moderately thick plates and shells. The stresses are accurately taken at the nodal points without extrapolation. The plasticity is traced by applying the von Mises yield condition and Prandtl–Reuss flow rule to discrete points through the thickness. The multi-layered approach is based on equally spaced stations, including extreme fibers. A modified trapezoidal rule is used for the numerical integration of the constitutive relation in the plasticity part. Numerous tests are carried out for the non-linear validation of present 4-node shell element and the results are in good agreement with references.

ABSTRACT: In this paper, we investigate the natural frequencies and buckling loads of functionally graded material (FGM) plates and shells, using a quasi-conforming shell element that accounts for the transverse shear strains and rotary inertia. The eigenvalues of the FGM plates and shells are calculated by varying the volume fraction of the ceramic and metallic constituents using a sigmoid function, but the Poisson ratios of the FGM plates and shells are assumed to be constant. The expressions for the membrane, bending and shear stiffness of FGM shell elements are more a complicated combination of material properties than a homogeneous element. In order to validate the finite element numerical solutions, the Navier solutions for rectangular plates based on the first order shear deformation theory are also presented. The present numerical solutions for composite and sigmoid FGM (S-FGM) plates and shells are verified by the Navier solutions and various examples of composite and FGM structures. The present results are in good agreement with the Navier theoretical solutions.

ABSTRACT: The quasi-conforming technique was introduced in the 1980’s to meet the challenge of inter-elements conforming problems and give a unified treatment of both conforming and nonconforming elements. While the linear formulation is well established, the nonlinear formulation based on the quasi-conforming technique that includes geometric and material nonlinearity is presented in this paper. The formulation is derived in the framework of an updated Lagrangian stress resultant, co-rotational approach. The geometric nonlinear formulation provides solutions to buckling and postbuckling behaviour while the material nonlinear formulation considers the spread of plasticity within the element while maintaining an explicit construction of element matrices. Aside from the elasto-plastic constitutive relation, formulations on laminate composites and reinforced concrete are also presented.
The formulations of laminate composite and reinforced concrete material are present based on the layer concept, the material properties can vary throughout the thickness and across the surface of a shell element. The various failure criteria for laminate composite are included in the formulation which makes it possible to analyses the progressive failure of fibre and matrix. For the reinforced concrete material, the nonlinearities as a result of tensile cracking, tension stiffening between cracks, the nonlinear response of concrete in compression, and the yielding of the reinforcement are considered. The steel reinforcement is modeled as a bilinear material with strain hardening.

ABSTRACT: In this paper the ability of the basic shell triangular (BST) element to perform linearized buckling analysis is evaluated. The results have been compared with analytical solutions and other finite elements in the literature, such as ANDES3, ANDES4, QSEL, FFQC and BCIZ. This type of analysis is applied to the design of steel structures to obtain the collapse load of panels using the effective width of the plate. In this approach, which is currently recommended by most of the design standards, a semi-empirical/analytical method is used to take into account the nonlinear geometric and material behavior, geometric imperfections and residual stresses. To obtain the critical loads two methods have been mainly applied: the finite strip method and the finite element method, which is more appropriate to deal with any boundary condition and loading pattern. In practice, to obtain the local and distortional buckling, some assumptions related to the interaction between plates are made in order to obtain practical formulae that can be applied; these simplifications can lead to unsafe results, so the linearized buckling analysis must be carried out in a proper way, taking into account the interactions. It is concluded that the BST element presents an excellent behavior to predict the critical loads in compression and shear, and therefore this element must be utilized in future codes when this type of analysis turns out to be mandatory.

ABSTRACT: A nonlinear resultant shell element is developed for the solution of problems of composite plates and shells undergoing nonlinear static and nonlinear dynamic behavior with progressive layer failure. The formulation of the tangent stiffness is defined on the mid-surface and is efficient for analyzing thick laminated plates and shells by incorporating bending moments and transverse shear resultant forces in the geometric stiffness. The composite element is free of both membrane and shear locking behavior by using the assumed natural strain method, such that the element also performs very well as thin laminate shells. An equilibrium approach is used to derive the improved transverse shear stiffness, instead of using a shear correction factor. The proposed formulation is computationally efficient and the test results show good agreement with references. The composite shell element is extended to determine ply failures in laminated composite structures undergoing nonlinear static or dynamic behavior. The failure analysis is done by first, computing for the inter-laminar stresses at each gauss point in an element. Having obtained the stresses in each layer, checking for failure is performed based on a chosen failure criterion. Four failure criteria are available to enable the user to adopt the appropriate criterion for the type of problem parameters present.

ABSTRACT: In computing eigenvalues for a large finite element system it has been observed that the eigenvalue extractors produce eigenvectors that are in some sense more accurate than their corresponding eigenvalues. From this observation the paper uses a patch type technique based on the eigenvector for one mesh quality to provide an eigenvalue error indicator. Tests show this indicator to be both accurate and reliable. This technique was first observed by the authors for an error estimation for the buckling and natural frequency of beams and for two-dimensional in plane structures. This paper produces an error indicator for the more complex problem of out-of-plane plate buckling analysis.
ABSTRACT: The main objective of this article is to present an overview of the modelling that has been proposed by various workers in the field of smart or intelligent structures. Before the main discussion on the various models, some background information will be presented in relation to intelligent structures and the types of adaptive materials that are available. Although there are several categories of materials that can be implemented in intelligent structures, this article will focus on models that use piezoelectric materials as sensors and/or actuators (S/A). The modelling of the intelligent structures can be categorized in terms of the structural configuration (e.g., rod composites, fibre composites, monolithic structures, etc.) and also according to the type of modelling whether by finite element modelling or by analytical exact solutions. Models in this field of work had incorporated concepts from different background including three-dimensional linear elastic theory and dielectric theory to give rise to the linear piezoelectric model. Rules of Mixture and methods for calculating effective properties of fibre composites were extended to include piezoelectric fibre composite models. Classical Laminated Plate Theory was also adopted in laminated composite models where some laminae were piezoelectric materials. Exact solutions were applied to simple models and illustrated the potential of using piezoelectrics. Finite element techniques were used for more complicated problems that included complex geometries, nonlinear behaviour and dynamic control of the structure. The difference between induced strain and actuation strain is usually not addressed when using FE techniques, instead the piezoelectric strain can be regarded as an equivalent external force/moment or incorporated into the strain energy. In regard to control algorithms, the most common form applied by investigators in this field seems to be the negative velocity feedback control with single input and single output and some included linear quadratic control. More advanced control algorithms such as using multiple input and multiple output or even neural networks are less established.

ABSTRACT: The nonlinear mechanics for piezoelectric laminates and plates is presented, including nonlinear effects due to large displacements and rotations. The mechanics is incorporated into the piezoelectric mixed-field laminate theory. Using this mechanics, a nonlinear finite-element method and an incremental solution are formulated for the nonlinear analysis of adaptive plate structures. An eight-node-plate finite element is developed. The mechanics is applied to predict the buckling of piezoelectric plates induced by combined electromechanical loading. Application cases quantify the mechanical buckling of composite beams and plates with piezoelectric sensors, the piezoelectric buckling of active beams and plates, and the feasibility of active buckling compensation.

ABSTRACT: A theoretical framework for analyzing the pre- and postbuckling response of composite laminates and plates with piezoactuators and sensors is presented. The mechanics include nonlinear effects due to large rotations and stress stiffening, and are incorporated into a coupled mixed-field piezoelectric laminate theory. Using the previous mechanics, a nonlinear finite element method and an incremental-iterative solution are formulated for the analysis of nonlinear adaptive plate structures subject to in-plane electromechanical loading. A novel eight-node nonlinear plate finite element is also developed. Evaluation cases predict the buckling and postbuckling response of adaptive composite beams and plates with piezoelectric actuators and sensors. The case of piezoelectric buckling and postbuckling induced by the actuators is addressed and quantified. Finally, the possibility to actively mitigate the mechanical buckling and postbuckling response of adaptive piezocomposite plates is illustrated.

Ishikawa, Takashi; Matsushima, Masamichi; Hayashi, Yoichi (Composite Structure Section, Airframe Division, National Aerospace Laboratory, 6-13-1 Ohsawa, Mitaka-shi, Tokyo 181, Japan), “Improved correlation of predicted and experimental initial buckling stresses of composite stiffened panels”, Composite Structures, Vol. 26, Nos. 1-2, 1993, pp. 25-38, doi:10.1016/0263-8223(93)90041-N

ABSTRACT: Experimental and numerical investigations are conducted for rigorous correlation of initial buckling properties of stiffened panels made of carbon fiber/poly-ether-ether-ketone (CF/PEEK) and CF/epoxy. Decreasing longitudinal elastic modulus of unidirectional CF composites lamina in compression plays a key role for better numerical predictions. A consideration of end fixtures in finite element modeling plays another key role in correlation and both initial buckling stress and mode for the short panels used here. A quarter finite element model with an end fixture by hypothetical symmetry is considered as the irreducible minimum in the modeling. A careful setting of lamina thickness is also important for better predictions. Initial imperfection close to the real shape of CF/PEEK panels is taken into account and an improvement in correlation of predicted and experimental results is reached. A conventional Rayleigh-Ritz approach considering only a local buckling mode of skin is developed. This analytical prediction compares fairly well with the numerical and experimental results in the preceding work in which their stringers are stiff enough.

ABSTRACT: Numerical predictions of linear buckling and post-buckling behavior of CFRP T-stiffeners are conducted by Finite Element Analysis. Such behavior is crucially important in aircraft structural design. Comparison between numerical predictions and experimental behavior is executed in detail. Width-to-thickness ratio in flange or web mainly governs linear buckling stresses. Inserted filler along the intersection line between flange and web also considerably affects the linear buckling behavior. By taking realistic initial imperfection into account, geometrical nonlinear analysis provides fairly descriptive post-buckling deflection behavior in flange and web. It is also possible to predict the final failure stress by assuming simple failure criteria and non-progressive failure.
ABSTRACT: This paper investigates the sensitivity of the buckling and post-buckling behaviour of imperfect steel plates used in ship and related marine structures when subject to variations in their initial conditions. The different aspects analysed comprise of variation in aspect ratio, boundary conditions, initial out-of-plane imperfection and material elastic and plastic properties such as strain hardening. The analyses were carried out using the non-linear finite element program ABAQUS. The results obtained for the several plate models show that the three most relevant parameters affecting the buckling and post-buckling of uniaxially loaded plates are aspect ratio, unloaded edges boundary conditions and initial out-of-plane imperfection amplitude.

ABSTRACT: Equations are derived to assess the strength of plates subjected to biaxial compressive loads, including the effect of initial distortions and residual stresses. These equations are then extended to the case of simultaneous lateral pressure loads. In calibrating the proposed methods and in assessing their model uncertainty published results of experiments and of numerical calculations have been used. The proposed methods were shown to be unbiased as regards plate slenderness and aspect ratio. The model uncertainty of each method was quantified and thus can be used to derive design formulations with the desired level of safety.

ABSTRACT: This paper presents the results of a parametric study to quantify the effect of lateral pressure on the collapse of square and rectangular steel plates under a predominantly compressive load. The load-shortening behaviour of square and rectangular plates under the combined effect of longitudinal compression and lateral pressure were obtained using a general-purpose non-linear finite element code for different breadth to thickness ratios. Finally design curves are proposed to predict the collapse strength of the compressed plates under lateral pressure.

ABSTRACT: This paper presents the results of an experimental investigation to determine the torsional ultimate strength of a ship-type hull girder with a large deck opening. A comparison between nonlinear finite element calculations and the experimental results for the two models is presented. The effect of different assumptions and of the variation of different parameters is studied.

ABSTRACT: A method for reliability assessment of the post-buckling compressive strength of laminated composite plates and stiffened panels under axial compression is presented in the paper. The prediction of the post-buckling compressive strength is performed by a progressive failure analysis which was developed based on a progressive stiffness degradation model and a nonlinear finite element analysis with a new explicit through-thickness integration scheme. A method coupled with the finite element analysis is proposed for reliability assessment where a finite difference method combined with an improved first-order reliability algorithm that omits the non-important random variables but retains sufficient accuracy was developed for reliability estimation. Two numerical examples are described demonstrating the capabilities of the method developed.

ABSTRACT: Test results are presented of eight stiffened panels subjected to axial compression until collapse and beyond. The specimens are three-bay stiffened panels with associated plate made of very high tensile steel S690. The use of this very high strength steel led to the unconventional solution of using U stiffeners and this paper aims at understanding the difference of performance of this stiffener type as compared with the conventional ones. Four different configurations are considered for the stiffeners, which are made of mild or high tensile steel for bar stiffeners and mild steel for ‘L’ and ‘U’ stiffeners. The influence of the stiffener's geometry on the ultimate strength of the stiffened panels under compression is analyzed.

ABSTRACT: Results of eight tests on long stiffened panels under axial compression until collapse are presented. The specimens are three-bay panels with associated plates made of very high tensile steel S690. Four different configurations are considered for the stiffeners, which are made of mild or high tensile steel for bar stiffeners and mild steel for L and U shape stiffeners. The influence of the stiffener’s geometry on the ultimate strength of the stiffened panels under compression is analyzed. This series of experiments belongs to an extended series of tests that include short and intermediate panels, which allows analyzing the effect of space framing on the strength of stiffened panels.

ABSTRACT: A system reliability analysis of an oil tanker bottom component which consists of a stiffened panel under combined uniaxial compression and lateral sea pressure loads is presented in this paper. The stiffened panel is idealized as a structural system composed by several stiffeners with attached plating in parallel. The structural capacity of each stiffener with attached plating or system component is described by a nonlinear finite element model, considering as failure criterion the buckling collapse under the combined uniaxial compression and lateral sea pressure loads. These load components are defined considering a typical seagoing operational condition of the oil tanker in ballast load. The uncertainty in the relevant design basic variables is quantified using stochastic models proposed in the literature. To efficiently solve the structural system reliability problem a Monte Carlo based reliability estimation method recently proposed is combined with a response surface method. The combination of these two methods has been shown to be an efficient technique to solve structural system reliability problems that involve computationally demanding numerical models to describe the structural capacity of the system components. Annual probabilities of buckling collapse failure of the stiffened panel are estimated using this solution technique. The effect of corrosion on the stiffened panel reliability is quantified. The importance of considering the lateral sea pressure and correlation between the local and global wave-induced loads in the reliability problem are evaluated.

ABSTRACT: Five specimens are tested under axial compression until collapse to investigate the ultimate strength of wide stiffened panels with four stiffeners. To avoid the side bays collapse and reduce the influence of the clamped boundary condition on the collapse behaviour, the tests are made on panels with two half bays plus one full bay in the longitudinal direction with simply supported condition at the end edge of loading. Initial loading cycles are used to release the residual stresses of the stiffened panels and the gap between the stiffened panels and the supported steel block. Strain gauges are installed on the plates and the stiffeners to record the distribution of strain. This series of experiments is compared to a series of tests with narrow panels (two stiffeners), which allows analysing the effect of the width on the strength of stiffened panels.

ABSTRACT: The results of five tests on narrow stiffened panels under axial compression until collapse and beyond are presented to investigate the collapse behaviors of stiffened panels. Tension tests were used to evaluate the material properties of the stiffened panels. The tests were made on panels with two half bays plus one full bay in the longitudinal direction. Initial loading cycles were used to eliminate the residual stresses of the stiffener panels. The strain gauges were set on the plates and the stiffeners to record the strain histories. The
displacement load relationship was established. The collapse behavior, modes of failure and load-carrying capacity of the stiffened panels are investigated with the experiment.

ABSTRACT: The aim of this paper is to determine an appropriate configuration of the boundary conditions and geometric model to calculate the ultimate strength of a continuous stiffened panel under compressive loading in the finite element (FE) analysis. The $1 + 1$ spans model with periodical symmetric boundary conditions is proposed to be used in the FE analysis, whose results are compared with the $1/2 + 1 + 1/2$ span model with periodical symmetric and symmetric boundary condition, and the $1/2 + 1 + 1 + 1/2$ span model with symmetric boundary conditions. The effects of the continuity of the stiffened panel with different geometric models and boundary conditions on its collapse mode are investigated. A beam tension test has been used to define the true stress-strain relationship in the FE analysis. The two-span model, either $1 + 1$ or $1/2 + 1 + 1/2$, with periodical symmetric conditions give a reasonable FE modeling, which can consider both odd and even number half waves and, thus, have the smallest model uncertainty.

DOI: 10.1016/j.marstruc.2013.09.002

ABSTRACT: A series of finite element analyses are conducted to investigate the influence of boundary conditions and geometry of the model on the predicted collapse behaviour of stiffened panels. Periodic and symmetric boundary conditions in the longitudinal direction are used to calculate the ultimate strength of stiffened panels under combined biaxial thrust and lateral pressure. The calculated ultimate strength of stiffened panels are compared with those by different FEM (finite element method) code and are assessed. The periodic boundary condition in the longitudinal direction for two spans or bays model provides an appropriate modelling to a continuous stiffened panel and can consider both odd and even number of half waves and thus, is considered to introduce the smaller model uncertainty for the analysis of a continuous stiffened panel.

ABSTRACT: This work deals with the evaluation of the ultimate bending moment of a severely corroded box girder subjected to uniform vertical bending moment through a series of nonlinear finite element analysis. Two models of corrosion degradation have been adopted, one is an average general corrosion thickness reduction,
and the other is the real thickness of the corroded plates. New stress–strain relations have been developed to account for the effect of corrosion on the flexural rigidity. To validate the new developed stress–strain relationships, a comparison between the finite element analysis results using the existing stress–strain models, the newly developed ones and the experimental test results of a severely corroded box girder have been conducted. The comparison showed a good agreement and supported the choice of the newly developed stress–strain relationships of corroded structures.

ABSTRACT: Recent developments in the aircraft industry towards substantially improving fuel economy and extending flight range have accelerated interest in the use of advanced composites as primary structural materials. The airframes of next-generation airliners will have substantial parts made of light-weight composites. This means that the engineering demands on the performance of fiber-reinforced composites will become greater. There is therefore a need to better understand and predict the multiple complex failure mechanisms in composite structures, and to devise more reliable failure theories and damage progression models. There is a large body of literature on progressive damage analysis in composites, much of which employs damage mechanics and material stiffness degradation methods. This article reviews some of the more recent work in this area and describes the issues pertinent to application in composite structures. The authors' ongoing research efforts in modeling and prediction of progressive damage through the relatively novel element-failure method (EFM), which has been coded into a user-defined UEL code in Abaqus, are discussed. In particular, results for notched composite laminates and pin-loaded (PL) analyses are shown and compared to experimental data. Although EFM is the computational platform on which the damage is advanced in the structure, the results are dependent on the choice of the failure criterion. Various failure criteria are used throughout the cases discussed herein, from the more traditional Tsai—Wu (TW) criterion to the very recently proposed micromechanics-based failure (MMF) criterion. The EFM may also be used with cohesive elements, with the former intended for modeling in-plane damage progression, while the latter for delamination onset and propagation. This hybrid EFM-cohesive element approach is illustrated with an analysis of double-notched composite laminate. The computational models are relatively robust up to and including ultimate load, and enable the mapping of extensive damage patterns in composite structures. They represent a suite of computational tools that extend the capability to model damage and failure propagation beyond initial failure prediction.

ABSTRACT: The object of this paper is to develop a finite displacement theory of naturally curved and twisted rods undergoing finite rotations. Particular attention is paid to investigate the coupling of finite rotations in space under the Bernoulli-Euler hypothesis. A finite rotation vector is employed to derive the displacement field available for finite rotations. A new variable is introduced as a fourth parameter associated with rotations of cross sections. Then the twist and curvatures after the deformation are expressed in terms of four parameters without using small-strain assumptions. The equilibrium equations and the associated boundary conditions, in
which second order terms with respect to displacement components are fully taken into account, are derived from the principle of virtual work. The accuracy of the present equilibrium equations is confirmed through comparisons with those obtained by the equilibrium method.

ABSTRACT: This paper deals with finite rotations, and finite strains of three-dimensional space-curved elastic beams, under the action of conservative as well as nonconservative type external distributed forces and moments. The plausible deformation hypothesis of “plane sections remaining plane” is invoked. Exact expressions for the curvature, twist, and transverse shear strains are given; as is a consistent set of boundary conditions. General mixed variational principles, corresponding to the stationarity of a functional with respect to the displacement vector, rotation tensor, stress-resultants, stress-couples, and their conjugate strain-measures, are stated for the case when conservative-type external moments act on the beam. The momentum-balance conditions arising out of these functionals, either coincide exactly with, or are equivalent to, those from the “static method”. The incremental variational functionals, governing both the Total and Updated Lagrangian incremental finite element formulations, are given. An example of the case of the buckling of a beam subject to axial compression and non-conservative type axial twisting couple, is presented and discussed.

Atluri (Computational Modeling and Infrastructure Rehabilitation Center, Georgia Institute of Technology, 30332-0356, Atlanta, GA, USA), “Postbuckling analysis of stiffened laminated composite panels, using a higher-order shear deformation theory”, Computational Mechanics, Vol. 9, No. 6, pp 390-404, 1992

ABSTRACT: The investigation aims at: (i) constructing a modified higher-order shear deformation theory in which Kirchhoff’s hypotheses are relaxed, to allow for shear deformations; (ii) validating the present 5-parameter-smeared-laminate theory by comparing the results with exact solutions; and (iii) applying the theory to a specific problem of the postbuckling behavior of a flat stiffened fiber-reinforced laminated composite plate under compression. The first part of this paper is devoted mainly to the derivation of the pertinent displacement field which obviates the need for shear correction factors. The present displacement field compares satisfactorily with the exact solutions for three layered cross-ply laminates. The distinctive feature of the present smeared laminate theory is that the through-the-thickness transverse shear stresses are calculated directly from the constitutive equations without involving any integration of the equilibrium equations. The second part of this paper demonstrates the applicability of the present modified higher-order shear deformation theory to the post-buckling analysis of stiffened laminated panels under compression. To accomplish this, the finite strip method is employed. A C²-continuity requirement in the displacement field necessitates a modification of the conventional finite strip element technique by introducing higher-order polynomials in the direction normal to that of the stiffener axes. The finite strip formulation is validated by comparing the numerical solutions for buckling problems of the stiffened panels with some typical experimental results.

ABSTRACT: An analytical investigation is conducted to predict the post-buckling strength of laminated composite stiffened panels under compressive loads. When a stiffened composite panel buckles, the skin would deform into a sinusoidal mode shape, and hence induces additional moments and forces near the skin-stiffener interface region. These induced loads would cause the existing small edge delamination cracks to propagate along the skin-stiffener interface, and this in turn would lead to the global failure of the stiffened panel. To reduce the cost of the analytical investigation, the failure of the stiffened panel under post-buckling loads is modeled in two stages: a global analysis to model the post-buckling behavior of the stiffened panel; and a local analysis to model the onset of propagation of the edge delamination crack at the skin-stiffener interface. The results from this study are compared with an experimental investigation conducted by Starnes, Knight, and Rouse (1987). It is found that for the eight different specimens that are considered in this study, the calculated critical energy release rate for the propagation of the edge delamination crack in each specimen differs substantially from those for the others; hence it may be concluded that the total energy release rate would not be a suitable fracture parameter for predicting the post-buckling strength of the stiffened panels. On the other hand, using the fracture criterion based on the critical mixed-mode stress intensity factors, the predicted post-buckling strength of the stiffened panels compares quite favorably with the experimental results and the standard deviation of the error of prediction is less than 10%. Furthermore, by applying the criterion of critical mixed-mode stress intensity factors on a simple damage model, the present analysis is able to predict the significant reduction in the post-buckling strength of stiffened panels with a damage due to a low-speed impact at the skin-stiffener interface region.

ABSTRACT: An efficient formulation for dynamic analysis of planar Timoshenko’s beam with finite rotations is presented. Both an inertial frame and a rotating frame are introduced to simplify computational manipulation. The kinetic energy of the system is obtained by using the inertial frame so that it takes a quadratic uncoupled form. The rotating frame together with the small strain assumption is employed to derive the strain energy of the system. Since the exact solutions for linear static theory of Timoshenko’s beam are used to obtain the strain energy, the present stiffness operator is free from the locking problem without using any special technique. The resulting equations of motion of the system are defined in terms of a fixed global coordinates system. Nonlinear effects appear only in the transformation of displacement components between global and local coordinates. This results in a drastic simplification of nonlinear dynamic analysis of flexible beams. Numerical examples demonstrate the accuracy and efficiency of the present formulation.

ABSTRACT: A simple method to follow the postbuckling paths in the finite element analysis is presented. During a standard path-following by means of arc-length method, the signs of diagonal elements in the triangularized tangent stiffness matrix are monitored to determine the existence of singular points between two adjacent solution points on paths. A simple approach to identify limit or bifurcation points is developed using the definition of limit points and the idea of generalized deflections. Instead of the exact bifurcation points, the approximate bifurcation points on the secants of the solution paths are solved. In order to follow the required
postbuckling branches at bifurcation points, the asymptotic postbuckling solution at the approximate bifurcation points, and the initial postbuckling behaviour based on Koiter's theory are given and used for the branch-switching. Some numerical examples of postbuckling behaviour of metallic as well as laminated composite structures are computed using a “quasi-conforming” triangular shell element to demonstrate the proposed method.

ABSTRACT: In this paper, a unified method is presented: (i) to model delaminated stiffened laminated composite shells; (ii) for synthesising accurate multiple post-buckling solution paths under compressive loading; and (iii) for predicting delamination growth. A multi-domain modelling technique is used for modelling the delaminated stiffened shell structures. Error-free geometrically nonlinear element formulations — a 2-noded curved stiffener element (BEAM2) and a 3-noded shell element (SHELL3) — are used for the finite element analysis. An accurate and simple automated solution strategy based on Newton type iterations is used for predicting the general geometrically nonlinear and postbuckling behaviour of structures. A simple method derived from the 3-dimensional J-integral is used for computing the pointwise energy release rate at the delamination front in the plate/shell models. Finally, the influence of post-buckling structural behaviour and the delamination growth on each other has been demonstrated.

ABSTRACT: Results from an experimental and analytical study of a curved stiffened aluminum panel subjected to combined mechanical and internal pressure loads are presented. The panel loading conditions were simulated using a D-box test fixture. Analytical buckling load results calculated from a finite element analysis are presented and compared to experimental results. Buckling results presented indicate that the buckling load of the fuselage panel is significantly influenced by internal pressure loading. The experimental results suggest that the stress distribution is uniform in the panel prior to buckling. Nonlinear finite element analysis results
correlates well with experimental results up to buckling.

ABSTRACT: An initial experimental and analytical investigation was conducted to examine the effects of the inherent mechanical couplings exhibited in fully anisotropic (i.e. unsymmetric) graphite/epoxy laminates on the buckling loads and mode shapes. Experimental techniques were devised to test 254 mm square plates of AS1/3501-6 graphite/epoxy under uniaxial compressive load with free, simply-supported and clamped edges. The results indicate that the mechanical couplings, especially those which relate stretching and bending behavior, cause out-of-plane deflections prior to buckling and reduce the buckling load significantly, i.e. the load at which out-of-plane deflections become large. The analytical results also show that the buckled mode shapes exhibit twisting due to the mechanical couplings. Suggestions are offered for improvements in the experimental and analytical techniques to better understand these phenomena.

ABSTRACT: A study was conducted to evaluate the reliability of a sandwich column specimen for uniaxial compressive tests. Both stress-strain and failure behavior were observed, and comparisons were made with predictions from existing techniques. The properties of the aluminum honeycomb core were also measured and included in the analysis to show its limited effects on the overall behavior of the specimen. Control tests were performed on specimens with aluminum facesheets to further quantifiy the effect of the honeycomb core on the overall behavior of the structure. The main battery of tests was conducted with graphite/epoxy facesheets of [theta12], [+theta/-theta/0]s, and [0/+theta/-theta]s configurations. The general excellent correlations between
the observed moduli and Poisson’s ratios and predicted values indicate that the specimen provides true stress-strain behavior. Moreover, consistent failure modes within the test section including both in-plane failure and ply buckling or delamination failure followed by in-plane failure indicate that the specimen is valid for failure behavior data.

ABSTRACT: The response of laminated cylindrical composite shell structures to transverse loading was studied through impact and quasi-static testing. A highly nonlinear structural instability phenomenon, closely resembling a snap-through instability, was found to have a strong influence on the loading/impact response including the resulting damage. Because of this structural instability, the behavior of convex shells under static or dynamic (i.e., impact) transverse loading is found to be much different than that for plates. These differences include trends displayed in the response parameters as well as damage extent and distribution. Convex shells with a response instability are found to have increased impact damage resistance compared with plates. A concept is proposed wherein the instability provides a mechanism, not available in plates, by which shell structures dissipate impact energy through structural deformation and thus exhibit improved impact damage resistance. Conversely, convex shells with no response instability have decreased impact damage resistance compared with plates. The differences in composite shell and plate behavior, particularly damage resistance, have important ramifications to the design of damage tolerant aerospace components and are discussed.

ABSTRACT: The damage resistance of thin composite structures was investigated experimentally. Specifically, surface damage in the form of dent-depth measurements are compared with internal damage states obtained by the X-radiography technique to better understand the implications of "barely visible impact damage" (BVID). Impact and quasi-static tests were conducted on plate and shell graphite/epoxy specimens between 0.804 mm and 2.412 mm thick in a [45n/10n], layup configuration. Damage was measured via visual, transducer, and X-ray methodologies. No correlation was found between internal (nonvisible) damage from the X-ray data and measured characteristics of the surface damage, specifically the depth of the dent. The results indicate that the use of dent depth as a metric can be misleading, particularly in that no dent depth can be found in some cases where substantial subsurface damage exists. Other examples are given wherein substantial (relative to other specimens) dent depths are measured with no corresponding internal damage. In previous work, peak force was found to correlate the resulting internal damage for both shell and plate specimens. However, dent depth shows no such general trend or correlation with peak force. This, coupled with previous damage tolerance work, places into question the use of dent-depth for thin (less than 2.4 mm, or 0.10") composite plate and shell structures in current damage tolerance methodologies.

ABSTRACT: The transverse-loading response of laminated composite shell structures is studied experimentally and numerically. Monolithic graphite-epoxy shell structures having layups of $[\pm 45\theta_n/0\theta_n]$ ($n = 1, 2, \text{and} 3$) closely represent commercial fuselage structures in both geometry and boundary conditions. A combined experimental and numerical approach is used to assess shell response to centered transverse loading. Experimentally, load-deflection response and mode-shape evolutions are measured and damage resistance characterized via dye-penetrant enhanced x radiography and sectioning. Nonlinear finite element analyses including buckling and dynamic collapse are conducted for comparison to the experimental data. Modeling results allow a more refined interpretation of observed bifurcation phenomena, particularly premature transition to a secondary equilibrium path attributed to geometric imperfections. A novel finite element technique introduced in previous work is found to be superior to traditional methods for identifying and traversing bifurcation points in this work. A simply supported axial boundary condition is found to give a much more complex buckling response (bifurcation and limit-point buckling, as well as dynamic collapse) than specimens with a free axial edge (bifurcation or limit-point buckling). Experimental and numerical comparisons for the range of thicknesses considered indicate that elasticity of the in-plane boundary condition and transverse shear effects need further consideration. Observed shell damage is typical of that observed for composite plates. Results of this work give new insight into the response of composite fuselage panels to damaging transverse events, particularly in regard to instability/buckling behavior.

ABSTRACT: The transverse loading response of convex composite shell structures typical of aircraft fuselage sections was investigated, and the experimental work is reported. Important mechanisms in the response, particularly instabilities (buckling), were studied by investigation of the force-deflection response and the evolution of full-field deformation shapes. Quasi-static tests were conducted to simulate impact of convex shells. The specimens were laminated, cylindrical shell sections in [±45n/0n]s configurations, where n takes on values of 1, 2, and 3. The three structural parameters of radius, span, and thickness were varied according to a scaling relation and were chosen to represent approximate fuselage dimensions of general aviation and commercial transport aircraft. All specimens were evaluated for damage with dye-penetrant enhanced x-ray radiography and sectioning after mechanical testing. The structural response changes both quantitatively and qualitatively for the different shell geometries and was categorized into three types based on the existence of the instability transition characteristics such as deformation shapes. The presence of the instability becomes more likely for deeper, thinner specimens where the ratio of membrane stiffness to bending stiffness is higher. This can be characterized by a structural parameter involving geometric and material factors. The majority of the specimens showed no damage, but the limited experimental evidence did show plate-like damage occurring in the shell specimens before any instability. Suggestions for further work to extend these findings are made.
Laminated shells are in excellent agreement with measured load-deflection and mode-shape evolutions as previously reported. Two cases of extraordinarily good agreement between the data and model, particularly large-deflection asymmetric deformations modes through a bifurcation point and far into the postbuckling regime, clearly establish validated new benchmarks. Asymmetries in both directions of the shell plane, relative to the centrally applied point load, are discussed with regard to bifurcation and material couplings in the composite laminate. Asymmetric stress distributions are discussed in the context of composite damage resistance and previous experimental findings on atypical shell damage mode and extent. The influence of test fixture compliance is evaluated and briefly discussed.

ABSTRACT: The structural response, including the mechanisms associated with snap-through buckling, of cylindrical composite shell panels subjected to transverse loading was investigated via experiments and numerical analysis. Specimens of Hercules AS4/3501-6 graphite/epoxy in [±45n/On]s (n=1,2,3) configurations and with a planar aspect ratio of 1 were tested in static indentation with pinned-free boundary conditions. Structural parameters (radius, span, and thickness) were varied to encompass values utilized in the structural configurations of transport aircraft fuselages. Force-deflection response and panel deformation-shapes were determined during the tests and the damage from the tests was evaluated using x-ray photography and sectioning techniques. A range of experimental force-deflection responses was observed including smooth-stable, smooth with an instability region and nonsmooth responses with an instability region. Deformation-shapes were generally three-dimensional and exhibited both symmetry and unsymmetry. A switching between symmetric and unsymmetric deformation-shapes occurred in some specimens corresponding with load-drops or the panel snapping away from the indentor. The geometric ratio of specimen height to thickness characterizes the structural response as specimens with larger values of this parameter were more likely to exhibit an instability in the force-deflection response, unsymmetric deformation-shapes, and panel snap-away. Force-deflection and deformation-shape behavior for pinned-free and simply-supported-free boundary conditions were determined using a finite element analysis and the predicted results for the two boundary conditions either bounded the experimental response or matched the experimental response well for one of the two boundary conditions. The existence of nonzero in-plane compliance in the test fixture accounts for the variation of the experimental response with respect to the predicted results as the relative magnitudes of the in-plane stiffnesses of the shell and of the boundary conditions is a key consideration in determining the structural response of shell panels. An experimental comparison of different boundary conditions along the axial edges showed that increased rotational restraint increases the critical snapping load, decreases the magnitude of the load reduction within the instability region of the force-deflection response, and prevents the formation of unsymmetric spanwise deformation-shapes. Damage in the form of matrix cracking and delaminations in the specimen backside was detected in only the deepest, thickest specimen geometry. Such damage forms near the critical snapping load and may be similar to that found in plates due to the localized concave configuration which develops beneath the loading point resulting in tensile bending stresses. Further work based on these results is recommended to investigate the effects of unsymmetric deformations, in-plane compliance, and various boundary conditions on the structural response and damage characteristics of similar shells. Further experimental work to pinpoint the transition in damage behavior due to the formation of localized concavity is also suggested.

ABSTRACT: This project demonstrated the implementation of embedded optical fibers as sensors for detecting the onset of shell buckling instabilities and compressive failure in composite cylinders. In the present work, five 6-inch diameter cylinders (four filament-wound and one prepreg tape) with integrated optical fiber strain sensors were fabricated and tested in compression. The cylinders were instrumented with an axial strain gage for local strain measurements and a helically wound 633 nm optical fiber for integrated strain measurement. The integrated strains along the optical fiber path were obtained by using a modified Mach-Zehnder interferometer with feedback electronics controlling PZTs in the reference arm. This distributed sensing technique provides a more reliable and sensitive means of detecting critical strains and the onset of pre-buckling deformations than the conventional local strain gage.

ABSTRACT: The local and global compressive buckling behavior of stability-critical, high-aspect ratio, cantilevered composite IsoTruss grid structure columns was examined. The influence of local bay length and number of carbon fiber tows in the longitudinal and helical members on the compressive strength of IsoTruss columns was examined. Four 3-m (118.0 in.) long IsoTruss specimens were fabricated and tested in axial compression with fixed-free boundary conditions. The test results exhibit the same trend as the finite element predictions, although the error is higher for shorter bay lengths. Local buckling depends on bay length, with higher buckling loads observed for shorter bay lengths. Global buckling, on the other hand, is independent of bay length; although increasing the bay length reduces the weight and thus increases the overall efficiency of an IsoTruss structure. The Euler column buckling prediction only considers the overall diameter and the axial stiffness of the longitudinal members; therefore, Euler buckling predictions are accurate only for IsoTruss configurations that fail in global buckling.

ABSTRACT: Simulating the mechanical behavior of a cloth is a very challenging and important problem in computer animation. The models of bending in most existing cloth simulation approaches are taking the assumption that the cloth is little deformed from a plate shape. Therefore, based on the thin-plate theory, these bending models do not consider the condition that the current shape of the cloth under large deformations cannot be regarded as the approximation to that before deformation, which leads to an unreal static bending. [This paper introduces a dynamic bending model which is appropriate to describe large out-plane deformations such as cloth buckling and bending, and develops a compact implementation of the new model on spring-mass systems. Experimental results show that wrinkles and folds generated using this technique in cloth simulation, can appear and vanish in a more natural way than other approaches.]

ABSTRACT: A facet shell element based on an anisoparametric plate bending element and a quadratic plane-stress element with vertex rotations is formulated for geometrically nonlinear analysis of shells. The updated Lagrangian formulation which proves to be effective for three-node elements is employed. The restriction of small rotation between the increments is removed by using Hsiao's finite rotation method in which the rigid body motion is eliminated from the total displacement. The displacement control is used to alleviate the singularity of the tangential stiffness matrix in the limit point type problems. Numerical solutions are presented for beams, plates and shells to evaluate the performance of the element.

ABSTRACT: Analytical predictions of the postbuckling response of curved composite panels are difficult, especially under in-plane compression, because of the presence of snap-back with a steep negative slope beyond the bifurcation point. In this study, the pre- and postbuckling response of curved laminated panels with cutouts is investigated by developing a new finite element based on the free formulation. This triangular, flat, shell element, in conjunction with the updated Lagrangian form of the co-rotational approach, accounts for the coupling terms arising from general material anisotropy, as well as large displacements and rotations. The analysis predictions correlate well with the corresponding experimental data available in the literature. Review of the studies in this subject area reveal that none of the available methods, including the STAGS-C1 finite element program, is capable of providing the full description of the postbuckling phenomenon beyond bifurcation for curved composite panels with small cutouts.

ABSTRACT: A flat shell element based on the free-formulation finite element concept is developed for analysing geometrically non-linear thin composite shells. A corotational form of the updated Lagrangian formulation is utilized. Numerical results for typical validation problems are presented in order to demonstrate the accuracy and validity of this element. These results are obtained by solving the incremental equilibrium equations through the cylindrical arc-length method.

ABSTRACT: This study presents a nonlinear analysis with application to a doubly curved shallow shell element free of ‘locking’. The ‘locking’ phenomenon is eliminated by explicitly determining the shear and membrane correction factors. The element formulation utilizes the Reissner-Mindlin and Marguerre theories. The analysis of thin and moderately thick composite shells undergoing large displacements and rotations is achieved by using the corotational form of an updated Lagrangian formulation. The validity of the analysis is established by correlating present results with various benchmark cases that involve large displacements and rotations, as well as elastic stability.

ABSTRACT: A new stiffened shell element combining shallow beam and shallow shell elements is developed for geometrically nonlinear analysis of stiffened composite laminates under mechanical loading. The formulation of this element is based on the principle of virtual displacements in conjunction with the corotational form of the total Lagrangian description of motion. In the finite element formulation, both the shell and the beam (stiffener) elements account for transverse shear deformations and material anisotropy. The cross section of the stiffener (beam) can be arbitrary in geometry and lamination. In order to combine the stiffener with the shell element, constraint conditions are applied to the displacement and rotation fields of the stiffener. These constraint conditions ensure that the cross section of the stiffener remains co-planar with the shell section after deformation. The resulting expressions for the displacement and rotation fields of the stiffener involve only the nodal unknowns of the shell element, thus reducing the total number of degrees-of-freedom. Also, the discretization of the entire stiffened shell structure becomes more flexible. The robustness of the stiffened shell element has been proven by comparison against other shell elements considered previously.

ABSTRACT: The response of moderately thick laminated panels experiencing large displacements and rotations under non-uniform thermal loading is investigated through a nonlinear finite element analysis. The present nonlinear thermoelastic analysis incorporates an anisoparametric, doubly curved, shallow shell element that is free of the 'locking' phenomenon. The effects of large displacements and rotations, transverse shear deformations, the coupling between stretching and bending due to shallow geometry, and Duhamel–Neumann-type thermoelastic material anisotropy are included in the element formulation. The equations of equilibrium are derived from the virtual work principle, along with the co-rotational form of the total Lagrangian formulation. A non-uniform temperature field across the shell surface is approximated by piecewise-uniform temperature distributions over individual elements. In the thickness direction, the temperature distribution is approximated linearly. Accuracy of the present analysis is established by comparison with benchmark solutions. The numerical results are presented for various configurations, including cutouts under uniform and non-uniform temperatures. The numerical results demonstrate that the present finite element analysis is computationally robust and efficient.

ABSTRACT: A semi-analytical method is developed for pre-buckling and buckling analyses of thin, symmetrically laminated composite panels with an elliptical cutout at an arbitrary location and orientation under general thermo-mechanical loading conditions. Both the pre-buckling and buckling analyses are based on the principle of stationary potential energy utilizing complex potential functions and complete polynomials. The complex potential functions capture the steep stress gradients and local deformations around the cutout, and the “complete” polynomials improve the global buckling response of the laminate. The complex potential functions in the pre-buckling state automatically satisfy the in-plane equilibrium equations, thus reducing the first variation of the total potential energy in terms of line integrals only. Because the complex potential functions for out-of-plane displacements are augmented by the “complete” polynomials, the area integral terms in the second variation of the total potential energy, referred to as the Trefftz criterion, are retained in the buckling analysis. The kinematic boundary conditions are idealized by employing extensional and rotational springs (elastic restraints) with appropriate stiffness values. Based on the numerous validation problems, this analysis is proven credible for predicting the buckling load of rectangular and non-rectangular panels with a cutout.

ABSTRACT: A semianalytical solution method to predict stress field and structural bifurcation in laminates having a cutout by employing a simple \{3,0\}-plate theory is presented. The stress analysis includes both in-plane and bending stress fields. In this theory, the in-plane and out-of-plane displacement fields are respectively assumed in the forms of cubic and uniform through-the-thickness expansions. The cubic expansion ensures the correct behavior of transverse shear deformations while satisfying the condition of zero transverse shear stresses at the laminate faces. The equations of equilibrium for the stress and buckling analysis are derived based on the principle of stationary potential energy. Comparison against the classical laminate and \{1,2\}-plate theories proves this semianalytical method credible.

ABSTRACT: A finite element analysis is carried out for the bending and buckling of unstiffened, sandwich and hat-stiffened orthotropic, rectangular plates. Systematic calculations are performed for deflection, stress and critical buckling load of the plate using first order shell elements, and first and second order three-dimensional solid elements. The calculated results are compared with available analytical solutions for unstiffened plates. First-order shell and second-order three-dimensional solid elements are found to model accurately bending and buckling of the plate structures, but first-order three-dimensional solid elements give very inaccurate, inconsistent results even when the mesh density is high. For thin, unstiffened plates, one layer of second-order three-dimensional solid elements through-the-thickness is found to give sufficient accuracy. The same is found to be true for thin sandwich plates using one layer of second-order three-dimensional elements for each of the skins and one layer for the core. For a hat-stiffened plate clamped along the short edges and simply supported along the long edges, the first buckling mode occurs in the region between the stiffeners. Different approaches for joining the stiffeners to the plate are discussed.

ABSTRACT: The buckling characteristics of a typical free-standing welded steel containment vessel are considered. The results of analyses utilizing computer codes are compared for a variety of load combinations. Practical conclusions of the vulnerability of such a containment vessel to buckling for a variety of load inputs and combinations are drawn.

ABSTRACT: A review of the relationship between the theory of shell stability and design is presented. The classic problem of buckling of a spherical shell is used to illustrate the lack of correspondence between theory and experiment. The influence of theory on current design codes and its application to a practical problem are discussed.

ABSTRACT: In this paper the effect of random geometric imperfections on the critical load of isotropic, thin-walled, cylindrical shells under axial compression with rectangular cutouts is presented. Second moment characteristics of geometric imperfections are estimated by data of available measurements, a simulation procedure based on the Karhunen-Loeve expansion is applied for generating realizations of geometric imperfections. Nonlinear static Finite Element analyses are carried out for the calculation of the response statistics of the critical load of the cylindrical shells. Histograms of the critical load as obtained by direct Monte Carlo simulation are presented.

ABSTRACT: In this paper the effect of random geometric imperfections on the limit loads of isotropic, thin-walled, cylindrical shells under deterministic axial compression is presented. Therefore, a concept for the numerical prediction of the large scatter in the limit load observed in experiments using direct Monte Carlo simulation technique in context with the Finite Element method is introduced. Geometric imperfections are modeled as a two dimensional, Gaussian stochastic process with prescribed second moment characteristics based on a data bank of measured imperfections. (The initial imperfection data bank at the Delft University of Technology, Part 1. Technical Report LR-290, Department of Aerospace Engineering, Delft University of Technology). In order to generate realizations of geometric imperfections, the estimated covariance kernel is decomposed into an orthogonal series in terms of eigenfunctions with corresponding uncorrelated Gaussian random variables, known as the Karhunen–Loève expansion. For the determination of the limit load a geometrically non-linear static analysis is carried out using the general purpose code STAGS (STructural Analysis of General Shells, user manual, LMSC P032594, version 3.0, Lockheed Martin Missiles and Space Co., Inc., Palo Alto, CA, USA). As a result of the direct Monte Carlo simulation, second moment characteristics of the limit load are presented. The numerically predicted statistics of the limit load coincide reasonably well with the actual observations, particularly in view of the limited data available, which is reflected in the statistical estimators.

“Non-Linear Static Analysis”, Chapter 5 in Uncertainty Assessment of Large Finite Element Systems

ABSTRACT: The state of the art in the capability to predict the stability behavior of shell structures refers to

areas such as asymptotic analysis \[69\] and general nonlinear analysis (see e.g. \[16, 30\]). In both approaches, the

solution of equilibrium equations under variation of a number of parameters such as load level, imperfection

magnitude etc., is necessary. Of paramount interest is the determination of the so-called critical points. Two

fundamental problems have to be distinguished in the field of structural stability: the buckling problem and the

collapse or snap-through problem, respectively. The corresponding critical points are denoted as bifurcation

points and limit points. By definition a bifurcation point describes the equilibrium state of a structure where

distinct non-interacting solutions are possible. The limit point on the other hand characterizes the local

maximum of the load-deflection curve. Contrary to perfect structures, imperfect structures do not show a clear
separation of response modes. Instead, the response is a combination of all excited modes. Depending on the magnitude of the imperfection, it is possible that bifurcation points may vanish.

Abstract: The treatment of uncertainties in the analysis of engineering structures remains one of the premium challenges in modern structural mechanics. It is only in recent years that the developments in stochastic and deterministic computational mechanics began to be synchronized. To foster these developments, novel computational procedures for the uncertainty assessment of large finite element systems are presented in this monograph. The stochastic input is modeled by the so-called Karhunen-Loeve expansion, which is formulated in this context both for scalar and vector stochastic processes as well as for random fields. Particularly for strongly non-linear structures and systems the direct Monte Carlo simulation technique has proven to be most advantageous as method of solution. The capabilities of the developed procedures are demonstrated by showing some practical applications.
parameters have an insignificant influence on the response, all parameters of the INTEGRAL FE model have been included in the analysis. More than 1300 independent random variables have been used to model uncertainties of the material and geometric data. A similar approach has been applied to the Ariane 5 FE model, i.e. all uncertain parameters of the model have been included in the analysis. Within the study an efficient procedure for calculating non-exceedance probabilities of the structural response has been developed. A novel sampling procedure has been introduced, which allows a significant reduction of the variance of the estimator of the probability of failure when compared to that of direct Monte Carlo simulation. This is particularly important in view of the large computational effort associated with a single analysis, especially with the coupled load analysis where a single run could take up to 30 minutes. The only prerequisite for the application of this sampling procedure is an estimate of the gradient of the performance function of the structure. The calculation of the gradient is carried out efficiently benefiting from the correlation between a randomly chosen input and the corresponding output of the system.

ABSTRACT: In this paper, the effect of random geometric imperfections on the critical load of isotropic, thin-walled, cylindrical shells under axial compression with rectangular cutouts is presented. Second moment characteristics of geometric imperfections are estimated by data of available measurements, a simulation procedure based on the Karhunen–Loève expansion is applied for generating realizations of geometric imperfections. Nonlinear static finite-element analyses are carried out for the calculation of the response statistics of the critical load of the cylindrical shells. Cumulative distribution functions of the critical load as obtained by direct Monte Carlo simulation are presented. Furthermore, the individual and combined effects of random boundary and geometric imperfections on the limit loads of isotropic, thin-walled, cylindrical shells under axial compression are also treated. Again, second moment characteristics of these imperfections are estimated by data of available measurements of imperfections, a simulation procedure also based on the Karhunen–Loève expansion is applied for generating realizations of both boundary and geometric

ABSTRACT: A simple four-noded geometrically nonlinear shell element, which handles arbitrarily large displacements and rotations, is presented in this paper. Based on the assumption of small incremental strain in each load step, a corotational procedure is employed to extract the pure deformational displacements and rotations and update element stresses and internal force vectors through a piece-wise linearized strain-displacement relation. To derive the tangent stiffness matrix, a three-dimensional degenerate, isoparametric shell model is employed. The ‘locking’ problem is alleviated by using mixed interpolation of tensorial transverse shear strain components. The approach described in this paper is ideally suited for implementation in existing linear finite element programs. A number of numerical examples are also presented.

ABSTRACT: A stiffened shell element is presented for geometrically non-linear analysis of eccentrically stiffened shell structures. Modelling with this element is more accurate than with the traditional equivalent orthotropic plate element or with lumping stiffeners. In addition, mesh generation is easier than with the conventional finite element approach where the shell and beam elements are combined explicitly to represent stiffened structures. In the present non-linear finite element procedure, the tangent stiffness matrix is derived using the updated Lagrangian formulation and the element strains, stresses, and internal force vectors are updated employing a corotational approach. The non-vectorial characteristic of large rotations is taken into account. This stiffened shell element formulation is ideally suited for implementation into existing linear finite element programs and its accuracy and effectiveness have been demonstrated in several numerical examples.

ABSTRACT: A co-rotational, updated Lagrangian formulation for geometrically nonlinear analysis of shells is presented. In this finite element procedure, a standard updated Lagrangian formulation is employed to generate the tangent stiffness matrix, and a co-rotational theory is used for updating element strain, stress and internal force vectors during the Newton-Raphson iterations. Large rotation theory has been accommodated to take into account the non-vectorial characteristic of the rotational degrees-of-freedom. The present procedure is ideally suited for implementation in existing linear finite element programs and its effectiveness have been demonstrated.
by a number of numerical examples.

ABSTRACT: An improved method is presented for solving nonlinear problems with multiple limit points and snap-back points. It is formulate in N + 1 dimensional space that includes one load parameter and N displacements as the unknowns. To solve these unknowns, a constraint equation is needed in addition to the N equations of equilibrium. Whether the constraint equation is proper can be justified from the bounded nature of the load parameter. The method presented herein may be referred to as the “generalized displacement control method.” With the introduction of a general stiffness parameter, the method has been demonstrated to be numerically stable at the critical points, effective in adjusting the step sizes, and self-adaptive in changing the loading directions. Two examples with curves of the looping type have been solved by the present method for illustration.

ABSTRACT: Buckling of arches is studied using a corotational finite element model in conjunction with a modified Riks-Wempner technique. The corotational formulation allows for separation of rigid body displacements from deformation displacements of the element. The program can equally be applied to rigid or prestressed arches, as it takes into account the sequential fabrication of stressed (i.e. prebuckled) arches. Looping paths tracing nonlinear response of arches have been successfully obtained for several cases, including rigid and prestressed elastica arches with both symmetric and asymmetric modes of buckling. Comparisons are made with the results for prestressed arches using shooting method, and with the benchmark results for various rigid arches using discrete element method. When compared to a discrete element technique, the present method appears to be more cost-effective, as a finite element mesh with 60% fewer elements can result in virtually the same degree of accuracy.

ABSTRACT: Structural components are prone to corrosion damage, especially when exposed to a sea environment. This article describes an investigation on the effects of local corrosion applied to plates and stiffened panels typically found in ship structures. Finite element investigations of initial buckling, ultimate collapse and post-ultimate responses are presented and described through the use of load-shortening collapse curves. Geometric imperfections and residual stresses were included in the model and results are compared to analytical calculations and available experimental measurements. This improved knowledge of the structural integrity of a damaged ship structure can be used to develop more efficient maintenance practices.
ABSTRACT: Sandwich pipes can be a potentially optimal system for use in deep-water applications. In recent years, there has been considerable interest in understanding the stability characteristics of these pipes under the governing loading conditions, with the aim of generating optimal design. External hydrostatic pressure is a critical loading condition that a submerged pipeline experiences during its installation and operational period. This article presents an analytical approach for estimating the buckling capacity of sandwich pipes with various structural configurations and core materials, subject to external hydrostatic pressure. The influence of adhesion between the core layer and inner or outer pipes is also a focus of this study. Beside the exact solution, two simplified equations are developed for estimating the buckling capacity of two configurations commonly used in practice. Details of both the exact and simplified analytical formulations are presented and the required parameters are defined. The efficiency and integrity of the proposed simplified solutions are compared with a solution developed by other researchers. A comprehensive series of finite element eigenvalue buckling analyses was also conducted to evaluate the accuracy and applicability of the proposed solutions.

References listed at the end of the paper:

ABSTRACT: Sandwich Pipes (SP) can be considered as an enhanced design configuration for Pipe in Pipe (PIP) systems. By improving the structural properties of the core layer and the components’ interface adhesion, SP systems can be an effective design alternative for deepwater applications. However, designing such a hybrid structure demands more knowledge of the response of the system under the governing loading and environmental conditions. A SP system would be a suitable design alternative for offshore pipelines that are subjected to very large hydrostatic pressure in deepwater. Therefore, full understanding of the behavior of such systems under the external hydrostatic pressure is a prerequisite for designing optimum SPs. In this paper a set of parametric models are generated based on practical design configurations. The Finite Element (FE) software package, ABAQUS, is used to create the models and analyze them. The FE models are analyzed through eigenvalue buckling and post-buckling analyses with the assumptions of linear and nonlinear buckling. Appropriate initial imperfections and FE parameters are administered. Moreover, the integrity of FE models is investigated through a mesh convergence study and also by considering various types of element locking mechanism. The results of these three methods of analysis are compared and the discrepancy between the results obtained through the linear analysis in comparison to the nonlinear post-buckling analysis is highlighted. Moreover, the influence of using various material plasticity models on the buckling and post-buckling responses is also investigated. Different models describing the materials stress-strain curves in the form of the elastic perfectly plastic, elastic followed by plastic exponential hardening, as well as the existence of the Lüder’s bands are also considered. Furthermore, the effect of core material’s stiffness on the buckling and post-buckling response of the system is also examined. Based on the equivalent plastic strain, it will be shown that in order to ensure system’s effective composite sandwich action, the core must have a certain minimal stiffness. Finally, the influence of the enhancement in the steel grade used to form either the internal or external pipe on the stability response of both PIP and SP systems will be illustrated.

ABSTRACT: This paper presents a model for optimum design of three panel forms, namely tee stiffened, flat-bar stiffened and corrugated panels to be used in ship structures. Scantlings of the three forms have been modelled as free design variables. Limit values against different possible failure modes in conjunction with safety factors and load effects have formed the sets of design constraints. Some production restrictions are also incorporated in the model. An optimization algorithm based on sequential linear programming has been used for optimum design of the three forms. Some special features are incorporated in the optimization algorithm to avoid numerical instability problems and to handle integer variables and more than one design criterion. The capability of the model is demonstrated in a series of practical applications against a wide range of design parameters such as loads, variation of span, price ratio index (labour rate to material price ratio) and design criteria (minimum cost, minimum weight and equal priority). Appropriate presentation and analysis of results have produced a practical guide to strive for improvement in the overall ship structure even satisfying
conflicting design demands. Moreover, the designer's capability to reflect his preference level to particular criteria has been demonstrated through the investigation of a wide range of Pareto-optimal designs.

ABSTRACT: This paper is concerned with the numerical solution of large deflection structural problems involving finite strains, subject to contact constraints and unilateral boundary conditions, and exhibiting inelastic constitutive response. First, a three-dimensional finite strain beam model is summarized, and its numerical implementation in the two-dimensional case is discussed. Next, a penalty formulation for the solution of contact problems is presented and the correct expression for consistent tangent matrix is developed. Finally, basic strategies for tracing limit points are reviewed and a modification of the arc-length method is proposed. The good performance of the procedures discussed is illustrated by means of numerical examples.
PARTIAL INTRODUCTION: It is our belief that a thorough understanding of the mathematical underpinnings of elasticity is crucial to its analytical and numerical implementation. For example, in the analysis of rotating structures, the coupling of the equations for geometrically inexact models obtained by linearization or other approximations with those for rotating rigid bodies can easily lead to misleading artificial “softening” effects that can significantly alter numerical results. … In this paper we consider fully nonlinear geometrically exact models for rods, plates (and shells) which take into account shear and torsion as well as the usual bending effects in traditional rod and plate models. These models can be obtained either from the three-dimensional theory by a systematic use of projection methods … or by a direct approach within the context of Cosserat continuum…

ABSTRACT: (no abstract given)

ABSTRACT: Computational aspects of a linear stress resultant (classical) shell theory, obtained by systematic linearization of the geometrically exact nonlinear theory, considered in Part I of this work, are examined in detail. In particular, finite element interpolations for the reference director field and the linearized rotation field are constructed such that the underlying geometric structure of the continuum theory is preserved exactly by the discrete approximation. A discrete canonical, singularity-free mapping between the five and the six degree of freedom formulation is constructed by exploiting the geometric connection between the orthogonal group (SO(3)) and the unit sphere (S2). The proposed numerical treatment of the membrane and bending fields, based on a mixed Hellinger-Reissner formulation, provides excellent results for the 4-node bilinear isoparametric element. As an example, convergent results are obtained for rather coarse meshes in fairly demanding, singularity-dominated, problems such as the classical rhombic plate test. The proposed theory and finite element implementation are evaluated through an extensive set of benchmark problems. The results obtained with the present approach exactly match previous solutions obtained with state-of-the-art implementations based on the so-called degenerated solid approach.

ABSTRACT: Computational aspects of a geometrically exact stress resultant model presented in Part I of this work are considered in detail. In particular, by exploiting the underlying geometric structure of the model, a configuration update procedure for the director (rotation) field is developed which is singularity free and exact regardless the magnitude of the director (rotation) increment. Our mixed finite element interpolation for the membrane, shear and bending fields presented in Part II of this work are extended to the finite deformation case. The exact linearization of the discrete form of the equilibrium equations is derived in closed form. The formulation is then illustrated by a comprehensive set of numerical experiments which include bifurcation and post-buckling response, as well as comparisons with closed form solutions and experimental results.

ABSTRACT: This paper is concerned with the extension of the shell theory and numerical analysis presented in Part I, II and III to include finite thickness stretch and initial variable thickness. These effects play a significant role in problems involving finite membrane strains, contact, concentrated surface loads and delamination (in composite shells). We show that a direct numerical implementation of the standard single extensible director shell model circumvents the need for rotational updates, but exhibits numerical ill-conditioning in the thin shell limit. A modified formulation obtained via a multiplicative split of the director field into an extensible and inextensible part is presented, which involves only a trivial modification of the weak form of the equilibrium equations considered in Part III, and leads to a perfectly well-conditioned formulation in the thin-shell limit. In sharp contrast with previous attempts in the context of the degenerated solid approach, the thickness stretch is an independent field, not a dependent variable updated iteratively via the plane stress condition. With regard to numerical implementation, an exact update procedure which automatically ensures that the thickness stretch remains positive is presented. For the present theory, standard displacement models would exhibit ‘locking’ in the incompressible limit as a result of the essentially three-dimensional character of the constitutive equations. A mixed formulation is described which circumvents this difficulty. Numerical examples are presented that illustrate the effects of the thickness stretch, the performance of the proposed mixed interpolation, and the well-conditioned response exhibited by the present approach in the thin-shell (inextensible director) limit.

ABSTRACT: This paper considers the formulation and numerical implementation of a geometrically exact resultant based shell model for the analysis of large deformations of thin and moderately thick shells. The model is essentially a single extensible director Cosserat surface. Variable thickness and thickness stretch effects are properly modeled via the extensibility condition on the director field. A simple linear elastic constitutive model is given which possesses the correct asymptotic limits as the thickness tends to zero and recovers the plane stress constitutive relations in the thin shell limit. On the computational side, a configuration update procedure for the director field is presented which is singularity free and exact regardless of the magnitude of the director (rotation and thickness stretch) increment. The performance of the shell model is assessed through an extensive set of numerical examples.

ABSTRACT: The continuum basis and numerical implementation of a finite deformation plasticity model formulated within the framework of the geometrically exact shell model presented in Parts I and III of this work, is discussed in detail. The model is formulated entirely in stress resultants, and hence the expensive integration through the thickness associated with the traditional degenerated solid approach is entirely by-passed. In particular, the classical Ilyushin-Shapiro plasticity model for shells is extended to accommodate kinematic and isotropic hardening, and consistently formulated to accommodate finite deformation. The corresponding closest-point-projection return mapping algorithm is shown to reduce to the solution of a system of two nonlinear scalar equations, and proved to be amenable to exact linearization leading to a closed form expression of the consistent elastoplastic tangent moduli. Numerical simulations are presented and comparisons with exact and approximate solutions are made which demonstrate the excellent performance of the proposed methodology.

ABSTRACT: If the mid-surface of a shell is smooth, the classical theory describes the orientation of the director field attached to the mid-surface by two independent (rotational) degrees of freedom. At a shell intersection, where this smoothness assumption no longer holds, it is shown that the director field in the full nonlinear continuum shell equations must be necessarily described by three degrees of freedom. This added degree of freedom, however, is totally unrelated to the so-called drill rotation, widely used as a means of tackling the shell intersection problem. A computational procedure involving a trivial modification of the global singularity-free update procedure described in Part III of this work is described, which completely resolves the shell intersection problem without introducing ‘drill springs’ or related ad-hoc devices. The proposed approach leaves unchanged standard finite element formulations in terms of 5 DOF/node, affects only the global update formulae and exhibits excellent performance, as illustrated by representative numerical simulations.

ABSTRACT: The accurate prediction of the buckling load of thin shell structures is an important yet elusive goal. It is particularly important in the aerospace industry where thin shell members are commonly used as structural elements. Due to a lack of adequate analytical results, current practices in industry put heavy reliance on experimental testing and empirical data to supplement theoretical analysis (see D. Bushnell, Computerized Buckling Analysis of Shells, Martinus Nijhoff, Dordrecht, 1985). This paper focuses on recent results of the group theoretic approach to a numerical, global postbuckling analysis of a perfect, axially compressed cylindrical shell with “built-in” end conditions. The “built-in” end conditions obviate the existence of a “trivial” membrane solution branch. The example of an axially compressed cylindrical shell was chosen because it is well known that for thin shells, the primary axisymmetric solution branch is riddled with closely spaced, symmetry-breaking bifurcation points. In a numerical arc-length continuation scheme, the close proximity of the bifurcation points on the primary path manifests itself in severe ill-conditioning of the tangent stiffness matrix. Group theory helps one systematically find an “optimal” set of basis vectors, or symmetry modes, which reflect the symmetry of a given solution path. The immediate payoff in using these symmetry modes as basis vectors is that the tangent stiffness matrix block-diagonalizes and the numerical ill-conditioning is avoided. Thus, an efficient and accurate technique for computing solution branches of a specific type and a subsequent diagnosis for symmetry-breaking bifurcations is made relatively simple. Understanding the global behavior of the perfect structure is crucial in identifying critical imperfections and will ultimately diminish the heavy reliance on expensive experimental verification.

PARTIAL ABSTRACT: Over the past ten years there has been a growing interest within the mechanics community towards the application of group theoretic methods to aid in the global buckling analysis of symmetric imperfection-free structures. Within the context of a numerical arc-length continuation procedure, group theory helps one systematically find an “optimal” set of basic vectors which reflect the symmetry of a given problem. The immediate payoff in formulating the numerical procedure with respect to the symmetry-adapted basis is a global de-coupling of the equilibrium equations which in turn leads to: (1) a dimensional reduction in the problem size; (2) improved numerical conditioning while computing solutions in the vicinity of singular points; (3) a systematic method for detecting and diagnosing for symmetry-breaking bifurcations.
ABSTRACT: Progress in the application of group theoretic methods to the nonlinear bifurcation analysis of symmetric structures has provided new hope in understanding the global postbuckling behavior of symmetric thin shell structures. However, what is still lacking in the computational mechanics community is a general purpose FE code with a group theoretic capability designed to take ‘optimal’ advantage of existing symmetry. This paper addresses some of the important issues associated with developing such a code—the long term goal being to provide structural analysts with new numerical tools for doing careful global analyses of imperfection sensitive structures which may eventually lead to more accurate predictions of the maximum load-carrying capacity of thin imperfection sensitive shell structures.

ABSTRACT: Due to the very nonlinear behavior of thin shells under collapse, numerical simulations are subject to challenges. Shell finite elements are attractive in these simulations. Rotational degrees of freedom do, however, complicate the solution. In the present study a co-rotated formulation is employed. The deformation of the shell is decomposed into a contribution from large rigid body rotation and a strain-producing term. A triangular assumed strain shell finite element is used. Hence, a high performance elastic element is combined with the co-rotated formulation. In the co-rotated co-ordinate system the plasticity is accounted for by a simplified Ilyushin stress resultant yield surface. The stress update is determined from the backward Euler difference, and a consistent geometrical and material tangent stiffness is derived. Comparison with other published analysis results show that the present formulation gives acceptable accuracy. (27 references’ cannot cut and paste from this pdf file.)

ABSTRACT: The geometrically nonlinear constant stress triangle of Morley is implemented and extended to include material nonlinearity. The facet element was designed in a total Lagrangian approach and is valid for moderate rotations. In a search for a simple plasticity formulation, stress resultants plasticity (involving a solution of single scalar yield function) is employed. A modification is introduced in the Ilyushin yield surface such that it is rendered a hyperellipse to avoid corner discontinuities. Explicit plasticity equations are derived so as to avoid the most involving matrix operations and attain faster computations. In this work it is aimed to study the performance of the element and assess its application to practical problems such as plate buckling in offshore structures. The formulation appears to work well.

ABSTRACT: In this study we present a new approach to analyse cracked shell structures subjected to large geometric changes. It is based on a combination of a rectangular assumed natural deviatoric strain thin shell finite element and an improved linespring finite element. Plasticity is accounted for using stress resultants. A power law hardening model is used for shell and linespring material. A co-rotational formulation is employed to represent nonlinear geometry effects. With this, one can carry out nonlinear fracture mechanics assessments in structures that show instabilities due buckling (local/global), ovalisation and large rigid body motion. By numerical examples it is shown how geometric instabilities and fracture compete as governing failure mode.

ABSTRACT: The dynamic stiffness method is introduced to analyze thin-walled structures including thin-walled straight beams and spatial twisted helix beam. A dynamic stiffness matrix is formed by using frequency dependent shape functions which are exact solutions of the governing differential equations. With the obtained thin-walled beam dynamic stiffness matrices, the thin-walled frame dynamic stiffness matrix can also be
formulated by satisfying the required displacements compatibility and forces equilibrium, a method which is
similar to the finite element method (FEM). Then the thin-walled structure natural frequencies can be found by
equating the determinant of the system dynamic stiffness matrix to zero. By this way, just one element and
several elements can exactly predict many modes of a thin-walled beam and a spatial thin-walled frame,
respectively. Several cases are studied and the results are compared with the existing solutions of other
methods. The natural frequencies and buckling loads of these thin-walled structures are computed.

ABSTRACT: In standard stability investigations of structures applying the finite element method usually bifurcation and snap-through loads – so-called singular or stability points – are detected, see e.g. [4],[6],[7]. It is well-known that for complex structures like cylindrical shells these loads depend strongly on the geometrical and other imperfections, see [8],[9],[10]. It has been shown in [1] that the singular points and the corresponding modes vary significantly for small deviations of the approximated geometry using different ansatz-functions. Furthermore investigations in [1] have shown that the converging behavior for imperfect structures is non-monotonic. Particular limitations exist for the stability analysis of shell structures which involve contact between parts or with surrounding objects. In the end it could be followed that stability points and the corresponding loading determined numerically by static stability analysis are often of limited use for design purposes. In contrast to the loading obtained for singular points the so-called post-buckling loads, which are the stable equilibrium states in the post-buckling region, are rather independent of geometrical imperfections and of approximation order, see [1]. Therefore it is advantageous to use post-buckling loads for design purposes instead of loads obtained for singular points. Since the applicability of static analyses in the computation of
post-buckling paths like proposed e.g. in [5] is rather limited, it is favorable to model the complete loading and deformation behavior by a time dependent process, see [3], [2], [11], [12]. The major advantage of a purely transient analysis is the complete simulation of the buckling process as it happens in reality. This is possible with moderate numerical effort, since the matrices used in the solution are usually better conditioned compared to pure static analysis. In addition, this allows to take the changing boundary conditions as found in contact situations properly into account. For practical design purposes not only the equilibrium state itself is significant but also the “robustness” of such states against finite perturbations in contrast to infinitesimal perturbations. In the case of systems with many equilibrium states at a defined load level finite perturbations can transfer the mechanical system from a stable equilibrium state to another equilibrium state or in some cases even to an unbounded motion initiating buckling. Then a sensitivity measure can be defined as the reciprocal value of the minimum perturbation energy, necessary for this transfer S = 1/Wper,min, see [2]. In the present paper stability and sensitivity studies are performed for simple stability problems (beams) and finally for rather general shell structures involving geometrical imperfections and in particular contact.

ABSTRACT: A numerical model for layered composite structures based on a geometrical nonlinear shell theory is presented. The kinematic is based on a multi-director theory, thus the in-plane displacements of each layer are described by independent director vectors. Using the isoparametric approach a finite element formulation for quadrilaterals is developed. Continuity of the interlaminar shear stresses is obtained within the nonlinear solution process. Several examples are presented to illustrate the performance of the developed numerical model.

ABSTRACT: A numerical model for the nonlinear analysis of thick laminates is presented. Using a multiplicative decomposition of the displacement vector in shell space, the 3D problem is reduced to a 2D problem. Although the total number of degrees of freedom is comparable to 3D brick elements this approach provides several advantages, e.g. a simplified mesh generation due to a 2D-type data structure and a better bending behavior. The developed isoparametric quadrilateral finite element is capable of predicting interlaminar stresses and local effects. Several linear and nonlinear examples are presented to illustrate the performance of the developed numerical model.

ABSTRACT: A numerical model for the non-linear analysis of laminates is presented. The developed element
is based on piecewise polynomial interpolation in thickness direction. Although the total number of degrees of freedom is comparable to a discretization with 3D brick elements this approach provides several advantages, e.g. a simple mesh generation due to a 2D-type data structure and a better bending behavior. The developed isoparametric quadrilateral finite element allows prediction of the complete stress state. Furthermore, a transition element is presented which is used to couple the developed element with 5-parameter shell elements. Several linear and non-linear examples are presented to illustrate the performance of the developed numerical model.

ABSTRACT: Moderate and finite rotation theories [7] [4] [6] are available including the finite element analysis, especially the treatment of shear locking problems. The five parameter shell model used in this paper is based on geometrically non-linear Reissner-Mindlin kinematics where the finite element formulation may be derived using the Biot—or 2. Piola—Kirchhoff stress resultants, alternatively. The description of finite rotations of the shell normal is expressed in terms of a skew-symmetric tensor.

ABSTRACT: In this paper a finite shell element for large deformations is presented based on extensible director kinematics. The essential feature is an interface to arbitrary three-dimensional material laws. The non-linear
The Lagrangian formulation is based on the three-field variational principle, parametrized with the displacement vector, enhanced Green-Lagrangian strain tensor and second Piola Kirchhoff stress tensor. The developed quadrilateral shell element is characterized by a course mesh accuracy and distortion insensitivity compared with bilinear displacement approaches. Furthermore, plane stress response is approximately recovered in the asymptotic case of vanishing thickness. A number of example problems investigating large deformation as well as finite strain applications are presented. Compressible and incompressible hyperelastic materials of the St. Venant-Kirchhoff, Neo-Hookean and Mooney-Rivlin type are particularly used.

“Finite element formulations for geometrical and material nonlinear shells based on a Hu-Washizu functional”, VIII International Conference on Computational Plasticity (COMPLAS VIII), E. Enate and D.R.J. Owen, Editors, CIMNE, Barcelona, 2005

ABSTRACT: The paper deals with the nonlinear finite element analysis of thin shells. Numerical tests show the advantages of the developed mixed hybrid quadrilateral element. The essential feature of the element formulation is the robustness in nonlinear computations with large rigid body motions. It allows very large load steps in comparison to standard displacement models or enhanced strain models.

ABSTRACT: In this paper we consider compressed flat thin films on rigid substrates. Residual compressive stresses arising e.g. from temperature loading are the driving quantities of the irreversible delamination process. A Reissner–Mindlin shell formulation is used as a model for the thin film, since small geometrical imperfections are considered to initiate buckling. For the interface we postulate the existence of a cohesive free energy as a function of the opening displacement vector and internal variables. The irreversible delamination process is described using a cohesive law of exponential type, where the parameters depend on the combination of the modes I, II and III. In order to analyse the delamination process exactly we use the energy criterion of the steady-state growth.

References listed at the end of the paper:

ABSTRACT: The delamination process of thin films on rigid substrates is investigated. Such systems are typically subject to high residual compression and modest adhesion causing them to buckle driven blisters. In certain cases buckles with the shape of telephone cords are observed. A finite element model for quasi-static delamination growth is developed. Applying a Reissner-Mindlin shell kinematic for the film allows continuous shape functions. The traction vector at the film-substrate interface is obtained from the derivative of a cohesive free energy. Incorporation of loading and unloading conditions is considered for the irreversible process. The equilibrium state is computed iteratively in dependence of the compressive residual stresses. The computed telephone cord delaminations are stable asymmetric configurations whereas the symmetric configurations are unstable.

ABSTRACT: Based on the kinematic assumptions of Mindlin-Reissner a three-field variational formulation with independent displacements, stress resultants and shell strains is presented. Within the finite element formulation the interpolation of the independent shell strains consists of two parts. The first part corresponds to the interpolation of the stress resultants. Within the second part thickness strains are incorporated, which allows direct implementation of nonlinear three-dimensional constitutive equations. A mixed hybrid quadrilateral shell element is formulated. The essential feature of the element is the remarkable robustness in nonlinear applications.

ABSTRACT: In this paper, a practical test and finite element analysis has been undertaken to further investigate the effects of contact buckling. A test rig was designed and constructed to record vertical and transverse deflections of compressively loaded steel skin plates. The boundary conditions were modeled as fully fixed. A finite element analysis was also undertaken using the software package Strand7. Results from both analyses have been examined and compared to data established from previous studies on contact buckling. Both the finite element analysis and practical results correlate well with this data. The result of the investigation has confirmed contact buckling theories and has foreshadowed the onset of the newly observed phenomenon of secondary contact buckling.

ABSTRACT: On the basis of Kirchhoff–Love-hypothesis and small elastic strains a geometrically nonlinear theory of thin shells is derived in symbolic tensor notation. Furthermore, an incremental version for finite increments of the displacements is formulated and the corresponding incremental principle of virtual work. This is the starting point of FEM with curved triangular elements, each containing 63 kinematical DoFs. Different levels of geometrical nonlinearity are implemented in the developed computer programs for nonlinear, critical and postcritical calculations. As examples quadrilateral sections of circular cylindrical shells with different boundary conditions are investigated for normal pressure, normal point loads, axial loads and combined loads, considering additionally imperfections. Comparisons with published results are made as far as possible. The results show the validity of Donnell’s approximation in a wide range.

“An Efficient Algorithm For The Computation Of Stability Points Of Dynamical Systems Under Step Load”,
Engineering Computations, Vol. 9 No. 6, 1983, pp. 669 – 679,
doi: 10.1108/eb023890
ABSTRACT: Many engineering structures exhibit loss of stability under static and dynamic loading. Due to the significance of these phenomena in engineering design this topic has attracted considerable attention during the last decades. In recent years much effort has been made to devise algorithms within finite element analysis to investigate the static stability behaviour of structures. With these methods stable and unstable paths can be traced, and limit or bifurcation points can be computed efficiently. The associated arc-length or branch-switching procedures are today standard tools in existing finite element codes.

ABSTRACT: In this paper a class of non-linear problems is discussed where stability as well as post-buckling behaviour is coupled with contact constraints. The contact conditions are introduced via a perturbed Lagrangian formulation. From this formulation the penalty and Lagrangian multiplier method are derived. Both algorithms are investigated together with an algorithm based on an augmented Lagrangian method. The resulting finite element formulation is applied to structural problems of beams and shells undergoing finite elastic deflections and rotations. For the examination of the post-buckling behaviour the arc-length method is used. The performance of the element formulation and a comparison of the different contact algorithms are demonstrated by numerical examples.

References listed at the end of the paper:

ABSTRACT: The practical behaviour of problems exhibiting bifurcation with secondary branches cannot be studied in general by using standard path-following methods such as arc-length schemes. Special algorithms have to be employed for the detection of bifurcation and limit points and furthermore for branch-switching. Simple methods for this purpose are given by inspection of the determinant of the tangent stiffness matrix or the calculation of the current stiffness parameter. Near stability points, the associated eigenvalue problem has to be solved in order to calculate the number of existing branches. The associated eigenvectors are used for a perturbation of the solution at bifurcation points. This perturbation is performed by adding the scaled eigenvector to the deformed configuration in an appropriate way. Several examples of beam and shell problems show the performance of the method.

ABSTRACT: In the analysis of nonlinear elastic shells often the stability and postbuckling behaviour governs the response. Here we discuss problems which also include contact constraints. A nonlinear cylindrical shell element is derived directly from the associated shell theory using one point integration and a stabilization technique. Within a general solution algorithm a simple but effective branch-switching procedure is presented. Additional considerations allow the treatment of bifurcation problems with contact constraints. Several examples of beam and shell problems show the performance of the developed algorithms and elements.

ABSTRACT: In this paper we discuss theoretical and numerical aspects of the formulation of a cylindrical shell element for composite materials. The element is based on a direct introduction of the finite element approach into the shell equations, especially for the base vectors, see Simo, J. C. et al. (1989–1992) |Comp. Meth. Appl.
Mech. Engng (Part I) 72, 267–304, (Part II) 73, 53–92, (Part III) 79, 21–70, (Part IV) 81, 91–126, (Part V) 96, 133–171 and Gruttmann et al. (1989) [Ing. Arch. 59, 54–67]. Introducing the special geometry of cylinders we end up with a simple but highly accurate element which can be formulated in an easy way and which shows excellent convergence behavior in linear and nonlinear problems.

ABSTRACT: The investigation of the non-linear response of shell-like structures requires insight into stability behaviour. In the paper we compare two strategies to compute singular points based on different eigenvalue problems. We show a simple algorithm to calculate critical load factors $A$ used in engineering buckling analysis from the eigenvalues of the standard eigenvalue problem…Some numerical examples illustrate the derived results and algorithms.

ABSTRACT: This paper is concerned with a geometrically non-linear solid shell element to analyse piezoelectric structures. The finite element formulation is based on a variational principle of the Hu–Washizu type and includes six independent fields: displacements, electric potential, strains, electric field, mechanical stresses and dielectric displacements. The element has eight nodes with four nodal degrees of freedoms, three displacements and the electric potential. A bilinear distribution through the thickness of the independent electric field is assumed to fulfill the electric charge conservation law in bending dominated situations exactly. The presented finite shell element is able to model arbitrary curved shell structures and incorporates a 3D-material law. A geometrically non-linear theory allows large deformations and includes stability problems. Linear and non-linear numerical examples demonstrate the ability of the proposed model to analyse piezoelectric devices.

ABSTRACT: Buckling of trapezoidally corrugated panels under in-plane loading is analyzed by a spline finite strip method. The influence on the elastic buckling load of various parameters, such as geometry, loading forms and boundary conditions, etc., is studied. It is found that: (1) for longitudinal compression the buckling load increases with the corrugation angle $\alpha$, and for a given $\alpha$ the highest buckling load is achieved when the “proportion parameter” $y = 1$; (2) for shear loading the buckling load increases as $\alpha$ increases, and for a given $\alpha$ the highest buckling load is obtained when $y = 2$; and (3) for a combined loading of compression and shear, interactive curves can be approximated by unit circles when $\alpha = 15, 30, 45, 60$ and $90$ degrees. However, when $\alpha = 75$ degrees a parabola seems to be a better approximation. Based on the numerical experiments, simplified formulae and interactive curves are suggested for practical design.

Buckling and postbuckling behaviour of isotropic shells, especially cylinders” (a review paper), Structural Control and Health Monitoring, Vol. 14, No. 4, pp. 693-713, June 2007, doi: 10.1002/stc.202

ABSTRACT: The large discrepancies between observed buckling loads for thin shells and the predictions of the classical theory have been a great challenge to many researchers since the 1920s. In this paper, the basic behaviour and characteristics are described and recent research, mainly from the last 10 years, is reviewed. The focus is on cylindrical shells and on the influence of initial imperfections on the buckling behaviour.

ABSTRACT: Local buckling of web plates having a longitudinal stiffener in different positions under simultaneous shear and in-plane bending is investigated. The interaction study is carried out by both numerical simulation of the problem utilizing finite element method, and by an analytical procedure based on energy method using trigonometric functions. Interaction curves show that the existence of small amounts of in-plane bending may increase the shear buckling capacity, and that the introduction of a longitudinal stiffener significantly increases the critical stress of web plates. Also a very good correlation between the proposed energy method and the finite element method is obtained.

ABSTRACT: In [1], nonlinear large deflection finite element analysis was implemented to depict the characteristics of the shear failure mechanism of steel plate girders. That paper aimed at clarifying how–when–why and where plastic hinges form in flanges. The present paper extends those results to the state of stresses in web plates. It is shown that although the principal compressive stresses in the center of the web plates remain constant after an elastic buckling, they do increase considerably in other regions. In addition, the angles at which tension fields form; and the ultimate strength of plate girders is discussed and compared to those obtained by different theoretical and experimental hypotheses.

“Buckling and postbuckling behavior of unstiffened slender curved plates under uniform shear”, Thin-Walled Structures, Vol. 49, No. 8, April 2011, pp. 1017-1031, doi:10.1016/j.tws.2011.03.007

ABSTRACT: Buckling and postbuckling behavior of curved plates under in-plane shear are investigated. After revisiting classic elastic buckling results, the elastoplastic postbuckling behavior and the effects of curvature parameter and aspect ratio are simulated via geometrical and material nonlinear analyses. Imperfection sensitivity is studied for various imperfection shapes and magnitudes. An increase in curvature parameter raises the elastic buckling load, produces unstable buckling and reduces postbuckling reserves. The buckling load and shear capacity are higher in shorter plates. Small initial imperfections are found to have severe effects on the initial buckling load of plates with large curvature parameter, but little effect on ultimate postbuckling capacity.

ABSTRACT: Two principal possibilities for analyzing the structural response of quasi-statically loaded steel shell structures to different actions are available: the commonly used static path tracing and the dynamic analysis with slowly changing loads, i.e. quasi-static loading. However, the failure process of thin-walled shells can often not be traced into the deep post-buckling area with static methods. The current research is focused on a thin-walled circular cylindrical steel shell collapse analysis under constant shear loading. It is shown that it is possible to overcome the difficulties and inconsistencies of the static analysis by using quasi-static analysis. This method allows to distinguish local and global instability points and to determine too the experimentally observed post-buckling strength.

M.R. Eslami and M. Shariyat (Mechanical Engineering Department, Amirkabir University of Technology, (Tehran Polytechnic), 424 Hafez Avenue, Tehran 15914, Iran), “A high-order theory for dynamic buckling and

ABSTRACT: Using a high-order Reissner-Mindlin-type shear deformation theory in a power series form, the general large deformation form of the Green strain tensor for imperfect cylindrical shells is introduced. Then, based on Hamilton’s principle, the equations of motion are derived for laminated composite shells. Related constitutive equations are also proposed. In this formulation, temperature dependency of material properties is considered, too. No simplifications are made in solving the coupled nonlinear equations of motion. Finally, few examples of the well-known references are reconsidered for comparison purposes.

ABSTRACT: Buckling behavior of rectangular functionally graded plates with geometrical imperfections is studied in this paper. The equilibrium, stability, and compatibility equations of an imperfect functionally graded plate are derived using the classical plate theory. It is assumed that the nonhomogeneous mechanical properties of the plate, graded through thickness, are described by a power function of the thickness variable. The plate is assumed to be under in-plane compressive loading. Simultaneous solving of the stability and compatibility equations in conjunction with the equilibrium equations leads to the buckling relation of the plate. The critical buckling load of a sample plate is obtained and compared for different geometrical ratios. The results are reduced and compared with the results of perfect functionally graded and imperfect isotropic plates.

ABSTRACT: Thermal buckling analysis of rectangular functionally graded plates (FGPs) with geometrical imperfections is presented in this paper. The equilibrium, stability, and compatibility equations of an imperfect functionally graded plate are derived using the classical plate theory. It is assumed that the nonhomogeneous mechanical properties of the plate, graded through thickness, are described by a power function of the thickness variable. The plate is assumed to be under three types of thermal loading as uniform temperature rise, nonlinear temperature rise through the thickness, and axial temperature rise. Resulting equations are employed to obtain the closed-form solutions for the critical buckling temperature change of an imperfect FGP. The results are reduced and compared with the results of perfect functionally graded and imperfect isotropic plates.

ABSTRACT: Buckling analysis of rectangular thick functionally graded plates under mechanical and thermal loads is presented in this paper. It is assumed that the non-homogeneous mechanical properties vary linearly
through the thickness of the plate. The plate is assumed to be under three types of mechanical loadings, namely; uniaxial compression, biaxial compression, and biaxial compression and tension and two types of thermal loadings, namely; uniform temperature rise and non-linear temperature rise through the thickness. The equilibrium and stability equations are derived using the third order shear deformation plate theory. Resulting equations are employed to obtain the closed-form solution for the critical buckling load for each loading case. The results are verified with the known data in the literature.

ABSTRACT: Composite materials are formed by the combination of two or more materials that retain their respective characteristics when combined together to achieve desired properties (physical, chemical, etc.) that are superior to those of individual constituents. The main components of composites are reinforcing agents and matrix. Composites have high strength-to-weight ratio and high stiffness-to-weight ratio as compared to conventional materials. Composite are used in many sectors like civil, aerospace, automobiles, marine, medical and power transmission etc., but in this paper more emphasis is given on structural applications. This seminar presents the literature review of application and behaviour of laminated composite material in structural members. Being a thin walled structure, their behaviour is governed by stability criteria. Here a brief review of stability behaviour of laminated composite stiffened panels is presented along with addition the knowledge are also identified into which more comprehensive analysis is needed.

Mana Behnamasl, “Comparison of the behaviour of curved and straight types of steel shell roof structures”,
Master’s thesis, Dept. of Civil Engineering, Eastern Mediterranean University, Cazimagusa, North Cyprus, 2010
ABSTRACT: In this research, the straight and curved models of the steel shell roof with different plates were
analysed, designed and the results were compared with one another. Through this exercise it is aimed at
achieving an ideal shell roof structure which could cover a larger surface. Therefore, three types of shell roofs
were considered duopitch, cylindrical and dome and the main objective was to compare the straight and curved
model of the shells. According to the findings of the literature review, this is the first time for such comparison
to be carried out among the basic types (duopitch, cylindrical, dome) of shell roof structure. In addition to the
advantage of covering large openings the shell roof structures also use the least materials to do this. Most of its
resistance against the forces imposed on it is due to its curved surface. It is this particular characteristic of the
shell structures that has been attracting architects and civil engineers more in the recent years. This research
shows how effective the curved surfaced shell roof can be with different angles in helping the structure to
resistance its self weight and applied loads. Moreover, it also indicates under which conditions a particular
structure can be more reliable. This kind of shell roof is not common in all shapes and each model needs special
characteristics. When all the comparisons were made, an optimal structure with the largest span of shell roof
and resistance to loads was obtained. In this research, three different angles were used in three shell roof models
in simple and general conditions and the results were compared in order that a structure with ideal condition can
be obtained in future while basic conditions also need to be understood. For each shell roof type, three plates
were considered for analyses and designed. A metal box with either 5cm or 7cm I-section edges, each box has
0.5m length and breadth and I-section edges with either 0.05m or 0.07m height and 0.003m thickness. A metal
box with L-section edges, each box has 0.5m length and breadth and L section edge with 0.05m height and
0.02m edge and 0.03m thicknesses. The comparison between these plates indicates the load carrying capacity
and span capability of the structures. When all different shell roof types are able to cover the same opening,
then it is these plates which determine the weight and the amount of stresses in the structure. The research
showed that it is necessary and important to consider the maximum possible loads these structures could carry
and also to find out the maximum span and the loads that these types of structures can tolerate. This kind of
design is very economic in shell structures and has the capability of replacement and frequent usage in different
areas while the other structures do not have this ability.

ABSTRACT: The effect of cutouts on load-bearing capacity and buckling behavior of cylindrical shells is an essential consideration in their design. In this paper, simulation and analysis of thin steel cylindrical shells of various lengths and diameters with elliptical cutouts have been studied using the finite element method and the effect of cutout position and the length-to-diameter (L/D) and diameter-to-thickness (D/t) ratios on the buckling and post-buckling behavior of cylindrical shells has been investigated. For several specimens, buckling test was performed using an INSTRON 8802 servo hydraulic machine and the results of experimental tests were compared to numerical results. A very good correlation was observed between numerical simulation and experimental results. Finally, based on the experimental and numerical results, formulas are presented for finding the buckling load of these structures.

ABSTRACT: Shell structures have been widely used in pipelines, aerospace and marine structures, large dams, shell roofs, liquid-retaining structures and cooling towers [1]. Buckling is one of the main failure considerations when designing these structures [2]. At first, researchers focused on the determination of the buckling load in the linear elastic zone, but experimental studies showed that the buckling capacity of thin cylindrical shells is much lower than the amount determined in the classic theories [3, 4]. Shell structures, like other types of structures, are usually susceptible to various types of defects and damages such as initiation and propagation of cracks, corrosion, chemical attack and time-dependent material degradation, which impair their structural soundness. The presence of cracks in a shell structure can play the role of geometrical imperfection and thus reduce the load carrying capacity of the shell structure [5-7]….

ABSTRACT: Numerical simulation and analysis of steel cylindrical shells with various diameter and length having an elliptical cutout, subjected to axial compression were systematically carried out in this paper. The investigation examined the influence of the cutout size, cutout angle and the shell aspect ratios L/D and D/t on the pre-buckling, buckling, and post-buckling responses of the cylindrical shells. For several specimens, an experimental investigation was also carried out via an INSTRON 8802 servo hydraulic machine and the results obtained from the experiments were compared with numerical results. A very good accordance was observed between the results obtained from the finite element simulation and the experiments. Furthermore, some equations in the form of a buckling load reduction factor were developed.

ABSTRACT: Research at the University of Sydney in the stainless steel area has for the last three years concentrated on the local buckling strength of stainless steel plates with application to cold-formed sections. The research has encompassed tests on single stainless steel plates, and the finite element modelling of stainless steel plates. Research was also carried out to determine the stress-strain curves for stainless steel materials over the full strain range solely in terms of the Ramberg-Osgood parameters (n, s0, E0). Advanced finite element models have been used to derive direct expressions for the plate strength in terms of the Ramberg-Osgood parameters using a modified Winter curve. The explicit plate strength equations showed that as a result of gradual yielding, the strength of stainless steel plates is reduced below the strength of carbon steel plates, as predicted by the standard Winter equation, by up to 13% depending on the alloy and cold-working history. Most recently, the explicit strength equations were applied to cold-formed sections and design models were proposed for determining the strength of such sections. It was shown that the corners of cold-formed sections play a more important role for stainless steel sections than for carbon steel sections because the corner areas can be cold-worked to much higher strengths than in the case of carbon steel sections. Because of the enhanced mechanical properties of the corners, the standard Winter equation can in many cases be used safely for the design of cold-formed stainless steel sections. There are however a number of exceptions, which have been identified. The present paper summarises the research on the local buckling strength conducted at the University of Sydney over the last three years.

reliability analysis shows the method to be suitable for design. The theoretical elastic buckling stress of the composite steel sections delays local buckling and subsequently results in significant increases in elastic buckling stress, axial capacity and strength-to-weight ratio of the compression members. The experiments are an extension of a previous study [Bambach MR, Elchalakani M. Plastic mechanism analysis of steel SHS strengthened with CFRP under large axial deformation. Thin-Walled Structures 2007;45(2):159–70] in which 25 commercially produced SHS with plate slenderness values between 0.3 and 1.6 were strengthened with CFRP in the same manner. A design method is developed whereby the theoretical elastic buckling stress of the composite steel–CFRP sections is used to determine the axial capacity, and is shown to compare well with the 45 test results. A reliability analysis shows the method to be suitable for design.

ABSTRACT: In this paper, the buckling and post-buckling of steel thin-walled semi-spherical shells are investigated under different loadings, both experimentally and numerically. Various vertical compression
loadings are applied to specimens using the following methods: a rigid flat plate and some rigid bars with circular, square and spherical cross sections, a rigid tube, a plate with a hole, and an indented tube. The effects of geometrical parameters of specimens on the buckling load, such as the diameter and thickness, are studied. The numerical analysis is carried out by ABAQUS software and the experimental tests are performed using an Instron 8802 servo-hydraulic machine. The numerical and experimental results are similar to one another. Therefore, the numerical results are valid.

ABSTRACT: The effects of the length, sector angle, and different boundary conditions on the buckling load and post buckling behavior of cylindrical panels have been investigated using experimental and numerical methods. The experimental tests have been performed using a servo-hydraulic machine, Instron 8808, and for numerical analysis, Abaqus finite element package has been used. The numerical results are in good agreement with the experimental tests.

ABSTRACT: A series of finite element analysis on the cracked composite cylindrical shells under combined loading is carried out to study the effect of loading condition, crack size and orientation on the buckling behavior of laminated composite cylindrical shells. The interaction buckling curves of cracked laminated composite cylinders subject to different combinations of axial compression, bending, internal pressure and external pressure are obtained, using the finite element method. Results show that the internal pressure increases the critical buckling load of the CFRP cylindrical shells and bending and external pressure decrease it. Numerical analysis show that axial crack has the most detrimental effect on the buckling load of a cylindrical shell and results show that for lower values of the axial compressive load and higher values of the external pressure, the buckling is usually in the global mode and for higher values of axial compressive load and lower levels of external pressure the buckling mode is mostly in the local mode.

ABSTRACT: Within this contribution, buckling of tubular steel shells with circular cutout will be analyzed. The experimental results will be compared by FEM simulation results within circular cutouts of the specimen. The experimental buckling tests have been conducted using a Servo-hydraulic machine (Instron 8802). Considering the broad application range of tubular thin-walled shells, prediction of the behavior of these elements in combined loading case (especially for buckling behavior) has gained a great level of importance. In this study, the influence of shell length, shell diameter, shell angle and diameter of circular cutouts on the predicted buckling values for the tubular shell has been explored. Numerical simulations of tubular shell subjected to combined loading were conducted. The analytical solutions show excellent agreement with the numerical results predicted by FEM.

ABSTRACT: This study deals with free vibrations and buckling analysis of nanocomposite Timoshenko beams reinforced by single-walled carbon nanotubes (SWCNTs) resting on an elastic foundation. The SWCNTs are assumed to be aligned and straight with a uniform layout. Four different carbon nanotubes (CNTs) distributions including uniform and three types of functionally graded distributions of CNTs through the thickness are considered. The rule of mixture is used to describe the effective material properties of the nanocomposite beams. The governing equations are derived through using Hamilton's principle and then solved by using the generalized differential quadrature method (GDQM). Natural frequencies and critical buckling load are obtained for nanocomposite beams with different boundary conditions. Effects of several parameters, such as nanotube volume fraction, foundation stiffness parameters, slenderness ratios, CNTs distribution and boundary conditions on both natural frequency and critical buckling load are investigated. The results indicate that the above-mentioned parameters play a very important role on the free vibrations and buckling characteristics of the beam.

ABSTRACT: A structural mechanics model is employed for the investigation of the bending buckling behavior of perfect and defective single-walled carbon nanotubes (SWCNTs). The effects of different types of defects (vacancies and Stone-Wales defects) at various locations on the critical bending buckling moments and curvatures are also studied for zigzag and armchair nanotubes with various aspect ratios (length/diameter). The locations of defects are along the length of the nanotube and around the circumference. Moreover, the results of this structural mechanics model are compared with a finite element model. The simple continuum model, especially, could be adopted to predict the critical buckling moments and curvatures of SWCNTs with large aspect ratio. Finally, the results of the present structural model are compared with those from molecular dynamics (MD) simulation, and there is good agreement between our model and the MD model.

“Buckling behavior of perfect and defective DWCNTs under axial, bending and torsional loadings via a structural mechanics approach”, Meccanica, Vol. 48, No. 8, pp 1959-1974, October 2013
ABSTRACT: The buckling behavior of perfect and defective double-walled carbon nanotubes (DWCNTs) under axial compressive, torsional and bending loadings is investigated using a structural mechanics model. The effects of van der Waals (vdW) forces are further modeled using a nonlinear spring element. Critical buckling loads, critical buckling moments and the effects of vacancy defects were studied for armchair nanotubes with various aspect ratios. The results show that vacancy defects greatly reduce the critical buckling load of DWCNTs. The density of defects plays an important role in buckling of DWCNTs. The results of this numerical model are in good agreement with their comparable existing works.

“Buckling Load Analysis of Oblique Loaded Stainless Steel 316ti Cylindrical Shells with Elliptical Cutout”,
Research Journal of Recent Sciences, Vol. 1, No. 8, pp. 53-63, August 2012

ABSTRACT: This paper concerns with experimental and numerical studies on buckling of thin-walled cylindrical shells under oblique loading. The buckling loads are obtained from finite element models. Experiments are conducted on several Specimens made of stainless steel 316ti by using an INSTRON 8802 servo-hydraulic machine. Then results are compared. A very good correlation was observed between numerical simulation and experimental results. Investigations on buckling and post-buckling behavior of cylindrical shells with cutout were carried out for shell length (L), shell diameter (D) and cutout position (CP/L ratio). The specimens were constrained by fixtures that design for this result and inserted at both ends, which mimics the fixed boundary condition used in the finite element simulations.

ABSTRACT: The interactive mechanisms between internal blast loading and dynamic elastic response of spherical containment vessels are studied in this paper. The blast loading history in containment vessels can be divided into three periods, i.e. the primary-shock period, the shock-reflection period and the pressure-oscillation period. It is shown that the initial response of the containment vessel depends on both the impulse and the shape of the primary-shock depending on the ratio of the loading period to the breathing mode period. However, during the shock-reflection period, the response of the containment vessel can be coupled with the reflected shock waves in the vessel, especially when the dominant frequency of reflected shock waves is close to the breathing mode frequency of the vessel. During the pressure-oscillation period, the dynamic loading is mainly the oscillation of the internal pressure due to the oscillatory volume change of the vessel, which couples dissipatedly with the vibration of the vessel leading to reduced vibration amplitudes. The effects of the influential non-dimensional parameters on the resonant interaction in shock-reflection period are discussed, based on which guidelines are recommended for avoiding the strain growth in the shock-reflection period in the design of spherical containment vessels.

ABSTRACT: This paper treats the dynamic response and energy absorption of aluminum semi-spherical shells under axial loading using non-linear finite element techniques. Aluminum and steel spherical shells of various radii and thicknesses were made by spinning. The influence of geometrical, material and loading parameters on the impact and quasi-static response is investigated using validated numerical models. Also the axial inward inversions of semi-spherical shells are investigated. The research information generated will be useful in developing guidance towards the design of these devices in impact applications.

PARTIAL INTRODUCTION: Thin-walled members are the elements of many engineering structures. They become unstable and start to buckle if they subjected under a compressive loads greater than their ultimate buckling load. Moreover, some of these members usually have cut outs due to their applications and these discontinuities can affect on their stability. The stability analysis of thin-walled structures under axial compression has been investigated by some researchers. Obviously, the stability of these structures is dependent on the type of support and loading. The buckling and the geometrically nonlinear elasto-plastic collapse of perforated plates were investigated using finite element solutions. Elasto-plastic postbuckling of damaged orthotropic plates based on the elasto-plastic mechanics and continuum damage theory have been studied. El-Sawy et al. employed the FEM to determine the elasto-plastic buckling stress of uniaxially loaded square and rectangular plates with circular cutouts. Plates with simply supported edges in the out-of-plane direction and subjected to uniaxial end compression in their longitudinal direction were considered.

ABSTRACT: In this research, softening and ratcheting behaviors of Ck20 alloy steel cylindrical shells were studied under displacement-control and force-control cyclic axial loading and the behavior of hysteresis curves of specimens was also investigated. Experimental tests were performed by a servo-hydraulic INSTRON 8802 machine. The mechanical properties of specimens were determined according to ASTM E8 standard. Under force-control loading with non-zero mean force, ratcheting behavior occurred on cylindrical shell and plastic strain accumulation continued up to the collapse point of cylindrical shell. The rate of ratcheting strain became higher using the higher force amplitude. Softening behavior was observed under displacement control loading and, due to the occurred buckling in compression zone, this behavior became more extreme. The behavior of hysteresis curves of this alloy was not symmetrical under tensile and compressive loads. Moreover, the influence of loading history was studied on the behavior of hysteresis curves of the specimens under various types of loadings.

ABSTRACT: This research was an experimental and numerical investigation of the cylindrical expanded Sheets under impact loading. Two types of absorbers with different cell angles were examined (i.e. α = 0 and α = 90). The experiments were performed using the drop hammer setup, and the numerical simulations were conducted by ABAQUS. In this study, the type of collapse, force-displacement diagrams, the crushing length, and the absorbed energy were investigated. The experimental and numerical results were compared, and it was observed that they were in good agreement. Results showed that the absorbers with the cell angle of α = 0 had a symmetric collapse and a high energy absorption capacity. Also, various heights of fall were considered for the impact mass to examine the type of collapse in the models. The crushing amounts of the models were also compared in different heights. Multi-walled expanded metal tubes were studied, and the effect of being multi-walled in collapse was examined.

“Buckling analysis of carbon nanotube bundles under axial compressive, bending and torsional loadings via a
ABSTRACT: A structural mechanics model is employed for the investigation of the buckling behavior of carbon nanotube bundles of three single-walled carbon nanotubes (SWCNTs) under axial compressive, bending and torsional loadings. The effects of van der Waals (vdW) forces are further modeled using a nonlinear spring element. The effects of different types of boundary conditions are studied for nanotubes with various aspect ratios. The results reveal that bundles comprising longer SWCNTs exhibit lower critical buckling load. Moreover, for the fixed-free boundary condition the rate of critical buckling load reduction is highest, while the lowest critical buckling load occurs. Simulations show good agreement between our model and molecular dynamics results.

ABSTRACT: Buckling of steel thin-walled semi-spherical shells with square cutout due to axial compressive loads has been studied by numerical simulations, and results were compared with those from the experiments. Three vertical compression loadings were applied to specimens using the following methods: a rigid flat plate and a rigid bar with circular and spherical cross sections. The main aim of this study is to determine the influence of the cut-out size-to-location (a/H) and the thickness-to-diameter (t/D) on the mean collapse load of the semi-spherical shells. The finite element models were analyzed using ABAQUS nonlinear buckling analysis and the experimental tests were performed using an INSTRON 8802 servo-hydraulic machine. Finally, the different results obtained using the two analysis methods were compared. The comparison reveals that experimental and numerical nonlinear model results match closely with each other.

ABSTRACT: Numerical analysis of cracked composite cylindrical shells under combined loading is carried out to study the effect of crack size and orientation on the buckling behavior of laminated composite cylindrical
The interaction buckling curves of cracked laminated composite cylinders subject to different combinations of axial compression, torsion, internal pressure and external pressure are obtained, using the finite element method. In general, the internal pressure increases the critical buckling load of the CFRP cylindrical shells while torsion and external pressure decrease it. Numerical analyses show that axial crack has the most detrimental effect on the buckling load of a cylindrical shell while for cylindrical shells under combined external pressure and axial load, the global buckling shape is insensitive to the crack length and crack orientation.

Hamidreza Allahbakhsh and Ali Dadraei (Mechanical Department, Islamic Azad University, Shahrood Branch, Shahrood, Iran), “Buckling Analysis of Laminated Composite Panel with Elliptical Cutout Subject to Axial Compression”, Modelling and Simulation in Engineering, Vol. 2012 (2012), Article ID 171953, 10 pages, doi:10.1155/2012/171953

ABSTRACT: A buckling analysis has been carried out to investigate the response of laminated composite cylindrical panel with an elliptical cutout subject to axial loading. The numerical analysis was performed using the ABAQUS finite-element software. The effect of the location and size of the cutout and also the composite ply angle on the buckling load of laminated composite cylindrical panel is investigated. Finally, simple equations, in the form of a buckling load reduction factor, were presented by using the least square regression method. The results give useful information into designing a laminated composite cylindrical panel, which can be used to improve the load capacity of cylindrical panels.

ABSTRACT: This thesis reports on a series of experimental and finite element modeling studies of sandwich panels typical of wind turbine blade construction. Buckling is a common failure mode in composite structures such as fiberglass wind turbine blades and sandwich construction is often employed in sensitive areas to increase buckling resistance with minimum weight and cost. The panels were flat or curved with fiberglass facesheets and balsa cores. The primary objective of the study was to investigate the accuracy of linear and nonlinear finite element buckling predictions for panels of this type. Modeling procedures used for composite structures like blades often utilize linear eigenbuckling and geometrically nonlinear incremental buckling analyses. Often, the nonlinear model used the linear mode shape to perturb the model and to produce a buckling shape on the perfect geometry. The present study uses the random nodal displacement perturbation method for the nonlinear analysis which is entirely independent of the linear mode shape. The random perturbation method can be used for complicated structures and does not impose a mode shape on the model which may or may not be correct. Both methods, linear and nonlinear, were validated with buckling experiments on idealized blade substructures: curved and flat fiberglass/balsa sandwich shells. Five different series of panels were tested incorporating changes to four parameters: support conditions (simple-free-simple-free and four sided simply supported), radius of curvature (flat, shallow and deep), facesheet lay-up, and core thickness. Good correlation between tests and shell element FE modeling was found for both the linear and nonlinear cases for the critical buckling loads for most models. Good correlation was also found for the early postbuckling response, with late postbuckling strains becoming invalid and deflections being rough approximations after some response shift (mode shift or mesh rippling). Certain combinations of numerical and/or structural parameters were found to present problems to some of the analysis techniques. The combination of curvature and free side edges caused problems for predicting the correct critical buckling mode for both the linear and nonlinear analyses. Deep curvatures and high mesh densities also caused problems predicting the correct mode shape for four sided simply supported panels. Complex boundary conditions tended to compound these problems. Proper modeling of the boundary conditions was found to be critical for accurate results, especially for the curved panels. In this study, this required modeling the load supports of the test fixture. Finally, closed form solutions found in the literature had poor correlation for both critical buckling loads and mode shapes. The random nodal displacement perturbation method was found to have several general characteristics. First, it tended to give conservative
results as compared to the linear models. A statistical study demonstrated relatively consistent results with a standard deviation of 3.7% (down to 2.2% for smooth responses). The random method also tended to exacerbate any problems encountered with all nonlinear models, such as snap-through critical buckling responses, mode shifts to non-symmetric shapes and mesh rippling behavior. Additionally, a model would occasionally pass the critical buckling mode and continue loading until finally buckling into a higher mode shape. These last two problems were a function of the average size of the perturbations (slight for the mode shifts, significant for snap-through and higher buckling modes). Finally, large perturbations would sometimes violate curvature requirements for sandwich modeling due to high local curvatures caused by the random displacements.

Masuto Tanaka, Development of incompressible hyper-elastic shell elements using assumed strains and their application to buckling analysis of thin-walled tube under bending, Ph.D. dissertation, Science for Open and Environmental Systems, University not given, year not given (2007?)

ABSTRACT: The numerical implementation of nonlinear finite element procedures for flexible thin-walled structures using incompressible hyper-elastic shells is indispensable in the application of practical engineering and medical fields to predict and evaluate the behaviors of rubber-like shell structures and biological soft tissues. The investigation of a flexible thin-walled tube under bending is especially important in various branches of modern technology such as the forming limit of bent pipe, manufacturing of medical tubes, elastomer seals and numerical model for blood vessels. When a long thin-walled tube, such as a hydraulic hose, is subjected to a bending moment, its cross-section becomes distorted. Due to the reduction of the geometrical moment of inertia as its cross-section flattens, the stiffness of the tube decreases with the increase of load. With further moment, the tube collapses with a local kink in its longitudinal direction. The ovalization phenomenon of the cross-section in bending thin-walled tubes was first investigated by Brazier. However, since this work was based on the assumption of infinitesimal strain, his theory could not cope with the kink phenomenon which is shown physically. The pre/post buckling analysis of this kink instability of thin-walled tubes under bending is still an open issue due to its strong nonlinearity. In order to conduct finite element analysis of the above flexible thin-walled tube, not solid elements but shell structure elements which can treat the constitutive law for rubber-like materials allowing large elastic strains are required in view of computational efficiency, modeling effort and accuracy. In recent years, these finite strain shell elements accounting for thickness change have been presented. The elements use additional degrees of freedom for thickness change and three dimensional constitutive relations. However, these additional degrees violate computational efficiency and simplicity of modeling which are primary advantages of shell structure elements, and then derive the complicated formulations. In order to overcome this difficulty, a lot of formulations for the large strain shell elements are still being developed. The objective in this study is to present a new formulation for robust and efficient finite shell elements to investigate the instability problem which shows strong nonlinearity such as buckling analysis of flexible thin-walled tube under bending. Firstly, a high-accurate incompressible hyper-elastic shell element using two dimensional constitutive relations is developed. Then, the performance of the presented shell element is illustrated by its applications to several numerical examples including bending analysis of a thin-walled tube. Finally, the nonlinear mechanism of kink phenomenon of flexible thin-walled tube under bending is clarified.

The composition of this thesis and the contents in each chapter are shown as follows. In chapter 1, the
background and the purpose of the present study are described. In chapter 2, definition of hyper-elasticity and derivation of the constitutive law are summarized as the fundamental review of this study. In chapter 3, a finite strain shell element with its material restricted to hyper-elasticity is developed. This shell element is based on the MITC shell element developed by Bathe to perform locking-free behavior using assumed transverse shear strains. In addition to this MITC formulation, an assumed transverse normal strain is introduced to treat thickness change. In this formulation, the transverse normal strain is assumed to be uniform throughout the element, and evaluated at the middle surface using the incompressibility condition. Indeterminate pressure, which occurs in incompressible materials, is eliminated at the element level using the plane stress condition. The advantage of this technique is that well-conditioned tangent stiffness for a large strain shell element can be obtained without any additional variables. In chapter 4, a numerical implementation of the solid element and shell element with the Ogden material model is presented. This formulation derives the efficient constitutive law of Ogden material using invariants of the right Cauchy-Green tensor in the extension form of the Mooney-Rivlin’s law, without solving eigenvalue problems or coordinate system transformations. This chapter also validates the relationship between the present expression of the constitutive law and numerical stability. In chapter 5, buckling analysis of thin-walled tube under bending is investigated using the present hyper-elastic shell elements. Firstly, in order to compare with Brazier’s solution, the numerical analysis of a Hookean cylindrical tube is conducted using MITC4 shell elements that neglect thickness changes. From the numerical analyses, it is revealed that there are two critical points, a bifurcation point and a limit or turning point that causes the snap-back phenomenon before the limit point that Brazier estimated. The critical point where the bifurcation point coincides with the limit point is called the "hilltop branching point". Symmetrical kinks are observed along the primary path in the final, largely deformed, configuration, while only one kink is observed along the bifurcation path. Then, by using the developed large strain shell elements in which the Ogden material model is utilized, the pre/post buckling behavior of a rubber tube under bending with thickness changes is thoroughly investigated. It is revealed that there is hilltop branching point consisting of one turning point that causes the snap-back phenomenon and two bifurcation points. The results of Ogden material model also shows two symmetrical kinks in the final deformed configuration, which are located on the inside of the tube relative to the results of the Hookean model. In chapter 6, the concluding remarks of this thesis and the future works are given.

ABSTRACT: This thesis presents a series of analytical models, based on the Generalized Beam Theory (GBT), to describe the buckling and post-buckling behaviour of thin-walled prismatic cold-formed steel structural members under compression and/or bending. GBT has a unique feature of enabling an theoretical significance to the structural analysis of these members, which can not be achieved by any other known method. Initially, a review of the current state of the art in GBT is carried out, together with a review on the most recent bibliography of alternative methods for post-buckling analysis of thin-walled structures, allowing to define the specific goal of the present work – the setting up of a consistent GBT-based methodology for post-buckling analysis. Next, a consistent formulation based on the concept of Total Potential Energy in the framework of the classical GBT theory, for post-buckling analysis, was created, enabling the rigorous study of open non-branched and closed mono-cellular sections. Subsequently, a series of refinements in the GBT theory and in the adopted numerical strategies, namely in the Rayleigh-Ritz method and in the bifurcational calculus techniques, were made in order to analyze the perfect structural member, without making resource to imperfections, made by plane plates rigidly connected along the folding lines with a general cross section. Finally, the developments
were illustrated and validated by the resolution of several examples, which were compared to other methods of analysis for the critical behaviour and for the post-buckling equilibrium paths, like the Finite Strip and the Finite Elements Method.

ABSTRACT: A numerical stability analysis of an axially compressed multilayered composite shell is presented. The authors examine how the stability performance of a panel can be influenced by a centrally located square cut-out. The computations are performed within FEM computer program NX-Nastran (ver. 6.0). The stability is investigated by means of a linearized buckling analysis as well as of a non-linear large deformations incremental analysis. To get more insight into the performance of the layered structure, the failure index according to Tsai–Wu criterion is monitored in the study.

ABSTRACT: A numerical study of the local buckling and fracture response of a thin composite plate with an inclined crack and subjected to tension is presented. Local buckling of the unsupported edges of the crack occurs due to compressive stresses caused by a Poisson effect in the neighborhood of the crack. The relationship between fracture of a plate with a crack and the local buckling and postbuckling responses of the plate is established through a geometrically nonlinear finite-element analysis in conjunction with concepts from fracture mechanics. The analysis is based on a co-rotational form of the updated Lagrangian formulation that is implemented with a triangular shell element that includes transverse shear deformation effects. The potential energy release rate results are computed for a predetermined radial crack propagation direction that coincides with the location of the maximum stationary strain energy density near the crack tip. The results indicate that the local buckling load increases and the potential energy release rate decreases as the crack orientation changes from a transverse crack to a longitudinal crack aligned with the direction of the applied tension load. The effect of stacking sequence on the local buckling load and on the energy release rate for specific crack orientations is also discussed.

ABSTRACT: A nonlinear boundary-value problem for shells is formulated. The problem statement permits us to analyze the behavior of the postbuckling solutions in a finite-dimensional space with the dimension independent of the discretization technique. A branching pattern is established for the solutions of the problem in the case of a uniform external pressure. Four characteristic types of solution are recognized in the case of an arbitrary external pressure. The associated buckling loads are determined. It is found out that five significant parameters are sufficient for a qualitative analysis of a cylindrical shell.

ABSTRACT: Buckling loads and postbuckling behavior of cylindrical shells subjected to localized external pressure are considered. The modified extended Kantorovich method with path-tracing technique is applied to
determine the buckling loads of the cylindrical shells. It is found that the load is dependent nonmonotonically on geometrical parameters of the area subjected to external pressure. Respective postbuckling shapes show correlation with the shapes corresponding to secondary bifurcation paths for the cases of a cylindrical shell under uniform external pressure and a cylindrical shell under uniform axial load.

ABSTRACT: In this article, the buckling of cylindrical shells with longitudinal joint has been investigated through the experimental and numerical analysis. It was clarified that the buckling behavior of cylindrical shells with longitudinal joints under lateral external pressure is not only related to its dimension, but also longitudinal joint and an imperfection. The buckling of cylindrical shells with rigid joint buckles only once and in multi-lobed buckling, whereas one with flexible joints buckles twice and firstly in single-lobed buckling in the vicinity of the joint, secondly in multi-lobed buckling in remaining undeformed area. And the more flexible the longitudinal joint, the lower the critical pressure, with respect to the same dimension of jointed cylindrical shells and
imperfection condition. Moreover the numerical analysis approaches were also presented and verified, by which the imperfection can greatly enlarge the effect of joint on buckling has been demonstrated.

ABSTRACT: The major problems due to welding effects are the residual stresses and distortions of which the levels affect more or less the resistance and lifetime of welded structure. In steel industry and particularly in shipbuilding, during these last few decades, thin plates are used more and more in ship construction in order to lighten the structure weight. Unfortunately, excessive distortions occurred on these thin stiffened panels and straightening works must be executed in respecting the limit tolerance fixed by the Quality Standard of Ship Construction. These futile works reduce Productivity and Quality, increase Construction Cost and get longer Fabrication Delay. Thus, it is necessary to evaluate, control and minimize the distortion and stress levels of thin welded panels before welding assembly operations. In this paper, a short presentation of the Methodology and its industrial applications in shipbuilding are presented for two panels of a Chemical Parcel Tanker (1996) and a large “Testing” Panel in full scale of a Passengers Ship (2002). The numerical results due to welding effects so obtained within short computer-time (three hours and half for a 3D FE model of more than two million of degrees of freedom) on a linear FEM software were verified with measured stress values and identified with the buckling state of the “Testing” Panel before and after welding operations by photographs.

ABSTRACT: A simplified method to estimate the ultimate strength of a continuous plate, typical in ship bottom plating, subjected to combined transverse thrust and lateral pressure is developed. A series of elastic/elastoplastic large deflection finite element analysis (FEA) of a continuous plate supported along the lines of longitudinal stiffeners and transverse frames is performed. Attention is focused on the effect of a continuity of plating on its buckling and ultimate strengths, while the previous studies are mainly concerned with an isolated plate. Based on the FEA results, a set of formulae has been derived for the estimation of the ultimate strength of a continuous plate under combined transverse thrust and lateral pressure. An increase of elastic buckling strength and a change in the collapse mode from a simply supported mode to a clamped mode
are considered as an effect of a continuity of plating. It has been proven from a comparison with FEA that the proposed formulae give very accurate predictions of the ultimate strength.

ABSTRACT: A set of design formulae to estimate the ultimate strength of a continuous stiffened panel subjected to combined transverse thrust and lateral pressure is presented, extending the basic idea proposed for a continuous plate in Part-1 study. The effect of plate/stiffener interaction on the elastic buckling strength of local plate panel is introduced in the formulation as well as the effect of continuity of plating. The overall collapse of stiffeners under lateral pressure is included in the possible failure modes. It has been proven from a comparison with FEA results that the proposed formulae give a good prediction of the ultimate strength of a continuous stiffened panel.

ABSTRACT: The main objective of this paper is to present the results of the finite element method for non-linear analysis of stiffened plates subjected to axial compression load considering post-buckling behaviour up to collapse. For this purpose two series of well executed experimental data on longitudinally stiffened steel plates with and without transversal stiffeners subjected to uniform axial in-plane load carried out to study the buckling and post-buckling up to final failure have been chosen. The first series are those of Ghavami where the influences of stiffener cross-section of the type rectangular (R), L and T, their spacing and the presence of rigid transversal stiffeners have been studied. The second series of Tanaka & Endo, where the behaviour of stiffened plates having three and two flat bars for longitudinal and transversal stiffeners respectively were analysed. For the purpose a well-established commercially available Finite Element program ANSYS has been chosen. The selected element was SHELL43, which can trace the full-range, elastic-plastic behaviour of the stiffened plates. It is seen that the simulated results of FEM are in good consistency with the test results.

“Ultimate strength and ductility characteristics of intermittently welded stiffened plates under in-plane axial
ABSTRACT: The ultimate strength and ductility characteristics of the intermittently welded stiffened plates under the action of in-plane axial compression are investigated in this paper. A series of detailed numerical analyses of longitudinally stiffened steel plates subjected to in-plane compressive load is performed using the ADINA commercial finite element code. Complete equilibrium paths are traced up to collapse for a nonlinear elastic-plastic response of stiffened plates. Analyzed stiffened plates are imperfect and their aspect ratio, plate slenderness, and column slenderness are changed in a systematic manner. Different types of stiffener are chosen for stiffened plate models. Three different stiffener-to-plate welding procedures are considered: continuous, chain intermittent, and staggered intermittent fillet welding.

“A comparative study on three different construction methods of stiffened plates—strength behaviour and ductility characteristics”, Revista Escola de Minas, Vol. 60, No. 2, April/June 2007

ABSTRACT: Strength and ductility characteristics of non–continuously welded stiffened plates under in plane axial compression are the main focus of this research. A series of detailed numerical analyses of stiffened steel plates subjected to in plane compressive load is performed. Complete equilibrium paths are traced up to collapse for non–linear elastoplastic response of stiffened plates. Stiffened plates are selected from the deck structure of real sea–going ships and inland waterway vessels. Three different stiffener–to–plate welding procedures are considered: continuous, chain intermittent and staggered intermittent fillet welding. Special attention is paid to the finite element modeling of the fillet welds in either of welding practices. Some available tests are simulated applying finite element method.

ABSTRACT: Intermittent fillet welding of stiffeners to plates and its influence on the collapse behaviour of stiffened plates is investigated applying the finite element method. Special attention is paid to the modelling of the fillet welds at the plate-to-stiffener junction. Some available experimental results are simulated in order to obtain reliable numerical results. A series of numerical analyses of stiffened steel plates subjected to an in plane axial compressive load has been performed. Stiffened plates are selected from the deck structure of real seagoing ships and inland waterway vessels. Complete equilibrium paths are traced up to collapse for the nonlinear elastoplastic response of stiffened plates. Finally a proposal is presented for the permissible gap of welds in intermittent fillet welding of stiffened plates.

ABSTRACT: Cracks of any size may occur at various locations and orientations throughout thin-walled structures. The presence of cracks in such structures can considerably affect their load bearing behaviour. This paper addresses a finite element study on the buckling strength of a cracked plate with simple supports subjected to an axial compressive edge load. The effects of crack location, crack orientation, crack length and plate aspect ratio are analysed. The size of the crack as well as its location and orientation are shown to have significant effects on the buckling behaviour of the plate under compressive loading. Some new results are also discussed in detail.

ABSTRACT: In this paper, the results of an investigation into the post-buckling behaviour of high-strength aluminium alloy stiffened plates subjected to combined axial compression load and different magnitudes of lateral pressure using non-linear finite element approach is presented. Both material and geometric non-linearities have been taken into account. The principal variables studied are the plate thickness, boundary conditions and the stiffener geometries beside the geometrical imperfection, the width of the welding heat-affected zone (HAZ) and welding residual stresses. The influence of these variables on the post-buckling behaviour and ultimate strength of such stiffened plates has been investigated in details.

ABSTRACT: The main target of this research is to identify the merits and disadvantages of the application of a newly proposed design of stiffened aluminium plates incorporating transverse floating frames, from buckling/ultimate strength points of view. In order to achieve this, an extensive investigation into the buckling and ultimate strength of orthogonally stiffened aluminium plates with different structural arrangements of transverse frames is presented in this paper. The transverse frames are assumed to be either in fixed or floating position. Other combined placements of the transverse frames are also proposed and included in the comparative study. Nonlinear finite element analyses are performed on the models. Average stress–average strain relationships and also stress and deflection contours are obtained from the analyses. Buckling and ultimate strength characteristics of all models are identified and compared to each other. The key findings show that the model with transverse floating frames does not necessarily has the highest buckling strength as is believed in common practice. Also, the mixed or complex pattern of the installation of the transverse frames may lead to the highest ultimate strength.

ABSTRACT: The present research was undertaken based on the results obtained by the same authors in a sensitivity study on the buckling and ultimate strength of continuous stiffened aluminium plates. Empirical expressions are developed for predicting ultimate compressive strength of welded stiffened aluminium plates used in marine applications under combined in-plane axial compression and different levels of lateral pressure. Existing data of the ultimate compressive strength for stiffened aluminium plates numerically obtained by the authors through the previously performed sensitivity analysis are used for deriving formulations that are expressed as functions of two parameters, namely the plate slenderness ratio and the column (stiffener) slenderness ratio. Regression analysis is used in order to derive the empirical formulations. The formulae implicitly include effects of the weld on initial imperfections, and the heat-affected zone.

ABSTRACT: The paper addresses the problem of the influence of randomly distributed corrosion wastage on the collapse strength and behaviour of unstiffened/stiffened steel plates in longitudinal compression. A series of elastic-plastic large deflection finite element analyses is performed on both-sides randomly corroded steel plates and stiffened plates. The effects of general corrosion are introduced into the finite element models using a novel random thickness surface model. Buckling strength, post-buckling behaviour, ultimate strength and post-ultimate behaviour of the models are investigated as results of both-sides random corrosion.

ABSTRACT: The main targets of this research are mainly divided in to two parts: (1) identifying the effects of parabolic curvature on the buckling strength and behaviour of stiffened plates under in-plane compression, (2) generating practical graphs for extracting eigenvalue buckling stress of parabolic curved stiffened plate to dimensionless parameters. A parametric model for study of the problem is created. The model includes different parameters related to plate, stiffeners and also parabolic curvature. Three distinct sensitivity cases are assumed. In each sensitivity case, many different models are analysed and their buckling strengths are obtained using a finite element commercial program (ANSYS). Buckling strength and behaviour of all models with different ratios of parabolic curvature are compared to each other.

“Nonlinear large deflection analysis of stiffened plates”, Chapter 4 in Finite Element Analysis – Applications in Mechanical Engineering, edited by Farzad Ebrahimi, October 2012, DOI: 10.5772/48368

PARTIAL INTRODUCTION: Stiffened plates are basic structural members in marine structures as shown in Figure 1, and include also aeronautic and space shuttles among other structures. Due to the simplicity in their fabrication and high strength-to-weight ratio, stiffened plates are also widely used for construction of land based structures such as box girder and plate girder bridges. The stiffened plate has a number of one-sided stiffeners in either one or both directions, the latter configuration being also called a grillage (Figure 2). Ultimate limit state design of Stiffened plates’ structures requires accurate knowledge about their behaviour when subjected to extreme loading conditions. One of the most important loads applied on stiffened plates is the longitudinal in plane axial compression arising for instance from longitudinal bending of the ship hull girder as presented in Figure 3. The need to improve our knowledge of the buckling modes of such plates was emphasised after the collapse of several offshore structures and some ships in Brazil as well as the failure of several box girder bridges in the seventies of the twentieth century, Merrison Committee [1], Crisfield [2], Murray [3], Frieze, et.al. [4]. Stiffened plates are efficient structures, as a large increment of the strength is created by a small addition of weight in the form of stiffeners. However the collapse mechanisms of stiffened plates under predominantly compressive load present a complex engineering problem due to the large number of possible combinations of plate and stiffener geometry, materials, boundary conditions and loading. The design of such structure has to meet several requirements such as minimization of the weight and maximization of the buckling load. Thus, the designer of this structure is confronted with the problem of satisfying two conflicting objectives; such problems are called multi-objective or vector optimisation problems. In general, the objective-functions do not attain their optimum in a common point of the feasible points, Brosowski & Ghavami [5, 6].

ABSTRACT: The main target of this research is to identify the effects of camber parabolic curvature on the ultimate strength and behavior of stiffened plates under in-plane compression. A parametric model for the study of the problem is created. The model includes different parameters related to plate, stiffeners, and also parabolic camber curvature. Three distinct sensitivity cases are assumed. In each sensitivity case, many different models are analyzed and their ultimate strengths are obtained using an in-house finite element program. Ultimate strength and behavior of the models with different ratios of parabolic curvature are compared to each other and interpreted.

ABSTRACT: The post-buckling behavior of composite ships' stiffened plate panels has been studied. In this study, the average strain-average stress curves for these panels are derived using progressive failure method as well as nonlinear finite element method. The boundary conditions are appropriate for the continuous plate panels used in shipbuilding. The effects of the aspect ratio, initial geometrical imperfection and stiffener size on the post-buckling of these stiffened panels are evaluated.

ABSTRACT: Within the last years, a wide variety of complicated geometrically and physically nonlinear shell problems was approximately solved using mainly the Finite Element Method (FEM). Complex engineering structures need large systems of nonlinear equations for incremental load paths. Own investigations, using the SHEBA-element with 63 DOF's /4/, /8/, have shown that the limit capacity even of large and fast scalar computers (in our case a Cyber 76/73 configuration) may be exceeded in the case of critical and postcritical calculations.

ABSTRACT: The present paper couples the geometrically nonlinear shear deformation theory of thin shell structures [finite rotations; small strains; Başar (1987)] with the Hermitian-method (Collatz 1966; Almannai 1976). It presents a brief review of a nonlinear theory considering shear deformations by means of an operator formulation and the transformation of partial differential equations into algebraic equations by means of appropriate two-dimensional finite-difference operators. The nonlinearity can be treated by an incremental-iterative procedure. Finally the efficiency of the developed numerical method will be demonstrated by selected examples. Special attention is focussed on the convergence behaviour and the reliability of geometrically interpretable forces with respect to engineering applications.

“On the nonlinear analysis of thin shells by the generalized moving-least squares approximation”, 8th. World Congress on Computational Mechanics (WCCM8); 5th European Congress on Computational Methods in Applied Sciences and Engineering (ECCOMAS 2008); June 30 –July 5, 2008 Venice, Italy
ABSTRACT: In the present contribution a geometrically exact thin shells formulation is presented. An analysis procedure based on a meshfree approximation is outlined. As no restrictions are imposed on the rotational fields, the present formulation falls on the category of the geometrically exact structural theories. The derivation is made by imposing the kinematic hypothesis on the three-dimensional continuum. Contrary to previously presented works [1,2], where shear deformation was accounted, here only the bending deformation is included. We define energetically conjugated cross sectional stresses and strains based on the first Piola-Kirchhoff stress tensor and the deformation gradient, respectively. The complete linearization of the weak form is presented. For hyperelastic materials and conservative loadings the tangent bilinear form, i. e., the generalized stiffness matrix, is always symmetric even in points far from the generalized equilibrium positions. Initially curved shells are regarded as a stress-free deformed state from a chosen plane reference configuration [3]. The mapping between both configurations allows the exact consideration of the initial configuration. As the variational basis of the formulation requires the use of C1 approximations, the generation of compatible of finite elements is not trivial in the present case. In order to circumvent this inconvenience, meshless approximations are used. The first-order Generalized Moving-Least Squares Approximation has been successfully used in the solution of thin plate bending problems [4,5,6]. Although it increases the number of degrees-of-freedom per node, its performance is clearly superior to the conventional Moving-Least Squares Approximation in this specific class of problems. As
the approximation does not possess the Kronecker-delta property, the imposition of the essential boundary conditions is not immediate. These are enforced using a hybrid-displacement version of the shell formulation. To this end, the steps indicated in [7] are followed. This thin shell formulation has the basic advantage over their shear-deformable counterpart: no special devices have to be taking into account in order to avoid shear-locking.

ABSTRACT: This work presents a fully nonlinear Kirchhoff-Love shell model. In contrast with shear flexible models, our approach is based on the Kirchhoff-Love theory for thin shells, so that transversal shear deformation is not accounted for. We define energetically conjugated cross-sectional generalized stresses and strains. The fact that both the first Piola-Kirchhoff stress tensor and the deformation gradient appear as primary variables is also appealing. The weak form of the equilibrium equations and their boundary conditions of the model are consistently derived. Elastic constitutive equations are obtained from fully three-dimensional finite strain constitutive models in a consistent way. A genuine plane-stress condition is enforced by the vanishing of the mid-surface normal nominal stress (first Piola-Kirchhoff stress), yet rendering a symmetric linearized weak form. A plane reference configuration is assumed for the shell mid-surface, but, initially curved shells can be accomplished, if one regards the initial configuration as a stress-free deformed state from the plane position. As a consequence, the use of convective non-Cartesian coordinate systems is not necessary and only components on orthogonal frames are employed.

- P.M. Pimenta. Geometrically-Exact Analysis of Initially Curved Rods. In Advances in Computational Techniques for Structural
ABSTRACT: The current work discusses the application of the TUBA finite elements [1,2], initially developed for thin plates problems, to geometrically exact thin shell analysis. The proposed geometrically exact shell model is derived from the 3D continuum mechanics. The shell kinematics is based on the Kirchhoff-Love assumption and is characterized by the deformation gradient, which yielded the generalized cross-section strain measures — stretches and curvatures, written in terms of first- and second-order derivatives of displacements [3]. As the energetically conjugate quantity, the first Piola-Kirchhoff stress tensor is chosen. The shell’s initial geometry is exactly represented using a mapping from a reference configuration. A neo-Hookean material functional, supplemented by the plane stress condition, is incorporated in the constitutive level of the model. The theory is derived independently from the specific numerical method to be used, thus allowing any available approximation of C1 type to be used for the implementation. Special attention is given to the treatment of the natural and essential boundary conditions. The TUBA family of plate finite elements is considered for the discretization of the displacement vector field. These triangular elements, with necessarily straight sides in the reference configuration, provide C1 continuous approximations, mandatory for the proper implementation of the Kirchhoff-Love model. The family contains 3 pairs of elements (primary and reduced), which provide polynomial approximants of degrees k = 5, 6 and 7 respectively. The reduced elements have a simpler structure and a smaller number of nodes, but still guaranty C1 continuity [4]. The boundary normal derivative of the approximation in these elements is constrained, such that its order is reduced by one unit, from (k − 1), as for the primary elements, to (k − 2). Due to complexity of the elements degrees of freedom (which are the function value, its first- and second-order derivatives), the imposition of the essential boundary conditions is not trivial and needs some preliminary analysis of the boundary behavior. The proposed model is assessed by means of numerical nonlinear shells problems examples.

ABSTRACT: The current work discusses the application of the TUBA finite elements, initially developed for linear thin plates problems, to geometrically exact thin shell analysis. The proposed geometrically exact shell model is derived from the 3D continuum mechanics. The shell kinematics is based on the Kirchhoff-Love assumption and is characterized by the deformation gradient, which yielded the generalized cross-section strain measures — stretches and curvatures, written in terms of first- and second-order derivatives of displacements. As the energetically conjugate quantity, the first Piola-Kirchhoff stress tensor is chosen. The shell’s initial geometry is exactly represented using a mapping from a reference configuration. A neo-Hookean material functional, supplemented by the plane stress condition, is incorporated in the constitutive level of the model. The theory is derived independently from the specific numerical method to be used, thus allowing any available approximation of C1 type to be used for the implementation. Special attention is given to the treatment of the natural and essential boundary conditions. The TUBA family of plate finite elements is considered for the discretization of the displacement vector field. These triangular elements, with necessarily straight sides in the reference configuration, provide C1 continuous approximations, mandatory for the proper implementation of the Kirchhoff-Love model. The family contains 3 pairs of elements (primary and reduced), which provide polynomial approximants of degrees k = 5, 6 and 7 respectively. The reduced elements have a simpler structure and a smaller number of nodes, but still keep C1 continuity. The boundary normal derivative of the approximation in these elements is constrained, such that its order is reduced by one unit, from (k − 1) to (k − 2). Due to complexity of the elements degrees of freedom (which are the function value, its first- and second-order derivatives), the imposition of the essential boundary conditions is not trivial and needs some preliminary analysis of the boundary behavior. The proposed model is assessed by means of numerical nonlinear shells problems examples.

ABSTRACT: Nowadays aluminum stiffened plates are one of the major constituents of the marine structures, especially high-speed vessels. On one hand, these structures are subject to various forms of loading in the harsh sea environment, like hydrostatic lateral pressures and in-plane compression. On the other hand, fusion welding is often used to assemble those panels. The common marine aluminum alloys in the both 5,000 and 6,000 series, however, lose a remarkable portion of their load carrying capacity due to welding. This paper presents the results of sophisticated finite-element investigations considering both geometrical and mechanical imperfections. The tested models were those proposed by the ultimate strength committee of 15th ISSC. The presented data illuminates the effects of welding on the strength of aluminum plates under above-mentioned load conditions.

ABSTRACT: This paper presents the results of an extensive sensitivity analysis carried out by the Committee III.1 “Ultimate Strength” of ISSC’2003 in the framework of a benchmark on the ultimate strength of aluminium stiffened panels.

Previously, different benchmarks were presented by ISSC committees on ultimate strength. The goal has typically been to give guidance to the designer on how to predict the ultimate strength and to indicate what level of accuracy would be expected. This time, the target of this benchmark is to present reliable finite element models to study the behaviour of axially compressed stiffened aluminium panels (including extruded profiles). Main objectives are to compare codes/models and to perform quantitative sensitivity analysis of the ultimate strength of a welded aluminium panel on various parameters (typically the heat-affected zone). Two phases were planned. In Phase A, all members analysed the same structure with a defined set of parameters and using different codes. It was expected that all the codes/models predict the same results. In Phase B, to boost the scope of the analysis, the different members (using their own model) performed FE analyses for a range of variation of different parameters (sensitivity analysis).
ABSTRACT: Results are presented of compression tests on two large-scale longitudinally stiffened GRP panels representing ships’ deck structures. Two distinct types of collapse are demonstrated, one involving debonding of stiffeners precipitated by local, interframe buckling of the laminate and the other resulting from outer-fibre failure of the stiffeners caused by overall column-like buckling. Test results are correlated with theoretical analysis, including estimates of initial buckling stress using accurate folded plate analysis together with evaluation of large-displacement postbuckling behaviour using non-linear finite element analysis. Recommendations are made regarding design procedure and safety factors.

ABSTRACT: Recent advancement in manufacturing technology has initiated a new phase of buckling structures analysis and structural design research development. As the ability to manufacture stiffeners in complex shapes has become increasingly more sophisticated, researchers are able to further enhance the design of thin-walled stiffeners. This paper presents an attempt to discover a structural design which employs the use of sub-stiffeners and the ability to retain maximal buckling load. FEM analysis was performed on compression loaded rectangular stiffened panels clamped on all sides to determine optimal attributes of two panel concepts: (1) stiffeners height changes according to sinusoidal law across the panel width, (2) stiffeners area changes according to sinusoidal law across the panel width. In both cases, total volume of the material was held constant. Non-dimensional parameters of the optimal panels were obtained. It was found that there was a positive correlation between the amount of change in buckling patterns caused by a sub-stiffener, and the amount of initial buckling load which could be obtained.

ABSTRACT: This work describes the theoretical modal analysis model for the stiffened bottom plate of a tank that is filled with fluid having an undisturbed free surface. In the analysis model, the effects of bending, transverse shear and rotary inertia in both the plate and the stiffener are considered. Analytical results concerning the natural frequencies of the stiffened plate correlate well with experimental modal testing (EMT) results for above the second mode. To overcome the complexities in the modal analysis of the fluid–structure interaction, the Mindlin plate theory and the potential flow theory are applied; the velocity potential is also expressed using double finite Fourier transforms. Additionally, a parametric study was also performed for eigenfrequencies of the plate with a stiffener, in terms of the ratio of the depth of the stiffener to the thickness of the plate and that of the width of the stiffener to the thickness of the plate. Analysis results revealed the phenomenon of “mode reversal”, i.e. the first and second mode shapes of the plate with a deep stiffener in contact with air and water, respectively, are reversed. An occurring condition of “mode reversal” is derived and verified by both finite element analysis and EMT.

ABSTRACT: An investigation of the deformation and buckling characteristics of a composite, oblate bulkhead that has an inverted geometry and is subjected to pressure-only loading is presented for three bulkhead geometries and thicknesses. The effects of a stiffening support ring at the bulkhead to cylinder interface are also evaluated. Buckling analyses conducted using the axisymmetric shell code BOSOR4 are discussed for several bulkhead configurations. These results are analytically verified using results from the Structural Analysis of General Shells (STAGS) code for a selected bulkhead configuration. The buckling characterization of an inverted, oblate bulkhead requires careful attention as small changes in bulkhead parameters can have a significant effect on the critical buckling load. Comparison of BOSOR4 and STAGS results provided a very good correlation between the two analysis methods. In addition, the analysis code BOSOR4 was found to be an efficient sizing tool that is useful during the preliminary design stage of a practical shell structure. Together, these two aspects should give the design engineer confidence in sizing these stability critical structures. Additional characterization is warranted, especially for a composite tank structure, since only one bulkhead configuration was examined closely.

ABSTRACT: A great deal of attention has been focused on plates subjected to shear loading over the past decades. One main fact in design of such elements, which fall in the category of thin-walled structures, is their buckling behavior. Plate girders and recently shear walls are being widely used by structural engineers, as well as ship and aircraft designers. The role of stiffeners is proved to be vital in design of such structures to minimize their weight and cost. In this work, by using ANSYS finite element method of analysis, some 1200 plates are analyzed in order to study the role of stiffeners and to come up with some limits for an optimized design procedure. This eigenvalue method of analysis is first validated with the theoretical calculations and known cases for a wide range of typical panel geometries. The results show that the number of panels produced by
intermediate transverse stiffeners should not be less than the value of plate's aspect ratio. In other words, the transverse stiffeners should divide the length of the plate to portions equal or less than its width. It is also shown that the optimum geometric properties of the stiffeners correspond to the point when the buckling shape of a plate changes from the overall mode to local mode. Furthermore, all stiffened plates, with a similar aspect ratio and number of stiffeners, have a specific value of EI/aD, for which the critical shear stress is optimal. In addition, some expressions to predict these properties are presented.

ABSTRACT: It is generally accepted that cracks degrade the load bearing capacity of thin plates. The aim of the present paper is to investigate the influence of central cracks on the residual strength and stiffness degradation of shear panels using numerical finite element analysis. Various geometrical and mechanical characteristics of cracked panels such as the crack length, crack angle of inclination, panel aspect ratio, slenderness of panel, boundary conditions, Poisson's ratio, and Young's modulus are considered in the analyses. It is shown that the length and the angle of cracks may change the buckling behaviour of shear panels, and their combinational effects can result in substantial degradation.

ABSTRACT: Utilizing shear panels is a common practice in civil, naval and aerospace engineering structures and the performance of the one with thin steel plate shear walls is an interesting issue of ongoing related researches. It is a well-recognized phenomenon that the behaviour, and consequently the design procedure, of shear panels are mostly dominated by pre-yield buckling occurrence. However the existence of crack defects due to corrosion, fatigue, welding or mishandling may shed more complexities to such panels in terms of bearing capacity degradation. In this paper, a procedure for modelling and analysis of shear panels containing central or edge cracks, using the finite element method, is presented. Results can be incorporated to recognize the required mesh refinements around the crack tips and edges. In addition, the effect of relative crack length on buckling capacity of shear panels is investigated.

ABSTRACT: A perturbation method for determining the buckling strength of imperfection-sensitive structures is presented. The method is based on an extended system which was first used by Seydel in computation of limit points of nonlinear systems. The effects of various possible sources of structural imperfections on perfect structures with simple buckling loads are investigated by the method. The derivations and results of the present exposition are equally applicable to discrete and continuous systems. In the finite element implementation of the
new formulation, the perturbation expansions are determined by solving numerically several linear problems with a single positive-definite sub-stiffness matrix. The method is illustrated with its application to the analyses of imperfection-sensitivity of a simply supported column on a linear-elastic foundation subjected to axial compression.

ABSTRACT: A finite element asymptotic analysis for determining the lower bound dynamic buckling estimates of imperfection-sensitive structures under step load of infinite duration is presented. The lower bound dynamic buckling loads and the corresponding displacements are sought in the form of asymptotic expansions based on the static stability criterion and they can be determined by solving numerically (FEM) several linear problems with a single nonsingular sub-stiffness matrix.

ABSTRACT: This paper is concerned with the direct calculation of buckling strength of an imperfect structure. The main assumptions are that, for the perfect structure, there is a symmetric or a linear fundamental path and the corresponding first critical point is a simple symmetry-breaking or a simple bifurcation point. An extended system of limit points is proposed for which the newly introduced scaling parameters are regular solution and thus standard methods can be used to compute them. Using the extended system, one can directly obtain the exact buckling loads without tracing the postbuckling paths. An efficient implementation of Newton’s method solving the extended system is presented and numerical examples are given.

Baisheng Wu, Yongping Yu and Zhengguang Li (Department of Mechanics and Engineering Science, School of Mathematics, Jilin University, Changchun 130012, PR China), “Analytical approximations to large post-buckling deformation of elastic rings under uniform hydrostatic pressure”, International Journal of Mechanical
ABSTRACT: This paper presents analytical approximations to large post-buckling deformation of a circular, elastic, and inextensional ring under uniform hydrostatic pressure. By combining the Newton's method with the method of harmonic balance, we establish analytical approximations to large deformation of the ring. Unlike the classical method of harmonic balance, the linearization is performed prior to proceeding with harmonic balancing thus resulting in a set of linear algebraic equations instead of one of non-linear algebraic equations. We are hence able to establish analytical approximate solutions. These approximate solutions show excellent agreement with the exact solution, and are valid for small as well as large difference of the curvatures of the undeformed and the deformed ring.

ABSTRACT: Many structural applications require nonlinear finite element analyses in order to assess response and capacity. Plastic deformations may be accounted for by means of thickness integration or stress resultants. The stress resultant model employed herein is based on Ilyushin’s linear yield criterion for thin shells. The corners present with this criterion are circumvented by means of a simplification, hence, there is no need for multi-surface stress resultant updates. A backward Euler difference is employed in the stress resultant update, and a consistent tangent is used in the Newton–Raphson iterations on the global equilibrium. Limit points are traversed by means of an orthogonal trajectory method. The response of compression dominated shells with imperfections typically corresponds to limit point behaviour. For stress resultant plasticity, the nonlinear transition from initial yield to full plasticity in shell bending is missed. Hence, the efficiency obtained by eliminating thickness integration is countered by some inaccuracy in the response simulation. This is investigated by means of comparison with finite element simulations employing integration through thickness (with linear or nonlinear hardening). Both steel and aluminium alloys are considered. In collapse response of slender structures, the straining of the material may be moderate, but the motion may be governed by large rigid body translations and rotations. A way of accounting for this by means of the co-rotated approach is presented. Triangular high-performance facet shell elements are employed. By example computations, the importance of nonlinear geometry contributions is illustrated.

PARTIAL INTRODUCTION: In the designing of plates and shells, especially in calculations of their stability, it is of particular importance to take into account their geometrically nonlinear behavior. The most widely used
Method of stress analysis of structures is the finite element method. However, the literature has not dealt adequately with shells of anisotropic composite materials in geometrically nonlinear statements: the finite elements are usually constructed by proceeding from an actual theory of shells [1,2], and this does not provide the possibility of endowing them with a universally valid nature. This problem can be solved with the so-called degenerate finite elements of shells: finite element discretization is applied to three-dimensional equations of equilibrium in which the magnitudes are expressed in accordance with the adopted hypotheses through the magnitudes on the surface of the reference shells corresponding to them. In the present work we generalize the above-mentioned type of element [3,4] in relation to the calculation of anisotropic composite shells in geometrically nonlinear statement…

ABSTRACT: The post-buckling behaviour of composite cylindrical panels in axial compression is investigated using the nonlinear finite element theory. A branch-switching algorithm with an ‘eigenmode injection’ is discussed. The effect of the reinforcement angle on the buckling load, as well as the post-buckling behaviour of the panels, are analysed. Examples are considered for separated and closely spaced bifurcation points. By varying the reinforcement angle of the panels from 0 to 90°, two kinds of buckling modes are discovered for asymmetric and unstable symmetric lowest points of bifurcation. Local minima for the secondary branches of geometrically perfect panels are no less than 15% of their buckling loads, while values of the buckling loads alter more than twice in this region. A 16-node degenerated shell element with full integration scheme is used.

ABSTRACT: In this paper, we explore the capabilities of some nonlinear strategies based on domain decomposition for nonlinear analyses, and more particularly for post-buckling analyses of large slender structures. After having recalled the classical Newton–Krylov–Schur methods, chosen here to serve as a reference, we propose two versions specifically developed to treat nonlinear phenomena at the most relevant scale through nonlinear localizations per substructure. All these different strategies lead to solving similar condensed problems on which we apply classical Domain Decomposition Methods. Performances are discussed and comparative results in terms of convergence are presented in the case of beam frames with large rotations and local buckling.

ABSTRACT: This paper investigates a computational strategy for studying the interactions between multiple through-the-width delaminations and global or local buckling in composite laminates taking into account possible contact between the delaminated surfaces. To achieve an accurate prediction of the quasi-static response, a very refined discretization of the structure is required, leading to the resolution of very large and highly nonlinear numerical problems. In this paper, a nonlinear finite element formulation along with a parallel iterative scheme based on a multiscale domain decomposition is used for the computation of three-dimensional mesoscale models. Previous works by the authors already dealt with the simulation of multiscale delamination assuming small perturbations. This paper presents the formulation used to include geometric nonlinearities into this existing multiscale framework and discusses the adaptations that need to be made to the iterative process to
ensure the rapid convergence and the scalability of the method in the presence of buckling and delamination. These various adaptations are illustrated by simulations involving large numbers of DOFs.

ABSTRACT: Buckling failure is quite a common occurrence in plates under compression, in particular when the plate’s thickness is sufficiently small with respect to others plates’ sizes; such a mode of crisis can often precede strength failure. Buckling failure under tension loading can also be a practical occurrence, especially in cracked plates in which it often takes place as a local buckling phenomenon, due to compression stresses transverse to the loading direction which develop around such imperfections. The aim of the present paper is to analyse the buckling phenomena of variously cracked rectangular elastic thin plates under tension or compression, by considering the effects of various geometrical, mechanical and boundary characteristics of the problem. A short explanation of the buckling phenomena in plates is recalled and several numerical parametric analyses are performed, employing the finite element method, in order to determine the critical load multiplier, in compression or in tension, by varying some of the problem’s geometrical and mechanical parameters. In particular, the buckling critical load multiplier is determined for different crack lengths, crack orientations and material Poisson coefficients and by varying the plate’s boundary conditions. Furthermore, some cracked configurations are analysed by means of a fully geometrical non-linear analysis, with contact between crack faces taken into account, in an effort to understand the effective whole structural behaviour also beyond the critical load. The results obtained are summarised graphically in figures and some interesting and useful conclusions are drawn on the sensitivity to the above-mentioned parameters to the buckling failure of variously restrained cracked compressed or tensioned plates.

ABSTRACT: In this paper, a general theory on the asymptotic field near the crack tip for plates and shells with and without shear deformation effect is established. It is found that four stress intensity factors, two for symmetrical and antisymmetrical stretching and two for symmetrical and antisymmetrical bending, are required to describe arbitrary asymptotic fields near the crack tip for plates without shear deformation. An additional stress intensity factor is required for the transverse shearing force induced by antisymmetrical bending when the shear deformation is included in the analysis. It is also proven by means of the complex variable technique that for problems of plates with shear deformation, there exist similarities in the asymptotic expressions of moments and membrane forces and also in the asymptotic expressions of in-plane displacements and rotations of the mid-surface. The energy release rate associated with crack growth in the direction of the crack line can be expressed in terms of stress intensity factors by means of Irwin's method of work and energy associated with a virtual crack extension. A combined stress intensity factor can be defined through the total energy release rate. The
theory of the fracture of plates is generalized and applied to the study of problems in the fracture of shells. An example of an infinitely long cylindrical shell with a circumferential crack subjected to remote axial tension is given to demonstrate the application of the theory and to test the accuracy of the numerical analysis used for the problem.

ABSTRACT: In this paper, the problem of the fracture of a fuselage stiffened by longitudinal longerons and circumferential frames is analyzed by means of the finite element method. Our research is motivated by the fail-safety design concept of fuselage for civil aircraft. In this study, the total energy release rate are evaluated for five types of basic loading, namely, axial extension, pure bending, twisting, transverse shearing, and radial expansion due to internal pressure. The crack is located either at the mid-point or near the end of the fuselage. It extends in two bays with the stiffener at its center. The stiffener which bisects the crack is assumed to be broken at the location of the crack. Computational results indicate that the total energy release rate $G_t$ increases with the increasing crack length. However, when the crack tip approaches the stiffener, the value of $G_t$ decreases as a result of the reinforcement from the stiffener. For a crack near the end of the fuselage, as a result of boundary effect, the value of $G_t$ is larger in comparison with the case of the crack at the mid-point of the fuselage. We also find that the effect of geometrical nonlinearity can reduce the value of $G_t$ for the fuselage under axial tension or pure bending. For the fractured fuselage under pure bending, shell buckling can occur at the concave side of the fuselage prior to crack growth. The maximum tensile stress in the stiffener in front of the crack tip is also investigated.

ABSTRACT: The present paper investigates the formulation of 3D co-rotational beam elements for the buckling and post-buckling analysis of frame structures. Following Pacoste and Eriksson [Comput. Methods Appl. Mech. Engrg. 144 (1997) 163], the term co-rotational relates here to the provision of a local reference frame that continuously rotates and translates with the element. Within this context, several issues are emphasised. The first one refers to the parameterisation of finite 3D rotations. The alternative put forth in the paper is based on the spatial form of the incremental rotational vector. The second issue concerns warping effects which are introduced by adding a seventh degree of freedom at each node. Different types of local formulations are considered and it is shown that at least some degree of non-linearity must be introduced in the local strain definition in order to obtain correct results for certain classes of problems. Within the present approach the centroid and shear center of the cross-section are not necessarily coincident. Finally, in the context of instability problems, a method for the direct computation of critical points is also briefly discussed. This is based on a minimal augmentation procedure as developed by Eriksson [Comput. Methods Appl. Mech. Engrg.
Ten examples, including large displacement and stability problems, are used in order to assess the performances of the elements.

ABSTRACT: In the context of corotational triangular shell elements, the objective of this paper is to show that for certain stability problems it is interesting to choose a local element frame invariant to the element node ordering. Two methods of obtaining such a local frame are presented. These two methods, already proposed by other authors, are reformulated. For the first one, based on the minimisation of local nodal displacements, it is shown that the iterative process can be avoided.

ABSTRACT: The corotational formulation for triangular thin shell elements presented in [A. Eriksson, C. Pacoste, Element formulation and numerical techniques for stability problems in shells, Comput. Methods Appl. Mech. Engrg. 191 (2002) 3775–3810] is further developed in order to incorporate elasto-plastic deformations. Several local formulations are implemented and tested. These local elements are geometrically linear and are obtained by the by superposition of a membrane and a plate part. Eleven elastic and elasto-plastic examples are presented. Both the incremental and deformation theories of plasticity are considered. The first objective is to assess the performance of the present formulation in modelling elasto-plastic instability problems. The second objective is to compare the different linear local formulations: it is shown that some of them give better results in instability problems.

doi:10.1016/j.cma.2006.10.006  
ABSTRACT: The corotational framework for triangular shell elements has been presented by different authors (see the Introduction). The purpose of this paper is to introduce three modifications in this approach. The first one is a simplified definition of the local rotations. The second one is a reduction of the number of local degrees of freedom from 18 to 15. The third and principal one concerns the parameterisation of the global finite rotations. A new approach based on Euler parameters (quaternion) is proposed. In particular, it is shown that only three parameters are required. The purpose of these three modifications is to obtain a formulation which gives the same numerical results but which is computationally more efficient than the original one. This aspect
is illustrated in several numerical examples.

ABSTRACT: The present work deals with a numerical–experimental investigation into the post-buckling behavior of two demonstrators representative of the bottom skin panel of an unpressurized aircraft fuselage: one represents an undamaged reference structure, the other includes debonding and impact damage. Tests have been developed for static compression loading up to the ultimate load. The recorded data from five transducers and one strain gauge have been utilized to obtain numerical–experimental correlation. Numerical analyses have been developed using two available commercial codes and by different modeling approaches and analytical procedures. Further results have been obtained and compared with each other and with experimental evidence in order to assess the capability and feasibility of numerical predictions in the post-buckling field.

ABSTRACT: A non-linear 9-node stress resultant shell finite element with six degrees of freedom per node is formulated. The material non-linearity is based on an implicit integration scheme using the von Mises yield criterion and linear isotropic hardening. The small strain geometric non-linearity is formulated using the polar decomposition theorem of continuum mechanics via a corotational updated Lagrangian method, which represents finite rotations with accuracy. Reduced integration is used to remove locking and calculate the stresses at their optimal stress accuracy points. A practical procedure is employed to stabilize the troublesome spurious zero energy modes. A number of tests covering the non-linear material and geometry ranges and buckling show the good performance of the new element.

ABSTRACT: In this paper, the stability of carbon fiber reinforced plastics (CFRP) cylinders under axial compression was studied by the finite element analysis method. According to the Riks method, compressive capacity of the composite structures was investigated by nonlinear analysis, in which the eigen buckling modes were considered in the form of initial defects. And the post-buckling performances of different structures were also compared.

ABSTRACT: Fuselage panels are commonly fabricated as skin-stringer constructions, which are permitted to locally buckle under normal flight loads. The current analysis methodologies used to determine the post-buckling response behaviour of stiffened panels relies on applying simplifying assumptions with semi-empirical/empirical data. Using the Finite Element method and employing non-linear material and geometric analysis procedures it is possible to model the post-buckling behaviour of stiffened panels without having to place the same emphases on simplifying assumptions or empirical data. Previous work has demonstrated that using a commercial implicit code, the Finite Element method can be used successfully to model the post-buckling behaviour of flat riveted panels subjected to uniform axial compression. This paper expands the compression modelling procedures to flat riveted panels subjected to uniform shear loading, investigating element, mesh, idealisation and material modelling selection, with results validated against mechanical tests. The work has generated a series of guidelines for the non-linear computational analysis of flat riveted panels subjected to uniform shear loading, highlighting subtle but important differences between shear and compression modelling requirements.

Reliability Based Buckling Analysis of Composite Panels22 April 2004, Palm Springs, California

ABSTRACT: New skin alloys are being developed that are both damage tolerant and strong in compression. At the same time, stiffener alloys are still getting stronger. Stiffened panel designs need to be optimized in new ways to fully benefit from these new material properties. FEA has shown that, provided the joint between skin and stiffeners is good and stringers are strong enough, the overall efficiency of a stiffened panel with large attach flanges is greater than that of a panel which has very high quadratic section moment. Stringer pitches can thus be kept at economic levels while panel buckling performance is increased by the use of new higher strength, high damage tolerance skin and the next generation of high strength stiffeners. The tangent modulus curves of the new materials mentioned are generally steeper than those of current materials. The present analyses have demonstrated that because the strain in a post-buckled stiffened panel is far from uniform, this does not present any particular risks with respect to sudden loss of stiffness of the panel.

“Buckling And Post-Buckling Of Sub-Stiffened Or Locally Tailored Aluminium Panels”, ICAS 2006, 25th
International Congress Of The Aeronautical Sciences

ABSTRACT: Today's high-strength and damage tolerant materials permit significant increases in working- and limit stresses. In order to fully exploit these stress increases as weight savings on aircraft, it is important to improve the buckling stability of stiffened panels. The (post-)buckling performance of panels with sub-stiffening or local tailoring of the skin thickness (“skin sculpting”) was investigated using linear variable thickness finite strip analysis, (non-linear) finite element analysis and experiments on stiffened panels. Four different slender, high post-buckling ratio aluminium panels were crushed, revealing gains in post-buckling collapse loads of more than 10%. Gains in initial skin buckling were over 15%, accompanied by a gain in post-buckling stiffness. Non-linear FEA helped to understand the behaviour of these panels and select the most promising designs. Linear finite strip analysis allowed optimisation of one of these, revealing a potential for further improvement of the initial buckling load by over 10%. Design rules for sub-stiffened panels were derived. Using these design rules, the concept of sub-stiffening was successfully transposed to more optimised, stockier sections, and non-linear FEA was used to predict the associated gains in post-buckling performance. In spite of extensive plasticity, the gain was still of the order of 10% on the post-buckling collapse load, with good post-buckling stiffness. The better understanding of the behaviour of locally tailored structures led to the evaluation of two other new concepts for stiffened panels: one with gradually increasing skin thickness toward the pad-ups under stiffeners (“sculpted skins”) and one with curved sub-stiffening patterns, resulting in skins with varying stiffness in both of the in-plane directions. For the sculpted skins, variable thickness finite strip optimisation was used to obtain insight into the importance of different design variables, and derive a method for sizing. Non-linear FEA of an application of this concept to realistic, optimised aircraft panels loaded in slight bi-compression confirmed initial buckling gains of up to 30% and predicted post-buckling performance gains of the order of 10%. For the variable stiffness sub-stiffening, a numerical experiment was designed in order to study linear eigenmodes of various configurations. The potential improvement in buckling performance over unstiffened plates of equal weight was as high as 450%. More relevantly, the effect of variable stiffness sub-stiffening was estimated over two times higher than that of orthogonal sub-stiffening.

ABSTRACT: Recent advances in aeronautics and material science allow for a significant increase in load capacity; consequently, structural parts are more stressed than in the past. In most cases, stresses and strains cannot be determined accurately enough using conventional closed form engineering formulae. Therefore, even if much more time-consuming, finite element analysis is used. Because of a high ratio between panel length and adhesive thickness, models need a large number of elements. Thus, computing time can be very long. The aim of this paper is to present a global-local approach to reduce this time. First, a global shell elements model is developed. Second, a local solid elements model is generated from the displacement obtained in the global model. Finally, global-local FEA enables greater precision.

ABSTRACT: To increase the structural efficiency of integrally machined aluminium alloy stiffened panels, it is plausible to introduce plate sub-stiffening to increase the local stability and thus panel static strength performance. Reported herein is the experimental validation of prismatic sub-stiffening, and the computational verification of such concepts within larger recurring structure. The experimental work demonstrates the potential to ‘control’ plate buckling modes. For the tested sub-stiffening design, an initial plate buckling performance gain of +89% over an equivalent mass design was measured. The numerical simulations, modelling the tested sub-stiffening design, demonstrate equivalent behaviour and performance gains (+66%) within larger structures consisting of recurring panels.

ABSTRACT: Previous work has demonstrated the potential to introduce plate element sub-stiffening to increase the local stability and thus static strength performance of integrally machined aluminium alloy stiffened panels. The introduction of plate element prismatic sub-stiffening modifies local plate buckling behaviour and within realistic design constraints, may produce sizable performance gains with equivalent mass designs. This article examines through experimental and computational analysis the potential of non-prismatic sub-stiffening for tailoring local plate stability performance. Using non-prismatic sub-stiffening, the experimental work demonstrates potential initial buckling performance gains with equivalent mass designs (+185%), and computationally, potential mass savings with equivalent static strength performance designs (–9.4%).

ABSTRACT: This paper was to verify the STAGS (general shell, geometric and material nonlinear) code and the critical crack-tip-opening angle (CTOA) fracture criterion for predicting stable tearing in cracked panels that fail with severe out-of-plane buckling. Materials considered ranged from brittle to ductile behavior. Test data used in this study are reported elsewhere. The STAGS code was used to model stable tearing using a critical CTOA value that was determined from a cracked panel that was “restrained” from buckling. The analysis methodology was then used to predict the influence of buckling on stable tearing and failure loads. Parameters like crack-length to-specimen-width ratio, crack configuration, thickness, and material tensile properties had a significant influence on the buckling behavior of cracked thin-sheet materials. Experimental and predicted results showed a varied buckling response for different crack-length-to-sheet-thickness ratios because different buckling modes were activated. Effects of material tensile properties and fracture toughness on buckling response were presented. The STAGS code and the CTOA fracture criterion were able to predict the influence of buckling on stable tearing behavior and failure loads on a variety of materials and crack configurations.

ABSTRACT:
This paper presents the fracture analyses conducted on the FAA/NASA stiffened and unstiffened panels using the STAGS (STructural Analysis of General Shells) code with the critical crack-tip-opening angle (CTOA) fracture criterion. The STAGS code with the “plane-strain” core option was used in all analyses. Previous analyses of wide, flat panels have shown that the high-constraint conditions around a crack front, like plane strain, has to be modeled in order for the critical CTOA fracture criterion to predict wide panel failures from small laboratory tests. In the present study, the critical CTOA value was determined from a wide(unstiffened)panelwithanti-bucklingguides. Theplane-straincoresizewasestimatedfromprevious fracture analyses and was equal to about the sheet thickness. Rivet flexibility and stiffener failure was based on methods and criteria, like that currently used in industry. STAGS and the CTOA criterion were used to predict load-against-crack extension for the wide panels with a single crack and multiple-site damage cracking at many adjacent rivet holes. Analyses were able to predict stable crack growth and residual strength within a few...
percent (5%) of stiffened panel tests results but over predicted the buckling failure load on an unstiffened panel with a single crack by 10%.

fracture criterion to characterize the fracture behavior and a material and a geometric nonlinear finite element shell analysis code to perform the structural analyses. The present paper presents the results of a study to evaluate the fracture behavior of 2024-T3 aluminum alloys with thickness of 0.04 inches to 0.09 inches. The critical CTOA and the corresponding plane strain core height necessary to simulate through-the-thickness effects at the crack tip in an otherwise plane stress analysis, were determined from small laboratory specimens. Using these parameters, the CTOA fracture criterion was used to predict the behavior of middle crack tension specimens that were up to 40 inches wide, flat panels with riveted stiffeners and multiple-site damage cracks, 18-inch-diameter pressurized cylinders, and full scale curved stiffened panels subjected to internal pressure and mechanical loads.

ABSTRACT: This paper presents the results of residual strength analyses on stiffened and unstiffened panels using the STStrucural Analysis of General Shells (STAGS) finite-element shell code and the critical crack-tip-
opening angle (CTOA) fracture criterion. Previous analyses of wide, flat panels have shown that high-constraint conditions around a crack front must be modeled in order for the critical CTOA fracture criterion to predict wide panel failures from small laboratory tests. Thus, the STAGS code with the _plane-strain _core option was used in all analyses. In the present study, the critical CTOA (\_c\_c) value and the plane-strain core height were determined from a fit to the experimental load-against-crack-extension results from a series of middle-crack tension specimens (76 _1016 mm wide) tested with anti-buckling guides. In the residual strength analyses of the 305-mm wide stiffened panels with a single crack, modeling of the sheet, stiffeners, rivet flexibility and buckling were based on methods and criteria, like that currently used in industry. STAGS and the CTOA criterion were used to predict load-against-crack extension for the single stiffened panels for both intact and cut stiffeners. Analyses were able to predict stable crack growth and residual strength of the single stiffened panels within about ±5% of the test failure loads.

ABSTRACT: This paper highlights the results from fracture analyses conducted on the FAA/NASA wide panels (with and without stiffeners) using structural analysis of general shells code and the critical crack-tip-opening angle (CTOA) fracture criterion. The critical CTOA and plane-strain core height values, calibrated from a fit to the experimental load-against-crack-extension results from a series of unstiffened panels (76–1016 mm wide) tests with anti-buckling guides (Part I of this paper), were used in the analyses of wide stiffened and unstiffened panels. As discussed in Part I of this paper, high constraint around the crack front like plane strain has been accounted for by using the “plane-strain core” option in all analyses. By accounting for high constraint around crack front, it was possible for the critical CTOA fracture criterion to predict wide panel failures from small laboratory tests. As followed in Part I of this paper, rivet flexibility and stiffener failures in the analyses of wide panels were based on methods and criteria like that currently used in the industry. Analyses were able to predict stable crack growth and residual strength of both stiffened and unstiffened panels with various amounts of multiple-site damage within ±10% of the test results. Finally, it has been demonstrated that, it is possible to predict the residual strength of wide stiffened and unstiffened panels with critical CTOA calibrated from small laboratory coupons.

ABSTRACT: The results of residual strength pressure tests and nonlinear analyses of stringer- and frame-stiffened aluminum fuselage panels with longitudinal cracks are presented. Two types of damage are considered: a longitudinal crack located midway between stringers, and a longitudinal crack adjacent to a stringer and along a row of fasteners in a lap joint that has multiple-site damage (MSD). In both cases, the longitudinal crack is centered on a severed frame. The panels are subjected to internal pressure plus axial tension loads. The axial tension loads are equivalent to a bulkhead pressure load. Nonlinear elastic-plastic residual strength analyses of the fuselage panels are conducted using a finite element program and the crack-tip-opening-angle (CTOA) fracture criterion. Predicted crack growth and residual strength results from nonlinear
analyses of the stiffened fuselage panels are compared with experimental measurements and observations. Both the test and analysis results indicate that the presence of MSD affects crack growth stability and reduces the residual strength of stiffened fuselage shells with long cracks.

ABSTRACT: In this work we study the time-stepping schemes for shell models, which describe the shell-director vector motion by the finite rotations. Different possibilities for choosing director rotations are examined and their relationships are cast in terms of the commutative diagram. The Newmark time-stepping schemes, making use of different rotation parameters, are then developed. The mid-point scheme modified to either conserve or dissipate the total energy is further examined. Several numerical simulations are presented to illustrate the performance of each developed scheme.

Brian: Hello, how can I assist you today?
ABSTRACT: In the context of the geometrically nonlinear analysis of structures by continuation methods, a technique for the determination of the imperfection sensitivity is carried out. The technique is based on Galerkin's reduction of equilibrium equations in the subspace of extrapolation branches emanating from the bifurcation points. The pre- and post-critical behaviour in the neighbourhood of bifurcation points, however, is well approximated provided that extrapolations have a large convergence domain. To this end an efficient asymptotic representation of the primary and secondary equilibrium paths and procedures that overcome the ill-conditioning of the systems defined in the critical points is used here.

ABSTRACT: A finite element method is presented for the transient analysis of large-displacement, small-strain problems with material non-linearities. The method employs a convected coordinate technique and a direct nodal force computational scheme of considerable efficiency. Detailed formulations are given for a plane, constant strain triangular element and a Euler-Bernoulli beam element. Results are presented for several example problems and compared with experimental data and other numerical solutions.

S. Lopez and K. Russo (Dipartimento di Modellistica per l’Ingegneria Universit`a della Calabria 87030 Rende, Cosenza, Italy), “Statical and dynamical structural analysis by a kinematical description of the small strains involving finite rotations”, Laboratorio di Meccanica Computazionale Rapporto Interno, Report n. 52, November 2008

ABSTRACT: A geometrically nonlinear formulation to analyse structures in the hypotheses of large displacements and rotations and small strains is presented. In this formulation, applied to low-order elements and based on the total Lagrangian kinematics, the use of the rotation matrices is bypassed. A selective based definition of the strain tensor, used in order to avoid shear-locking problems, is effected by the linear definition of deformations because it is element reference system independent. In addition, complex manipulations required to obtain conservative descriptions and well-posed transformation matrices are avoided. Numerical tests have been carried out to evaluate the validity of the developed technique both in the statical and in the dynamical context.

ABSTRACT: Both analytical and finite element investigations are performed for the various static and dynamic aspects of the mode jumping phenomenon of a simply-supported rectangular plate heated deeply into the post-buckling regime. For the analytical method, the von Kármán plate equation is reduced to a system of non-linear ODEs by expressing the transverse deflection as a series of linear buckling modes. The ODEs, combined with the non-linear algebraic constraint equations obtained from in-plane boundary conditions, are then solved numerically under the parametric variation of the temperature. The results are checked by the finite element method, where a hybrid static–dynamic scheme is implemented. The contribution of each assumed (buckling) mode component is studied systematically. Characterized by the strong geometrical non-linearity, the secondary bifurcation point of the thermally loaded plate with fixed in-plane boundary conditions occurs far beyond the primary buckling point, and the jump behavior cannot be predicted correctly without sufficient assumed modes. Stationary bifurcation analysis indicates that while the post-buckling deflection before mode jumping is composed of pure symmetric modes, additional pure antisymmetric modes will appear after the occurrence of the snapping and they play the role of destabilizing the equilibrium. Furthermore, by monitoring natural frequencies and modal shapes, we find that a mode shifting phenomenon (the exchanging of vibration modes) exists in the primary post-buckling regime. Breaking of the symmetry of the dynamic modes is also found. By introducing a linear temperature sweeping scheme, transient analysis is performed to capture the snapping phenomenon dynamically, which occurs with moderate heating ratio. Comparison between the analytic and finite element results shows good agreement.

ABSTRACT: Various static and dynamic aspects of post-buckled thin plates, including the transition of buckled patterns, post-buckling dynamics, secondary bifurcation, and dynamic snapping (mode jumping phenomenon), are investigated systematically using asymptotical and non-stationary finite element methods. In part I, the secondary dynamic instability and the local post-secondary buckling behavior of thin rectangular plates under generalized (mechanical and thermal) loading is investigated using an asymptotic numerical method which combines Koiter’s nonlinear instability theory with the finite element technique. A dynamic multi-mode reduction method—similar to its static single-mode counterpart: Liapunov–Schmidt reduction—is developed in this perturbation approach. Post-secondary buckling equilibrium branches are obtained by solving the reduced low-dimensional parametric equations and their stability properties are determined directly by checking the eigenvalues of the resulting Jacobian matrix. Typical post-secondary buckling forms—transcritical, supercritical and subcritical bifurcations are observed according to different combinations of boundary conditions and load types. Geometric imperfection analysis shows that not only the secondary bifurcation load but also changes in the fundamental post-secondary buckling behavior are affected. The post-buckling dynamics and the global analysis of mode jumping of the plates are addressed in part II.

Hui Chen and Lawrence N. Virgin (Department of Mechanical Engineering, Pratt School of Engineering, Duke University, Durham, NC 27708-0300, USA), “Finite element analysis of post-buckling dynamics in plates. Part

ABSTRACT: With the secondary bifurcation and the local post-secondary buckling behavior being analyzed in Part I, Part II of this study consists of developing an adaptive non-stationary load sweeping algorithm to investigate post-buckling dynamics and mode jumping phenomena of generally (mechanically and thermally) loaded thin plates in a global context. The non-stationary sweeping procedure has the merits of adapting large load steps to capture static characteristics of stable equilibrium paths both before and after mode jumping and reduce automatically the step size to ensure a dynamic transition between the two stable branches. Thus, it is computationally effective. Furthermore, by adopting the non-stationary sweeping scheme, this procedure can avoid spurious convergence of the transient response to an unstable equilibrium. Corresponding to different post-secondary bifurcation forms, which are determined using asymptotical finite element analysis developed in Part I, subsequent buckling patterns of various complexity occurring after mode jumping are obtained using the method developed in this article. Qualitative changes in post-buckled patterns are observed after the occurrence of the secondary bifurcation or the mode jumping. Free vibration analysis using the tangent stiffness matrix obtained from the converged static or dynamic solutions shows a vibration modal shifting phenomena occurs during the process of the load sweep. The spurious convergence phenomenon caused by the application of the traditional hybrid static–dynamic method is found and explained.

ABSTRACT: An analytic method is presented in this paper to study the postbuckling and mode jumping behavior of bi-axially compressed composite laminates. The governing partial differential equations (PDEs) are derived rigorously from an asymptotically correct, geometrically non-linear theory. A novel and relatively simpler solution approach is developed to solve the two coupled fourth-order PDEs, namely, the compatibility equation and the dynamic governing equation. The generalized Galerkin method is used to solve boundary value problems corresponding to antisymmetric angle-ply and cross-ply composite plates, respectively. The variety of possible modal interactions is expressed in an explicit and concise form by transforming the coupled non-linear governing equations into a system of non-linear ordinary differential equations (ODEs). The comparison between the present method and the finite element analysis (FEA) shows a pretty good match in their numerical results in the primary postbuckling region. While the FEA may lose its convergence when solution comes close to the secondary bifurcation point, the analytic approach has the capability of exploring deeply into the post-secondary buckling realm and capture the mode jumping phenomenon for various combinations of plate configurations and in-plane boundary conditions. Free vibration along the stable primary postbuckling and the jumped equilibrium paths are also studied.

ABSTRACT: In this chapter the optimal design of laminated composite structures is considered. A review of the literature is proposed. It aims at giving a general overview of the problems that a designer must face when he works with laminated composite structures and the specific solutions that have been derived. Based on it and
on the industrial needs an optimization method specially devoted to composite structures is developed and presented. The related solution procedure is general and reliable. It is based on fiber orientations and ply thicknesses as design variables. It is used daily in a European industrial context for the design of composite aircraft box structures located in the wings, the center wing box, and the vertical and horizontal tail planes. This approach is based on sequential convex programming and consists in replacing the original optimization problem by a sequence of approximated sub problems. A very general and self adaptive approximation scheme is used. It can consider the particular structure of the mechanical responses of composites, which can be of a different nature when both fiber orientations and ply thicknesses are design variables. Several numerical applications illustrate the efficiency of the proposed approach.

“Buckling optimization of composite stiffened panels: some important issues”, 2nd International Conference on Engineering Optimization, September 6 - 9, 2010, Lisbon, Portugal

ABSTRACT: In this paper, the buckling optimization of thin-walled stiffened composite panels is studied. Some important issues are recalled, and an efficient solution procedure is discussed. It is shown how to properly represent the buckling behavior with the finite element method. Several approximations of the Sequential Convex Programming method (SCP) are compared on an industrial test case consisting in the optimization of a curved stiffened composite panel submitted to compression and shear.

Fernanda Mariana Nunes Ravetti and Sérgio Frascino Müller de Almeida, “Post buckling of composite panels subjected to thermal residual stresses”, MSC Software Presentation Number 2007-21, 2007

ABSTRACT: Composite material structures are completely stress free during curing or consolidating process, under high temperatures that vary between 120 deg. C and 400 deg. C. After this process, temperature decreases and material starts to get stiffer. As material physical properties are different in transverse and longitudinal direction, thermal residual stresses appear due to this difference, mainly because of thermal expansion coefficient. Thermal residual stresses effects can be null if the structure is a uniform (not stiffened) square plan panel symmetrically laminated, without external constraints. However, if the panel is reinforced or not symmetrically laminated, the resultant stresses can be not null and affect the panel mechanical behavior. This research studies post-buckling behavior of graphite-epoxy reinforced panels under compression in the presence of thermal residual stresses, considering two different stringer types and three different stringer widths. According to the results found, thermal residual stresses can affect the panel mechanical behavior - depending
on type and width of the stringers - increasing stiffness and changing buckling modes, mainly for smaller loads and wider stringers.

ABSTRACT: A fully 3D failure model to predict damage in composite structures subjected to multiaxial loading is presented in this paper. The formulation incorporates shear nonlinearities effects, irreversible strains, damage and strain rate effects by using a viscoplastic damageable constitutive law. The proposed formulation enables the prediction of failure initiation and failure propagation by combining stress-based, damage mechanics and fracture mechanics approaches within an unified energy based context. An objectivity algorithm has been embedded into the formulation to avoid problems associated with strain localization and mesh dependence. The proposed model has been implemented into ABAQUS/Explicit FE code within brick elements as a userdefined material model. Numerical predictions for standard uniaxial tests at element and coupon levels are presented and discussed.

ABSTRACT: A technique for enhancement of buckling loads of composite plates is proposed. The technique relies on using stress stiffening to create a non-zero tensile force acting along the plate plane which ultimately permits the application of higher external compressive forces that lead to traditional buckling instabilities. The idea is to completely restrain the plate movements in its plane direction, at all edges, and to apply voltages to pairs of symmetrically bonded piezoelectric patches. This voltage is applied such that the piezoelectric patches contract resulting in a uniform tensile force over the plate plane.

ABSTRACT: An axisymmetric finite element that can model rubber-like hyper-elastic material has been employed to study post-critical response in the inflation of axisymmetric membranes. An extensive parametric study has been performed to investigate the non-linear response of a tube under internal pressure. The issue of combined proportional and non-proportional loading in the context of incremental-iterative solution is discussed. Further, a robust bracketing procedure, useful to compute clustered bifurcation points, is proposed. Finally, the eigen-mode injection method is used to branch into the post-critical paths. Contrary to previous findings, the Newton-Raphson method worked satisfactorily in all the cases tested.

ABSTRACT: This paper deals with buckling and free vibrations of multilaminated structures of arbitrary geometry and lay-up using a single layer higher order shear deformation theory discrete model. This model is based on an eight-node C0 serendipity finite element with 10 degrees of freedom per node to contemplate general applications. The present model is tested on the evaluation of buckling loads and free vibrations of multilaminated plates and shells. The effects of different number of layers, lamination angles, material anisotropy, and length or radius to thickness ratios are studied.

ABSTRACT: This paper presents a discrete model for the design sensitivity analysis of thin laminated angle-
ply composite structures using a plate shell element based on a Kirchhoff discrete theory for the bending effects. To overcome the nondifferentiability of multiple eigenvalues, which may occur during a structural optimization involving free vibrations or buckling design situations, a nonsmooth eigenvalue based criterion is implemented. Angle-ply design variables and vectorial distances from the laminated middle surface to the upper surface of each layer are considered as design variables. The design sensitivities and the directional derivatives are evaluated analytically. The efficiency and accuracy of the model developed is discussed with two illustrative cases which show the need to compute sensitivities of multiple eigenvalues as directional derivatives for laminated composite structures.

ABSTRACT: This paper presents a discrete model for the buckling sensitivity analysis of thin multi-layered angle-ply composite structures. The model is based on a simple and efficient plate-shell element with 18 d.f. using the discrete Kirchhoff theory for the bending effects. Angle-ply design variables and vectorial distances from the middle surface to the upper surface of each layer, indirectly the thickness of each layer, are considered as design variables. The objective of the design is the maximization of the constrained or unconstrained buckling load parameter. The optimization process can be carried out using a two-level approach. The design sensitivities are evaluated analytically, quasi-analytically and by global finite difference. The efficiency and accuracy of the model developed is discussed with reference to several applications.

ABSTRACT: Shell buckling under circumferential strain loading appears often in many biomedical problems, such as collapse of asthmatic airways, esophagus etc. Currently there is no analytic solution from which the critical buckling load can be calculated from the geometrical and material properties of the shell layers. The theoretical analysis leads to the numerical solution of a generalized eigenvalue problem. The purpose of the present paper is to present a method with which the sensitivity of the buckling load (minimum positive eigenvalue) to uncertainties of the geometrical and material parameters can be calculated. It is shown that the sensitivity can be evaluated with the aid of the left (adjoint) eigenvectors. The proposed method is validated against separate global computations using the finite difference method. Finally, we employ the information on sensitivity to optimize the thickness of the outer shell layer in order to maximize the buckling load.

ABSTRACT: A high order shear deformation theory is used to develop a discrete model for the sensitivity
analysis and optimization of laminated plate and shell structures in non-linear response. The geometrically non-linear analysis is based on an updated Lagrangian formulation associated with the Newton–Raphson iterative technique, which incorporates an automatic arc-length procedure. Fiber orientation angles and vectorial distances from middle surface to the upper surface of each layer are considered as the design variables. Different objectives, such as generalized displacements at specified nodes, volume of structural material, and limit load, and constraints of displacement and stress failure criterion are considered. The design sensitivities are evaluated analytically and are compared with sensitivities evaluated by the global finite difference. Numerical examples are given to show the accuracy of the proposed model in the non-linear response and the corresponding design sensitivity analysis, and to show the applicability in the optimal design.

ABSTRACT: In this paper is presented a numerical method for the structural analysis of laminated conical shell panels using a quadrilateral isoparametric finite element based on the higher order shear deformation theory. The displacement expressions used for the longitudinal and circumferential components of the displacement field are given by power series of the transversal coordinate and the condition of zero stresses in the top and bottom surfaces of the shell is imposed. The shape functions used for the transversal displacement are C1 conforming and the finite element is a conical/cylindrical panel with 8 nodes and 40 degrees of freedom. The model presented performs static analysis with arbitrary boundary conditions and loads, as well eigenvalue problems (free vibration and buckling). Illustrative examples are presented and discussed.

ABSTRACT: A general semi-analytical finite element model is developed for bending, free vibration and buckling analysis of shells of revolution made of laminated orthotropic elastic material. The 3D elasticity theory is used and the equations of motion are obtained by expanding the displacement field and load in the Fourier series in terms of the circumferential coordinate, \( \Pi \). The coefficients of the expansion are functions of \((r,z)\), and are approximated using the finite element method. This leads to a semi-analytical finite element in the \((r, z)\) plane. The element is validated by comparing the present results with the analytical and numerical solutions available in the literature.

ABSTRACT: This paper presents the development of a semi-analytical axisymmetric shell finite element model with piezoelectric layers using the 3D linear elasticity theory. The piezoelectric effect of the material could be used as sensors and/or actuators in way to control shell deformation. In the present 3D axisymmetric model, the equations of motion are expressed by expanding the displacement field using Fourier series in the circumferential direction. Thus, the 3D elasticity equations of motion are reduced to 2D equations involving circumferential harmonics. In the finite element formulation the dependent variables, electric potential and loading are expanded in truncated Fourier series. Special emphasis is given to the coupling between symmetric and anti-symmetric terms for laminated materials with piezoelectric rings. Numerical results obtained with the present model are found to be in good agreement with other finite element solutions.

ABSTRACT: In the present work, a study of thermoelastic analysis of functionally graded cylindrical shells subjected to transient thermal shock loading is carried out. A semi-analytical axisymmetric finite element model using the three-dimensional linear elasticity theory is developed. The three-dimensional equations of motion are reduced to two-dimensional ones by expanding the displacement field in Fourier series in the circumferential direction involving circumferential harmonics. The material properties are graded in the thickness direction according to a power law. The model has been verified with the results of simple analytical isotropic cylindrical shells subjected to a transient thermal loading. Additional FGM results for stresses and displacements are presented.

ABSTRACT: In the present work, a study of free vibrations of functionally graded cylindrical shells made up of isotropic properties is carried out. A semi-analytical axisymmetric finite element model using the 3D linear elastic theory is developed. The 3D equations of motion are reduced to 2D by expanding the displacement field in Fourier series in the circumferential direction involving circumferential harmonics. The material properties are graded in the thickness direction according to a power law. The model has been verified with simple benchmark problems and the results show that the frequency characteristics are found to be close to published results of isotropic cylindrical shells. New results are included for FGM shells.
**ABSTRACT:** This paper focuses on the development of the partitioned solution method (PSM) for analyzing the stability behavior of doubly-curved shallow orthotropic panels under external pressure, covering both the buckling and postbuckling responses. Adjacent equilibrium method (AEM) is used to verify the developed PSM method and the associated stability results. The equilibrium and compatibility equations are derived using Donnell-type thin shell theory, with the Airy stress function and the out-of-plane displacement as unknowns. Based on AEM and PSM, both an eigenvalue problem and non-linear algebraic equations are obtained which are used as the basis for the stability criteria, respectively. Results obtained from those two methods are presented and compared with each other for a few arbitrary sets of system parameters, wherein no postbuckling solutions are presented with AEM. The influence of the boundary conditions on the stability behavior is also investigated using the PSM.

**ABSTRACT:** The focus of this paper is on the investigation of the mathematical nature of buckling from the point of view of bifurcation theory. For the doubly curved orthotropic panels subjected to quasi-static uniform load and with hinged boundary conditions, the solution to the non-linear partial differential equation is partitioned into two parts and projected onto the complete space spanned by the eigenfunctions of the linear operator of the governing equation. Furthermore, the fundamental branch, from which a new solution will emanate, is approximated by the first single mode pair which is close to the real membrane state. Whereas the ensuing bifurcated branch is approximated by the other single mode pair, under the assumption that the coupling between modes can be neglected. The present analysis could give a deep insight into the mechanism of the instability of panel structures, and show that there exists a mode transition at the critical point and the snap-through, then results from saddle-node bifurcation on the bifurcated branch. As a conclusion, the buckling of the system studied can be stated as: a bifurcated branch emanates from the fundamental branch at a critical point, and a saddle-node bifurcation, behaving as jumping, then occurs on the ensuing bifurcated branch.

**ABSTRACT:** In the frame of the geometrically nonlinear theory of thin elastic shells with moderate rotations a
set of consistent equations for the nonlinear stability analysis is derived by application of energy criteria. Some methods of functional analysis are used which enable to prove the symmetry of the stability equations and to calculate bifurcation buckling from linear and nonlinear equilibrium branches and also snap-through buckling loads by variational approximating procedures.

ABSTRACT: In this paper the non-linear stability and post-buckling analysis of elastic structures is considered in the frame of a geometrically non-linear shell theory with moderate rotations. Using a total Lagrangian description variational statements as well as associated sets of shell equations including boundary conditions are derived to determine the fundamental equilibrium path, critical points of snap-through or bifurcation buckling and also the post-buckling deformations. To present these equations in a compact form a unified operator description is introduced. It also allows one to prove some important properties, which are needed to construct appropriate approximation procedures like finite element methods. A shell example is calculated numerically by using a simple Rayleigh-Ritz approximation. It is shown that for a two-parameter loading the collection of critical snap-through buckling points is a catastrophe of the ‘cusp’ type.

ABSTRACT: In the first part of this paper a Lagrangean nonlinear theory of thin elastic shells for unrestricted rotations is considered, where the boundary conditions are non-rational functions of the shell deformations. Using energy considerations the equations of critical equilibrium are derived, which define the general eigenvalue problem of shell buckling. Furthermore post-buckling equations are obtained by application of the static perturbation technique. If the rotations of the shell elements can be restricted to be moderate, essential simplifications in the prebuckling, buckling and post-buckling equations are achieved, which is shown in the second part.

ABSTRACT: A nonlinear shell theory is derived for large strain—large bending deformations of shells composed of highly nonlinear materials. Expressions for the stress resultants and stress couples are presented. The equilibrium equations are obtained as weak solution of the stationary principle of total potential energy. A modified Kirchhoff hypothesis is used which accounts for thickness changes as well as for a shift in the location of the original midsurface of the shell. As example the eversion of a spherical shell is calculated numerically.

References listed at the end of the paper:

ABSTRACT: For the geometrically nonlinear first approximation theory of elastic shells three energy-consistent large rotation shell variants are constructed. The governing shell equations are derived as Euler-Lagrange equations of an associated variational principle of stationary total potential energy. The numerical applicability is considered for a highly nonlinear shell problem. To incorporate the presented theories into the frame of shell models published in the literature a comparative analysis is carried out for a large number of shell equations.

ABSTRACT: A rigorous theory of small deformation superimposed on finite deformation is developed within a fully general theory of elastic shells. The mathematical structure of the configuration space and its associated tangent space is examined for the underlying shell model. Essential features of the theory are examined in the context of applications to the buckling analysis of specific problems.

ABSTRACT: The paper is concerned with the nonlinear theory and finite element analysis of shell structures with an arbitrary geometry, loading and boundary conditions. A complete set of shell field equations and side conditions (boundary and jump conditions) is derived from the basic laws of continuum mechanics. The developed shell theory includes the so-called drilling couples as well as the drilling rotation. It is shown that this property is crucial in the analysis of irregular shell structures, such as those containing folds, branches, column supports, stiffeners, etc. The relevant variational principles with relaxed regularity requirements are also presented. These principles provide the mathematical basis for the formulation of various classes of shell finite elements. The developed finite elements include a displacement/rotation based Lagrange family, a stress resultant based mixed and a semi-mixed family as well as so-called assumed strain elements. All elements have six degrees of freedom at each node, three translational and three rotational ones, including the drilling rotation formulated on the foundation of an exact (in defined sense) shell theory. As such, they are equally applicable to smooth as well as to irregular shell structures. The general applicability of the developed elements is illustrated through an extensive numerical analysis of the representative test examples. In order to obtain a still deeper insight into the problem a Lagrange family of standard degenerated shell elements with five degrees of freedom per node and an element with six degrees of freedom per node based on the von Kármán plate theory are considered as well. The presented numerical results include complex plate and doubly-curved shell structures. Linear and non-linear solutions with a pre- and post-buckling analysis are discussed.

ABSTRACT: The effect of buckling on stress distribution in the crack tip vicinity is explored. The computed stress state reveals that the buckling leads to a weaker crack tip singularity than the one of linear elastic fracture mechanics. The change of the singularity has been studied in this work by post-buckling analysis using FE method. The weaker singularity has been taken into account in a modified fracture mechanical theory. The implications for fracture mechanical predictions are discussed.

ABSTRACT: his paper discusses different types of implicit time integration algorithms for the dynamics of spatial beams. The algorithms are based on a form of co-rotational technique which is external to the element.
Both end-point and mid-point formulations are presented. The latter can be considered as an `approximately energy conserving algorithm'. A new method is described for introducing numerical damping. Finally some numerical examples are presented in order to illustrate the differences in performance of the different integration schemes.

ABSTRACT: The simplest facet-shell formulation involves the combination of the constant-strain membrane triangle with a constant-curvature bending triangle. The paper describes a technique whereby this facet-formulation is extended to handle geometric non-linearity by means of a co-rotational procedure. Emphasis is placed on the derivation of a technique that is increment-independent with both the internal force vector and tangent stiffness matrix being derived from the 'total strain measures' in a 'consistent manner'. Numerical examples are presented which demonstrate an excellent numerical performance.

ABSTRACT: The main theme of the paper is the development of a simple but efficient facet element for the non-linear analysis of shells. A sub-theme involves the development of an efficient ‘resultant approach’ for dealing with plasticity. Finally, the paper considers some recent developments in relation to path-following for problems involving instabilities or ‘near instabilities’.

ABSTRACT: The paper describes a unified framework for applying the co-rotational method to the analysis of solids, shells and beams. The general method stems from an unusual application of the technique which involves solid elements. The proposed framework allows a formulation that is simpler than many of the earlier procedures and, in addition, gives a direct indication of the terms in the tangent stiffness which may be ignored.

ABSTRACT: A new procedure is proposed for implicit dynamic analysis using the finite element method. The main aim is to give stable solutions with large time-steps in the presence of significant rigid body motions, in particular rotations. In contrast to most conventional approaches, the time integration strategy is closely linked
to the “element technology” with the latter involving a form of co-rotational procedure. For the undamped situation, the solution procedure leads to an algorithm that exactly conserves energy when constant external forces are applied (i.e. with gravity loading).

ABSTRACT: The paper discusses four separate aspects of the non-linear finite element method: (i) An alternative formulation for the static co-rotational technique in conjunction with a simple faceted shell idealisation. (ii) Solution procedures for non-linear dynamics with emphasis on energy conserving techniques (iii) The use of interface elements and fracture energy related softening “stress-strain” curves for modelling mixed mode delamination in “composites” (iv) Hybrid static/dynamic solution procedures. While the topics are separate, there are links and these are explored.

ABSTRACT: The simplest facet-shell formulation involves the combination of the constant-strain membrane triangle with a constant-curvature bending triangle. The paper first describes an alternative co-rotational procedure to the one initially proposed by Peng and Crisfield in 1992. This new formulation introduces a spin matrix which allows a simpler formulation for the consistent tangent stiffness matrix. The paper then moves to the dynamics of the element. To obtain stable solutions, an energy-conserving mid-point time-integration scheme is developed. This scheme exactly conserves the total energy when external forces are constant and when the physical system does not present any damping. The performance of this scheme is compared with other more conventional implicit schemes through a set of numerical examples involving large-scale rotations.

ABSTRACT: The paper describes a simple corotational formulation applied to one-dimensional interface elements which embed a fracturing procedure for mixed-mode delaminations. Having thereby introduced geometric non-linearity, the technique can be applied to situations involving a combination of buckling and delamination. Detailed comparisons are made with experimental results for such a problem.

ABSTRACT: This paper deals with the computation of buckling behaviour and with the prediction of
delamination growth in a compressively loaded delaminated laminate. The laminate is modelled as an assembly of three plates with account for geometric non-linearities. Both local and global bucklings are investigated. We propose analytical formulae for computing the energy release rate along the delamination front. Our approach consists in adapting the J-integral method of 2D elasticity to our plate model, dealing with discontinuities instead of singularities. Numerical results are discussed and compared to experiments.

Sébastien Baguet and Bruno Cochelin (Laboratory of Mechanics and Acoustics, Marseille, France), “Stability of thin-shell structures and imperfection sensitivity analysis with the asymptotic numerical method”, Revue Européenne des Eléments Finis, Hermès, 2002, 11/2-3-4, pp.493-509. <10.3166/reef.11.493-509>

ABSTRACT: This paper is concerned with stability behaviour and imperfection sensitivity of thin elastic shells. The aim is to determine the reduction of the critical buckling load as a function of the imperfection amplitude. For this purpose, the direct calculation of the so-called fold line connecting all the limit points of the equilibrium branches when the imperfection varies is performed. This fold line is the solution of an extended system demanding the criticality of the equilibrium. The Asymptotic Numerical Method is used as an alternative to Newton-like incremental-iterative procedures for solving this extended system. It results in a very robust and efficient path-following algorithm that takes the singularity of the tangent stiffness matrix into account. Two specific types of imperfections are detailed and several numerical examples are discussed.

PARTIAL ABSTRACT: This paper concerns the computation of non-linear modes of elastic structures under large displacements. We present as numerical method that we have implemented in a general purpose finite element code. Bifurcation of modes will be also addressed.

ABSTRACT: A path-following technique is presented for the numerical solution of a class of elastic structural problems. The principle is to follow a non-linear solution branch by applying a perturbation technique in a stepwise manner. The solution is represented by a succession of local polynomial approximations. The perturbation technique used here is the asymptotic-numerical method proposed by Damil and Potier-Ferry. It is a combination of asymptotic expansions and finite element calculations which permits one to determine a large part of a non-linear branch by inverting only one stiffness matrix. The present continuation technique requires less computing time than the classical predictor-corrector schemes. Moreover, it is very robust and completely automatic, thanks to the analytical representation of the branch within each step. Various numerical examples are presented to evaluate the performance of the method.
ABSTRACT:
This special publication contains the papers presented at the special sessions honoring Dr. Manuel Stein during the 38th AIAA/ASME/ASCE/AHS/ASC Structures, Structural Dynamics, and Materials Conference held in Kissimmee, Florida, April 7-10, 1997. This volume, and the SDM special sessions, are dedicated to the memory of Dr. Manuel Stein, a major pioneer in structural mechanics, plate and shell buckling, and composite structures. Many of the papers presented are the work of Manny's colleagues and co-workers and are a result, directly or indirectly, of his influence. Dr. Stein earned his Ph.D. in Engineering Mechanics from Virginia Polytechnic Institute and State University in 1958. He worked in the Structural Mechanics Branch at the NASA Langley Research Center from 1943 until 1989. Following his retirement, Dr. Stein continued his involvement with NASA as a Distinguished Research Associate.

ABSTRACT: A wide column test of a composite isogrid panel subjected to quasi-static, axial compression is modeled with a hybrid-static dynamic computational method. The data from the test panel exhibited discontinuous responses in the compressive load for slowly increased end-shortening. The computational model was developed to corroborate these discontinuities with the phenomenon of mode jumping. Mode jumping refers to the transient response of the panel from an unstable bifurcation point on a postbuckled equilibrium path to a second stable equilibrium state on a new equilibrium path. On the new equilibrium path, both the analysis and test show that the panel can resist increased end-shortening beyond that of the unstable critical point. Fair agreement is achieved between the analysis and test.

ABSTRACT: Bifurcation of an initially longitudinal through crack in an internally pressurized cylindrical shell at a circumferential stiffener is investigated using a finite element analysis. The finite element model is developed from a fracture test of an aluminum shell having a 22.9 cm radius, a 1.02 mm wall thickness, and stiffened by two externally bonded circumferential straps spaced 40.6 cm apart. After initial stable crack growth in the longitudinal direction with increasing pressure, the crack propagated dynamically toward the strap, bifurcated near the strap into circumferential branches running parallel to the straps. Stable and unstable crack growth curves of pressure versus half-crack length are determined from the nonlinear analysis using a critical value of the crack tip opening angle as the criterion to predict crack growth. Although the crack growth curves are determined from a static analysis, they corroborate the test results for the location of crack path bifurcation. Also, the principal stress criterion for predicting crack turning is consistent with the test.

ABSTRACT: A numerical method is presented for the initial post-buckling analysis of folded plate structures. The method combines Koiter's initial post-buckling theory with the spline finite-strip method. Splines replace the often used Fourier series, in order to facilitate the description of both local non-periodic buckles which may
occur under concentrated transverse loading, and of oblique buckling modes pertaining to shear. Because determination of the shape of the buckle in axial direction requires more unknowns than in the classical finite-strip method, this method can be placed mid-way between the semi-analytical finite-strip method and a full finite element method. A numerical example pertaining to a thin-walled beam loaded by a concentrated transverse force, demonstrates the interactions between two distortional buckling modes.

ABSTRACT: This paper is a contribution to the understanding of the interaction between overall lateral-torsional buckling and local buckling of a beam under transverse loading. It concentrates on the case where the critical load for local buckling is smallest. Three approaches have been used: numerical analysis using the asymptotic theory; a qualitative analysis using an a priori simple discrete model; and experiments. The study suggests that just three modes in the asymptotic analysis are adequate to describe the interactive behaviour. The resulting reduced potential energy expression is quite similar to that of the a priori simple discrete model and provides insight into the destabilizing phenomenon. The experiments confirm these results.

ABSTRACT: Second-order post-buckling fields emanate from the solutions of a constrained minimization
problem. Two iterative solution algorithms for this specific type of constrained problem are described. A classical augmented Lagrangian algorithm is compared with a simpler one utilizing the specific feature of the initial post-buckling analysis. Numerical examples of prismatic plate-type structures are presented.

David Camenish Gelder, “Buckling and crippling of square steel thin-walled tubes fabricated with symmetrically-overlapping U-channels and foam”, Master’s thesis, Dept. of Civil and Environmental Engineering, Brigham Young University, Provo, Utah, August 2012

ABSTRACT: Testing and analysis has been performed on square steel thin-walled tubes fabricated using symmetrically-overlapping U-channels and foam. This research analyzes flange-to-flange attachment, effect of foam in the columns, effect of adhesive stiffness, and influence of steel thickness, as related to the local buckling loads, global buckling loads, and crippling loads. Four 14-foot (4.27 m) foam-filled, thin-walled, galvanized steel columns were manufactured by Novatek, Inc. and tested in axial compression with pinned boundary conditions. For three of the four configurations, the two-piece 4-in. (10.2-cm) square shell surrounded prefabricated polystyrene foam inserts; the fourth column had no foam insert. The column outer shells were composed of two 16-gauge galvanized steel channels with overlapping flanges and the webs on opposite sides of the column. The two adjacent flanges on each side of the columns were adhesively bonded together in all cases. In addition to the adhesive, two columns had either periodic screws or short welds spaced evenly along the length of the columns to delay the onset of flange buckling of the outer channel, and potentially increase the compression strength. The other two columns had adhesive only bonding the flanges, one of which had no foam filler. The various configurations all exhibited similar compression strengths. Failure for all columns initiated with local buckling, followed by global buckling and local crippling, which occurred simultaneously. The method of flange attachment, the effect of the foam in the columns, and flange thicknesses were isolated and analyzed using mechanics-based analysis, parametric studies, and finite element analysis. The results show the ideal spacing of screws or short-welds, if used, is less than or equal to 5 in (12.7 cm) for the given column length. This increases the local buckling load to the Euler buckling load and preserves the original shape of the cross-section. The adhesive needs only a tensile strength of approximately 1 ksi (6.4 kPa) to prevent local buckling for any spacing of screws or short-welds, but needs to be applied uniformly (much of the adhesive in the column tests had been scraped off of the flanges during assembly). The results also show that foam core does not increase the Euler buckling load, but does increase the crippling load by delaying inward buckling of the column webs and flanges. Using foam with the given stiffness and a yield strength of 50 psi (345 kPa), uniform foam-to-steel bonding could increase the crippling strength up to 21% even without adhesive between the flanges. Using adhesive with the given stiffness between the flanges could increase the crippling strength by up to 63% without foam. The crippling strength could increase up to 72% if both adhesive between the flanges and a foam insert are used.

SUMMARY: Aluminium extrusions applied in daily practice are often thin-walled with complex cross-
sectional shapes. These shapes are based on a variety of demands that are in general non-structural. As a result, several types of instability may occur, including overall and cross-sectional instability modes as well as mode interactions. Research on overall buckling is usually based on simple and symmetrical cross-sections, whereas cross-sectional instability is simplified to buckling of individual plates. It is therefore highly unlikely that these design rules provide an accurate description of the actual buckling behaviour of arbitrary cross-sections. As predicted failure modes not necessarily agree with actual ones, the outcome of the results may be overly conservative but could be unsafe as well. In order to investigate the actual cross-sectional stability behaviour of aluminium extrusions, a large experimental program is executed at Eindhoven University of Technology. This program consists of aluminium extrusions under uniform axial compression. Test specimens with rectangular hollows (SHS), U-sections (US), as well as very complex cross-sectional shapes (CS) have been tested. A detailed investigation is made into the influence of the test set-up, initial imperfections, as well as the material characteristic. This results in is a large set of test data on the actual buckling behaviour of aluminium extrusions, including local, distortional, flexural and flexural-torsional buckling, as well as mode interaction. To support the findings of the experiments, a numerical program using the finite element (FE) method is executed. Most experiments are simulated using the actual geometry, material, and imperfections. Comparison of the experimental and numerical results shows that an accurate prediction is achieved. Furthermore, the FE-analyses allow a detailed investigation of specific aspects like the bifurcation load, the influence of imperfections and materials, the test set-up, and mode interaction. The FE-results enable the development of a new and general prediction model for the local buckling behaviour of aluminium extrusions. Based on the actual local buckling behaviour of cross-sections, it is derived for uniformly compressed aluminium extrusions with arbitrary cross-sections consisting of flat plates. As such, it allows an accurate and conservative prediction of the strength and stiffness of a large range of commercial extrusions. The promising results of this model may result in design rules that enable more economical designs and are able to include distortional buckling and mode interaction. This combination of experimental, numerical (FE), and analytical work results in a thorough investigation on the actual local buckling behaviour of aluminium extrusions with arbitrary and complex cross-sections.

ABSTRACT: A Kirchhoff–Love type curved triangular finite element is proposed for geometrically nonlinear analysis of elastic isotropic shells undergoing small strains but large displacements. The finite-element formulation is based on the expression of the strain energy in terms of invariants of the strain and curvature-change tensors of the shell middle surface. The element sides are chosen as three independent directions for determining the strains and curvature changes. The emphasis is put on improvement of the bending behavior of the element so that the element is able to undergo finite curvature changes. Recursive relations are obtained for exactly calculating the coefficients of the first- and second-order variations of the strain energy of the finite element which are necessary to formulate the equilibrium and stability conditions of the discrete model of a shell. A shell finite element with 15 degrees of freedom is developed and tested. Numerical examples are presented to demonstrate the accuracy and mesh convergence of the finite-element solutions.

ABSTRACT: An engineering approach for constructing a curved triangular finite element of a thin shell is considered. The approach is based on the assumption that the triangle sides are planar nearly circular curves before and after deformation. A geometrically nonlinear formulation of a triangular finite element of a thin Kirchhoff–Love shell is given. The predictive capabilities of the element are tested using benchmark problems of nonlinear deformation of elastic plates and shells.

ABSTRACT: This paper describes the improvements in the B2000 system in order to simulate the behaviour of composite stiffened panels. For improved non-linear numerical behaviour, use was made of shell elements following the theory from Bathe with a total Lagrangian formulation. The non-linear Newton-Raphson processor required modification to jump past the initial buckling point into the post-buckling domain. Examples are presented to demonstrate the new capabilities.

ABSTRACT: A finite element based hybrid subspace analysis procedure to predict the non-linear behaviour of statically loaded structures is presented. The basic idea is to reduce the total number of degrees of freedom significantly, utilizing global shape functions like buckling modes and path derivatives in a so-called Rayleigh–Ritz approach. The transformation from the full into the reduced system and vice versa as well as the calculation of the global shape functions is detailed. The presented flow-chart of the computational procedure has been implemented in a finite element environment. Numerical examples provide an insight into the potential of the approach to solve accurately and efficiently non-linear problems within the design phase.

ABSTRACT: European aircraft industry demands for reduced development and operating costs, by 20% and 50% in the short and long term, respectively. Structural weight reduction by exploitation of structural reserves in composite aerospace structures contributes to this aim, however, it requires accurate and experimentally validated stability analysis of real structures under realistic loading conditions. This paper presents new achievements from the area of computational and experimental stability research of composite aerospace structures which contribute to that field. The first four topics focus on stringer stiffened panels and the last one on imperfection sensitive unstiffened cylinders.
Section 1 presents new results achieved so far in the running EU (European) project COCOMAT, which deals with an accurate and reliable simulation of collapse. The main objective of COCOMAT is a future design scenario which exploits considerable reserves in fibre composite fuselage structures by accurate simulation of collapse. The project results comprise an experimental data base, improved slow and fast computational tools as well as design guidelines.

Section 2 deals with validated postbuckling simulation of stiffened CFRP-panels by experiments. The validation procedure to ensure reliable numerical simulations requires extensive experimental data, especially in the case of nonlinear calculations with the possibility of several bifurcation and limit points in the postbuckling region. Therefore, the experiments have to be planned carefully, to ensure a reliable and goal-oriented validation with respect to the numerical analysis.

Section 3 presents the fast tool IBuck for the simulation of the postbuckling behaviour. It is a semi-analytical tool for the simulation of axially loaded panels that are stiffened in both axial and circumferential direction. In today’s design process dynamic loading, e.g. due to gusts or landing impact, is assumed to be uncritical, since the dynamic process increases buckling stability. Section 4 shows that rapidly applied loading of stiffened panels can yield critical dynamic behavior in the postbuckling regime. When applying the new design philosophy it has either to be assured that these critical interactions do not occur under the loading velocities to be expected, or they have to be taken into consideration.

Section 5 presents a recently developed approach for unstiffened shells which are usually susceptible to imperfections. This robust design approach is based on a single buckle as the worst imperfection mode leading directly to the load carrying capacity of a cylinder. It also promises to improve the knock-down factors which are according the current guidelines very conservative.

Future work should facilitate full applicability of the analysis methods in preliminary design. For that purpose speed of the collapse analysis of stiffened panels needs to be increased and for collapse simulation degradation must be taken into account. The application field of the robust design method should be widened towards imperfection sensitive stiffened shells (skin-dominant designs).

ABSTRACT: A fibre–metal laminate is a composite of metal and fibre-reinforced prepreg layers. An example of such a material is Glare. It consists of alternating layers of aluminium and glass-fibre-reinforced prepreg. The material can be sensitive to delamination buckling, which occurs when a partially delaminated panel is subjected to a compressive force. The interaction of local buckling and extension of the delaminated zone typically results in a decrease of the residual strength and, eventually, in a collapse of the structure. This phenomenon can be observed in experimental tests, but numerical analyses are needed to obtain a better understanding of the mechanisms and the critical parameters. In this paper, some experimental observations are discussed regarding delamination buckling in Glare and, on the basis of these observations, a numerical model is constructed at a meso-mechanical level. In this approach, solid-like shell elements are used to model the individual layers. They are connected by interface elements, which are capable of modelling delamination between the layers.

ABSTRACT: Lithographic techniques applied to a substrate prior to film deposition can create areas of low
interface adhesion surrounded by regions of high adhesion. If the film is under compression and if buckle
delamination is nucleated, conditions can be controlled such that delaminations are confined to the patterned
areas of low adhesion. When the area of low adhesion is a strip, the width of the strip controls the buckle
morphology: smooth Euler buckles for narrow strips, asymmetric telephone cord buckles for wider strips, and
symmetric varicose buckles under a very limited range of conditions. Results for the elastic energy in the
buckled state show that above a critical stress the telephone cord morphology is the preferred morphology.
Energy release rates for propagating delaminations are determined for each of the three morphologies. Tapered
strips provide an accurate means of measuring interface adhesion based on the width of the strip where the
delamination arrests.

ABSTRACT: It is shown that unless the substrate is at least as stiff as the film, the energy stored in the substrate contributes significantly to the energy release rate of film delamination under compression either with or without cracking. For very compliant substrates, such as polyethylene terephthalate (PET) with a indium tin oxide (ITO) film, the energy release rate allowing for the deformation of the substrate can be more than an order of magnitude greater than the value obtained neglecting the substrate's deformation. The argument that buckling delaminations tunnel at the tip rather than spread sideways because of increase in mode-mixity may need modification; it is still true for stiff substrates, but for compliant substrates the average energy release rate decreases with delamination width and the limitation in buckled width may be due to this stability as much as the increase in mode-mixity.

M. Ahmer Wadee (Department of Civil and Environmental Engineering, Imperial College of Science, Technology & Medicine, London, SW7 2AZ, UK), “Nonlinear buckling in sandwich structs: mode interaction

ABSTRACT: Recent developments in the variational modeling of nonlinear interactive buckling phenomena found in compression sandwich panels are presented. Strong interactions between local and global modes are found to lead to localized buckling in the more compressed face-plate after the global instability. Important features such as the effect of using orthotropic core materials and face-plates of differing thicknesses, the potential for face-core delamination, panels under combined bending and compression, and the sensitivity to imperfections are discussed. The combination of modal interactions and the introduction of initial geometric imperfections in the struts shows that the critical buckling loads from linear analysis can significantly overestimate their true elastic strength.

ABSTRACT: A geometrically nonlinear model is developed to investigate the buckling behaviour of plates with a pre-existing delamination under uniaxial compression. The Rayleigh–Ritz procedure, based on trigonometric out-of-plane displacement functions, is used in conjunction with potential energy principles to describe the buckling and postbuckling response. The formulation is enhanced with the introduction of a discrete cohesive zone model to allow the delamination to grow under further loading. Different cases are investigated with residual capacities of the plates being evaluated in the neighbourhood of a transitional depth of delamination, where the postbuckling behaviour changes from thin film to mixed mode to global buckling. The model is validated with the commercial finite-element code Abaqus and criteria are proposed such that the component may be exploited beyond the critical loads.

ABSTRACT: A finite-difference method was proposed and used for analysis of critical loads of shells that have initial imperfections of different types, both regular and local. Ribbed shells were analyzed with allowance for the discreteness in the arrangement of the ribs.

ABSTRACT: The paper proposes a new approach to estimate the lower bounds of critical loads for circular cylindrical shells. These bounds are compared with the ordinary lower bound of critical load under which a shell with initial deflections loses stability. The lower bound produced by the approach is higher than the ordinary bound and can be used in design.

Experimental justification of the analytical method for determining the upper and lower bounds of the critical loads in ribbed shells
G. D. Gavrilenko and V. I. Matsner

ABSTRACT: The method developed for determining the upper and lower bounds of the critical load parameters in elastic ribbed shells is described. The critical parameters for cylindrical shells with three types of stiffening, namely, by cross ribs, by stringers and by rings only, are justified experimentally. It is shown that the lower bounds of the critical loads agree with the minimum experimental parameters much better than the upper bounds of the critical loads determined from the linear momentless theory.

ABSTRACT: A technique for stability analysis of stringer shells is proposed. It is used to analyze the minimum critical stresses. The dependence of the dimensionless parameters $\sigma_{cr}/\sigma_{el}$ on the number of stringers is plotted. The linear and nonlinear theories of ribbed shells are used to examine the features of how stringer shells lose stability. It is shown that the minimum critical stresses determined using the theory of ribbed shells and a structurally orthotropic model are close within the range of stiffness parameters considered

Stability and load-bearing capacity of smooth and ribbed shells with local dents
ABSTRACT: A method for analysis of the stability and load-bearing capacity of imperfect smooth and ribbed shells is developed. This method is based on the finite-difference method and is implemented as an algorithm for fast calculation of critical forces, as opposed to the finite-element method. The theoretical results discussed include both early and recent results. The emphasis is on shells with local dents. The numerical results are successively corrected and compared with available experimental data for shells with a single dent and with other data. The method enables us to discover new features in the behavior of thin-walled structures under loading: development of precritical state, change in the dent shape, and exhaustion of load-bearing capacity. The lower local critical loads and upper stresses are determined. They correspond to general buckling and agree well with available experimental data.

Calculation of Load-Carrying Capacity of Elastic Shells with Periodic Dents (Theory and Experiment)

G. D. Gavrilenko and V. L. Krasovskii
Strength of Materials, 2004, Volume 36, Number 5, Pages 511-517
ABSTRACT: The phenomenon of the local loss of stability (buckling) earlier discovered by the authors experimentally was simulated theoretically. An approach to assessing the load-carrying capacity of circular cylindrical shells with periodic dents is presented. The authors show that application of the linear theory or solution of the problem in the nonlinear formulation with few iterations (when calculating the subcritical state) results in large quantitative errors. To get more accurate and reliable numerical data, one needs to solve the problem of the nonuniform subcritical state in the nonlinear formulation with many iterations. The local buckling loads determined numerically are lower than the experimental values, i.e., the errors are on the safe side. The loads characterizing the overall buckling are either close to the experimental values or also lower.

Reduced-Stiffness Method in the Theory of Shells

G. D. Gavrilenko and J. G. A. Croll
International Applied Mechanics, 2004, Volume 40, Number 7, Pages 715-743
ABSTRACT: The fundamentals of the reduced-stiffness method, which is used in buckling analysis of reinforced and perfect and imperfect nonreinforced shells, are set out. The method is validated analytically and experimentally. The lower bound determined by this method is very close to the experimental lower bound. Some aspects of the current state and prospects for development and generalization of the method are discussed.

Stability of Circular Cylindrical Shells with a Single Local Dent
G. D. Gavrilenko and V. L. Krasovskii
ABSTRACT: The theoretical-and-experimental investigation has been performed on the stability of smooth cylindrical shells of steel with a single local dent. All the shells manufactured using the same process were tested with the fulfillment of identical conditions for observations and measurements. Theoretical calculations were carried out by the mesh method with the use of the nonlinear theory of shells. A comparison of the experimental and theoretical values of the critical loads has been made. The theoretical-and-experimental approach proposed enables one to evaluate the quality of shells by studying local dents and other specific imperfections.

ABSTRACT: We propose a nonlinear approach to the stability analysis of imperfect cylindrical shells under axial compression. The approach takes into account the initial deflections (imperfections) of the shell shape from cylindrical. A series of typical initial deflections is analyzed: local and longitudinal bulges (dents) and unilateral annular corrugations. A nonlinear stability problem is solved. The results are represented as plots of the nondimensional stress versus the nondimensional amplitude of initial deflections. It is shown that the capabilities of the nonlinear theory for estimating the critical stresses for thin shells have not been exhausted yet and that it could be used in future to explain some phenomena experimentally observed in shells

ABSTRACT: The FETI algorithms are a family of numerically scalable domain decomposition methods. They have been designed in the early 1990s for solving iteratively and on parallel machines, large-scale systems of equations arising from the finite element discretization of solid mechanics, structural engineering, structural dynamics, and acoustic scattering problems, and for analyzing complex structures obtained from the assembly of substructures with incompatible discrete interfaces. In this paper, we present the second generation of these methods that operate more efficiently on large numbers of subdomains, offer greater robustness, better performance, and more flexibility for implementation on a wider variety of computational platforms. We also
report on the application and performance of these methods for the solution of geometrically non-linear structural analysis problems. We discuss key aspects of their implementation on shared and distributed memory parallel processors, benchmark them against optimized direct sparse solvers, and highlight their potential with the solution of large-scale structural mechanics problems with several million degrees of freedom.

ABSTRACT: Sandwich plate systems (SPS) are advanced materials that have begun to receive extensive attention in naval architecture and ocean engineering. At present, according to the rules of classification societies, a mixture of shell and solid elements are required to simulate an SPS. Based on the principle of stiffness decomposition, a new numerical simulation method for shell elements was proposed. In accordance with the principle of stiffness decomposition, the total stiffness can be decomposed into the bending stiffness and shear stiffness. Displacement and stress response related to bending stiffness was calculated with the laminate shell element. Displacement and stress response due to shear was calculated by use of a computational code write by FORTRAN language. Then the total displacement and stress response for the SPS was obtained by adding together these two parts of total displacement and stress. Finally, a rectangular SPS plate and a double-bottom structure were used for a simulation. The results show that the deflection simulated by the elements proposed in the paper is larger than the same simulated by solid elements and the analytical solution according to Hoff theory and approximate to the same simulated by the mixture of shell-solid elements, and the stress simulated by the elements proposed in the paper is approximate to the other simulating methods. So compared with calculations based on a mixture of shell and solid elements, the numerical simulation method given in the paper is more efficient and easier to do.

ABSTRACT: A non-linear shallow thin shell element is described. The element is a curved quadrilateral one with corner nodes only. At each node, six degrees of freedom (i.e. three translations and three rotations) make the element easy to connect to space beams, stiffeners or intersecting shells. The curvature is dealt with by Marguerre's theory. Membrane bending coupling is present at the element level and improves the element behaviour, especially in non-linear analysis. The element converges to the deep shell solution. The sixth degree of freedom is a true one, which can be assimilated to the in-plane rotation. The present paper describes how overstiffness due to membrane locking on the one hand and to the sixth degree of freedom on the other hand can be corrected without making use of numerical adjusted factors. The behaviour of this new element is analysed in linear and non-linear static and dynamic tests.

“Composite panel optimization with nonlinear finite-element analysis and semi-analytical sensitivities”, NAFEMS Seminar: November 6 - 7, 2007 “Simulating Composite Materials and Structures”, Bad Kissingen, Germany

ABSTRACT: This paper describes some recent developments of software tools for the optimization of fuselage composite stiffened panels. The two most innovative features of the underlying work are related to the evaluation of buckling and collapse reserve factors and the associated sensitivities, the latter being computed in the framework of both linear and nonlinear finite element analyses. Results obtained with an industrial test case are also presented to confirm the successful integration of these tools in a powerful software environment.

ABSTRACT: Advanced nonlinear analyses developed for estimating structural responses for recent applications for the aerospace industry lead to expensive computational times. However optimization procedures are necessary to quickly provide optimal designs. Several possible optimization methods are available in the literature, based on either local or global approximations, which may or may not include sensitivities (gradient computations), and which may or may not be able to resort to parallelism facilities. In this paper Sequential Convex Programming (SCP), Derivative Free Optimization techniques (DFO), Surrogate Based Optimization (SBO) and Genetic Algorithm (GA) approaches are compared in the design of stiffened aircraft panels with respect to local and global instabilities (buckling and collapse). The computations are carried out with software developed for the European aeronautical industry. The specificities of each optimization method, the results obtained, computational time considerations and their adequacy to the studied problems are discussed.

“Design of fiber metal laminate shear panels for ultra-high capacity aircraft”, Aircraft Design, Vol. 4, Nos. 2-3,
ABSTRACT: Due to their excellent fatigue characteristics and relatively low density, fiber metal laminates (FML) are considered as candidates for fuselage materials in future generation ultra-high capacity aircraft (UHCA). To exploit the postbuckling behavior, as is the practice in conventional aluminum alloy fuselage structures, an existing engineering design method for postbuckled shear panels was adapted for applications with FML materials. To verify the adapted design methodology, two stiffened FML shear panels were designed and tested until failure. The dimensions of the panels were taken to be representative of an UHCA fuselage structure. In addition, detailed finite element analyses were performed with STAGS to predict panel response during testing. The finite element results showed very good agreement with experimental data, giving confidence in replacing very costly actual panel tests with computer simulations. It was found that the test panel dimensions were outside the region where the current engineering design method for postbuckled panels is valid. To account for this phenomenon, an extension to the current design method is proposed.

ABSTRACT: Multiple delamination causes severe degradation of the stiffness and strength of composites. Interactions between multiple delamination, and buckling and postbuckling under compressive loads add the complexity of mechanical properties of composites. In this paper, the buckling, postbuckling and through-the-width multiple delamination of symmetric and unsymmetric composite laminates are studied using 3D FEA, and the virtual crack closure technique with two delamination failure criteria: B-K law and power law is used to predict the delamination growth and to calculate the mixed-mode energy release rate. The compressive load-strain curves, load-central deflection curves and multiple delamination process for eight composite specimens with different initial delamination sizes and their distributions as well as two angle-ply configurations $0^\circ$//$(\pm \theta)$//$0^\circ$ ($\theta$ = 0° and 45°, and “/’” denotes the delaminated interface) are comparatively studied. From numerical results, the unsymmetry decreases the local buckling load and initial delamination load, but does not affect the global buckling load compared with the symmetric laminates. Besides, the unsymmetry affects the unstable delamination and buckling behaviors of composite laminates largely when the initial multiple delamination sizes are relatively small.

ABSTRACT: A sandwich panel with initial through-the-width debonds is analyzed to study the buckling of its faceskin when subject to an in-plane compressive load. The debonded faceskin is modeled as a beam on a Winkler elastic foundation in which the springs of the elastic foundation represent the sandwich foam. The Rayleigh-Ritz and finite-difference methods are used to predict the critical buckling load for various debond lengths and stiffnesses of the sandwich foam. The accuracy of the methods is assessed with a plane-strain finite-element analysis. Results indicate that the elastic foundation approach underpredicts buckling loads for sandwich panels with isotropic foam cores.

ABSTRACT: A progressive failure analysis method has been developed for predicting the failure of laminated composite structures under geometrically nonlinear deformations. The progressive failure analysis uses C1 shell elements based on classical lamination theory to calculate the in-plane stresses. Several failure criteria, including the maximum strain criterion, Hashin’s criterion, and Christensen’s criterion, are used to predict the failure mechanisms and several options are available to degrade the material properties after failures. The progressive failure analysis method is implemented in the COMET finite element analysis code and can predict the damage and response of laminated composite structures from initial loading to final failure. The different failure criteria and material degradation methods are compared and assessed by performing analyses of several laminated composite structures. Results from the progressive failure method indicate good correlation with the existing test data except in structural applications where interlaminar stresses are important which may cause failure mechanisms such as debonding or delaminations.

ABSTRACT: This study applies the crack growth resistance curve (R-curve) method to predict the residual strength of a composite fuselage panel with discrete source damage. The R-curve is constructed from the energy release rates computed from cracked tensile plate test specimens at their failure loads. To predict the residual strength of a curved fuselage panel with discrete source damage using the R-curve method, G-curves of the energy release rate of the damaged fuselage panel need to be established. These G-curves are generated for various fuselage pressures over a range of crack lengths. Since this study found that the membrane stiffening effect could significantly reduce the energy release rate at the crack tip of a pressurized fuselage, geometrically nonlinear behavior was considered in the calculations. The residual strength of the damaged fuselage panel was determined by comparing the energy release rates with the “allowable-like” R-curve. The correlation between the crack growth predictions and the damage progression results obtained from experiments is very good. Therefore, the R-curve method has the potential to be a practical engineering method for predicting the residual strength of damaged fuselage panels.

ABSTRACT: In this paper, we derive weakly nonlinear equations for the dynamics of a thin elastic plate of large extent under conditions of heavy fluid loading. Two situations are then considered. First, we consider the case in which transverse motion of the plate generates a weaker in-plane motion, which is in turn coupled back to the evolution of the transverse motion. This results in the familiar nonlinear Schrödinger equation for the amplitude of a transverse plane wave, and we show that solitary-wave solutions are possible over the range of (non-dimensional) frequencies $\omega > \omega_c$, which depends on the material properties. Dimensional values of $\omega_c$ are physically realizable for a typical composite material underwater. Second, we consider the case in which the amplitudes of the transverse and in-plane motion are of the same order of magnitude, possible at a single resonant frequency, which leads to an evolution equation of rather novel type. We find a range of travelling-wave solutions, including cases in which incident in-plane waves can generate localized regions of transverse displacement.

ABSTRACT: A methodology for simulating the growth of long through cracks in the skin of pressurized aircraft fuselage structures is described. Crack trajectories are allowed to be arbitrary and are computed as part of the simulation. The interaction between the mechanical loads acting on the superstructure and the local structural response near the crack tips is accounted for by employing a hierarchical modelling strategy. The structural response for each cracked configuration is obtained using a geometrically non-linear shell finite element analysis procedure. Four stress intensity factors, two for membrane behaviour and two for bending using Kirchhoff plate theory, are computed using an extension of the modified crack closure integral method. Crack trajectories are determined by applying the maximum tangential stress criterion. Crack growth results in localized mesh deletion, and the deletion regions are remeshed automatically using a newly developed all-quadrilateral meshing algorithm. The effectiveness of the methodology, and its applicability to performing practical analyses of realistic structures, is demonstrated by simulating curvilinear crack growth in a fuselage panel that is representative of a typical narrow-body aircraft. The predicted crack trajectory and fatigue life compare well with measurements of these same quantities from a full-scale pressurized panel test.

ABSTRACT: …The primary objective of the project was to create a capability to simulate curvilinear fatigue crack growth and ductile tearing in aircraft fuselages subjected to widespread fatigue damage. The second objective was to validate the capability by way of comparisons to experimental results. Both objectives have been achieved. … The document is derived primarily from the PhD thesis of Dr. Chen.)

Falzon (Department of Aeronautics, Imperial College London, London, SW7 2AZ, United Kingdom), “Optimizing Postbuckling Composite Panels For Damage Resistance”, 16th International Conference On Composite Materials (year and publisher not given. Most recent reference is dated 2006)

ABSTRACT: The design of current composite primary aerostructures, such as fuselage or wing stiffened panels, tends to be conservative due to the susceptibility of the relatively weak skin-stiffener interface. This weakness is due to through-thickness stresses which are exacerbated by deformations due to buckling. This paper presents a finite-element-based optimization strategy, utilizing a global-local modelling approach, for postbuckling stiffened panels which takes into account damage mechanisms which may lead to delamination and subsequent failure of the panel due to stiffener debonding. A genetic algorithm was linked to a finite element package to automate the iterative procedure and maximize the damage resistance of the panel in postbuckling. For a given loading condition, the procedure optimized the panel’s skin layup leading to a design displaying superior damage resistance compared to non-optimized designs.

ABSTRACT: The behavior of blade-stiffened graphite-epoxy panels with impact damage is examined to determine the effect of adding through-the-thickness stitches in the stiffener flange-to-skin interface. The influence of stitches is evaluated by examining buckling and failure for panels with failure loads up to 3.5 times greater than buckling loads. Analytical and experimental results from four configurations of panel specimens are presented. For each configuration, two panels were manufactured with skin and flanges held together with through-the-thickness stitches introduced prior to resin infusion and curing and one panel was manufactured with no stitches holding the flange to the skin. No mechanical fasteners were used for the assembly of any of these panels. Panels with and without low-speed impact damage were loaded to failure in compression. Buckling and failure modes are discussed. Stitching had little effect on buckling loads but increased the failure loads of impact-damaged panels by up to 30%.

Dawn C. Jegley (NASA Langley Research Center, Hampton, VA 23681, USA), “Study of compression-loaded and impact-damaged structurally efficient graphite-thermoplastic trapezoidal-corrugation sandwich and semisandwich panels” (publisher and date not given, ProQuest-CSA)
ABSTRACT: The structural efficiency of compression-loaded trapezoidal-corrugation sandwich and semisandwich composite panels is studied to determine their weight savings potential. Sandwich panels with two identical face sheets and a trapezoidal corrugated core between them and semisandwich panels with a corrugation attached to a single skin are considered. An optimization code is used to find the minimum weight designs for critical compressive load levels ranging from 3000 to 24,000 lb/in. Graphite-thermoplastic panels based on the optimal minimum weight designs were fabricated and tested. A finite element analysis of several test specimens was also conducted. The results of the optimization study, the finite element analysis, and the experiments are presented. The results of testing impact damage panels are also discussed.

ABSTRACT: The results of an analytical and experimental investigation of 4-ply Kevlar-49-epoxy panels loaded by in-plane shear are presented. Approximately one-half of the panels are thin-core sandwich panels and the other panels are solid-laminate panels. Selected panels were impacted with an aluminum sphere at a velocity of either 150 or 220 ft/sec. The strength of panels impacted at 150 ft/sec was not reduced when compared to the strength of the undamaged panels, but the strength of panels impacted at 220 ft/sec was reduced by 27 to 40 percent. Results are presented for panels that were cyclically loaded from a load less than the buckling load to a load in the postbuckling load range. The thin-core sandwich panels had a lower fatigue life than the solid panels. The residual strength of the solid and sandwich panels cycled more than one million cycles exceeded the baseline undamaged panel strengths. The effect of hysteresis in the response of the sandwich panels is not significant. Results of a nonlinear finite element analysis conducted for each panel design are presented.

ABSTRACT: A composite isogrid panel design for application to a rotorcraft fuselage is presented. An optimum panel design for the lower fuselage of the rotorcraft that is subjected to combined in-plane compression and shear loads was generated using a design tool that utilizes a smeared-stiffener theory in conjunction with a genetic algorithm. A design feature was introduced along the edges of the panel that facilitates introduction of loads into the isogrid panel without producing undesirable local bending gradients. A low-cost manufacturing method for the isogrid panel that incorporates these design details is also presented. Axial compression tests were conducted on the undamaged and low-speed impact damaged panels to demonstrate the damage tolerance of this isogrid panel. A combined loading test fixture was designed and utilized that allowed simultaneous application of compression and shear loads to the test specimen. Results from finite element analyses are presented for the isogrid panel designs and these results are compared with experimental results. This study illustrates the isogrid concept to be a viable candidate for application to the helicopter lower fuselage structure.

ABSTRACT: An approximate method based on strut approach to predict the ultimate strength of simply-supported stiffened panels with initial imperfections and square cutouts, subjected to uniaxial compression is presented. The reduction in stiffness of the plate between stiffeners is considered by using an ‘effective width concept’. Tests are reported on welded stiffened steel panels with varying plate slenderness ratio and column slenderness ratio. Based on the experimental investigations and the proposed method, the influence of square openings, extending the full width between stiffeners, on the ultimate strength of stiffened panels is evaluated.

ABSTRACT: Experimental investigations are carried out up to collapse on eighteen stiffened steel plates having initial imperfections under uniaxial compression with simply supported boundary conditions on both loading and unloading edges. The thickness of the flange plates is varied as 4 mm and 5 mm respectively. Three types of commercially available open section rectangular flats are used as stiffeners. Six panels without cutout, six panels with square cutout which extends the full width in between stiffeners (d/b=1.0), four panels with rectangular cutout (d/b=1.5) and two panels with reinforced rectangular cutout are fabricated. The initial geometric imperfections such as plate imperfection deltax, overall imperfection of the whole panel deltasx and torsional imperfection in stiffener deltasy are measured for all panels fabricated. The axial deformation of the whole panel, out-of-plane deflections and strains along the midsection of the panels measured during the tests is discussed. The reduction in strength of the panels due to the presence of square cutout, rectangular cutout and increase in strength due to reinforcement around rectangular cutout are calculated based on the experimental observations.

ABSTRACT: The high strength to weight ratio and high stiffness to weight ratio of stiffened plates find wide application in aircraft structures, ship structures, offshore oil platforms and lock gates. The strength and stability of stiffened plates is highly influenced by openings and initial imperfections. The main objective is to study the behaviour of stiffened steel plates with openings up to collapse and to trace the post-peak behaviour under axial and out-of-plane loads. Four stiffened steel plates with a square opening were fabricated for testing. Angle sections were used as stiffeners. Imperfections in the plate, stiffener and overall imperfection of the whole panel were measured. All fabricated panels were tested to failure. A finite element (FE) model was developed for the
analysis of stiffened plates with initial imperfections and validated with the test results. Parametric studies were conducted using the developed FE model, and interaction curves and equations were developed for the design of stiffened plates with initial imperfections and openings. The interactive effect for stiffened panels with a square opening was found to be linear, with proportional reduction of the ultimate axial load carrying capacity due to the constant out-of-plane load.

ABSTRACT: A simple energy-based approach to calculate stresses at skin-stiffener interfaces of composite stiffened panels under shear loads is presented. Solutions to the governing partial differential equations are sought that satisfy boundary conditions and traction continuity. The stress functional forms are determined by minimizing the energy using a variational approach. The resulting closed form stress expressions are compared to finite element solutions and are shown to be in very good agreement.

ABSTRACT: In the present paper the topological optimal design of isotropic/orthotropic thin structures performed via genetic algorithms is shown. Examples involving structural weight minimization under compressive load or buckling load maximization are presented. A modified finite strip method was developed and used to analyze parametric structures arranged in form of plates or stiffened panels with almost arbitrary cross-section shapes. Specific design variables were defined to assure a robust control over geometrical and topological features. In particular, a semi-analytical formulation for the determination of eigenvalues and eigenvectors was adopted in order to reduce computational efforts requested by the optimization task. A mesh-independent solver, involving a reduced number of degrees of freedom, was implemented and interfaced with a genetic optimizer for the purpose. The optimization procedure was based on a specific bit-masking oriented genetic algorithm, able to handle in parallel different genetic operators expressly conceived to process with proper metrics discrete and continuous design variables. As preliminary example, the buckling load maximization of a metallic plate with an arbitrary grid-shaped cross-section is described first. Then a topological optimization concerning the weight minimization of a composite stiffened panel subject to constraint about buckling load is illustrated and discussed in detail about parametric model definition and genetic procedure.

ABSTRACT: State-of-the-art nonlinear finite element analysis techniques are evaluated by applying them to a
realistic aircraft structural component. A wing panel from the V-22 tiltrotor aircraft is chosen because it is a typical modern aircraft structural component for which there is experimental data for comparison of results. A novel solution strategy which accounts for geometric nonlinearity through the use of corotating element reference frames and nonlinear strain displacement relations is used to analyze this detailed model. Results from linear analyses using the same finite element model are presented in order to illustrate the advantages and costs of the nonlinear analysis as compared with the more traditional linear analysis. Strain predictions from both the linear and nonlinear stress analyses are shown to compare well with experimental data up through the Design Ultimate Load (DUL) of the panel. However, due to the extreme nonlinear response of the panel, the linear analysis was not accurate at loads above the DUL. The nonlinear analysis more accurately predicted the strain at high values of applied load, and even predicted complicated nonlinear response characteristics, such as load reversals, near the observed failure load of the test panel. In order to understand the failure mechanism of the panel, buckling and first-ply failure analysis were performed. The predicted buckling load was 17% above the observed failure load while first-ply failure analyses indicated significant material damage at and below the observed failure load.

ABSTRACT: This paper presents a multilayered/multidirector and shear-deformable finite-element formulation of shells for the analysis of composite laminates. The displacement field is assumed continuous across the finite-element layers through the composite thickness. The rotation field is, however, layerwise continuous and is assumed discontinuous across these layers. This kinematic hypothesis results in independent shear deformation of the director associated with each individual layer and thus allows the warping of the composite cross section. The resulting through-thickness strain field is therefore discontinuous across the different material sets. Numerical results are presented to show the performance of the method.

ABSTRACT: This paper presents a continuum-based shear-deformable finite element formulation for geometrically nonlinear analysis of thick layered composite shells. The proposed variational formulation is based on an assumed strain method. From a kinematical viewpoint displacements and rotations are assumed finite while strains are infinitesimal. The model is then cast in a co-rotational framework which is derived consistently from the updated Lagrangian method. Close relationship between the co-rotational procedure and the underlying updated Lagrangian procedure is presented to highlight the efficiency of the method for application to composite shell analysis. Numerical examples are presented to demonstrate the accuracy and the range of applicability of the proposed formulation.

ABSTRACT: A continuum based layerwise shear-deformable finite element formulation is presented for elasto–plastic analysis of layered composites shells. The proposed formulation is cast in a corotational configuration for finite deformation analysis. The elasto-plastic constitutive equations that are based on rate-independent deviatoric plasticity are also written in the corotational kinematic framework. Issues of covariance
and spatial invariance are addressed, and an appropriate stress updating strategy is proposed. Numerical examples are presented to demonstrate the range of applicability of the proposed framework for bending-dominated response of elasto-plastic layered composite shells.

ABSTRACT: An implementation of solution strategies for controlling the analysis of the non-linear equilibrium behavior of elastic structures is presented. The automated procedure guides the solution-stepping process in the vicinity of critical stability points, including limit points, and bifurcation points of multiplicity one or two. The procedure was developed for use with analysis methods in which the total potential energy of a structure is expressed as a power series of finite order in an arbitrary number of generalized coordinates. Aspects of both the Riks-Wempner arc-length control method and the equivalence-transformation method of Thurston are incorporated. The procedure is applied to several plate and stiffened-panel problems in order to demonstrate key features, and to illuminate difficulties that arise in some situations.

ABSTRACT: Stability analysis is a crucial aspect of structural design, particularly for beam, plate and shell type structures. The stability of a structure is often governed by singular points in its equilibrium path. These points usually pose serious problems to ordinary finite element solution methods and require special treatment. In this paper, the state-of-the-art of finite element path-following techniques is critically reviewed with special attention to bracketing procedures for the singular points and branch switching algorithms. Some practical aspects involved will be explained in detail and demonstrated through numerical examples at the end.

ABSTRACT: The paper presents results of comparative experimental examinations and numerical analyses of rectangular plates subjected to shear treated as a skin of half–monocoque aircraft structure. There were considered: the plate without stiffeners 2 mm thick and structure with 1 mm thickness, stiffened by 15 integral ribs. Results of nonlinear numerical FEM analyses and experimental investigations with use of 3D DIC method were compared to ones conducted for smooth plate with equivalent mass. It was documented that introduction of sub–stiffening significant influence on both the form of deformation and distribution of stress in the structure. For smooth plate low cycle fatigue test was conducted.

ABSTRACT: A three-segment ten-member thin-shell structure with flat walls is considered made of material with instantaneous characteristic approximated by means of an ideally elastic-plastic material model. The structure material (polycarbonate) demonstrates the temporary double refraction effect in polarized light. The system is subject to twisting resulting in state of local post-critical deformation of skin segments within the structure area that is interpreted, in first approximation, as a field of drawing forces. As a result of non-linear numerical analysis in the course of which conformance of equilibrium paths obtained numerically and by means of the experiment is assured, the stress field is determined taking into account the structure’s flexural and membrane state.

ABSTRACT: The paper presents the methodology of determination of the stress distribution in post-critical state of deformation of the rectangular plate weakened with the crack subjected to tension. The problem was formulated as physically and geometrically non-linear. Using the finite elements method, numerical analyses were performed. While solving the nonlinear issue, the progressive change of geometry of the structure in successive incremental steps were compared with results of experimental studies, performed simultaneously.
The obtained results made the base for the assessment of reliability of effects of nonlinear numerical analysis, conditioned by the presence of imperfections of the plate in the neutral state. Two kinds of imperfections were considered: geometric-based on the assumption of the preliminary deflection of the plate in the zone of weakness and the second one – in form of load perturbation, normal to the middle surface of the plate.

PARTIAL INTRODUCTION: Rational approach to design of load-carrying structures seems to suggest the necessity of focusing special attention on crucial areas of these structures, which are decisive for durability and reliability of the structure. The presence of such crucial areas in a designed solution, resulting usually from its practical functions, should be given careful consideration in view of opportunity to introduce appropriate changes in the design solutions possibly before costly and time-consuming workshop realization of a prototype. The intent of the author is to draw attention to gravity of the factor integrating nonlinear numerical analysis with an experiment – in a broad sense of this word. Then, this chapter presents a methodology that can be used for assessment and current improvement of numerical models thus ensuring correct interpretation of results obtained from nonlinear numerical analyses of a structure. The proposed methodology is based on carrying out experimental examination of selected crucial elements of load-carrying structures parallel with their nonlinear numerical analysis. Special attention is paid to factors determining proper realization of adequate experiments with emphasis placed on the role…

INTRODUCTION: Modern aviation structures are characterised by widespread application of thin-shell load-bearing systems. The strict requirements with regard to the levels of transferred loads and the need to minimise a structure mass often become causes for accepting physical phenomena that in case of other structures are considered as inadmissible. An example of such a phenomenon is the loss of stability of shells that are parts of load-bearing structures, within the range of admissible loads.

Thus, an important stage in design work on an aircraft load-bearing structure is to determine stress distribution in the post-critical deformation state. One of the tools used to achieve this aim is nonlinear finite elements method analysis. The assessment of the reliability of the results thus obtained is based on the solution uniqueness rule, according to which a specific deformation form can correspond to one and only one stress state. In order to apply this rule it is required to obtain numerical model’s displacements distribution fully corresponding to actual deformations of the analysed structure.

An element deciding about a structure’s deformation state is the effect of a rapid change of the structure’s shape occurring when the critical load levels are crossed. From the numerical point of view, this phenomenon is interpreted as a change of the relation between state parameters corresponding to particular degrees of freedom of the system and the control parameter related to the load. This relation, defined as the equilibrium path, in case of an occurrence of mentioned phenomenon, has an alternative character, defined as bifurcation. Therefore, the fact of taking a new deformation form by the structure corresponds to a sudden change to the alternative branch of the equilibrium path [1-4].

Therefore, a prerequisite condition for obtaining a proper form of the numerical model deformation is to retain the conformity between numerical bifurcations and bifurcations in the actual structure. In order to
determine such conformity it is required to verify the results obtained by an appropriate model experiment or by using the data obtained during the tests of the actual object. It is often troublesome to obtain reliable results of nonlinear numerical analyses and it requires an appropriate choice of numerical methods dependent upon the type of the analysed structure and precise determination of parameters controlling the course of procedures.

ABSTRACT: The study presents results of research on the problem of obtaining credible results of nonlinear FEM analyses of thin-walled load-bearing structures subjected to post-critical loads. The similarity of numerical simulation results and actual stress distribution states depends on the correct numerical reproduction of bifurcations that occur during an advanced deformation process.

PARTIAL INTRODUCTION: The design work on aircraft constructions, with applicable standards and requirements imposed by regulations applicable to aircraft design taken into account, represents a discipline significantly different than other fields of modern engineering. In fact, as opposed to rules commonly applicable to design of technical structures, in view of the need to limit the mass, in the case of airframe structures there is a necessity to allow phenomena involving loss of stability with respect to some of their components under the in-flight conditions. From the historical point of view, the issue of the loss of stability was a factor significantly slowing down the progress in aviation at early stage of its development. In aspiration to ensure safety, a large group of designers adhered to the lattice structure concepts for many years. The first attempts to develop some more advanced solutions were based on the use of corrugated sheet metal as the skin material for wings and fuselages. Such solution was adopted in numerous constructions manufactured on a mass scale, e.g. Ford Trimotor or Junkers 52...

“Buckling and ultimate strength interaction in plates and stiffened panels under combined inplane biaxial and shearing forces”, Marine Structures, Vol. 8, No. 1, pp 1-36, 1995, DOI: 10.1016/0951-8339(95)90663-F

ABSTRACT: The main portion of a ship's structure is usually composed of stiffened plates. Between girders and floors, stiffeners are furnished to plates usually in the longitudinal direction. Under various loads applied to a ship, such as those due to cargo, buoyancy and waves, these stiffened plates are subjected to combined inplane and lateral loads. Imperfections due to fabrication exist mainly in the form of initial deflection and residual stresses. The behaviour of perfectly flat plates is, however, an important reference in design. In this paper, buckling, ultimate and fully plastic strength interaction relationships for rectangular perfectly flat plates and uniaxially stiffened plates subjected to inplane biaxial and shearing forces are derived and expressed in explicit forms based on the results of theoretical investigations of the non-linear behaviour of plates and stiffened plates.
The accuracy of these interaction relationships is confirmed through comparison with the results of other analysis methods. With the aid of these interaction relationships, buckling load, ultimate strength and/or fully plastic strength of such perfectly fat plates and uniaxially stiffened plates subjected to inplane loads may be predicted by hand calculation.

“Buckling strength of steel plating with elastically restrained edges”, Thin-Walled Structures, Vol. 37, No. 1, pp 27-55, May 2000, DOI: 10.1016/S0263-8231(00)00009-4

ABSTRACT: The twin aims of the present study are to investigate the buckling strength characteristics of steel plating elastically restrained at their edges and also to develop simple design formulations for buckling strength as a function of the torsional rigidity of support members that provide the rotational restraints along either one set of edges or all (four) edges. The characteristic equation for the buckling strength of steel plating that is elastically restrained along either long or short edges while the other edges are simply supported was derived by an analytical method. Using the computed results obtained by directly solving the buckling characteristic equation, closed-form expressions of the buckling strength of the plating with one set of edges elastically restrained while the other set of edges is simply supported are derived empirically by curve fitting. Based on the insights developed in the present study, approximate equations for the buckling strength for plating with all edges elastically restrained are proposed as a function of a relevant combination of the three simpler edge condition cases (i.e., long edges elastically restrained/short edges simply supported, long edges simply supported/short edges elastically restrained, and all edges simply supported). The effect of distortion of support members before the plating buckles is also approximately accounted for. The validity of the proposed closed-form buckling strength design formulations is studied by a comparison with theoretical and numerical solutions.

“A semi-analytical method for the elastic-plastic large deflection analysis of welded steel or aluminum plating under combined in-plane and lateral pressure loads”, Thin-Walled Structures, Vol. 39, No. 2, pp 125-152, February 2001, DOI: 10.1016/S0263-8231(00)00058-6

ABSTRACT: The aim of the present paper is to develop a semi-analytical method which can quickly and accurately compute the elastic–plastic large deflection response of welded steel or aluminum plating under a combination of biaxial compression/tension, biaxial in-plane bending, edge shear and lateral pressure loads, until the ultimate limit state is reached. The post-weld initial imperfections (i.e. initial deflection and residual stresses) are included in the method as parameters of influence. It is assumed that the plating is simply supported at all (four) edges which are kept straight. A unique feature of the developed method is that geometric nonlinearity associated with large deflection response of plating under combined loads is treated by analytically solving the nonlinear governing differential equations of the elastic large deflection plate theory, while material nonlinearity due to plasticity is dealt with implicitly by a numerical procedure. This approach reduces the magnitude of numerical computations, resulting in a saving of modeling effort and computing time. As another
contribution, this paper investigates and discusses the ultimate strength characteristics of plating, by varying the plate properties and load combinations, based on elastic–plastic large deflection analysis using the developed method.

ABSTRACT: In the earlier publications [Paik JK, Thayamballi AK, Lee SK, Kang SJ. A semi-analytical method for the elastic–plastic large deflection analysis of unstiffened plates under biaxial loads, edge shear, biaxial in-plane bending and out-of-plane (lateral) pressure loads until the ultimate strength is reached. The effect of initial imperfections in the form of initial deflection and welding residual stresses is accounted for in the calculations. The validity of the developed method is demonstrated by comparing with existing theoretical and numerical results where relevant. The present theory can be useful for ultimate strength analysis of plates and stiffened panels made of steel or aluminium alloys.

ABSTRACT: In addition to corrosion, fatigue cracking is another important factor of age related structural degradation, which has been a primary source of costly repair work of aging steel structures. Cracking damage has been found in welded joints and local areas of stress concentrations such as at the weld intersections of longitudinals, frames and girders. Fatigue cracking has usually been dealt with as a matter under cyclic loading, but it is also important for residual strength assessment under monotonic extreme loading, because fatigue cracking reduces the ultimate strength significantly under certain circumstances. In this paper, an experimental and numerical study on the ultimate strength of cracked steel plate elements subjected to axial compressive or tensile loads is carried out. The ultimate strength reduction characteristics of plate elements due to cracking damage are investigated with varying size and location of the cracking damage, both experimentally and numerically. Ultimate strength tests on cracked steel plates under axial tension and cracked box type steel structure models under axial compression are undertaken. A series of ANSYS nonlinear finite element analyses for cracked plate elements are performed. Based on the experimental and numerical results obtained from the present study, theoretical models for predicting the ultimate strength of cracked plate elements under axial compression or tension are developed. The results of the experiments and numerical computations obtained are documented. The insights developed will be very useful for the ultimate limit state based risk or reliability assessment of aging steel plated structures with cracking damage.

ABSTRACT: The main objective of the present study is to examine the residual ultimate strength characteristics of steel plates with cracking damages under axial compressive actions through experimental investigations. The present study is a sequel of the author's previous paper (Paik, J.K., Satish Kumar, Y.V., Lee, J.M., 2005. Ultimate strength of cracked plate elements under axial compression or tension. Thin-Walled Structures, 43, 237–272). In contrast to the previous paper which dealt with transverse cracks located in the direction normal to the axial loading direction, the present paper is concerned with longitudinal cracks which are located in parallel to the axial loading direction. Similar to the previous paper, the orientation/location and size of cracks inside the plates are varied for the present experimental investigations. The details of experimental results are documented. The database and insights developed from the present work will be useful for cracking damage-tolerant design of steel-plated structures and also for condition assessment or health monitoring of aging steel-plated structures.

ABSTRACT: The main objective of the present paper is to numerically examine the residual ultimate strength
characteristics of steel plates with longitudinal cracks under axial compressive actions. The present paper is a sequel to the author's previous paper [Paik, J.K., 2008. Residual ultimate strength of steel plates with longitudinal cracks under axial compression—Experiments. Ocean Engineering 35, 1775–1783]. In contrast to the previous paper, the present paper deals with nonlinear finite element method investigations. Because the test programme is usually limited to a few test models in number for many reasons, the application of nonlinear finite element methods is often more beneficial to handle a more variety of parameters of influence. In the present paper, the insights developed from a series of ANSYS nonlinear finite element method computations are documented, where the effects of the crack orientation, the crack location, the crack size, the plate thickness, and the plate aspect ratio on the residual ultimate strength of steel plates with longitudinal cracks under axial compression are discussed. The insights developed from the present work will be useful for cracking damage-tolerant design of steel-plated structures and also for health monitoring or condition assessment of aging steel-plated structures with cracking damages.

ABSTRACT: The present paper (Part II) is a sequel to the previous paper (Part I) [Paik JK, Seo JK. Nonlinear finite element method models for ultimate strength analysis of steel stiffened-plate structures under combined biaxial compression and lateral pressure actions—Part I: Plate elements. Thin-Walled Struct 2008, this issue, doi:10.1016/j.tws.2008.08.005.] on the application of nonlinear finite element methods for ultimate strength analysis of steel stiffened-plate structures under combined biaxial compression and lateral pressure actions. In contrast to Part I dealing with plate elements, the present paper (Part II) treats stiffened panels surrounded by strong support members such as longitudinal girders and transverse frames. In similar to Part I, some important factors of influence such as structural dimensions, initial imperfections, loading types and computational techniques in association with ultimate limit states are studied. Some useful insights in terms of nonlinear finite element method modeling are developed using ANSYS code together with the ALPS/ULSAP semi-analytical method, the latter being for the purpose of a comparison.

Eisenberger (Faculty of Civil and Environmental Engineering, Technion-Israel Institute of Technology, Technion City, Haifa 32000, Israel), “Buckling of symmetrically laminated rectangular plates with general boundary conditions – A semi analytical approach”, Composite Structures, Vol.82, No. 4, February 2008, pp. 521-531, doi:10.1016/j.compstruct.2007.02.003
ABSTRACT: A semi-analytical extended Kantorovich approach for the buckling analysis of symmetrically laminated rectangular plates with general boundary conditions is presented. The solution is derived as a multi-function expansion that allows the analysis of laminated plates characterized by a non-separable solution. Among these, the cases of buckling of angle-ply laminates under inplane compression and shear buckling of any type of plate are the most common ones. The formulation is based on the variational principal of total energy minimization and the iterative extended Kantorovich method. The exact element method is adopted for
the solution of the resulting differential eigenvalue problem. The capabilities of the proposed approach and its applicability to buckling analysis of composite laminated plates that cannot be analyzed using the classical single-term extended Kantorovich method are demonstrated numerically. The results are compared with exact solutions (where available), and with approximate results from other numerical methods. The accuracy and convergence of the proposed approach are also discussed.

“Buckling of laminated plates with general boundary conditions under combined compression, tension, and shear—A semi-analytical solution”, Thin-Walled Structures, Vol. 46, Nos. 7-9, July-September 2008, pp. 925-938, Special Issue: to mark the Retiral of Professor Jim Rhodes, Founding Editor, doi:10.1016/j.tws.2008.01.040

ABSTRACT: A semi-analytical approach to the buckling analysis of generally supported laminated plates subjected to a general combination of inplane shear, compression, and tension loads is presented. Arbitrary out of plane and inplane boundary conditions at the edges of the plate are considered. The formulation is based on the variational principle of virtual work and the multi-term extended Kantorovich method. The semi-analytical method is used for the pre-buckling and buckling (stability) analyses of laminated rectangular plates with inplane restraints under arbitrary inplane loads. The accuracy and convergence are examined through a comparison with exact solutions (where available) and with finite element analyses. The applicability of the method is demonstrated through various numerical examples that focus on the buckling of rectangular composite plates with a variety of boundary conditions and various combinations of the inplane shear, compressive, and tensile loads.

ABSTRACT: A semi-analytical approach to the elastic nonlinear stability analysis of rectangular plates is developed. Arbitrary boundary conditions and general out-of-plane and in-plane loads are considered. The geometrically nonlinear formulation for the elastic rectangular plate is derived using the thin plate theory with the nonlinear von Kármán strains and the variational multi-term extended Kantorovich method. Emphasis is placed on the effect of destabilizing loads and on the derivation of the solution methodologies required for tracking a highly nonlinear equilibrium path, namely: parameter continuation and arc-length continuation procedures. These procedures, which are commonly used for the solution of discretized structural systems governed by nonlinear algebraic equations, are augmented and generalized for the direct application to the PDE. The boundary value problem that results from the arc-length continuation scheme and consists of coupled differential, integral, and algebraic equations is re-formulated in a form that allows the use of standard
numerical BVP solvers. The performance of the continuation procedures and the convergence of the multi-term extended Kantorovich method are examined through the solution of the two-dimensional Bratu–Gelfand benchmark problem. The applicability of the proposed approach to the tracking of the nonlinear equilibrium path in the post-buckling range is demonstrated through numerical examples of rectangular plates with various boundary conditions.

ABSTRACT: The initiation, growth, and stability of buckling driven debonding in structural assemblies of stiff blocks, compliant joints, and adhesively bonded composite layers are analytically investigated. The model is developed with focus on masonry walls externally strengthened with composite materials where static and, mainly, dynamic loads may induce compression in the strengthening layers triggering a buckling driven debonding near the joints. The model introduces the interfacial nonlinearity (debonding) through a cohesive interface approach. The geometrical nonlinearity is introduced through the kinematics of intermediate class of deformation (large deflections, moderate rotations, small strains), and the material nonlinearity of the masonry construction is introduced through the constitutive law for the mortar joints. A numerical study of the debonding process in strengthened masonry walls is presented. The study uses the periodicity of the wall for sub-structuring and examines configurations that include composite strips or sheets, strengthening on one face of the wall or on both faces, and compliant mortar materials. Emphasis is placed on the localized debonding near the joint, its stability characteristics, and the possibility to detect the debonding process before it reaches the point of instability.

ABSTRACT: This paper presents a Mindlin finite strip formulation which considers support displacements in all degrees of freedom at clamped and pinned boundaries. The support movements are introduced by adding special longitudinal functions to the Timoshenko beam functions used in standard finite strips. These special functions are derived from the deflection patterns of a Timoshenko beam under support displacements. The formulation also considers cross-ply composite plates. The material is linearly elastic and orthotropic. Geometric non-linearities are also considered. The proposed finite strip formulation makes it possible to analyse

ABSTRACT: This paper presents a Mindlin finite strip formulation which considers support displacements in all degrees of freedom at clamped and pinned boundaries. The support movements are introduced by adding special longitudinal functions to the Timoshenko beam functions used in standard finite strips. These special functions are derived from the deflection patterns of a Timoshenko beam under support displacements. The formulation also considers cross-ply composite plates. The material is linearly elastic and orthotropic. Geometric non-linearities are also considered. The proposed finite strip formulation makes it possible to analyse
problems that hitherto could not be handled by the standard finite strips. Three examples are used to demonstrate the applicability of the new finite strips.

ABSTRACT: The finite strip method based on the higher-order plate theory is developed for determining the natural frequencies of laminated plates. This method can accurately predict the through thickness effect of transverse shear deformation. Furthermore, only a few degrees of freedom are required in the finite strip method. Some numerical results for various span-to-thickness ratios, material properties and stack sequences are presented for illustrative purposes. The present model provides a better way to obtain more accurate natural frequency results.

ABSTRACT: A layerwise B-spline finite strip method is developed for free vibration analysis of truly thick and thin composite laminated plates within the context of a layerwise plate theory proposed by Reddy [Commun. Appl. Numer. Methods 3 (1987) 173]. The development is the extension of an earlier work [Int. J. Mech. Sci. 37 (1995) 645] in which a Bk,k"_1-spline finite strip method was developed based on the first-order shear deformable plate theory and B-splines of order k and k"_1 were used to avoid shear-locking. In this new method the composite laminated plates are divided into a number of numerical layers in the thickness direction. A linear variation of in-plane displacements are assumed within each numerical layer to represent the through thickness shear warping which can be significant for thick composite laminated plates due to their relatively low through thickness shear moduli. Numerical tests show that the method has the capability to produce accurate predictions for natural frequencies of truly thick and thin composite laminated plates.

ABSTRACT: A finite strip method for non-linear static analysis based on the tangential stiffness matrix has been developed using the new concept of polynomial finite strip elements, with Mindlin (first-order shear deformable element) plate-bending theory for composite plates. A progressive failure algorithm for composite laminates has been successfully developed for the new finite strip methods using a stress-based failure criterion, Tsai–Wu. A finite strip analysis programming package which is capable of performing non-linear progressive damage analysis for composite stiffened plates and shells has also been developed with Mindlin plate-bending
element. Good agreement with the finite element results has been observed through various test cases, confirming the accuracy and reliability of the new developed method.

ABSTRACT: The finite strip method has been employed for the analysis of shear-deformable composite laminates since 1976. A number of works have shown the high accuracy, efficiency and convenience of this method. In the present study, a new shear-deformable finite strip is developed to analyse the static and vibration behaviour of composite laminates. By selecting the proper displacement functions, the new strip includes all the effects of material anisotropy and suits arbitrary inplane boundary conditions at the ends. Thus, the present method is applicable not only to cross-ply laminates and symmetrical angle-ply laminates, but also to arbitrary angle-ply laminates, e.g. antisymmetrical angle-ply laminates and (0/45/–45/90 degree) laminates.

ABSTRACT: The finite strip method has been applied to the stability analysis of rectangular shear-deformable composite laminates. However, for the plates with two opposite simply supported sides, the existing analysis was restricted to the symmetrical cross-ply laminates under compression loading. In the present study, by selecting proper displacement functions and including the coupling between different series terms, the finite strip method is extended to the stability analysis of any anisotropic laminated plates under arbitrary in-plane loading. Furthermore, a number of numerical results are presented to show the effects of thickness, fibre orientation and stacking sequence on the buckling loads.

ABSTRACT: In the present study, a finite strip method for the elastic analysis of anisotropic laminated composite plates is developed according to higher-order shear deformation theory. This theory accounts for the parabolic distribution of the transverse shear strains through the thickness of the plate and for zero transverse shear stresses on the plate surfaces. In comparison with the finite strip method based on first-order shear deformation theory, the present method gives improved results while using approximately the same number of degrees of freedom. It also eliminates the need for shear correction factors in calculating the transverse shear stiffness.

“Three-dimensional finite strip analysis of laminated panels”, Computers & Structures, Vol. 85, Nos. 23-24,
ABSTRACT: In this paper, a combined finite strip and state space approach is introduced to obtain three-
dimensional solutions of laminated composite plates with simply supported ends. The finite strip method is used
to present in-plane displacement and stress components, while the through-thickness components are obtained
by using the method of state equation. The method can replace the traditional three-dimensional finite element
solutions for structures that have regular geometric plans and simple boundary conditions, where a full three-
dimensional finite element analysis is very often both extravagant and unnecessary. The new method provides
results that show good agreement with available benchmark problems having different material compositions,
thickness and boundary conditions. The new method provides a three-dimensional solution for laminated plates,
while the advantages of using the traditional finite strip method are fully taken. This solution also yields a
continuous transverse stress field across material interfaces that normally is not achievable by other numerical
modelling of laminates, such as the traditional finite element method.

“A refined finite strip method using higher-order plate theory”, International Journal of Solids and Structures,
ABSTRACT: The higher-order plate theory is adopted in the finite strip method to analyse orthotropic
laminated plates in this paper. Several examples with the existing elasticity solutions are illustrated to validate
the accuracy and efficiency of the present formulation. Although fewer degrees of freedom are required, the
present model yields the same or even better displacement and flexural stress results than the higher-order plate
element. The through-thickness distribution of transverse shear stress is also properly predicted through the
stress equilibrium equation.

Jacob Avrashi (Computational Mechanics and Material Mechanics Laboratories, Faculty of Mechanical
Engineering, Technion - Israel Institute of Technology, Haifa 32000, Israel), “Accuracy and numerical stability
of the non-uniform finite strip method”, Finite Elements in Analysis and Design, Vol. 17, No. 1, June 1994,
pp.75-88, doi:10.1016/0168-874X(94)90021-3
ABSTRACT: Two most significant aspects of the use of the non-uniform finite strip (NUFS) method for composite laminated plates are discussed in the present paper: The accuracy of the displacement and generalized forces and the numerical stability of the scheme. Numerical results for symmetric and asymmetric highly orthotropic plates are presented to show the strips' behavior characteristics regarding the spectral accuracy, finite element convergence, accuracy of displacement and generalized forces and the consumed CPU time. A comparison of the classical laminated plate strip and Mindlin strip shows some significant differences, especially for highly orthotropic plates.

ABSTRACT: The postbuckling behavior of circular cylindrical shells of finite length under uniform external pressure is analysed using the spline finite strip method. A Total Lagrangian formulation on the displacement dependent pressure load in the orthogonal curvilinear reference frame is derived. An improvement for the arc-length iteration method is presented. The postbuckling equilibrium path and the contour map of equal radial deflection computed are in good agreement with the experimental and analytical results reported in Esslinger, M. and Geier, B., Postbuckling Behaviour of Structures, Springer-Verlag, Wien, New York, 1975.

ABSTRACT: The postbuckling analysis of shells is studied by the spline finite strip method. The selection of higher order terms in the incremental variational principle is discussed. An improvement on the arc-length iteration method is presented. The examples all demonstrated the versatility and accuracy of the present method. The computed results for a circular cylindrical shell under axial compression correlate very well with the experiment results.

ABSTRACT: A spline finite strip is proposed to analyse thick isotropic or laminated composite plates. The formulation is based upon the principle of virtual work and the third-order plate theory developed by Reddy. The variational functional requires the satisfaction of C1-continuity of the assumed vertical deflection variable which can be easily fulfilled by the present method. The proposed spline finite strip is a conforming element with a smaller number of unknowns at each node compared to other existing elements based on the third-order theory. For the analysis of thin isotropic or laminated plates, the present element shows no sign of shear locking. A number of computational examples are given to demonstrate the efficiency and the accuracy of the present method.

ABSTRACT: The stability of shear-deformable plates under constant initial stresses is studied by the spline finite strip method. Third-order plate theory is used as the basis for developing the strip element. The classical B3-spline function is modified in such a way that the resulting spline finite strip element incorporates the merits of spline interpolation and the versatility of the finite element method. A set of demonstration analyses are presented to show the validity of the modified spline finite strip method.

ABSTRACT: A global-local approach is proposed to analyse thick laminated plates. This approach treats a thick laminated plate as a three-dimensional inhomogeneous anisotropic elastic body. The cross-section of a laminated plate is first discretized into conventional eight-node elements. The interpolation function along the span of the plate is defined by the cubic B3-spline function. The displacement functions can be expressed as the product of the usual isoparametric shape functions and the spline function. A set of global polynomials of an appropriate order is selected to transform the nodal variables of the cross-section to a much smaller set of generalized parameters associated with the polynomials. These parameters can be obtained by means of the standard Rayleigh-Ritz technique. The total number of unknowns involved is drastically reduced with a minor sacrifice of accuracy. The six components of stresses, the fundamental natural frequencies and the critical buckling loads can be determined with acceptable accuracy. Numerical examples are given to demonstrate the accuracy and effectiveness of the global-local procedures.

ABSTRACT: In this paper, the original spline finite strip, which is based upon the thin-plate theory, is modified and generalized in the sense that the formulation is based upon a third-order plate theory and is applicable to thin plates and shear-deformable plates (e.g. thick isotropic plates and laminated composite plates). To extend its application to nonlinear analysis, displacement formulation is employed with geometric nonlinearity and small initial imperfection taken into account. To demonstrate the performance of the present finite strip in the analysis of plates, a number of numerical examples are given.

ABSTRACT: The isoparametric spline finite strip method has been applied to the free vibration and stability analysis of shells. The convergence of the method is reviewed critically. Additional numerical examples on shells of different geometry are also employed to demonstrate the efficiency, accuracy and versatility of the method.

ABSTRACT: This paper deals with the development of a family of higher order B-spline finite strip models applied to the static and free vibration analysis of laminated plates, with arbitrary shape and lay-ups, loading and boundary conditions. The lamination scheme can be such that the embedded and/or surface bonded piezoelectric actuating and sensing layers are included. The structure is discretised in a specified number of strips, and the geometry and displacement components of each strip are represented by interpolating functions that are products of linear or cubic B-spline, and linear or quadratic Lagrange functions along the y and x orthonormal directions. The accuracy and relative performance of the proposed discrete models are compared and discussed among the developed and alternative models.

ABSTRACT: Description is given of both spline and semi-analytical finite strip method for predicting the post-buckling response of rectangular composite laminated plates with initial imperfections, when subjected to progressive end shortening. The initial imperfections are all assumed to be of the sinusoidal shape in the longitudinal direction, and of different shapes in the transverse direction. The laminates are simply supported out of their plane at the loaded ends as well as unloaded edges. The in-plane lateral expansion is allowed all around the plates. The plates are assumed to be thin so that the analysis can be carried out based on the classical plate theory. Geometric non-linearity is introduced in the strain-displacement equations in the manner of the von Karman assumptions. The formulations of the finite strip methods are based on the concept of the principle of the minimum potential energy. The Newton-Raphson method is used to solve the non-linear equilibrium equations. A number of applications involving plates with different shapes of initial imperfections are described to investigate the capability of both versions of finite strip method.

ABSTRACT: A geometrically non-linear finite strip for the post-buckling analysis of geometrically perfect thin symmetric cross-ply laminated plates under uniform end shortening is presented in this paper. The formulation of the aforementioned finite strip is based on the concept of the semi-energy approach. In this method, the out-of-plane displacement of the finite strip is the only displacement which is postulated by a deflected form. The postulated deflected form is substituted into von Kármán’s compatibility equation which is solved exactly to obtain the corresponding forms of the mid-plane stresses and displacements. The solution of von Kármán’s compatibility equation and the postulated out-of-plane deflected form are then used to evaluate the potential
Energy of the related finite strip. Finally, by invoking the Principle of Minimum Potential Energy, the equilibrium equations of the finite strip are derived. The developed finite strip is then applied to analyze the post-local-buckling behavior of thin flat laminates. The results are discussed in detail and compared with those obtained from finite element method (FEM) of analysis. It should be mentioned that the FEM analysis was carried out employing the general purpose ANSYS package. The study of the results has provided confidence in the validity and capability of the developed finite strip in handling the post-buckling problem of symmetric cross-ply laminated plates.

ABSTRACT: Description is given of semi-analytical finite strip method for predicting the geometrically non-linear response of rectangular composite laminated plates with initial imperfections, when subjected to progressive end shortening and pressure loading. In the finite strip formulations, the initial imperfections are all assumed to be of the sinusoidal shape in both of the longitudinal and transverse direction. The laminates are simply supported out of their plane at the loaded ends as well as unloaded edges. The plates are assumed to be thin so that the analysis can be carried out based on the classical plate theory. Geometric non-linearity is introduced in the strain–displacement equations in the manner of the von Karman assumptions. The formulations of the finite strip methods are based on the concept of the principle of the minimum potential energy. The Newton–Raphson method is used to solve the non-linear equilibrium equations. A number of applications involving plates with both initial imperfection and pressure load are described and discussed.

ABSTRACT: Two different versions of finite strip method, namely spline and semi-analytical methods, are developed for analyzing the geometrically non-linear response of rectangular composite laminated plates of arbitrary lay-up to progressive end-shortening in their plane and to pressure loading. The plates are assumed to be thin so that the analysis can be carried out based on the classical plate theory. The in-plane lateral deflection is allowed at the loaded ends of the plate, whilst the lateral expansion of the unloaded edges is either free or completely prevented. Geometric non-linearity is introduced in the strain–displacement equations in the manner of the von Karman assumptions. The formulations of the finite strip methods are based on the concept of the principle of the minimum potential energy. A number of applications involving isotropic plates, symmetric and unsymmetric cross-ply laminates are described to investigate the effects of pressure loading. The comparison between the two sets of results obtained by different finite strip methods is very good. The study of the results revealed that the response of the laminates is significantly influenced by the application of the normal pressure loading. Particularly, the response of unsymmetric laminates is strongly affected by the sign of the normal pressure loading.

ABSTRACT: In composite laminated plates various mechanical properties may be attained by changing the lay-up arrangement. The bend–twist coupling is one of the significant properties which dominate the mechanical performance of a laminated plate structure in large out-of-plane deformations. The effects of bend–twist coupling on the post-buckling behavior of composite laminated plates have been studied in this paper by implementing a finite strip approach based on the concept of a rigorous post-buckling solution for composite plates and plate structures, namely the semi-energy approach. All the plates are assumed to be symmetrically balanced laminates having uniform in-plane stiffness properties. As far as the out-of-plane stiffness properties are concerned, all the properties, except for the bend–twist coupling terms which are assumed to change from one laminate to another, are the same among different laminates. The orthotropic solutions have also been determined by precluding the bend–twist coupling terms. A comprehensive set of parametric studies have been carried out to investigate the effects of bend–twist coupling terms on the post-buckling load–displacement path, post-buckling deformations and stress distribution. The comparison between the results revealed markedly different behaviors among different laminates due to the bend–twist coupling effects. The outcome of the paper can help structural designers to have a better understanding of the effects of bend–twist coupling terms on the post-buckling behavior of laminated composite plates at the design stage.

ABSTRACT: This paper presents the theoretical developments of an exact finite strip for the buckling and initial post-buckling analyses of I-section struts. The so-called exact strip is developed based on the concept that it is effectively a plate. The presented method, which is designated by the name Full-analytical Finite Strip Method, provides an efficient and extremely accurate buckling solution. In the development process, the Von-Karman's equilibrium equation is solved exactly to obtain the buckling loads and mode shapes for the I-section struts. The investigation of buckling behavior is then extended to an initial post-buckling study with the assumption that the deflected form immediately after the buckling is the same as that obtained for the buckling. The current post-buckling study is effectively a single-term analysis, which is attempted by utilizing the so-called semi-energy method. Through the solution of the Von-Karman's compatibility equation, the in-plane displacement functions which are themselves related to the Airy stress function are developed in terms of the unknown coefficient in the assumed out-of-plane deflection function. All the displacement functions are then substituted in the total strain energy expressions. The theorem of minimum total potential energy is subsequently applied to solve for the unknown coefficient. Finally, the developed method is subsequently applied to analyze the initial post-buckling behavior of some representative I-sections for which the results were also obtained through the application of a Semi-energy Finite Strip Method [Ovesy HR. The development and application of a semi-energy post-local buckling finite strip. PhD dissertation, Cranfield University, UK, 1998]. Through the comparison of the results and the appropriate discussion, the knowledge of the level of capability of the developed method is significantly promoted.

ABSTRACT: In composite laminated plates, the mechanical coupling is one of the significant properties that dominate the performance of a laminated plate structure in large out-of-plane deformations. Some effects of mechanical coupling on the post-buckling behavior of composite laminated plates have been studied in this paper by implementing a finite strip approach based on the concept of a rigorous post-buckling solution for composite plates and plate structures, namely the semi-energy approach, which has been originally developed by the authors of this paper. Moreover, to check the validity and soundness of the presented semi-energy FSM the results obtained from the developed approach are compared with those obtained from a fairly conventional and well-exploited finite strip technique, namely the full-energy finite strip method as well as the results obtained from ANSYS (i.e., the general purpose finite element method software). In this paper, the post-buckling behavior of an anti-symmetric angle-ply square plate with the stacking sequence configuration as \([\pm 45]^2\) has been studied. Moreover, according to the anti-symmetric nature of lamination in the mentioned plate, there exists a mechanical coupling between in-plane membrane and out-of-plane twisting curvature; therefore, the results of this analysis have been referred as coupled solutions in this paper. In order to evaluate the effects of mechanical coupling on the post-buckling performance of mentioned plates, the uncoupled solution has also been determined by precluding the coupling terms (i.e., B16, B26). The post-buckling load–end shortening and load–maximum out-of-plane deflection paths have been obtained for coupled as well as uncoupled solutions. The comparison between the obtained results by coupled and uncoupled solutions revealed markedly different behaviors due to the presence of mechanical coupling in the anti-symmetric angle-ply laminates. The outcome of this paper can help structural designers have a better understanding of the effects of mechanical coupling on the post-buckling behavior of laminated composite plates at the design stage.

ABSTRACT: This paper presents theoretical developments of an exact finite strip for the buckling analysis of symmetrically laminated composite plates and plate structures. The so-called exact finite strip is developed based on the concept that it is effectively a plate and the von-Kármán’s equilibrium equation is solved exactly to obtain the general form of out-of-plane buckling deflection mode for the corresponding strip. This shape function is used to obtain a transcendental stiffness matrix for the strip through the minimization of the potential energy technique. The overall stiffness matrix for the whole section is obtained by assembling the individual strip stiffness matrices. Within the overall stiffness matrix, due to the special characteristics of the developed exact strip, it is not possible to identify a separate geometric stiffness matrix, which is independent of the buckling load parameter in the case of conventional FEM or FSM methods. In this paper, two secure methods (i.e., bisection method and recursive Newton’s method) for finding the buckling load and the corresponding buckling mode of the plate structures are used. The calculated buckling loads and the corresponding modes are exact in the sense that in their calculation, the usual approximations which are made in the conventional finite element or finite strip methods are avoided.

ABSTRACT: In the present paper, the linear eigen buckling analysis and the non-linear post-buckling equilibrium path of composite laminated plates and cylindrical shell structures are investigated. The method of analysis is the semi-analytical finite strip approach which has been developed originally on the basis of full energy methods. The strip established here is the one with the radius of curvature “R” in the transverse direction, whilst in the longitudinal direction the strip has no curvature. In the longitudinal direction, shape functions of trigonometric type are applied due to their continuous characteristics. The application of the latter shape functions has allowed the energy integrations to be performed analytically in the longitudinal direction. The method is generally known as “Semi-Analytical”. It is noted that the use of trigonometric functions has limited the boundary conditions at the loaded ends of the strip to the simple supported one. In the transverse direction, the first-order Lagrange shape functions are used for the in-plane displacements, and the third-order Hermite functions are utilized to estimate the out-of-plane displacements. In the linear buckling analysis, the strain–displacement relationships are based on the Koiter– Sanders theory of shells, whilst in the non-linear post-buckling developments Donnell’s type of shell theory (Donnell’s strain–displacement relationships) is applied. It is noted that to the authors’ knowledge the incorporation of Donnell’s shell theory into the formulations of the semi-analytical finite strip method for the post-buckling non-linear analysis of the structures has not been attempted elsewhere. To check the validity and soundness of the results, some case studies are performed by implementing the finite strip method as well as the finite element method. For further validation, the obtained results are also compared with those available in the literature.

ABSTRACT: Two versions of finite strip method (FSM) namely semi-analytical and spline methods are developed to calculate the stability and instability regions in the case of flat and curved thin-walled composite laminated structures under harmonic axial in-plane loads in the context of so-called parametric loading. The strain terms are expressed in terms of the Koiter–Sanders theory of shallow shells. In order to demonstrate the capabilities of the developed methods in predicting parametric behavior of the subject structures, some representing results are obtained and compared with those in the literature. Good accuracy in the results is achieved.

ABSTRACT: The application of the semi-energy CLPT-FSM for the non-linear analysis of symmetric laminates is extended to include the effects of normal pressure loading in addition to the end-shortening.
Moreover, a new semi-energy FSM is developed based on the concept of FSDT theory in order to attempt the large deflection solution for relatively thick laminates. It is noted that for a given level of accuracy, the developed semi-energy FSM requires a markedly lower number of degrees of freedom compared to those of FEM analysis. Hence, the semi-energy FSM is more computationally efficient than the conventional energy based schemes.

ABSTRACT: A Reddy type, third order shear deformation theory of shells is applied to the development of two versions of finite strip method (FSM), namely semi-analytical and spline methods, to predict the parametric stability and instability regions in the case of cylindrical moderately thick composite laminated panels. The structures are assumed to be under harmonic in-plane loads in the context of the so-called parametric loading. The linear strain terms are expressed in terms of the Koiter-Sanders theory of shallow shells. In order to demonstrate the capabilities of the developed methods in predicting parametric behavior of the subject structures, some representative results are obtained and compared with those in the literature wherever available.

This paper is concerned with buckling analyses of rectangular functionally graded plates (FGPs) under uniaxial compression, biaxial compression and combined compression and tension loads. It is assumed that the plate is a mixture of metal and ceramic that its properties changes as a function according to the simple power law distribution through the plate thickness. The fundamental eigen-buckling equations for rectangular plates of functionally graded material (FGM) are obtained by discretizing the plate into some finite strips, which are developed on the basis of the higher order plate theory (HOPT). The solution is obtained by the minimization of the total potential energy. Numerical results for a variety of FGPs are given, and compared with the available results, wherever possible. The effects of thickness ratio, variation of the volume fraction of the ceramic phase through the thickness, aspect ratio, boundary conditions and also load distribution on the buckling load capacity of FGM plates are determined and discussed. It is found that the buckling behavior of FGM plates is particularly influenced by application of HOPT, especially when the plates are thick.

This paper is concerned with the parameter sensitivity analysis of structures undergoing large displacements. The authors introduce the analytical sensitivity expressions for an element independent co-rotational formulation of a geometrically nonlinear finite element method. An extension of this formulation to treat follower forces is presented. The co-rotational framework uses a pre-existing linear finite element library and does not require the development and implementation of kinematically nonlinear element formulations. This feature along with the element independence makes the co-rotational framework an attractive option for the implementation of geometrically nonlinear analysis and sensitivity analysis capabilities. The sensitivity formulations with respect to shape and material parameters are presented and their numerical treatment is discussed. The importance of a consistent tangent stiffness, including unsymmetric terms, on the accuracy of computed sensitivities is addressed. The framework is applied to shape and topology optimization examples, verifying the methodology and highlighting the importance of accounting for large displacement effects in design optimization problems.

N. El-Abbasi and S. A. Meguid (Engineering Mechanics and Design Laboratory, Department of Mechanical and Industrial Engineering, University of Toronto, 5 King's College Road, Toronto, ON, M5S 3G8, Canada), “Finite element modeling of the thermoelastic behavior of functionally graded plates and shells”, International Journal of Computational Engineering Science, Vol. 1, Issue 1, June 2000

A new thick shell element is used to study the thermoelastic behavior of functionally graded structures made from shells and plates. The element accounts for the varying elastic and thermal properties across its thickness. It also accounts for the thickness change, normal stresses and strains. The nonlinear heat transfer equations governing the through-thickness thermal distribution are treated using the Rayleigh-Ritz method. Prescribed temperatures as well as convection conditions are imposed on both faces of the shell. Three examples involving functionally graded beams, circular plates and spherical shells are examined. The effect of the volume fraction of the constituent materials and the through-thickness integration order are also investigated.

J. Woo and S. A. Meguid (Engineering Mechanics and Design Laboratory, Department of Mechanical and
ABSTRACT: In this paper, an analytic solution is provided for the coupled large deflection of plates and shallow shells made of functionally graded materials (FGMs) under transverse mechanical loads and a temperature field. The material properties of the functionally graded shells are assumed to vary continuously through the thickness of the shell, according to a power law distribution of the volume fraction of the constituents. The fundamental equations for thin rectangular shallow shells of FGM are obtained using the von Karman theory for large transverse deflection, and the solution is obtained in terms of Fourier series. The effect of material properties, shell geometry and thermomechanical loading on the stress field are determined and discussed. The results reveal that thermomechanical coupling effects play a major role in dictating the response of the functionally graded shell.

ABSTRACT: In this paper, an analytical solution is provided for the postbuckling behaviour of moderately thick plates and shallow shells made of functionally graded materials (FGMs) under edge compressive loads and a temperature field. The material properties of the functionally graded shells are assumed to vary continuously through the thickness of the shell, according to a power law distribution of the volume fraction of the constituents. The fundamental equations for moderately thick rectangular shallow shells of FGM are obtained using the von Karman theory for large transverse deflection and high-order shear deformation theory.
for moderately thick plates. The solution is obtained in terms of mixed Fourier series and the obtained results are compared with those of the Reissner–Mindlin's theory for moderately thick plates and the classical theory ignoring transverse shear deformation. The effect of material properties, boundary conditions and thermomechanical loading on the buckling behaviour and the associated stress field are determined and discussed. The results reveal that thermomechanical coupling effects and the boundary conditions play a major role in dictating the response of the functionally graded plates and shells under the action of edge compressive loads.

“Accurate modeling of the crush behaviour of thin tubular columns using material point method”, Science China Physics, Mechanics and Astronomy, Vol. 56, No. 6, pp 1209-1219, June 2013

DOI: 10.1007/s11433-013-5073-x

ABSTRACT: In this paper, we apply the material point method (MPM), also known as a meshfree method, to examine the crush behaviour of thin tubular columns. Unlike the finite element method, randomly-distributed-weak-particle triggers were used to account for the deformation behaviour of collapse modes. Both symmetric and asymmetric modes of deformation and their associated mean collapse loads are determined for an elastoplastic constitutive law describing the tubular columns. Attention was devoted to the accuracy and the convergence of the MPM simulation, which is determined by the number of the particles and the size of the background cells used in our explicit solver. Furthermore, a novel contact approach was adopted to establish the crush behaviour of the tubular columns. Two aspects of the work were accordingly examined, including three different crush velocities (5, 10 and 15 m/s) and varied geometrical features of the tube (t/d and l/d) based on the deformation history. The results of our model, which were compared with existing analytical predictions and experimental findings, identify the critical geometric features of the tubular columns that would dictate the deformation mode as being either progressive collapse or following Euler’s buckling mode.

ABSTRACT: Interface technology for geometrically nonlinear analysis is presented and demonstrated. This technology is based on an interface element which makes use of a hybrid variational formulation to provide for compatibility between independently modeled connected sub-domains. The interface element developed herein extends previous work to include geometric nonlinearity and to use standard linear and nonlinear solution procedures. Several benchmark nonlinear applications of the interface technology are presented and aspects of the implementation are discussed.

Most recent reference is 1980.) ABSTRACT: Theoretical and experimental investigations of the dynamic behavior of ground-supported, deformable, cylindrical liquid storage tanks were conducted. The study was carried out in three phases: A) a detailed theoretical treatment of the coupled liquid-shell system, B) an experimental investigation of the dynamic characteristics of full-scale tanks, and C) a development of an improved design procedure based on an

ABSTRACT: The nonlinear analysis of elastic-plastic shells of revolution is performed by combining an efficient one-dimensional transfer-matrix approach on the element level with the usual finite element assemblage of the system. It is based on a Fourier-representation of the loading, the shell variables and initial imperfections in the circumferential direction. This semi-analytical procedure is formulated for geometrically and physically nonlinear problems. It is applied to the detailed investigation of the buckling behavior and imperfection sensitivity of various dished end closures under external pressure.

References listed at the end of the paper:
ABSTRACT: The paper deals with the results of systematic numerical studies on the nonlinear load-carrying and buckling behavior of ring-stiffened circular cylindrical shells under external pressure. In particular it focuses attention on the conditions under which stiffeners with rectangular cross-sections lead to either global or local (interstiffener) buckling and on the influence of elastic-plastic material behavior. The numerical results are presented in the form of nondimensional diagrams in which the buckling loads of stiffened shells are given directly as functions of a global stiffening parameter containing all relevant information on both the shell’s geometry and the type and arrangement of the stiffeners. They indicate the buckling mode as well as the amount by which the load-carrying capacity of a stiffened shell is larger than that of the corresponding unstiffened one. This makes them particularly useful for practical design purposes.

ABSTRACT: The dynamic behaviour of liquid-filled shells of revolution is investigated considering the soil–structure interaction and the fluid–structure interaction, respectively. In the circumferential direction the loads and variables are approximated by Fourier series. The shell is modelled through shell ring elements including non-linear behaviour, coupled with isoparametric continuum ring elements and special infinite elements for the soil and isoparametric pressure ring elements for the fluid. Transient loadings like earthquake excitation and the non-linearities of the shell and the soil require an analysis in the time domain. To reduce the size of the problem, linear parts of the system are condensed by the substructure technique. The soil region is divided into
two parts, a near field permitting non-linearities like plastification or uplifting of the shell, and a far field for the treatment of radiation of energy. The boundary conditions for the shell footing have a strong influence on the distribution of the axial membrane forces and, hence, on the stability limit, which is mostly governed by plastic collapse and caused by the dynamically activated pressure acting on the tank wall. It is shown how the soil properties influence the dynamic stability of the shell under harmonic excitation and under realistic earthquake motion.

ABSTRACT: For the evaluation of the imperfection-sensitivity of elastic and elastic-plastic shells a fully nonlinear finite-element-method has been developed that directly gives the ‘worst’ imperfection shape connected to the ultimate limit load. The approach uses no approximations such as asymptotical theories or computations in the deep postcritical range. The key point of the method is the description of imperfections as nodal degrees of freedom at the element level. These unknown quantities are implemented by isoparametric shape functions in a finite shell element including finite rotations and thickness stretch. The ultimate buckling load and the corresponding ‘worst’ imperfection shape is defined by two different criteria and numerically determined by an extended system of nonlinear equations. In the computation of the structurally stable collapse the deflections, the imperfection shape, the eigenvector and the lowest possible load-level are obtained. The method is illustrated by several numerical examples.

ABSTRACT: This paper deals with the numerical evaluation of the limit loads and of the imperfection sensitivity of shells. A semi-analytic treatment of the field equations governing the nonlinear static behaviour of shells of revolution as well as a novel approach for general shells to construct the relationship between the limit load and amplitudes and shapes of the ”worst” imperfections in a direct way are covered. Applying these methods a large number of results for thin shells are analyzed investigating the influence of the material behaviour, the geometry and the boundary conditions. Included are also combinations of shells and high imperfection sensitive shells. For several types of shells the load carrying behaviour and their imperfection sensitivity is discussed.

ABSTRACT: Liquid-filled storage tanks under earthquake excitation are loaded by hydrodynamic pressure due to the interactive motion with the containing fluid. The dynamic response and the buckling of these tanks have been studied by many authors both experimentally and theoretically, but a unified design procedure is still lacking. To gain insight more easily into the load carrying behavior and failure mechanism of anchored tanks, a quasistatic approach is presented in this paper instead of solving the coupled problem in the time domain. For these purposes, a nonlinear finite element procedure is applied using pressure eigenforms as equivalent loads. The numerical model used for the investigations is discretized by mixed ring shell elements taking geometric and physical nonlinearities into account. Different superpositions of the pressure eigenforms which are calculated by a special interactive model lead to different behavior of the tank-fluid system depending on the intensity of the horizontal and the vertical earthquake component. The results obtained are compared with classical values and with simplified design procedures provided in Eurocode 8, Part 4.

ABSTRACT: This paper deals with the dynamic behavior of flexibly supported liquid-filled storage tanks under earthquake excitation. A simplified mechanical model is proposed to simulate the characteristics of the surrounding soil with its energy absorbing properties. In addition, a quasistatic approach is presented to analyse certain types of instability phenomena. Some examples which are verified by more detailed investigations in the time domain give insight into the particular dynamic behavior of these tanks. The results are also compared to
those obtained by the current design procedure provided in the current draft of EC8, part 4.

ABSTRACT: For the design of spherical shells under external pressure relatively few information can be found in corresponding codes and recommendations, e.g. not at all in the new draft of Eurocode 3 ENV 1993-1-6. Under this aspect, new design rules for these shells were developed, which take into account relevant details like boundary conditions, material properties, and imperfections. They are usually based on a large number of systematic numerical simulations to obtain results describing the load carrying behaviour and imperfection sensitivity of thin spherical shells. In addition, previous theoretical and experimental results are discussed. Based on the results, diagrams and design rules have been developed which might be used for new recommendations in the design concept of the Eurocode.

ABSTRACT: Based on rigorous parametric non-linear elastic buckling analyses, the present work underlines the developments towards theoretical lower bounds of existing experimental buckling loads for some of the
most practical shell geometries and loading cases, namely circular cylindrical shells under external pressure and/or axial loads and spherical caps under external pressure. Simple equations and formulae are presented and their predictions for buckling loads are compared with available test results and values prescribed by some of the existing design codes. These explicit lower bounds are close and non-conservative estimates of buckling loads of imperfect shells and as such are proposed as a consistent and rational basis for design of these shell structures.

ABSTRACT: Elevated silos and tanks in steel usually consist of a cylindrical vessel and a conical hopper. One of the main areas of interest in design is the junction of the cylindrical and the conical structure where large circumferential compressive stresses may cause failure by instability. This paper describes the buckling behavior of the cylindrical and the conical wall in the junction area and the overall stability of a stiffening ring located at the junction.

ABSTRACT: Cylindrical steel containments, like silos and tanks, frequently rest on column-supports, which induce high local axial forces into the shell. This causes pronounced stress concentrations, which might impair the shell by local yielding or buckling failure above the support. The load-carrying behaviour of such axially loaded cylindrical shells has been investigated in recent years resulting in proposals for design rules. However, in many practical cases the axial loading acts in combination with internal pressure caused by the filling medium of the containment, which induces circumferential (hoop) stresses in the shell. The effect of these stresses on the load-carrying capacity is the objective of this paper. The study was carried out on the basis of numerical investigations, which were verified by experimental results of steel models. The calculations, based on geometrically nonlinear analyses, include the effects of geometrically imperfections as well as material plasticity. The scope of the paper covers unstiffened cylinders with a radius/thickness ratio of 500 and the steel grade Fe 360 resting on four local supports.

ABSTRACT: Many metal silos and tanks are locally supported on columns or other discrete supports to permit easy access beneath the vessel. The discrete supports introduce local forces into the cylindrical shell, which in turn produces zones of local high axial compression. The strength of compressed cylindrical shells has long been known to be governed by buckling considerations, but the buckling strength of discretely supported cylinders has only been investigated in recent years. Design rules which pre-date this study were empirical in nature and not based on rigorous buckling calculations or tests. In the present study, the theoretical buckling
behaviour in the elastic–plastic range has been found to be so complicated that much work is needed to define the buckling strength for the purposes of structural design. This paper presents a description of the linear and nonlinear behaviour of isotropic unstiffened cylinders which are discretely supported at the lower edge. Much of the information given here is vital to the development of a more reliable design rule for shells under these loading conditions.

ABSTRACT: This chapter comprises all cases of external pressure uniformly distributed around the circumference. Due to the uniform stress field in the prebuckling state, the theoretical buckling behaviour may consistently and directly be derived from the differential equations. Accordingly, a great number of solutions for different cases are available for shells of constant wall thickness. For variable, that is, stepped wall thickness and for cylinders restrained by stiffening rings, the solutions have been derived numerically on the basis of the linear buckling equations…

ABSTRACT: The impulsive collapse of cylindrical steel shells filled with air or water is investigated experimentally. It is established that this process has distinctive characteristics associated with the existence of water compression waves, which inhibit collapse of the walls to the point of complete closure of the interior duct of the shell.

References listed at the end of the paper:

ABSTRACT: The paper reports the results of an experimental investigation of impulsive collapse of steel pipelines (filled with water or air) by an impact from two opposite sides by two massive plates accelerated simultaneously towards each other by an explosive charge. The experimental results confirmed that the proposed method of closing the walls of various standard-size pipelines filled with a liquid or gas is promising. The numerical results of a three-dimensional modeling of the dynamic collapse of tubes impacted by accelerated plates are presented. Some features of the Euler calculation technique for elastoplastic flows as applied to the description of processes occurring in devices for emergency shut-down of liquid-filled steel pipelines are considered.

References listed at the end of the paper:

ABSTRACT: This paper deals with practical problems encountered in the design of seismically loaded liquid-filled vertical tanks. Global stability, buckling under combined action of axial compression and internal pressure and the effect of flexible boundaries on axial buckling are studied. The question of the mutual interaction of global and local failure modes is considered. Numerical studies on the basis of finite element-discretized-shell models are carried out which show the typical features of the different failure modes. Both the effect of internal pressure on axial buckling (elephant foot failure) as well as the flexibility of the base ring results in noteworthy reductions of the axial buckling resistance. Global stability effects turned out to play no major role in the present tank design.

ABSTRACT: A comprehensive nonlinear finite element elastic stability analysis was performed with the aim of explaining the effect of a deep single longitudinal initial dent on the load-carrying behaviour of an externally pressurized cylindrical shell. The numerical results are compared with available test results and agree well, at least qualitatively. Imperfection sensitivity studies were carried out comparing the effect of the single dent with the effect of evenly distributed periodic initial imperfections. Imperfection sensitivity tends to vanish for increasing amplitudes of the idealized case of a single dent.

ABSTRACT: Upright cylindrical thin-walled steel containment structures, like silos and tanks, are commonly supported on discrete supports or columns to permit access beneath the hopper for the gravity withdrawal of the contents. In practical silo structures a variety of different support designs are used…. 

ABSTRACT: The buckling of laminated plates with elliptic delamination under compressive loading was studied experimentally and analytically. In the experiment, a tensile test machine was used to determine the load-displacement behavior of the delaminated plates under uniaxial loading and the buckling strength was extracted therefrom. In analysis, a nonlinear finite element program based on the updated Lagrangian formulation was developed to analyze the response of the laminated plates. The formulation includes large displacements and large rotations. The plates were divided into finite elements and the degenerated shell elements were used. The Newton-Raphson method was used to solve the resulting equation for the nonlinear system and a displacement-controlled scheme was used in the solution procedure near the buckling load. This process was repeated until a desired accuracy was achieved. The buckling behavior of mixed and global types of the delaminated composite plates were examined. Four parameters, including the size of the delaminated region, the orientation of the fiber direction, the position of the delaminated region in the thickness direction and the orientation of the major axis of the elliptic region with the loading axis, were varied to assess their influence on the buckling behavior of the plates. Good agreement was obtained between the analytical and experimental results.

ABSTRACT: The buckling behavior of an elastoplastic cylindrical shell with a cutout under pure bending was investigated analytically and experimentally. For analysis, a finite element code based on an updated Lagrangian formulation was established to analyze the problem of bending buckling by considering nonlinear geometric and material properties. An iterative displacement-controlled scheme was adopted in the solution procedure to ensure the pure bending state and to avoid numerical instability near the limiting buckling moment. A testing device was used to perform experiments on bending buckling. The ratio of diameter to thickness of the aluminum specimens was 50; the ratio of length to diameter was 7.9. The shape of the cutout on the shell was circular or rectangular. The influence of the size and location of the cutout on the limiting buckling moment is discussed. Antisymmetric deformation around the cutout in the shells was observed after bending buckling of the shell.

ABSTRACT: Slender cylinders of intermediate length subjected to external pressure normally buckle into sinusoidal waves in the circumferential and meridional directions; the wave numbers are a function of the edge restraints, aspect ratio L/R and wall slenderness R/t. The influence of edge restraints diminishes with increasing L/R, and disappears in very long cylinders. All instability formulae purporting to evaluate the lowest eigenvalue require minimisation with respect to the circumferential wave number n; any ‘exact’ formulation requires the a
priori evaluation of \( n \). Therefore, in any investigation of the effect of boundary conditions on the buckling pressure \( q_{cr} \), the evaluation of \( n \) is crucial. The effects of imperfections and consequent non-linear response are significant in this context, and shall form the subject of a future publication. The classical solution for the estimation of \( n \) involves ‘standard’ end conditions which consist only of radial restraints, and is derived from a minimisation, for example, of the Southwell equation with respect to \( n \). For other sets of boundary conditions, the governing equations become almost intractable unless reduced theories, such as long wavelength theory, are used, and resort must be made to numerical methods such as Rayleigh-Ritz, finite differences or finite elements. To the authors' knowledge, a comprehensive theoretical or numerical study of the effect of boundary conditions on the buckling wavenumber and the critical pressure is not available in the literature.

ABSTRACT: In the present paper, numerical and experimental investigation have been undertaken into the buckling and post-buckling behavior of thin-walled cylindrical steel shells with varying thickness subjected to uniform external pressure. For the experimental study, four different cylindrical steel shell specimens with varying thickness were tested to collapse. For the post-buckling analysis of these structures, material and geometric nonlinear collapse analysis are carried out. To trace the equilibrium paths through limit points into the post-critical range, the ‘Arc-Length-Type Method’ has been used. In order to verify the accuracy and validity of the finite element modeling, the numerical results, obtained from nonlinear finite element collapse analyses, have been compared with the results of the experimental study. The study shows that the theoretical behavior predicted by the nonlinear finite element collapse analyses followed closely the experimental behavior. Consequently, it has been found that the finite element model is reliable enough to be used to undertake nonlinear analyses for investigation into the buckling and post-buckling behavior of thin-walled cylindrical steel shells with varying thickness. Also it has been found that the buckling mode can be generated in whole length of the shell if the thickness variation is low. However, in the case of high variation of thickness, the buckling mode is formed in thinner part only. Also, the considerable effects of circumferential and vertical weld line on the buckling strength and mode shapes are verified.

“Experimental study on the buckling and post-buckling behavior of thin-walled cylindrical shells with varying thickness under hydrostatic pressure”, Proceedings of the International Association for Shell and Spatial Structures (IASS) Symposium 2009, edited by Alberto Domingo and Carlos Lazaro, Valencia, Universidad Politecnica de Valencia, Spain, pp 2511-2522
ABSTRACT: The application of thin-walled cylindrical shells, as the essential structural members, has been known for engineers and functional duty of them is basic necessities of modern industries. These structures are prone to fail by buckling under external pressure which could be happened during discharging or wind load. Although the buckling capacity of the shells depends principally on two geometric ratios of "length to radius" (L/R) and "radius to thickness" (R/t), but the effect of thickness variation on the behavior of the shells is
complicated to be studied. On the other hand, the buckling strength of thin cylindrical shells is sensitive to the magnitude and shape of geometric imperfections. The effect of thickness variation and geometric imperfections on the buckling and postbuckling behavior of cylindrical shells is experimentally investigated in this paper. Top end of the specimens has conical roof and the bottom end has simply supported conditions. The measured data and obtained results are reported for the specimens under the effect of hydrostatic external pressure. Each specimen has different variation in thickness along its length. The slender parameters of tested shells are $L/R = 2, 1, 0.5$ and $R/t = 500, 600$. In addition, the considerable effect of circumferential and vertical weld line on the buckling strength and mode shapes is verified.

ABSTRACT: The buckling capacity of the cylindrical shells depends on two geometric ratios of $L/R$ and $R/t$. However the effect of thickness variation on the behavior of the shells is more complicated and the buckling strength of them is sensitive to the magnitude and shape of geometric imperfections. In this paper the effects of thickness variation and geometric imperfections on the buckling and postbuckling behavior of cylindrical shells are experimentally investigated. The obtained results are presented under the effect of uniform lateral pressure. It is found in this investigation that the buckling mode can be generated in the whole length of the shell, if the thickness variation is low.

ABSTRACT: Submarine pipelines are deemed as thin-walled structures in which relative external pressure may be created in some cases of fluid transmission. The certain effect of this type of loading is local buckling and its propagation along the considerable length of the line. In this study, an experimental program has been performed, in which the influence of ring stiffeners on the buckling strength of pipelines is investigated. In the tests, only hydrostatic pressure is considered as the major loading case, and the effect of further loads is neglected. The modes of initial buckling, buckling propagation, postbuckling, and development of yield lines and the final collapse of the pipeline have been closely appraised. It is verified that the buckling threshold highly hikes up by attaching some light ring stiffeners. By decreasing the ring spacing, the difference between buckling and failure loads is diminished and torsion-type yield lines at failure mode occur on the pipe skin.

ABSTRACT: Cylindrical shell structures are highly susceptible to buckling phenomena when they experience compressive stress. In fact, there are few experimental researches that give the real behavior of a cylindrical shell submitted to pure bending, especially thin shells. This is due to the difficulty of pure bending applying to such thin shells and that such structures behavior under bending is frequently considered rather similar to pure compression. This chapter describes an experimental investigation of a procedure including a system for applying pure bending to cylindrical shells with radius to thickness ratio equals 155. The instrumentation consists of a new loading system in which the pure bending is applied using concentrated loads at the ends of the test model. Ultimately, the critical values for moments as well as buckling modes were compared with finite element (FE) results.

“Experimental investigation on the effect of geometric imperfections on the buckling and post-buckling behavior of steel tanks under hydrostatic pressure”, Thin-Walled Structures, 01/2014; 74:59–69.
DOI: 10.1016/j.tws.2013.09.005

ABSTRACT: Weld-induced geometric imperfections have been reported to have especially detrimental effects on the buckling resistance of shells under hydrostatic pressure. The effect of circumferential imperfections caused by continuous welding on the joined areas between the curved panel edges of the cylindrical and conical shells of steel storage tanks with fixed conical roofs is the most important case in this context. The present paper discusses 12 laboratory specimens in three groups, labeled SP200 (S=Specimen, P=Perfect, 200=height (mm) and radius of Cylinder), SP250 (S=Specimen, P=Perfect, 250=height (mm) and radius of Cylinder) and SP300 (S=Specimen, P=Perfect, 300=height (mm) and radius of Cylinder) loaded under uniform hydrostatic pressure. The samples were modified to include circumferential imperfections at the junctions between the curved edges of the panels of the cylindrical and conical shells, with amplitudes of 2t, 4t and 8t in depth (where t is the thickness of the conical or cylindrical shell). The results of testing under different codes are compared. This study shows that geometrical imperfections at different ratios of t/R (where R the radius of the tanks) may have decreasing, neutral or increasing effects on buckling resistance and can result in softening or stiffening behaviors of the shells.

ABSTRACT: The load acting on a cylindrical shell, with added periodic stiffeners, under a transient pressure pulse propelling a pullet (gun case) has been experimentally studied. This study is based on two modes of velocities, the first is subcritical mode and the second is supercritical mode. The stiffeners are added to the gun tube of an experimental gun facility, of 14mm bore diameter. The radial strains are measured by using high-
frequency strain gage system in phase with a laser beam detection system. Time-resolved strain measurement of the wall response is obtained and both precursor and transverse hoop strains have been resolved. The time domain analysis has been done using “wavelet transform package” in order to determine the frequency domain modes of vibrations and detect the critical frequency mode. A complete comparison of the dynamic behavior of the shell tube before and after adding periodic stiffeners has been done, which indicated that a significant damping effect reaches values between 61.5 and 38% for subcritical and critical modes. The critical frequency of the stiffened shell is increased, so the supercritical mode is changed to subcritical mode. The amplification and dispersion factors are determined and constructed; there is a reduction in the corresponding speed frequencies by about 10%. Also the radial-bending vibrations and tube muzzle motions are detected at muzzle velocity ratio of 0.99%, the results indicated that there is a significant improvement in increasing the number of rounds per second by about 36% and increasing the pointing precision by about 47%.

ABSTRACT: Using complex series representations, a quasi-analytical finite element procedure is developed which can analyze the static and dynamic mechanical fields of anisotropic axisymmetric shells and bodies. Due to its generality the procedure can handle arbitrary laminate construction with possible meridional and radial variations in locally or globally mechanically anisotropic materials. In this respect, in contrast to traditional quasi-analytical procedures which are limited to the ‘specially’ orthotropic case, the present treatment reveals several important effects of material and/or structural anisotropy. To illustrate the procedure as well as the significant effects of material anisotropy, several numerical examples are given along with comparisons with known analytical treatments.

ABSTRACT: A numerical integration procedure is developed which can obtain the frequency and buckling eigenvalues and associated eigenfunctions of prestressed rotating anisotropic shells of revolution. The axisymmetric prestress state incorporated in the analysis can consist of torque as well as anisotropy induced circumferential effects. Apart from the usual centripetal load, the rotation effects treated by the analysis also consist of Coriolis acceleration forces. The material and/or structural anisotropy included in the analysis is of the most general linear Hookean form. Hence, the stiffness matrix of the governing shell constitutive relation can be fully populated. To illustrate the numerical procedure as well as the significant effects of general axisymmetric prestress states (including torsion), Coriolis acceleration forces and material and/or structural anisotropy, several numerical experiments are given along with comparisons with analytical treatments.

ABSTRACT: A quasi-analytical finite element procedure is developed which can obtain the frequency and buckling eigenvalues of prestressed rotating anisotropic shells of revolution. In addition to the usual centrifugal forces, the rotation effects treated also include the contribution of Coriolis forces. Furthermore, since a nonlinear version of Novozhilov's shell theory is employed to develop the element formulation, the effects of moderately large prestress deflection states can be handled. Due to the generality of solution procedure developed, the axisymmetric prestress states treated can also consist of torque loads. In order to illustrate the procedures capabilities, as well as the significant effects of Coriolis forces, torque prestress and material anisotropy, several numerical experiments are presented.

ABSTRACT: Based on the finite element and perturbation procedures, an analytical-numerical approach to non-linear vibrations is developed. In particular, the overall solution employs the finite element method to handle spatial dependencies while the constrained version of the perturbation procedure is used to treat the temporal behavior. Due to the generality of the method developed, any combination of structure and boundary restraints can be treated as well as the possibility of conservative and non-conservative situations wherein the
system can have any number of frequency branches. Furthermore, the procedure is not restricted to excitations in the neighborhood of specific frequencies, but rather applies to the full range. To demonstrate the capabilities of the solution approach, the results of several numerical studies are included along with experimental verification.

ABSTRACT: Through the use of a family of generalized Rayleigh quotients, this paper considers the influence of nonstationary time dependent loads/disturbances on the spectral characteristics of structure modeled by 3-D nonpolar elasticity theory wherein the fields are treated as small excursions superposed on large. To generalize the results, the influence of nonconservatism and generalized inertia fields are admitted. The main emphasis of the work is given to determining the various properties of the eigenvalue problem arising out of such nonstationary loading situations. This includes ascertaining the occurrence of various types of spectral/critical speed shifts/bifurcations induced by moving disturbances. As a further extension of the work, the results are specialized to the eigenvalue problem arising from nonconservative gyroscopic FE simulations of moving load problems.

ABSTRACT: This paper considers the pre and post buckling behavior of general structures exposed to high temperature fields for long durations wherein creep effects become significant. The solution to this problem is made possible through the use of closed upper bounding constraint surfaces which enable the development of a new time stepping algorithm. This permits the stable and efficient solution of structural problems which exhibit indefinite tangent properties. Due to the manner of constraining/bounding successive iterates, the algorithm developed herein is largely self adaptive, inherently stable, sufficiently flexible to handle geometric material and boundary induced nonlinearity, and can be incorporated into either finite element or difference simulations. To illustrate the capability of the procedure, as well as, the physics of creep induced pre and post buckling behavior, the results of several numerical experiments are included.

ABSTRACT: This paper develops a multi phase self-adaptive predictor corrector type algorithm to enable the solution of highly nonlinear structural responses including kinematic, kinetic and material effects as well as potential pre/postbuckling behavior. The hierarchy of the strategy is such that three main phases are involved. The first features the use of a warpable hyperelliptic constraint surface which serves to upperbound dependent iterate excursions during successive INR type iterations. The second corrector phase uses an energy constraint to scale the generation of successive iterates so as to maintain the appropriate form of local convergence behavior. The third involves the use of quality of convergence checks which enable various self-adaptive modifications of the algorithmic structure when necessary. Such restructuring is achieved by tightening various conditioning parameters as well as switch to different algorithmic levels so as to improve the convergence
process. Included in the paper are several numerical experiments which illustrate the capabilities of the procedure to handle varying types of nonlinear structural behavior.

ABSTRACT: By introducing a moving updated Lagrangian observer, this paper develops traveling finite elements with the capacity to handle the global response resulting from steadily moving contact fields. The generality of the results is such that large deformation kinematics and kinetics as well as the full compliment of inertial fields can be handled. To streamline the handling of nonlinear behavior, an elliptically constrained solution algorithm is also developed. Employing this algorithm, the results of several numerical benchmarking studies are presented which illustrate the capacity of the moving updated Lagrangian formulation as well as the potential effects of nonlinearity.

ABSTRACT: This paper overviews the current state of solution schemes used to solve pre- and postbuckling problems. Main emphasis will be given to (i) defining the generic features of buckling, (ii) outline the shortcomings associated with classical incremental Newton-Raphson type schemes, (iii) introducing the constrained incremental Newton-Raphson methodology, (iv) review capacities of various currently available general purpose codes, and (v) point out several areas of further investigation.

ABSTRACT: This paper develops strategies which enable the automatic adjustment of the constraint surfaces recently used to extend the range and numerical stability/efficiency of nonlinear finite-element equation solvers. In addition to handling kinematic and material induced nonlinearity, both pre- and postbuckling behavior can be treated. The scheme developed employs localized bounds on various hierarchial partitions of the field variables. These are used to resize, shape, and orient the global constraint surface, thereby enabling essentially automatic load/deflection incrementation. Due to the generality of the approach taken, it can be implemented in conjunction with constraints of arbitrary functional type. To benchmark the method, several numerical experiments are presented. These include problems involving kinematic and material nonlinearity, as well as pre- and postbuckling characteristics.

ABSTRACT: In a three-part series of papers, a generalized finite element analysis scheme is developed to
handle the steady and transient response of moving/rolling nonlinear viscoelastic structure. This paper considers the development of the moving/rolling element strategy, including the effects of large deformation kinematics and viscoelasticity modeled by fractional integrodifferential operators. To improve the solution strategy, a special hierarchical constraint procedure is developed for the case of steady rolling/ translating as well as a transient scheme involving the use of a Grunwaldian representation of the fractional operator. In the second and third papers [R. Kennedy and J. Padovan, Comput. Struct. 27, 259–273 (1987) and Y. Nakajima and J. Padovan, Comput. Struct. 27, 275–286 (1987)], 3-D extensions are developed along with transient contact strategies enabling the handling of impacts with obstructions. Overall the various developments are benchmarked via comprehensive 2- and 3-D simulations. These are correlated with experimental data to define modeling capabilities.

ABSTRACT: In a three-part series of papers, a generalized finite element solution strategy is developed to handle traveling load problems in rolling, moving and rotating structure. The main thrust of this section consists of the development of 3-D and shell type moving elements. In conjunction with this work, a compatible 3-D contact strategy is also developed. Based on these modeling capabilities, extensive analytical and experimental benchmarking is presented. Such testing includes traveling loads in rotating structure as well as low- and high-speed rolling contact involving standing wave-type response behavior. These point to the excellent modeling capabilities of moving element strategies.

ABSTRACT: In a three-part series of papers, a generalized finite element methodology is formulated to handle traveling load problems involving large deformation fields in structure composed of viscoelastic media. The main thrust of this paper is to develop an overall finite element methodology and associated solution algorithms to handle the transient aspects of moving problems involving contact impact type loading fields. Based on the methodology and algorithms formulated, several numerical experiments are considered. These include the rolling/sliding impact of tires with road obstructions.

ABSTRACT: Employing an instantly centered moving Lagrangian observer (ICMLO), this two part series of papers develops a finite element (FE) modeling methodology which can handle multibody problems involving several rotating components each with its own distinct rotational history. The overall thrust of the work is to enable the modeling of mechanical systems as opposed to purely structural problems. This includes the ability to simulate rotating equipment, transportation systems, aircraft frame-engine interactions, i.e. complete machinery responses. In this part, emphasis is given to (i) establishing the ICMLO, (ii) developing the FE
formulation, and (iii) deriving the associated steady and transient solution algorithms. In Part II, extensive modifications are introduced to handle automotive type vehicular models. To demonstrate the scheme, simulations involving vehicular-obstruction rollover events are presented.

ABSTRACT: Employing an instantly centered moving Lagrangian observer (ICMLO), this two part series develops a finite element scheme and associated solution algorithms which can handle the modeling of machinery involving a variety of rotating components each with its own distinct rotational history. In this part, the methodology is extended to handle the steady and transient response of ground based automotive type vehicular systems. This includes the modeling of roadway-multiple tire-suspension-vehicular structural interactions during (i) steady rolling; (ii) obstacle envelopment, as well as; (iii) motion on generalized trajectories. In particular, the simulation accounts for such aspects as (i) contact impact; (ii) rolling friction; (ii) potential liftoff, free motion and recontact during obstacle envelopment. To illustrate the scheme, a full vehicular simulation is presented.

ABSTRACT: This paper develops a parallelizable multilevel multiple constrained nonlinear equation solver. The substructuring process is automated to yield appropriately balanced partitioning of each succeeding level. Due to the generality of the procedure, both sequential, partially and fully parallel environments can be handled. This includes both single and multiprocessor assignment per individual partition. Several benchmark examples are presented. These illustrate the robustness of the procedure as well as its capacity to yield significant reductions in memory utilization and calculational effort due both to updating and inversion.

ABSTRACT: By considering the characteristics of deformation of rotationally periodic structures subjected to rotationally periodic loads, the periodic structure is divided into several identical substructures in this paper. If the structure is really periodic but not axisymmetric, the number of the substructures can be defined accordingly. If the structure is axisymmetric (special in the case of the periodic), the structure can be divided into any number of substructures. It means, in this case, the number of substructures is independent of the
number of buckling waves. The degrees of freedom (DOFs) of joint nodes between the neighbouring substructures are classified as master and slave ones. The stress and strain conditions of the whole structure are obtained by solving the elastic static equations for only one substructure by introducing the displacement constraints between master and slave DOFs. The complex constraint method is used to get the bifurcation buckling load and mode for the whole rotationally periodic structure by solving the eigenvalue problem for only one substructure without introducing any additional approximation. Finite element (FE) formulation of shell element of relative degrees of freedom (SERDF) in the buckling analysis is then derived. Different measures of tackling internal degrees of freedom for different kinds of buckling problems and different stages of numerical analysis are presented. Some numerical examples are given to illustrate the high efficiency and validity of this method.

ABSTRACT: Shell element of relative degrees of freedom (SERDF) is a special transformation of solid element. It can be used in finite element (FE) analysis of both thin and thick shell structures and the formulation is simpler than normal shell elements. Introduction of additional internal degrees of freedom will improve the calculation precision. FE formulation of SERDF in the buckling analysis is derived in this article. Different measures of tackling additional internal degrees of freedom for different kinds of buckling problems and different stages of numerical analysis are presented. Some numerical examples are given to illustrate the validity of this element and the method.

ABSTRACT: In this paper a new finite element (FE) with relative degrees-of-freedom (DOF) is developed for modeling composite shells with arbitrary number of layers. With this shell element, satisfactory resolution can be ensured even if a relatively coarse FE mesh is employed. Moreover, this element can be easily connected with other solid type elements. All of these features enable its promising application in the simulation of modern composite structures, for example the buckling analysis of rotationally periodic laminated composite shells. For this kind of problem, a computational strategy that consists of the rotationally periodic FE method and this new shell element is adopted in this paper. The efficiency and accuracy of this proposed computational strategy are illustrated by two benchmarks as well as an implementation to a large scale practical structure.

ABSTRACT: This paper presents a finite element scheme to analyze the buckling behavior of composite shells subjected to thermal and mechanical loads. Firstly, a kind of multi-layered composite shell element with relative degrees-of-freedom is adopted to model laminated composite shells. Then the corresponding temperature
A new criterion of critical heat flux is proposed in place of the traditional criterion of critical temperature. Finally, the advantage of the proposed scheme is illustrated by calculating the stable region of thermal-mechanical loads for a honeycomb sandwich composite cylinder.

ABSTRACT: A finite element (FE) buckling analysis of rotationally periodic laminated composite shells is performed in this paper. Because the buckling mode of such structures is characterized as rotationally periodic, a corresponding FE buckling analysis scheme is proposed to reduce the computational expenses. Moreover, a new kind of relative degrees-of-freedom element is developed, which can be connected to other solid elements with ease and can yield satisfactory results with a relatively coarse FE mesh. Numerical results of two laminated cylindrical shells subjected to lateral pressure are compared with theoretical ones. The good agreement of them shows the validity of this new computational strategy. Finally, a practical structure is analysed to demonstrate the advantage of this method.

ABSTRACT: Buckling design of cylinders under axial compression is sensitive to the assumptions made in the modeling of initial imperfections. Normally, imperfection modes are selected solely on the basis of buckling mode considerations and their amplitudes determined using existing tolerance specifications. Whilst this approach may be used for metal cylinders, it cannot be readily applied to the design of fibre-reinforced composite cyoloinders where the effects of manufacturing on imperfection characteristics have not yet been studied in any detail. This paper presents results from a statistical analysis of imperfections on two groups of composite cylinders manufactured by lay-up. Dominant features are quantified and the effect of fibre orientation on imperfeclitons is examined. Simple models describing the random variability of imperfection modal amplitudes are presented in order to be used in buckling strength studies.

ABSTRACT: This paper presents a detailed statistical analysis on geometric imperfections recorded on two series of nominally identical composite cylinders. These defects can be classified in two categories, both due to the particular manufacturing method used: out-of-roundness and change of thickness due to the overlapping of various layers. The statistical analysis is developed for various purposes: to evaluate the common properties of cylinders with different laminations, to build up a characteristic model for the geometric imperfections suitable for probabilistic simulations in buckling analysis and to identify the parameters for quality control processes. The analysis of the change in thickness due to overlapping layers allows evaluation of the stiffening effects of the manufacturing process that, in some cases, could affect the buckling behaviour of composite cylinders. A standard procedure for the characterization and qualification of manufacturing processes for composite shells, with particular attention to the factors that influence their buckling behaviour, is proposed.

ABSTRACT: In most shell buckling codes, guidance on the design of conical shells is restricted to unstiffened cones and even in this case the clauses are based on the procedures for cylindrical shells. Virtually no guidance is offered on stiffened cones and the particular characteristics of conical shells are not treated in detail. In this paper, use is made of finite element analysis to quantify critical elastic response and imperfection sensitivity through numerical models, whose adequacy has been quantified through comparisons with test data. The finite element results obtained were aimed at validating existing design recommendations for unstiffened cones and at developing a design approach for stringer-stiffened cones under compression, with a philosophy and format compatible with the European Shell Buckling Recommendations (ECCS).

ABSTRACT: This article deals with the experimental buckling behaviour of glass fibre-reinforced plastic (GFRP) cylinders under concentric and eccentric compression. The laminates are of type ‘Rovimat 1200’ consisting of woven glass-fibre roving within a polyester resin matrix. Two-ply cylinders, for which the nominal radius-to-thickness ratio is about 108, with anti-symmetric lay-up of different orientation and overlapping procedure, are examined. In particular, the comparative response of cross-ply and angle-ply configurations is investigated and discussed. The results of experiments on eight models are presented including
thickness and imperfection mapping, load and strain measurements as well as salient observations regarding the behaviour of each model. Systematic and automated data acquisition techniques using a laser scanning system and computer-controlled loading procedures were used in order to provide the experimental measurements in a form that can be readily used for further analytical and design studies. The results demonstrate the significant influence of laminate orientation and loading eccentricity on the buckling strength of anti-symmetric cross-ply and angle-ply GFRP cylinders.

ABSTRACT: In thin-walled shells of revolution with widely-spaced meridional stiffeners loaded in compression, a local panel buckling may develop. For the particular case of cylindrical panels, the buckling and postbuckling behaviour has been investigated in detail, whereas limited research is available for the more general case of conical panels. In this paper, the linear and non-linear elastic buckling response of the conical panel is studied for a wide range of shell and stiffening parameters by means of an appropriate finite element model. The classical buckling load is determined on the basis of linear analysis. The imperfection sensitivity is studied through non-linear analysis of imperfect conical panels with imperfections affine to the critical mode. Different aspects of the behaviour are quantified through suitably defined curvature parameters.

ABSTRACT: Different modes of instability might occur in thin-walled stiffened shells. In particular, local shell and stringer buckling modes and global buckling mode might develop in axially stiffened cones. In this paper, such modes are studied in conical shells under axial compression through a linear eigenvalue finite element analysis. In order to examine buckling modes in isolation (in line with typical simplified formulae) as well as competing modes together, use is made of different finite element models, including discrete and smeared models. Changes of buckling modes are captured by varying stiffener slenderness, number of stiffeners and tapering angle, treated as design parameters. Some evidence of mode interaction is recorded by the clustering of eigenvalues/eigenmodes.

ABSTRACT: The paper presents the results obtained during a test programme involving unstiffened steel cones in compression. Due to the relatively low slenderness of the specimens, the failure was in all cases significantly influenced by plasticity effects. A plastic mechanism approach, including second order effects, is shown to be a simple and effective tool for predicting the collapse load and also for simulating the load-shortening response. The derivation of the theoretical expressions pertaining the mechanism are summarised and some aspects regarding the solution procedures are presented. Comparisons between the proposed mechanism approach and the experiments are reported. Finally, some design considerations and comments with regard to existing shell buckling codes are presented.

ABSTRACT: The design of some steel shells, like energy absorbers or bumpers, requires the knowledge of their behavior in large deformations. In this paper, the method of sequential limit analysis is presented and applied to axisymmetric shells in order to study their post-collapse response. Although the material behavior is assumed as rigid-plastic, results compare favorably with those produced by elastic-plastic incremental analyses and the procedure appears to be more efficient and numerically stable. Large displacement effects, both of stable and unstable nature, are implicitly accounted for by mesh updating.

ABSTRACT: The torsional buckling characteristic of an elastic cylinder with a hard surface coating layer is addressed in this paper. Deformations of the core and surface layer are obtained analytically through the Navier’s equation and thin shell model, respectively. Both infinitely and finitely long cylinders are studied and
the effects of the surface layer’s stiffness, thickness, residual stresses, as well as the cylinder lengths on the critical torsional angle and buckling morphologies, are discussed. It is found that either the surface rippling or global buckling mode may occur when there exist residual stresses within the surface layer. The critical torsional angle increases when the surface layer becomes stiffer and thinner. In addition, higher-order rippling modes frequently occur for a finite-length cylinder with stiffer and thinner surface layer.

ABSTRACT: Experimental and numerical simulation researches were presented on dynamic buckling behaviors of cylindrical shell subjected to explosion loading. An account is given of some principal observations made from a series of experiments in which steel cylindrical shells were subjected to central impact by 200g cylindrical TNT dynamite with different distances. By means of an finite element computer code LS-DYNA, the nonlinear dynamic response process of the cylindrical shells subjected to explosion
loading were numerically simulated with Lagrangian-Eulerian coupling method. The numerical simulation results were in good agreement with experimental data. The results provide a reference for the design of explosion-resisting structures.

ABSTRACT: In this work, surface effects including surface elasticity and residual surface stress on the buckling of nanowires are theoretically investigated. Based on modified core-shell (MC-S) model, the effective elasticity incorporating surface elasticity effect of the nanowire is derived, and by using the generalized Young-Laplace equation the residual surface stress is accounted for. The ratio of critical load with and without surface effects are obtained for a nanowire loaded in uniaxial compression. Taking silver (Ag) nanowires as an example, the analyzed results demonstrate that the influence of surface effects on the critical load of buckling becomes more and more significant as the nanowire diameter decreases. Moreover, it is shown that the influence of residual surface stress on the critical load is more prominent than that of surface elasticity.

ABSTRACT: A perturbation analysis for the impact torsional buckling of imperfective elastic cylindrical shells subjected to a step torque is given. The imperfection is supposed to be small and has arbitrary form. It is shown that only the imperfection which has the shape of static torsional buckling mode could influence the critical step torque. Finally a formula is presented for the critical step torque.

PARTIAL INTRODUCTION: Glass fibre-reinforced plastic (GFRP) shells could be an attractive structural form for a number of applications in construction due to their good strength-to-weight ratio, inherent corrosion resistance, and relatively low cost compared to other composite systems. However, their efficient use is restricted by the limited availability of design criteria and by fairly scant test data on which any such criteria can be validated.…

ABSTRACT: Nowadays building design can not prescind from high requirements both for structural and physic-energetic performances. It is well known that the behaviour of light-weight structures is even better than those built with traditional materials (concrete and steel), with respect to static and dynamic loads, due to the reduced impact of horizontal and vertical forces on the structure. FRPs, despite being a fragile material, have a
good structural behavior because of their low weight and, similarly to wood, for the high level of ductility that is achieved through the use of mechanical connections among elements. Present research involves the design and optimization of a GFRP load bearing panel that maximizes the structural response with respect to concentrated and distributed loads, even of great intensity. In particular, the panel should maximize the response to compression, that is problematic because of buckling in presence of axial forces. The structural analysis is carried on using FEA software and the panel is modeled as a pultruded – monoaxial – element. The study takes into account not only the structural issues and the panel is designed as an integrated element, for facades and floors, that responds to highest Italian standards for thermal performance. Panels can be assembled together, to create modular buildings. Moreover, the weight of the panel is optimized to reach significant advantages on the construction site and reduce the need for workforce. Starting from the design stage, is given emphasis to the life-cycle of the panel and particular attention is paid to the possibilities of reuse.

ABSTRACT: Externally pressurized thin-walled GFRP composite cylindrical shell strength was studied against failure. Fiber breakage, matrix breakage, interlamine shear deformation, delamination shear deformation and micro buckling failure were investigated employing maximum failure criteria as volumetric fiber fraction factor varied. One-ply cylindrical shell with fiber angle orientation of 0 degree was modeled in ABAQUS finite element simulation and the result was varied using analytical approaches. Moreover, the pressure fluctuations for various volumetric fiber fraction factors were quadratic according to plotted graphs obtained. Meanwhile, MATLAB software was used for theoretical analysis. The comparison of two approaches was proved to be accurate. Subsequently, failure strength of various laminated GFRP cylindrical shell with different fiber angle orientations at each ply was studied for diverse volumetric fiber fraction factors. Stacking sequence, fiber angle orientations were mainly effective on failure strength.

ABSTRACT: The buckling of an axially compressed truncated conical shell with rigid bulkheads is reinvestigated. Two improvements are made. First, the condition that the total horizontal displacement must vanish because of the rigid buckhead and axisymmetry is treated as a constraint. This constraint is brought into the system by use of the Lagrange multiplier; then a complete set of boundary conditions for conical shells is
derived by the variational method. Second, the stability is evaluated at the deformed state which is determined by the asymptotic solutions of the pair of Donnell-type equations for axisymmetric configuration. It is found that when the angle rotation at the smaller end during the loading process is taken into consideration the buckling strength is lowered to an extent comparable with the existing experimental results.

ABSTRACT: As is well known, the elastic stability of shell structures under certain loading conditions is characterised by a severely unstable postbuckling behaviour. The presence of simultaneous buckling modes (‘competing’ modes corresponding to the same critical buckling load) is deemed to be largely responsible for such a behaviour. In the present paper, within the framework of the so-called classical theory (linear bifurcation eigenvalue analysis), the buckling behaviour of axially compressed cylindrical shells is firstly reviewed. Accordingly, doubly periodic eigenvectors (buckling modes) corresponding to the same eigenvalue (critical buckling load) can be determined, and their locus in a dimensionless meridional and circumferential buckling wavenumber space is described by a circle (known as the Koiter circle). In the case of axially compressed conical shells, no clear evidence of the existence of simultaneous buckling modes can be found in the literature. Then, such a problem is studied here via linear eigenvalue finite element analyses, showing that simultaneous doubly periodic modes do also occur for cones, and that their locus in a specifically defined dimensionless wavenumber space can be described by an ellipse (hereafter termed as the Koiter ellipse) whose aspect ratio is dependent on the tapering angle of the cone.

ABSTRACT: This paper considers the dynamic stability of a nonhomogeneous orthotropic elastic cylindrical shell, the properties of which vary continuously with the coordinates in the longitudinal and thickness directions, under the effect of an external pressure varying with a power function of time. At first, the fundamental relations and the dynamic stability equations of a nonhomogeneous orthotropic elastic cylindrical shell, under the effect of an external pressure, are derived. Then, the general formulas for the critical load and the dynamic factor are obtained by using Bubnov-Galerkin and Sachenkov’s methods [1,2] and an asymptotic analysis. The respective formulas for homogeneous orthotropic and isotropic elastic cylindrical shells are found as special cases. Finally, carrying out some computations, the effect of the nonhomogeneity on the critical load and the dynamic factor are studied. The results obtained are compared with the experimental and theoretical results of other authors.

ABSTRACT: In this study, the dynamic stability of a laminated orthotropic truncated conical shell, subjected to an external pressure which is a power function of time, was considered. First, the modified Donnell-type dynamic stability and compatibility equations of a laminated orthotropic truncated conical shell, subjected to an
external pressure, were obtained. Applying the Galerkin and Sachenkov and Baktieva (1978) methods one after the other, the static and dynamic critical external pressures, the pertinent wave numbers and the dynamic factor were found explicitly. Finally, carrying out some computations for cross-ply laminated truncated conical shells, the effects of the variation of the number and orientation of the layers and the power function of time in the external pressure expression on the critical parameter were studied.

ABSTRACT: The subject of this investigation is to study the buckling of cross-ply laminated orthotropic cylindrical thin shells with variable elasticity moduli and densities in the thickness direction, under external pressure, which is a power function of time. The dynamic stability and compatibility equations are obtained first. These equations are subsequently reduced to a system of time dependent differential equations with variable coefficients by using Galerkin's method. Finally, the critical dynamic and static loads, the corresponding wave numbers, the dynamic factors, critical time and critical impulse are found analytically by applying a modified form of the Ritz type variational method. The dynamic behavior of cross-ply laminated cylindrical shells is investigated with: a) lamina that present variations in the elasticity moduli and densities, b) different numbers and ordering of layers, and c) external pressures which vary with different powers of time. It is concluded that all these factors contribute to appreciable effects on the critical parameters of the problem in question.

Abdullah H. Sofiyev (Department of Civil Engineering, Suleyman Demirel University, Isparta, Turkey), “The buckling of an orthotropic composite truncated conical shell with continuously varying thickness subject to a time dependent external pressure”, Composites Part B: Engineering, Vol. 34, No. 3, April 2003, pp. 227-233, doi:10.1016/S1359-8368(02)00105-1
ABSTRACT: In this study, the buckling of an orthotropic composite truncated conical shell with continuously varying thickness, subject to a uniform external pressure which is a power function of time, has been considered. At first, the fundamental relations and the Donnell type stability equations of an orthotropic composite truncated conical shell, subject to an external pressure, have been obtained. Then, employing Galerkin method, those equations have been reduced of time dependent differential equation with variable coefficients. Finally, applying the variational method of Ritz method type, the critical static and dynamic loads, the corresponding wave numbers and the dynamic factor have been found analytically. Using those results, the effects of the variations of the power in the thickness expression, the semi-vertex angle, the power of time in the external pressure expression and the ratio of the Young's moduli on the critical parameters are studied numerically, for the case when the thickness of the conical shell varies as a power and exponential function. It is observed, from the computations carried out, that these factors have appreciable effects on the critical parameters of the problem in the heading.
ABSTRACT: The subject of this investigation is to study the buckling of cross-ply laminated orthotropic truncated circular conical thin shells with variable Young's moduli and densities in the thickness direction, subjected to a uniform external pressure which is a power function of time. After obtaining the dynamic stability and compatibility equations we reduce both of them to a time dependent ordinary differential equation with variable coefficient by using Galerkin's method. The critical dynamic and static loading, the corresponding wave numbers, the dynamic factors, critical time and critical impulse are found analytically by applying the Ritz type variational method. The dynamic behavior of cross-ply laminated truncated conical shells is investigated with: (a) lamina that present variations in the Young's moduli and densities, (b) different numbers and ordering of layers, (c) variable semi-vertex angles, and (d) external pressures which vary with different powers of time. It is concluded that all these factors contribute to appreciable effects on the critical parameters of the problem in question.

ABSTRACT: The buckling of an orthotropic composite cylindrical shell with variable thickness, subjected to a dynamic loading, is reported here. At first, the fundamental relations and Donnell type dynamic buckling equation of an orthotropic cylindrical shell with variable thickness have been obtained. Then, employing Galerkin's method, these equations have been reduced to a time dependent differential equation with variable coefficients. Finally, for different initial conditions and approximation functions, applying the Ritz type variational method, analytical expression has been found for the dynamic factor. Using these results, the effect of the variations of the power of time in the external pressure expression, the loading parameter and the ratios of the Young's moduli on the dynamic factor are studied numerically for the case when the thickness of the cylindrical shell varies as a power and exponential functions. It has been observed that these effects change the dynamic factor of the problem in the heading appreciably.

ABSTRACT: This study considers torsional buckling of cross-ply laminated orthotropic composite cylindrical thin shells under loads, which is a power function of time. The modified Donnell type dynamic stability and compatibility equations are obtained first. These equations are subsequently reduced to a time dependent differential equation with variable coefficients by using Galerkin's method. The critical parameters are found analytically by applying the Ritz type variational method. According to theoretical solutions, numerical analyses are done.

Zihn Zerin (Department of Civil Engineering, Ondokuz Mayis University, Samsun, Turkey), “On the vibration of laminated nonhomogeneous orthotropic shells”, Meccanica, Vol. 48, No. 7, pp 1557-1572, September 2013
ABSTRACT: In this paper, an analytical procedure is given to study the free vibration of the laminated
homogeneous and non-homogeneous orthotropic conical shells with freely supported edges. The basic relations, the modified Donnell type motion and compatibility equations have been derived for laminated orthotropic truncated conical shells with variable Young’s moduli and densities in the thickness direction of the layers. By applying the Galerkin method, to the basic equations, the expressions for the dimensionless frequency parameter of the laminated homogeneous and non-homogeneous orthotropic truncated conical shells are obtained. The appropriate formulas for the single-layer and laminated complete conical and cylindrical shells made of homogeneous and non-homogeneous, orthotropic and isotropic materials are found as a special case. Finally, the influences of the non-homogeneity, the number and ordering of layers and the variations of the conical shell characteristics on the dimensionless frequency parameter are investigated. The results obtained for homogeneous cases are compared with their counterparts in the literature.

“The Buckling of Laminated Cylindrical Thin Shells under Torsion Varying as a Linear Function of Time”,


ABSTRACT: The buckling of laminated orthotropic cylindrical thin shells under torsion, which is a linear function of time, has been investigated. First, fundamental relations and the modified Donnell type stability equations of the laminated cylindrical thin shells are derived. Applying Galerkin’s method, a differential equation having a variable coefficient depending on time is obtained and by applying the Ritz-type variational method to these equations, general formulas for static and dynamic critical loads, corresponding wave numbers and the dynamic factor are obtained. Finally after performing the computations, the effects of the variations of the numbers and ordering of layers, loading speed, and the ratio of radius to thickness on the critical parameters are investigated.

References listed at the end of the paper:
ABSTRACT: This study considers the buckling of an elastic truncated conical shell having a meridional thickness expressed by an arbitrary function, subject to a uniform external pressure, which is a power function of time. At first, the fundamental relations and Donnell type dynamic buckling equation of an elastic conical shell with variable thickness have been obtained. Then, employing Galerkin's method, those equations have been reduced to a time-dependent differential equation with variable coefficients. Finally, applying the Ritz type variational method, the critical static and dynamic loads, the corresponding wave numbers, dynamic factor and critical stress impulse have been found analytically. Using the results, thus obtained, the effects of the thickness variations with a power or an exponential function, the variation of the semi-vertex angle and the variation of the power of time in the external pressure expression are studied through pertinent computations. It is observed that these factors have appreciable effects on the critical parameters of the problem in the heading.

ABSTRACT: In this work, the stability of conical shells made of functionally graded materials (FGMs) subject to a uniform external pressure, which is a power function of time, has been studied. The material properties of functionally graded shells are assumed to vary continuously through his thickness of the shell, according to a power law distribution of the volume fractions of the constituents. The fundamental relations, the dynamic stability and compatibility equations of functionally graded truncated conical shells are obtained first. Applying Galerkin's method, these equations have been transformed to a pair of time dependent differential equation with variable coefficient. This differential equation is solved for different initial conditions by variational method by using Lagrange–Hamilton type principle. Thus, general formulas have been obtained for the critical parameters. The results show that the critical parameters are affected by the configurations of the constituent materials, loading parameters variations, the variation of the semi-vertex angle and the power of time in the external pressure expression variations. Comparing results with those in the literature validates the present analysis.

“The stability of functionally graded cylindrical shells under linearly increasing dynamic torsional loading”,

ABSTRACT: In this study, a formulation for the stability of cylindrical thin shells made of functionally graded material (FGM) subjected to torsional loading varying as a linear function of time is presented. The properties are graded in the thickness direction according to a volume fraction power law distribution. The modified Donnell type dynamic stability and compatibility equations are obtained. Applying Galerkin’s method then applying Lagrange–Hamilton type principle to these equations taking the large values of loading speed into consideration, analytic solutions are obtained for critical torsional parameters values. The results show that the critical torsional parameters are affected by the configurations of the constituent materials variations. Comparing results with those in the literature validates the present analysis.

ABSTRACT: In this study, an analytic solution is provided for the stability and vibration behavior of truncated conical shells composed of Si3N4 and SUS304 under the axial compressive load. The material properties of the FG conical shells are assumed to vary continuously through the thickness of the shell according to quadratic and inverse quadratic distribution of the volume fraction of the constituents. The fundamental relations and governing equations for thin conical shells composed of Si3N4 and SUS304 is obtained by using Love’s shell theory and a solution is obtained by applying Galerkin’s method. The effects of the constituent volume fractions on the critical axial load and frequency parameter of the truncated conical shell are also elucidated.

ABSTRACT: In this study, the response of a FG (Functionally Graded) coated truncated conical shell subjected to an axial load is investigated by means of non-linear equations governing the finite deformations of the shell. In the solution of non-linear basic equations in the finite deflection the Superposition and Galerkin methods have been used. The effects of material property of FG composite coatings and geometrical parameters on the non-linear critical axial load are discussed in detail through a parametric study. The results are verified by comparing the obtained values with those in the existing literature.
ABSTRACT: In this study, the stability problem of a circular orthotropic cylindrical shell under the effect of an axial compression varying with a power function of time is considered. At first, the modified Donnell type dynamic stability and compatibility equations are obtained using Love’s shell theory. Applying the Galerkin and Rayleigh-Ritz variational techniques to these equations and taking the large values of loading parameters into consideration, analytics are obtained for critical parameter values. The results show that critical parameters are affected by loading parameters variations, ratio of the Young’s moduli variations, radius to thickness variations and the power of time in the axial compression expression variations. Comparing results with those in the literature validates the present analysis.

ABSTRACT: The dynamic stability of orthotropic cylindrical thin shells of exponentially variable geometric and mechanical parameters is studied by using Galerkin and Ritz type variational methods. The qualitative and quantitative effects of the external geometry, material properties, and design features on the critical loads, corresponding wave numbers, and the dynamic factor are evaluated. Comparing results with those in the literature validates the present analysis.

ABSTRACT: In this paper, the vibration and stability of a three-layered conical shell containing a functionally
graded material (FGM) layer subjected to axial compressive load are studied. The material properties of the functionally graded layer are assumed to vary continuously through the thickness of the shell. The variation of properties follows an arbitrary distribution in terms of the volume fractions of the constituents. The fundamental relations, the dynamic stability and compatibility equations of three-layered truncated conical shells containing an FGM layer are obtained first. Applying Galerkin’s method, these equations are transformed to a pair of time dependent differential equations, and critical axial load and frequency parameter are obtained. The results show that the critical parameters are affected by the configurations of the constituent materials and the variation of the shell geometry. Comparing results with those in the literature validates the present analysis.

ABSTRACT: The dynamic buckling of a cylindrical shell subject to a uniform axial compression, which is a linear function of time, is examined within the framework of small strain elasto-plasticity. The material of the shell is incompressible and the effect of the elastic unloading is not taken into consideration. Initially, employing the deformation theory, the fundamental relations and Donnell type stability equations have been obtained. Finally, by using the Galerkin’s methods the closed form solutions are presented. Comparing the results with those in the literature validates the present analysis.

ABSTRACT: The dynamic buckling of truncated conical shells made of functionally graded materials (FGMs) subject to a uniform axial compressive load, which is a linear function of time, has been studied. The material properties of functionally graded shells are assumed to vary continuously through the thickness of the shell. The variation of properties followed an arbitrary distribution in terms of the volume fractions of the constituents. The fundamental relations, the dynamic stability and compatibility equations of functionally graded truncated conical shells are obtained first. Applying Galerkin’s method, these equations have been transformed to a pair of time dependent differential equation with variable coefficient and critical parameters obtained using the Runge–Kutta method. The results show that the critical parameters are affected by the configurations of the constituent materials, compositional profile variations, loading speed variations and the variation of the shell geometry. Comparing the results of this study with those in the literature validates the present analysis.

ABSTRACT: The vibration and stability analysis is investigated for composite cylindrical shells that composed of ceramic, FGM, and metal layers subjected to various loads. Material properties of FG layer are varied continuously in thickness direction according to a simple power distribution in terms of the ceramic and metal volume fractions. The modified Donnell type stability and compatibility equations are obtained. Applying Galerkin’s method analytic solutions are obtained for the critical parameters. The detailed parametric studies are carried out to study the influences of thickness variations of the FG layer, radius-to-thickness ratio, lengths-to-radius ratio, material composition and material profile index on the critical parameters of three-layered cylindrical shells. Comparing results with those in the literature validates the present analysis.

ABSTRACT: In this study, the thermal buckling loads of truncated conical shells of functionally graded material are considered. The material properties of functionally graded shells are assumed to vary continuously through his thickness of the shell, according to a power law distribution of the volume fractions of the constituents. The fundamental relations, the modified Donnell type stability and compatibility equations of functionally graded truncated conical shells are obtained first. Then applying Galerkin’s method, the closed form solutions are presented for the truncated conical shell with simply supported boundary conditions subjected to three types of thermal loading. Using the obtained results, the effects of the variations of the
gradient index of materials, the semi-vertex angle and the ratio radius to thickness in the critical buckling temperature expression are studied through pertinent computations. Comparing results with those in the literature validates the present analysis.

ABSTRACT: In this study, the stability of a generic three-layered truncated conical shell containing a functionally graded (FG) layer subjected to uniform external pressure is investigated. The material properties of the functionally graded layer are assumed to vary continuously through the thickness of the shell. The variation of the properties follows an arbitrary distribution in terms of the volume fractions of the constituents. The fundamental relations, the stability and compatibility equations of three-layered truncated conical shells containing a FG layer are obtained, first. Then, applying Galerkin's method, the closed form solution for critical external pressure is obtained. The results show that the critical parameters are affected by the configurations of the constituent materials, the variations of the thickness of the FG layer and the variation of the shell geometry. Comparing the results with those in the literature validates the present analysis.

ABSTRACT: In this paper, the buckling of non-homogeneous isotropic truncated conical shells under uniform lateral pressure and resting on a Winkler foundation is investigated. The basic relations and governing equations have been obtained for non-homogeneous truncated conical shells. The critical uniform lateral pressures of non-homogeneous isotropic truncated conical shells with or without a Winkler foundation are obtained. Finally, carrying out some computations, effects of the variations of truncated conical shell characteristics the non-homogeneity and the Winkler foundation on the critical uniform lateral pressures have been studied. The results are compared with other works in the open literature.

ABSTRACT: In this study, the buckling of thin truncated conical shells made of functionally graded materials (FGMs) subjected to hydrostatic pressure is investigated. The material properties of functionally graded truncated conical shell are assumed to vary continuously through the thickness. The variation of properties followed an arbitrary distribution in terms of the volume fractions of the constituents. The fundamental relations, the stability and compatibility equations of FGM hybrid truncated conical shells are obtained. Using Galerkin's method, these equations were transformed to pairs of time-dependent differential equations and then hydrostatic buckling pressure expression was obtained. Numerical calculations have been made for fully metal, fully ceramic, Si3N4/Ni and ZrO2/Ti–6Al–4V truncated conical shells. The results reveal that the volume
fraction distributions have a significant effect on the buckling pressure of FGM hybrid truncated conical shells. Finally, results are validated through comparison of obtained values with those in the literature.

ABSTRACT: In this paper, the vibration and stability of orthotropic conical shells with non-homogeneous material properties under a hydrostatic pressure are studied. At first, the basic relations have been obtained for orthotropic truncated conical shells, Young's moduli and density of which vary continuously in the thickness direction. By applying the Galerkin method to the foregoing equations, the buckling pressure and frequency parameter of truncated conical shells are obtained from these equations. Finally, carrying out some computations, the effects of the variations of conical shell characteristics, the effects of the non-homogeneity and the orthotropy on the critical dimensionless hydrostatic pressure and lowest dimensionless frequency parameter have been studied, when Young's moduli and density vary together and separately. The results are presented in tables, figures and compared with other works.

ABSTRACT: In this paper, the free vibration and buckling of laminated homogeneous and non-homogeneous orthotropic truncated conical shells under lateral and hydrostatic pressures are studied. At first, the basic relations, the modified Donnell type dynamic stability and compatibility equations have been obtained for laminated orthotropic truncated conical shells, the Young's moduli and density of which vary piecewise continuously in the thickness direction. Applying superposition and Galerkin methods to the foregoing equations, the buckling pressures and dimensionless frequency parameter of laminated homogeneous and non-homogeneous orthotropic conical shells are obtained. The appropriate formulas for single-layer and laminated cylindrical shells made of homogeneous and non-homogeneous, orthotropic and isotropic materials are found as a special case. Finally, the effects of the number and ordering of layers, the variations of conical shell characteristics, together and separately variations of the Young's moduli and densities of the materials of layers on the critical lateral and hydrostatic pressures, and frequency parameter are found for different mode numbers. The results are compared with other works.

ABSTRACT: The purpose of this paper is to investigate the elastic buckling of FGM truncated thin conical
shells under combined axial tension and hydrostatic pressure. Here axial tensions are separately applied to small and large bases of the truncated conical shell, respectively. It is assumed that the cone is a mixture of metal and ceramic, and that its properties change as the power and exponential functions of the shell thickness. After giving the fundamental relations, the stability and compatibility equations of an FGM truncated conical shell, subject to combined axial tension and hydrostatic pressure, have been derived. Applying Galerkin’s method general formulas have been obtained for the critical combined and separate loads of FGM conical shells. The appropriate formulas for homogenous and FGM cylindrical shells are found as a special case. Effects of changing shell characteristics, material composition and volume fraction of constituent materials on the critical combined and separate loads of FGM shells with simply supported edges are also investigated. The results obtained for homogeneous cases are compared with their counterparts in the literature.

ABSTRACT: This article presents a method to study the free vibration and stability of laminated homogeneous and non-homogeneous orthotropic cylindrical, truncated and complete conical shells of general staking with clamped edges under a hydrostatic pressure. Based on the Love first approximation theory, the basic relations, the modified Donnell-type stability and compatibility equations have been obtained for laminated orthotropic truncated conical shells, the material properties of which vary piecewise continuously in the thickness direction. To solve this problem an unknown parameter $\lambda$ was included in the approximation functions. Applying Galerkin methods, the buckling pressures and fundamental natural frequencies of laminated homogeneous and non-homogeneous orthotropic conical shells are obtained. The parameter $\lambda$ which is included in the obtained formulas is obtained from the minimum conditions of critical stresses and frequencies. The different generalized values are obtained for the parameter $\lambda$ for buckling pressures and frequencies of cylindrical shells, truncated and complete conical shells. The appropriate formulas for single-layer and laminated cylindrical shells made of homogeneous and non-homogeneous, orthotropic and isotropic materials are found as a special case. Finally, the influences of the degree of non-homogeneity, the number and ordering of layers and the variations of conical shell characteristics on the critical hydrostatic pressure and natural frequencies are investigated. The results obtained for homogeneous cases are compared with their counterparts in the literature.

This paper presents an analytical study on the dynamic behavior of the infinitely-long, FGM cylindrical shell subjected to combined action of the axial tension, internal compressive load and ring-shaped compressive pressure with constant velocity. It is assumed that the cylindrical shell is a mixture of metal and ceramic that its properties changes as a function of the shell thickness. The problem is studied on the basis of the theory of vibrations of cylindrical shells. Derived formulas for the maximum static and dynamic displacements, dynamic factors and critical velocity for the FGM cylindrical shell subjected to moving loads. Numerical calculations have been made for fully metal, fully ceramic and FGM (Si3N4/SUS304) cylindrical shells. A parametric study is conducted to demonstrate the effects of the material property gradient, the radius to thickness ratio and the velocity of the moving load on the dynamic displacements and dynamic factors of the inner and ring-shaped pressures for FGM cylindrical shells.
ABSTRACT: In this study, the stability of cylindrical shells that composed of ceramic, FGM, and metal layers subjected to axial load and resting on Winkler-Pasternak foundations is investigated. Material properties of FGM layer are varied continuously in thickness direction according to a simple power distribution in terms of the ceramic and metal volume fractions. The modified Donnell type stability and compatibility equations on the Pasternak foundation are obtained. Applying Galerkin’s method analytic solutions are obtained for the critical axial load of three-layered cylindrical shells containing an FGM layer with and without elastic foundation. The detailed parametric studies are carried out to study the influences of thickness variations of the FGM layer, radius-to-thickness ratio, material composition and material profile index, Winkler and Pasternak foundations on the critical axial load of three-layered cylindrical shells. Comparing results with those in the literature validates the present analysis.

ABSTRACT: In this paper an analytical procedure is given to study the free vibration and stability characteristics of homogeneous and non-homogeneous orthotropic truncated and complete conical shells with clamped edges under uniform external pressures. The non-homogeneous orthotropic material properties of conical shells vary continuously in the thickness direction. The governing equations according to the Donnell’s theory are solved by Galerkin’s method and critical hydrostatic and lateral pressures and fundamental natural frequencies have been found analytically. The appropriate formulas for homogeneous orthotropic and isotropic conical shells and for cylindrical shells made of homogeneous and non-homogeneous, orthotropic and isotropic materials are found as a special case. Several examples are presented to show the accuracy and efficiency of the formulation. The closed-form solutions are verified by accurate different solutions. Finally, the influences of the non-homogeneity, orthotropy and the variations of conical shells characteristics on the critical lateral and hydrostatic pressures and natural frequencies are investigated, when Young’s moduli and density vary together and separately. The results obtained for homogeneous cases are compared with their counterparts in the literature.

ABSTRACT: This article presents to study the stability of laminated orthotropic cylindrical and truncated conical shells resting on elastic foundations and subjected to combined loads with the clamped and simply supported boundary conditions. Here, axial tensile loads separately applied to the small and large bases of a laminated truncated conical shell, respectively. The basic relations, the modified Donnell type stability and compatibility equations have been obtained for laminated orthotropic truncated conical shells on the Pasternak type elastic foundation. Applying Galerkin method, the critical combined loads of laminated orthotropic conical shells on the Pasternak type elastic foundation with different boundary conditions are obtained. The appropriate formulas for single-layer and laminated cylindrical shells on the Pasternak type elastic foundation made of orthotropic and isotropic materials are found as special cases. Finally, influences of the boundary conditions, the elastic foundation, the number and ordering of the layers and variations of the shell characteristics on the critical combined loads are investigated. The results are compared with their counterparts in the literature.

ABSTRACT: Non-linear buckling analyses of imperfect functionally graded truncated conical shells with simply supported boundary conditions and subjected to an axial compressive load have been presented in this work. The material properties of functionally graded shells are assumed to vary continuously through the thickness of the shell. The non-linear prebuckling deformations and initial geometric imperfections of an FGM truncated conical shell are both taken into account. The fundamental relations, modified Donnell type non-linear stability and compatibility equations of an imperfect FGM truncated conical shell are obtained and are solved by superposition and Galerkin methods, and the upper and lower critical axial loads has been found analytically. The numerical illustrations concern the non-linear buckling response of FGM truncated conical shells with different values of truncated conical shell parameters, initial imperfections and compositional profiles. Comparing the results of this study with those in the literature validates the present analysis.

ABSTRACT: In this study, the torsional stability analysis is presented for thin cylindrical with the functionally graded (FG) middle layer resting on the Winker elastic foundation. The mechanical properties of functionally graded material (FGM) are assumed to be graded in the thickness direction according to a simple power law and exponential distributions in terms of volume fractions of the constituents. The fundamental relations and basic equations of three-layered cylindrical shells with a FG middle layer resting on the Winker elastic foundation under torsional load are derived. Governing equations are solved by using the Galerkin method. The numerical results reveal that variations of the shell thickness-to-FG layer thickness ratio, radius-to-shell thickness ratio, lengths-to-radius ratio, foundation stiffness and compositional profiles have significant effects on the critical torsional load of three-layered cylindrical shells with a FG middle layer. The results are verified by comparing the obtained values with those in the existing literature.

ABSTRACT: In this study, the non-linear buckling behavior of truncated conical shells made of functionally graded materials (FGMs), subject to a uniform axial compressive load, has been investigated using the large deformation theory with von the Karman–Donnell-type of kinematic non-linearity. The material properties of functionally graded shells are assumed to vary continuously through the thickness of the shell. The variation of properties followed an arbitrary distribution in terms of the volume fractions of the constituents. The fundamental relations, the modified Donnell type non-linear stability and compatibility equations of functionally graded truncated conical shells are obtained and are solved by superposition and Galerkin methods and the upper and lower critical axial loads have been found analytically. Finally, the influences of the compositional profile variations and the variation of the shell geometry on the upper and lower critical axial loads are investigated. Comparing the results of this study with those in the literature validates the present analysis.

ABSTRACT: The vibration and stability analyses are presented for axially compressed three-layered truncated conical shells with a functionally graded (FG) middle layer surrounded by elastic media. The material properties of functionally graded materials (FGMs) are assumed to be graded in the thickness direction according to simple power law and exponential distributions in terms of the volume fractions of the constituents. Five sets of the material mixture are considered. The Pasternak model is used to describe the reaction of the elastic medium on the truncated conical shell. The fundamental relations, the modified Donnell-type dynamic stability and compatibility equations for the three-layered truncated conical shell with an FGM middle layer are derived. The governing equations are solved by using the Galerkin method and obtained expressions for dimensionless frequency parameters and dimensionless critical axial loads for three-layered truncated conical shells with the FG middle layer with and without an elastic foundation. The numerical results reveal that variations of the shell thickness-to-FGM thickness ratio, lengths-to-radius ratio, Winkler foundation stiffness, shear subgrade modulus of the foundation, material mixture and compositional profiles of the FG middle layer have significant effects on the values of dimensionless critical axial load and dimensionless frequency parameter. The results are verified by comparing the obtained values with those in the existing literature.

ABSTRACT: In this study, the buckling analysis of layered cylindrical shells with functionally graded material face sheets subjected to an axial compressive load is investigated. The dimensionless axial buckling load of layered cylindrical shells with functionally graded material face sheets is obtained. Effects of volume fractions of functionally graded material face sheets and cylindrical shell characteristics on the dimensionless axial buckling load have been studied.

ABSTRACT: In this study, the torsional vibration and stability problems of functionally graded (FG) orthotropic cylindrical shells in the elastic medium, using the Galerkin method was investigated. Pasternak model is used to describe the reaction of the elastic medium on the cylindrical shell. Mixed boundary conditions are considered. The material properties and density of the orthotropic cylindrical shell are assumed to vary exponentially in the thickness direction. The basic equations of the FG orthotropic cylindrical shell under the torsional load resting on the Pasternak-type elastic foundation are derived. The expressions for the critical torsional load and dimensionless torsional frequency parameter of the FG orthotropic cylindrical shell resting on elastic foundations are obtained. The effects of variations of shell parameters, the exponential factor characterizing the degree of material gradient, orthotropy, foundation stiffness and shear subgrade modulus of the foundation on the critical torsional load and dimensionless torsional frequency parameter are examined.

ABSTRACT: In this study, the vibration and buckling of functionally graded (FG) orthotropic cylindrical shells under external pressures is investigated using the shear deformation shell theory (SDST). The basic equations of shear deformable FG orthotropic cylindrical shells are derived using Donnell shell theory and solved using the Galerkin method. Parametric studies are made to investigate effects of shear deformation, orthotropy, compositional profiles and shell characteristics on the dimensionless frequency parameter and critical external pressures. Some comparisons among various theories have been performed in order to show the differences between the parabolic shear deformation theory (PSDT) and several higher-order shear deformation theories (HSDTs).

“Buckling of non-homogeneous orthotropic conical shells subjected to combined load”, Steel Composite Structures, 2015, DOI: http://dx.doi.org/10.12989/scs.2015.19.1.001
ABSTRACT: The buckling analysis is presented for non-homogeneous (NH) orthotropic truncated conical shells subjected to combined loading of axial compression and external pressure. The governing equations have been obtained for the non-homogeneous orthotropic truncated conical shell, the material properties of which vary continuously in the thickness direction. By applying Superposition and Galerkin methods to the governing equations, the expressions for critical loads (axial, lateral, hydrostatic and combined) of non-homogeneous orthotropic truncated conical shells with simply supported boundary conditions are obtained. The results are verified by comparing the obtained values with those in the existing literature. Finally, the effects of non-homogeneity, material orthotropy, cone semi-vertex angle and other geometrical parameters on the values of the critical combined load have been studied.

ABSTRACT: This article is the result of an investigation on the influence of a Pasternak elastic foundation on the stability of exponentially graded (EG) cylindrical shells under hydrostatic pressure, based on the first-order shear deformation theory (FOSDT) considering the shear stresses. The shear stresses shape function is distributed parabolic manner through the shell thickness. The governing equations of EG orthotropic cylindrical shells resting on the Pasternak elastic foundation on the basis of FOSDT are derived in the framework of Donnell-type shell theory. The novelty of present work is to achieve closed-form solutions for critical hydrostatic pressures of EG orthotropic cylindrical shells resting on Pasternak elastic foundation based on FOSDT. The expressions for critical hydrostatic pressures of EG orthotropic cylindrical shells with and without an elastic foundation based on CST are obtained, in special cases. Finally, the effects of Pasternak foundation, shear stresses, orthotropy and heterogeneity on critical hydrostatic pressures, based on FOSDT are investigated.

ABSTRACT: In this study, the non-linear stability of three-layered conical shells with functionally graded core have not been investigated previously. The purpose of this paper is to study this problem. The large de cition theory with von Karman -Donnell-type of kinematic non-linearity is used to deduce the basic equations. The basic equations are solved analytically by using Superposition and Galerkin methods. The influences of several parameters on the dimensionless non-linear critical axial loads are discussed.

ABSTRACT: The prime aim of the present study is to present analytical formulations and solutions for the stability analysis of heterogeneous orthotropic truncated conical shell subjected to external (lateral and hydrostatic) pressures with mixed boundary conditions using the Donnell shell theory. The mixed boundary conditions are as follows: at one end of FGM truncated conical shell is a sleeve that prevents its longitudinal displacement and rotation, and the other end is a freely support. The basic equations of heterogeneous
orthotropic truncated conical shells are derived and solved applying the Galerkin’s method for the two cases of mixed boundary conditions using new approximation functions. Then the expressions for dimensionless critical external pressures are obtained. The results are compared and validated with the results available in the literature. Finally, a detailed parametric study is conducted to study the effect of heterogeneity, material orthotropy and mixed boundary conditions on the critical external pressures.

ABSTRACT: This paper is concerned with the elastic buckling of vertical cylindrical shells under combined end pressure and body force. Such buckling problems are encountered when cylindrical shells are used in a high-g environment such as the launching of rockets and missiles under high-propulsive power. The vertical shells may have any combination of free, simply supported, and clamped ends. Based on the Goldenveizer-Novozhilov thin shell theory, the total potential energy functional is presented and the buckling problem is solved using the Ritz method. Highlight in the formulation is the importance of the correct potential energy functional which includes the shell shortening due to the circumferential displacement. The omission of this contributing term leads to erroneous buckling solutions when the cylindrical shell is not of moderate length (length-to-radius ratio smaller than 0.7 or larger than 3). New solutions for body-force buckling parameters are presented for stubby cylindrical shells to long tube-like shells that approach the behavior of columns. The effects of the shell thickness and length on buckling parameter are also investigated.

ABSTRACT: This paper is concerned with the development of a global p-element method for the analysis of self-weight buckling of thin cylindrical shells. Such buckling problems occur when cylindrical shells are subject to high-g acceleration, for instance the launching of rockets and missiles under high propulsive power. The cylindrical shells may have any combination of free, simply supported and clamped ends. A p-element computational method has been developed based on various thin shell theories including Donnell, Sanders and Goldenveizer-Novozhilov models. The strain energy for the global element during buckling is formulated and
an eigenvalue equation is derived. Unlike the conventional buckling problem where the eigenvalue is directly solved, a pre-determined buckling parameter is fixed at the outset for a geometric-dependent stiffness and a recursive numerical procedure is developed to compute the effect of critical buckling length. The critical buckling length is found to be proportional to thickness to a power of approximately 0.9. The effects of shell thickness and length on buckling parameter are also investigated. Comparison of results from various shell theories indicates solutions of the Sanders and Goldeneveizer-Novozhilov shell theories are in excellent agreement while the Donnel shell theory is good for buckling of short cylindrical shells.

ABSTRACT: Small submersibles, which permit man to observe and work as part of the three-dimensional undersea environment, are among the most promising tools for achieving effective exploitation of the oceans. An important element of any submersible is the pressure hull, frequently contributing one-fourth to one-half and more of the total vehicle weight. The Naval Ship Research and Development Center has played a major role in developing pressure hull structures for undersea vehicles. This paper describes some of the principal structural features of existing and envisioned small submersibles and summarizes recent advances in design and analysis methods. Particular emphasis is given to computer programs developed and/or used at the Center. Specifically, it describes advances in stress, stability, and vibration analyses as well as early stage developments in structural fatigue and reliability analyses. It also discusses computer programs and automated procedures designed for rapid response in feasibility studies and preliminary and final design cycles; these provide for both the generation of input data and the graphical display of computed results.

ABSTRACT: The correct formulations for solving nonlinear structural problems by the finite element method have now been established. Numerous investigators have given the derivation for the solution of problems by the incremental tangent stiffness method and total formulation methods. These derivations have been applied to many problems and the results have been shown to be quite accurate for the problems that have been selected. However there is one area of application that has received practically no attention. This is in the investigation of the buckling strength of pressure loaded rings and shells. The effect of pressure loading where the loading changes direction as the structure deforms has been included in several previous derivations, by what is known as the load stiffness matrix, but to the author's knowledge no one has investigated problems where this effect has been included in the solution procedure. For rings and some buckling modes of shells, the results can be in error by as much as 50%. This paper will describe an iterative process for solving the nonlinear equilibrium equations and correcting the loads to include the effect of changing geometry at each load level. This approach is different from the classical eigenvalue or bifurcation method. Several case studies will be described which were performed on ring and shell problems. The geometry of these example problems were axisymmetric and in order to apply a nonlinear collapse analysis, the structure had to be perturbed out of its axisymmetric pattern into a buckling pattern. Imperfect geometry and very small concentrated loads were used to cause this perturbation and this will be described in the paper. The sensitivity of the computed collapse pressure to the finite element mesh gradation will be discussed. A comparison will be made between results obtained by
including the effect of following pressure load and those obtained by not including this effect.

ABSTRACT: In this study cylindrical boundary conditions for finite element analysis are formulated that allow torsional displacement and buckling of a sector of a cylinder of half axial height, and of a circumferential arc angle that will divide into 360°. Finite element tests are carried out on unstiffened elastic cylinders to verify the method of analysis against classical elastic torsional buckling theory. Elastic–plastic limit point finite element tests are carried out on ring and stringer stiffened and stringer stiffened cylinders to investigate the effects of stiffeners on post-buckling behaviour in torsion. A stringer stiffened cylinder is subjected to many combinations of axial force and surface pressure in the elastic range of response and then tested to failure in torsion to investigate the effects of axial and surface pressure loads on the resistance to plastic collapse in torsion.

ABSTRACT: The buckling resistance of orthogonally stiffened cylinders is investigated for elastic critical buckling and non-linear elasto-plastic buckling tests. The effects of residual stresses arising from cold forming the cylinder and welding frame components are considered in the analysis of two stiffened cylinder models with similar material weights and different geometric spacings. A static axial load is applied to the models to represent loading from the supported structure followed by a non-linear elasto-plastic buckling step representing a wave loading combined with hydrostatic pressure, producing large displacement compartment buckling. Residual stress is shown to cause a reduction in buckling resistance of approximately 25% in the stiffened cylinder segments.

ABSTRACT: The buckle and collapse of offshore pipeline subjected to combined actions of tension, bending, and external pressure during deepwater installation has drawn a great deal of attention. Extended from the model initially proposed by Kyriakides and his co-workers, a 2D theoretical model which can successfully account for the case of simultaneous tension, bending, and external pressure is further developed. To confirm the accuracy of this theoretical method, numerical simulations are conducted using a 3D finite element model within the framework of ABAQUS. Excellent agreement between the results validates the effectiveness of this theoretical method. The model is then used to study the effects of several important factors such as load path,
material properties, and diameter-to-thickness ratio, etc., on buckling behaviors of the pipes. Based upon parametric studies, a few significant conclusions are drawn, which aims to provide the design guidelines for deepwater pipeline with solid theoretical basis.

ABSTRACT: By considering the characteristics of deformation of rotationally periodic structures under rotationally periodic loads, the periodic structure is divided into some identical substructures in this study. The degrees-of-freedom (DOFs) of joint nodes between the neighboring substructures are classified as master and slave ones. The stress and strain conditions of the whole structure are obtained by solving the elastic static equations for only one substructure by introducing the displacement constraints between master and slave DOFs. The complex constraint method is used to get the bifurcation buckling load and mode for the whole rotationally periodic structure by solving the eigenvalue problem for only one substructure without introducing any additional approximation. The finite element (FE) formulation of shell element of relative degrees of freedom (SERDF) in the buckling analysis is derived. Different measures of tackling internal degrees of freedom for different kinds of buckling problems and different stages of numerical analysis are presented. Some numerical examples are given to illustrate the high efficiency and validity of this method.

ABSTRACT: In case of buckling of spherical shells, most of experiments have been performed with the use of a spherical cap clamped along the circular boundary, and the buckling pressure obtained shows complicated trends which cannot be predicted by the conventional theory; in some cases, experimental buckling pressure raises beyond its theoretical prediction. This difficulty is settled in the present paper with the aid of the finite element calculations by introducing not only geometrical imperfections but also displacements of the clamped boundary of the spherical cap.

INTRODUCTION: The technical assessment studies of pool-type LMFBR have been made for the purpose of the costdown and the high reliability of power plants by Central Research Institute of Electric Power Industry and nuclear power plant makers (Hitachi, Toshiba and Mitsubishi Ltd.) in Japan. Since earthquakes take place frequently in Japan, one of the important subjects is the seismic analysis of the reactor vessels that may be subjected to various dynamic loads and may buckle in seismic excitations. It is known that shear type buckling modes take place for short cylindrical shells under lateral loads. Although there is much experimental and analytical data on the buckling of cylindrical shells under axial compression, not so many studies have been done on shear buckling problems which are necessary for the seismic analysis of nuclear reactor vessels, and there are many points to be clarified taking into account the various parameters affecting shear buckling. In this study the shear type buckling of cylindrical shells is investigated by experiments and nonlinear finite element analysis taking various parameters into account.
ABSTRACT: Buckling tests for nearly perfect cylinders and cylinders with intentional imperfection made by press-working technique were carried out subjected to transverse shearing loads. The radius-to-thickness ratios were 50-200 and bending-to-shear stress ratios were 1.2-5.0, where both types of buckling in shear and in bending might occur. The purposes of these tests were to evaluate the interaction relation between elastic-plastic buckling strength in bending and in shear and to clarify the imperfection effect on these two types of buckling. From test results, we proposed a weak interaction between buckling in shear and in bending and correction factors of buckling loads for larger imperfection in the interim buckling design guide of LMFBR.

ABSTRACT: A geometrically nonlinear stability analysis of a torispherical shell subjected to internal pressure was performed, using doubly curved finite elements which provide an exact description of the middle surface. The critical pressure and the corresponding buckling mode were calculated. Internal pressure-nodal displacement curves were obtained for the pre- and postbuckling regions for the computation model. The buckling modes in bifurcation points were calculated and the changes of the deflection shape on the postbuckling paths analyzed. The effect of geometric imperfections on the critical pressure was studied. Imperfection shapes affine to buckling modes in bifurcation points were investigated and critical pressure-imperfection amplitude curves obtained.

ABSTRACT: The elastic stability of an imperfect torispherical shell subjected to internal pressure was analyzed numerically using the finite element method. Imperfection patterns affine to the buckling mode in the bifurcation points of the perfect structure were studied and internal pressure-nodal displacement curves obtained for the pre- and postbuckling regions of the computation model. The effect of the imperfection pattern amplitude on the critical pressure and the postbuckling minimum was analyzed. The imperfection sensitivity was presented graphically.

ASBSRACT: The imperfection sensitivity of torispherical shells subjected to internal pressure was investigated numerically, using the finite element displacement method. Imperfection patterns affine to the first buckling mode at the bifurcation points of the perfect structure were considered. Load-normal displacement curves were obtained for the pre- and postbuckling regions of the perfect computation model and also for imperfect computation models with different imperfection amplitudes. The dependence of the critical pressure and the postbuckling minimum on the imperfection amplitudes was presented graphically. Torispherical shells subjected to internal pressure failed to demonstrate any significant imperfection sensitivity for the imperfection
patterns analysed.

ABSTRACT: The constitutive equation for an elastic-plastic material model was derived using the von Mises yield criterion and assuming isotropic strain hardening. A layered finite element permitting geometrically linear and geometrically nonlinear elastic-plastic analysis of thin shell structures is presented. The effect of linear strain hardening on the size of plastic regions and the distribution of internal forces in an internally pressurized torispherical shell was analyzed. At sufficiently high pressures a significant difference in the distribution of internal forces was observed between elastic, perfectly plastic and strain hardening material. The effect of the size of plastic regions on the difference in the magnitude of internal forces obtained by geometrically linear and geometrically nonlinear computations of the torispherical shell was studied. An increase in the size of the plastic region was found to produce greater differences in the computation of meridional bending moments than in the computation of hoop stress resultants.

P.M. Baiz and M.H. Aliabadi (Imperial College London, South Kensington, SW7 2AZ, London, UK),

ABSTRACT: In this work a boundary element (BE) formulation for buckling problem of shear deformable shallow shells is presented. A set of five boundary integral equations are obtained by coupling two-dimensional plane stress elasticity with shear deformable plate bending (Reissner). The domain integrals appearing in the formulation (due to the curvature and due to the domain load) are transferred into equivalent boundary integrals. The BE formulation is presented as an eigenvalue problem, to provide direct evaluation of critical load factors and buckling modes. Several examples are presented. The BE results for a cylindrical shallow shell with different curvatures are compared with other numerical solutions and good agreements are obtained.

P. M. Baiz and M. H. Aliabadi (Department of Aeronautical Engineering, Imperial College, London),

ABSTRACT: This paper presents applications where the DBEM formulations presented by Dirgantara and Aliabadi [3, 4] is combined with the multi region BEM presented recently by Baiz and Aliabadi [2], for the analysis of cracked shear deformable plates and shallow shell assemblies. Stress intensity factors are obtained using the CTOD technique. Several examples are solved to demonstrate the capabilities of the proposed technique. Comparing DBEM with FEM, it was clear that good accuracy and efficiency can be achieved with the present multi region DBEM.
ABSTRACT: Boundary element only formulations for the stability analysis of isotropic and anisotropic plates are presented. Domain integrals which arise in the formulation are transformed into boundary integrals by the radial integration method and the dual reciprocity method. Plate buckling equations are formulated as standard eigenvalue problem. The accuracy of the proposed formulations including buckling coefficients and buckling modes is assessed by comparison with results from literature.

ABSTRACT: This paper presents four boundary element formulations for post buckling analysis of shear deformable shallow shells. The main differences between the formulations rely on the way non-linear terms are treated and on the number of degrees of freedom in the domain. Boundary integral equations are obtained by coupling boundary element formulation of shear deformable plate and two-dimensional plane stress elasticity. Four different sets of non-linear integral equations are presented. Some domain integrals are treated directly with domain discretization whereas others are dealt indirectly with the dual reciprocity method. Each set of non-linear boundary integral equations are solved using an incremental approach, where loads and prescribed boundary conditions are applied in small but finite increments. The resulting systems of equations are solved using a purely incremental technique and the Newton–Raphson technique with the Arc length method. Finally, the effect of imperfections (obtained from a linear buckling analysis) on the post-buckling behaviour of axially compressed shallow shells is investigated. Results of several benchmark examples are compared with the published work and good agreement is obtained.

ABSTRACT: This chapter describes recent developments on the buckling and postbuckling analysis of thin walled structures by the Boundary Elements Method (BEM). Boundary integral equations are obtained by coupling two dimensional plane stress elasticity with boundary element formulation of Reissner plate bending. The linear buckling problem is formulated as a standard eigenvalue problem, in order to obtain directly critical loads and buckling modes as part of the solution. A multi-region BEM formulation is also introduced for the analysis of local buckling in thin walled assemblies. Nonlinear equations for large deflection and postbuckling analysis are also investigated. Nonlinear system of equations is solved using an incremental solution strategy, where displacements and tractions are applied in small but finite increments. Several examples of flat and curved plates (shallow shells) with different dimensions and boundary conditions are analyzed, including plate assemblies. Results are compared with other numerical and analytical solutions, and good agreement is obtained.
ABSTRACT: Multilevel optimization including progressive failure analysis and robust design optimization for composite stiffened panels, in which the ultimate load that a post-buckled panel can bear is maximized for a chosen weight, is presented for the first time. This method is a novel robust multiobjective approach for structural sizing of composite stiffened panels at different design stages. The approach is integrated at two design stages labelled as preliminary design and detailed design. The robust multilevel design methodology integrates the structural sizing to minimize the variance of the structural response. This method improves the product quality by minimizing variability of the output performance function. This innovative approach simulates the sequence of actions taken during design and structural sizing in industry where the manufacture of the final product uses an industrial organization that goes from the material characterization up to trade constraints, through preliminary analysis and detailed design. The developed methodology is validated with an example in which the initial architecture is conceived at the preliminary design stage by generating a Pareto front for competing objectives that is used to choose a design with a required weight. Then a robust solution is sought in the neighbourhood of this solution to finally find the layup for the panel capable of bearing the highest load for the given geometry and boundary conditions.

ABSTRACT: The postbuckling behaviour of a flat, stiffened, carbon fibre composite compression panel has been studied, theoretically and experimentally. The panel had a collapse load in excess of three times the buckling load. An initial failure mechanism leading to eventual explosive collapse of the panel is identified and the damaging stress resultant is measured in the panel and predicted from a finite element analysis.

ABSTRACT: In this paper, a finite element analysis is performed for buckling of the pressure vessels with ellipsoidal head subjected to uniform pressure. According to the characteristic of deformation of the pressure vessel, it is divided into some identical substructures. The degrees of freedom (DOFs) of joint nodes between the neighboring substructures are classified as master and slave ones. The stress and strain distributions of the whole structure are obtained by solving the static equations for only one substructure by introducing the displacement constraints between master and slave DOFs. The complex constraint method has been used to get the buckling load and mode for the whole structure by solving the eigenvalue problem for only one substructure without introducing any additional approximation. Some numerical examples have been given to illustrate the high efficiency and validity of this method.

ABSTRACT: For the accurate prediction of the collapse behaviour of thin cylindrical shells, it is accepted that geometrical and other imperfections in material properties and loading have to be accounted for in the simulation. There are different methods of incorporating imperfections, depending on the availability of accurate imperfection data. The current paper uses a spectral decomposition of geometrical uncertainty (Karhunen–Loève expansions). To specify the covariance of the required random field, two methods are used. First, available experimentally measured imperfection fields are used as input for a principal component analysis based on pattern recognition literature, thereby reducing the cost of the eigenanalysis. Second, the covariance function is specified analytically and the resulting Friedholm integral equation of the second kind is solved using a wavelet-Galerkin approach. Experimentally determined correlation lengths are used as input for the analytical covariance functions. The above procedure enables the generation of imperfection fields for applications where the geometry is slightly modified from the original measured geometry. For example, 100 shells are perturbed with the resulting random fields obtained from both methods, and the results in the form of temporal normal forces during buckling, as simulated using LS-DYNA, as well as the statistics of a Monte Carlo analysis of the 100 shells in each case are presented. Although numerically determined mean values of the limit load of the current and another numerical study differ from the experimental results due to the omission of
imperfections other than geometrical, the coefficients of variation are shown to be in close agreement.

ABSTRACT: The optimization of shell buckling is performed considering peak normal force and absorbed internal energy in the presence of geometrical imperfections implemented through Karhunen-Loève expansions. Initially, the mass of a shell is minimized in the presence of random initial imperfections by allowing cutouts in the material, subject to constraints on the average peak force and average internal energy. Then, robustness is considered by minimizing the coefficient of variation of the normal peak force while constraining the average peak force and average internal energy. LS-OPT is used both to generate an experimental design and to perform a Monte Carlo simulation (96 runs) using LS-DYNA at each of the experimental design points. The effect of imperfections when minimizing the mass is not large, but when considering robustness, however, the optimal design has a substantially increased hole size and increased shell thickness, resulting in a heavier design with maximal robustness within the constraints.

ABSTRACT: The buckling stresses of model grain bins with varying radius to wall thickness (r/t) ratios and levels of internal pressure were determined. No available analytical model effectively predicted the observed results. A best fit model with lower bounds is presented that relates the buckling stress to the level of lateral grain pressure and the r/t ratio of the bin wall.

ABSTRACT: In this paper we show the existence of global minimizers for the geometrically non-linear equations of elastic plates, in the framework of the general 6-parameter shell theory. A characteristic feature of this model for shells is the appearance of two independent kinematic fields: the translation vector field and the rotation tensor field (representing in total 6 independent scalar kinematic variables). For isotropic plates, we prove the existence theorem by applying the direct methods of the calculus of variations. Then, we generalize our existence result to the case of anisotropic plates.

ABSTRACT: The optimum design of stiffened shell structures is investigated using a robust and efficient optimization algorithm where the total weight of the structure is to be minimized subject to behavioral constraints imposed by structural design codes. Evolutionary algorithms and more specifically the evolution strategies (ES) method, specially tailored for this type of problems, are implemented for the solution of the structural optimization problem. The discretization of the stiffened shell is performed by means of cost-effective and reliable shell and beam elements that incorporate the natural mode concept. Three types of design variables are considered: sizing, shape, and topology. A benchmark test example is examined where the efficiency and robustness of ES over other optimization methods is investigated. Two case studies of stiffened shells are subsequently presented, where a parametric study is undertaken to obtain the most efficient design compatible with the regulations suggested by design codes such as Eurocode. The important role of the stiffeners and how they can be optimally chosen to improve the performance of shell structures in terms of carrying capacity and economy is demonstrated.

ABSTRACT: Stochastic finite-element analysis of shells is performed using the spectral representation method for the description of the random fields in conjunction with the local average method for the formulation of the stochastic stiffness matrix of the elements. A stochastic formulation of the nonlinear triangular composites facet triangular shell element is implemented for the stability analysis of cylindrical panels with random initial imperfections. The imperfections are described as a two-dimensional univariate homogeneous stochastic field. The elastic modulus and the shell thickness are also described as two-dimensional univariate homogeneous stochastic fields. The variability of the limit load of the cylindrical panel is then computed using the Monte Carlo simulation. Useful conclusions for the buckling behavior of cylindrical panels with random initial imperfections are derived from the numerical tests presented in this paper. These tests also demonstrate the applicability of the proposed methodology in realistic problems.

ABSTRACT: The effect of material and thickness imperfections on the buckling load of isotropic shells is investigated in this paper. For this purpose, the concept of an initial ‘imperfect’ structure is introduced involving not only geometric deviations of the shell structure from its perfect geometry but also a spatial variability of the modulus of elasticity as well as the thickness of the shell. The initial geometric imperfections are described as a two-dimensional uni-variate (2D-1V) stochastic field with statistical properties that are either based on an available data bank of measured initial imperfections or assumed, in cases where no experimental data is available. In order to describe the non-homogeneous characteristics of the initial imperfections, the spectral
representation method is used in conjunction with an autoregressive moving average model with evolutionary power spectra based on a statistical analysis of the experimentally measured imperfections. In cases where no experimental results is available, the initial imperfections are assumed to be homogeneous and their impact on the buckling load is investigated on the basis of ‘worst’-case scenarios with respect to the correlation length parameters of the stochastic fields. The elastic modulus and the shell thickness are described as 2D-1V non-correlated homogeneous stochastic fields, while the stochastic stiffness matrix of the shell elements is formulated using the local average method. The Monte Carlo Simulation method is used to calculate the variability of the buckling load, while for the determination of the limit load of the shell, a stochastic formulation of the elastoplastic and geometrically non-linear TRIC facet triangular shell element is implemented.

ABSTRACT: The optimum design of isotropic shell structures with random initial geometric, material and thickness imperfections is investigated in this paper and a robust and efficient methodology is presented for treating such problems. For this purpose, the concept of an initial “imperfect” structure is introduced involving not only geometric deviations of the shell structure from its perfect geometry but also a spatial variability of the modulus of elasticity as well as of the thickness of the shell. An efficient reliability-based design optimization (RBDO) formulation is proposed. The objective function is considered to be the weight of the structure while both deterministic and probabilistic constraints are taken into account. The overall probability of failure is taken as the global probabilistic constraint for the optimization procedure. Numerical results are presented for a cylindrical panel, demonstrating the efficiency as well as the applicability of the proposed methodology in obtaining rational optimum designs of imperfect shell-type structures.

ABSTRACT: The investigator and his colleagues focus on the efficient numerical computation of global solutions of problems of nonlinear elastostatics in a high-performance computational environment. Particular attention is paid to the global post-critical behavior of symmetric imperfection-free elastic shell structures --- the analysis of which has great significance in understanding the large deformation response and ultimate collapse scenario of realistic engineering structures. A major theme of the work is to exploit the natural parallelism, via group theoretic techniques, in an important class of engineering problems characterized by underlying symmetries. They also investigate the use of automatic differentiation software in the context of those problems. Finally, they study the effectiveness of symmetry-motivated preconditioners, within the context of Krylov iterative subspace methods, for a class of “almost-symmetric” problems in structural mechanics. Due to their high strength-to-weight ratios, thin shell structures have been used extensively in aerospace, civil, mechanical and nuclear engineering applications, e.g., dome roofs, aerospace vehicles, pressure vessels,
containment vessels, etc. Yet the ability of engineers to predict the ultimate failure of such systems has heretofore been more of an art than a science (relying heavily upon costly experimental verification -- see "Computerized Buckling Analysis of Shells", by D. Bushnell, Martinus Nijhoff 1985). The investigators combine new mathematical ideas of symmetry and nonlinear analysis with high-performance computing methodology to analyze such systems efficiently and systematically. A long-term goal is to provide engineers with useful tools for the systematic analysis (and ultimately better design) for this important class of structures. Funding for the project is provided by the Computational Mathematics program and the Office of Multidisciplinary Activities in MPS and by the New Technologies program in CISE.

ABSTRACT: Discrepancies observed in experimental buckling loads of thin shells are often due to the random nature of initial shape imperfections, material properties and non-perfect boundary conditions. The work presented in this paper aims at finding the optimal dimensions of a single bay of a ring-stiffened cylinder representative of a submarine pressure hull under external hydrostatic pressure. It accounts for uncertainties of material properties and amplitudes of imperfections, supposed distributed over the two most critical buckling modes in a first simplified approach (overall and interframe buckling modes). The Reliability-Based Design Optimization problem considered here consists in finding an optimal deterministic design minimizing the weight of the structure while meeting a prescribed safety level. The present work hinges on closed-form / semi-numerical solutions for the buckling problems in a first approach. FORM reliability results based on a 3D shell finite element model are presented in a second part, in an effort to base such a design optimization on a more accurate mechanical model and to provide a sound basis for the optimal design of structures prone to buckling.

ABSTRACT: In the present paper, the effect of random non-uniform axial loading on the buckling behaviour of isotropic thin-walled imperfect cylindrical shells is investigated. Random initial (out-of-plane) geometric imperfections, thickness and material property variability, together with a non-uniform stochastic axial loading are incorporated into a cost-effective non-linear stochastic finite element analysis using the non-linear TRIC shell element. For this purpose, the concept of an initial ‘imperfect’ structure is introduced involving not only deviations of the shell structure from its perfect geometry but also a spatial variability of the modulus of elasticity as well as of the thickness of the shell. The initial imperfections as well as the axial loading are modeled as stochastic fields with statistical properties that are either based on an available data bank of measured initial imperfections or assumed, in cases where no experimental data is available. Based on these simulation features, a simple and realistic approach is proposed for the estimation of the variability (scatter) of the limit loads by means of a brute-force Monte Carlo Simulation procedure. In addition, ‘worst case’ buckling scenarios are identified by means of a sensitivity analysis with respect to assumed parameters used for the description of stochastic fields that are not supported by corresponding experimental measurements. In addition it is shown that in the context of such sensitivity analysis, modeling of the non-uniformity of the axial loading is, from a computational point of view, fully equivalent to modeling the geometric boundary imperfections. The numerical tests performed demonstrate the significant role that the random varying axial loading plays on the buckling behaviour of imperfection sensitive structures like the axially compressed thin-walled cylinder considered in this study.

“A computationally efficient method for the buckling analysis of shells with stochastic imperfections”,

ABSTRACT: A computationally efficient method is presented for the buckling analysis of shells with random imperfections, based on a linearized buckling approximation of the limit load of the shell. A Stochastic Finite Element Method approach is used for the analysis of the “imperfect” shell structure involving random geometric deviations from its perfect geometry, as well as spatial variability of the modulus of elasticity and thickness of the shell, modeled as random fields. A corresponding eigenproblem for the prediction of the buckling load is solved at each MCS using a Rayleigh quotient-based formulation of the Preconditioned Conjugate Gradient method. It is shown that the use of the proposed method reduces drastically the computational effort involved in each MCS, making the implementation of such stochastic analyses in real-world structures affordable.

ABSTRACT: In this paper, the effect of material and thickness spatial variation on the buckling load of isotropic shells with random initial geometric imperfections is investigated. To this purpose, a random spatial variability of the elastic modulus as well as of the thickness of the shell is introduced in addition to the random initial geometric deviations of the shell structure from its perfect geometry. The main novelty of this paper compared to previous works is that a non-Gaussian assumption is made for the distribution of the two aforementioned uncertain parameters i.e. the modulus of elasticity and the shell thickness which are described by two-dimensional univariate (2D-1V) homogeneous non-Gaussian stochastic fields. The initial geometric imperfections are described as a 2D-1V Gaussian non-homogeneous stochastic field with properties derived from corresponding experimental measurements. Numerical examples are presented focusing on the influence of the non-Gaussian assumption on the variability of the buckling load, which is calculated by means of the Monte Carlo Simulation method. It is shown that the choice of the marginal probability distribution for the description of the material and thickness variability is crucial since it affects significantly the statistics of the buckling load of imperfection sensitive shell-type structures.

ABSTRACT: Buckling loads of thin-walled I-section beam-columns exhibit a wide stochastic scattering due to the uncertainty of imperfections. The present paper proposes a finite element based methodology for the stochastic buckling simulation of I-sections, which uses random fields to accurately describe the fluctuating size and spatial correlation of imperfections. The stochastic buckling behaviour is evaluated by crude Monte-Carlo simulation, based on a large number of I-section samples, which are generated by spectral representation and subsequently analyzed by non-linear shell finite elements. The application to an example I-section beam-column demonstrates that the simulated buckling response is in good agreement with experiments and follows key concepts of imperfection triggered buckling. The derivation of the buckling load variability and the stochastic interaction curve for combined compression and major axis bending as well as stochastic sensitivity studies for thickness and geometric imperfections illustrate potential benefits of the proposed methodology in buckling related research and applications.

ABSTRACT: An asymptotic spectral stochastic approach is presented for computing the statistics of the equilibrium path in the post-bifurcation regime for structural systems with random material properties. The approach combines numerical implementation of Koiter’s asymptotic theory with a stochastic Galerkin scheme and collocation in stochastic space to quantify uncertainties in the parametric representation of the load–displacement relationship, specifically in the form of uncertain post-buckling slope, post-buckling curvature, and a family of stochastic displacement fields. Using the proposed method, post-buckling response statistics for two plane frames are obtained and shown to be in close agreement with those obtained from Monte Carlo simulation, provided a fine enough spectral representation is used to model the variability in the random dimension.

ABSTRACT: The present paper addresses the problem of the response variability of structures, which experience bifurcation buckling. The buckling strength of such structures may be very sensitive to the small structural imperfections, which are practically inevitable in all real structures. A new general method is presented, which is particularly suitable for the treatment of the stochastic nature of the structural imperfections. The new method is exemplified with two well known buckling problems. The first problem is the buckling of a column on a linear elastic foundation. The shape imperfections of the column are treated as a weakly stationary random process with a pre-specified auto-correlation function. The second problem is the buckling of a thin cylindrical shell under axial compression. The shape imperfections of the shell are treated as a broad-band random Gaussian process with an arbitrarily specified power spectral density function. In both cases, representative numerical results are presented for the purpose of improving our understanding of the response variability of these structures.

ABSTRACT: In this paper, the effect of random initial geometric, material and thickness imperfections on the buckling load of isotropic cylindrical shells is investigated. To this purpose, a stochastic spatial variability of the elastic modulus as well as of the thickness of the shell is introduced in addition to the random initial geometric deviations of the shell structure from its perfect geometry. The modulus of elasticity and the shell thickness are described by two-dimensional univariate (2D-1V) homogeneous non-Gaussian translation stochastic fields. The initial geometric imperfections are described as a 2D-1V homogeneous Gaussian stochastic field. A numerical example is presented examining the influence of the non-Gaussian assumption on the variability of the buckling load. In addition, useful conclusions are derived concerning the effect of the various marginal probability density functions as well as of the spectral densities of the involved stochastic fields on the buckling behaviour of shells, as a result of a detailed sensitivity analysis.

OBJECTIVES: 1. To determine the worst imperfection shape for axially loaded cylinders, and 2. To develop an equivalent deterministic imperfection that brings the finite element solution into acceptable agreement with the lower bound of test results and can be used in the numerical analysis and design of cylindrical shells.

ABSTRACT: A simple general method for the evaluation of the effect of shape imperfections on the buckling strength of thin shells is briefly presented. This method is applied to the axially compressed thin cylindrical shell resulting in an efficient numerical procedure for the computation of its buckling strength. The procedure is applicable to any sufficiently smooth imperfection pattern and has given results in good agreement with the available experimental data.
ABSTRACT: It is well known that the response of structures subjected to bifurcation buckling may be affected radically, both quantitatively and qualitatively, by small structural imperfections. A new analytical method is presented for the determination of the buckling strength of such structures. The method results in the numerical solution of an ordinary matrix eigenvalue problem in a simple closed-form formula that is particularly suitable for the study of the response variability of these structures. The method is exemplified with the investigation of the well-known problem of the buckling of the axially compressed thin cylindrical shell. The structural imperfections of the shell are treated as a broadband random Gaussian process with an arbitrarily specified power spectral density function. Numerical results are obtained that demonstrate the inadequacy of Koiter’s analysis for such problems, the simplicity and efficiency of the present method, and the significant effect of the power spectral density function of the imperfection pattern on the variability of the buckling strength of the shell.

ABSTRACT: The present chapter addresses a sixty-year-old problem, namely the buckling analysis and design of imperfection-sensitive structures. The problem has been the focus of increased research interest recently because such structures are particularly common in advanced engineering applications. The chapter starts with an introductory-level overview of the problem and concentrates on the presentation of a new method which is particularly suitable and efficient for the problem. The new method has become feasible by modern advances in computer-aided algebra and calculus and has been tentatively named Critical Imperfection Magnitude Method or CIM Method, in short. It is based on three well-established pillars, namely the classical stability theory of structures, the perturbation methods of applied mathematics, and the reliability methods for the design of structures. As compared to previous methods in the field, the new method is much more general in scope, conceptually much simpler, and numerically much more efficient. A major result of the method is the clear identification of the significant imperfection sources and components from the very large number of possible sources and components. Furthermore, the new method can be easily combined with the finite element method in order to provide the design engineer with a readily available means for the rational design of imperfection-sensitive structures in buckling.

ABSTRACT: Buckling is a critical issue for structural stability in structural design. In most of the buckling analyses, applied loads, structural and material properties are considered certain. However, in reality, these parameters are uncertain. Therefore, a prognostic solution is necessary and uncertainties have to be considered. Fuzzy logic algorithms can be a solution to generate more dependable results. This study investigates the material uncertainties on column design and proposes an uncertainty model for critical column buckling reinforced concrete buildings. Fuzzy logic algorithm was employed in the study. Lower and upper bounds of elastic modulus representing material properties were defined to take uncertainties into account. The results show that uncertainties play an important role in stability analyses and should be considered in the design. The proposed approach is applicable to both future numerical and experimental researches. According to the study
results, it is seen that, calculated buckling load values are stayed in lower and upper bounds while the load values are different for same concrete strength values by using different code formula.

ABSTRACT: One possible avenue that may improve design against buckling is to recognise and account for the random nature of initial geometric imperfections introduced by manufacturing. This paper presents the application of a probabilistic methodology to the design and analysis of cylindrical shells under axial compression. Results from two cases are presented and compared: the first involves stringer-stiffened steel cylinders failing elastoplastically, whereas the second examines unstiffened composite cylinders buckling elastically. In both cases, the method is underpinned by statistical analysis of imperfections measured on nominally identical specimens. Nonlinear FE analysis is used for strength assessment and the results of the statistical analysis are introduced in the imperfection modelling. It is demonstrated that the method has advantages over code design based on ‘lower bound’ curves, in terms of the calculated buckling loads but also in offering a systematic and rational way by which randomness in imperfections can be assessed.

ABSTRACT: This paper describes a measurement system that was developed for an experimental study on buckling of glass reinforced composite cylinders. An automated non-contact laser device operating inside the test specimen provided a three dimensional scanning system for measuring the deformation of the shell wall. The measurement system was used to obtain the initial geometric imperfections, as well as the deformation under varying control axial displacement. All loading and data acquisition operations were carried out using
advanced computer controlled techniques. Due to the large number of measurements undertaken in each test, data collection was followed by processing and reduction techniques, thus delivering the data in a form suitable for finite element analysis and comparative studies. Typical results are presented in order to demonstrate the reliability, accuracy and versatility of the system.

ABSTRACT: This paper presents the results of buckling tests on laminated composite cylinders made from glass fibre reinforced plastic (GFRP). The laminates used are of type ‘DF1400’ consisting of woven glass fibre roving within a polyester resin matrix. In total, six cylinders constructed from two-ply laminates, in which the main variable is the laminate orientation, were tested under axial compression. The specimen details, experimental set-up and loading arrangements are described, and a detailed account of the test results is given. The results include thickness and imperfection mapping, and displacement, load and strain measurements. Use was made of an automated laser scanning system, which was developed for measuring the initial geometric imperfections as well as buckling deformations during various stages of loading. The results of this experimental study demonstrate the influence of laminate orientation on the buckling strength of composite cylinders, and provide detailed information necessary for analytical and design investigations.

References listed at the end of the paper:

ABSTRACT: The experimental behaviour of laminated glass fibre-reinforced plastic (GFRP) cylinders under compression and bending is examined in this paper. The laminates are of type ‘Rovimat 1200’ consisting of woven glass fibre roving, with a chopped mat on one side, within a polyester resin matrix. Two and three-ply cylinders with various orthogonal orientations were considered, for which the nominal radius-to-thickness ratio was about 108 and 72, respectively. Use was made of an automated laser scanning system for measuring geometric imperfections and progressive buckling deformations of the models. Following a description of the specimen and loading details, the results of experiments on ten models are presented. The results include thickness and imperfection mapping, displacement and load measurements as well as important observations regarding the failure mode and overall behaviour of each model. The findings highlight the effects of laminate construction and loading eccentricity on the buckling strength of cylinders within the range examined. Both elastic buckling and material-dominated failure modes were observed, depending on the slenderness and load type considered. The tests also provide detailed experimental data, which are necessary for further analytical and design studies.

ABSTRACT: This paper gives the details of a numerical finite element validation study for laminated GFRP cylinders subjected to concentric and eccentric compression. The laminates are of type ‘Rovimat 1200’ consisting of woven glass fibre roving, with a chopped mat on one side, within a polyester resin matrix. Two and three-ply cylinders with various orthogonal orientations are considered, for which the nominal radius-to-thickness ratio is about 108 and 72, respectively. The numerical results are compared to findings from a previous experimental investigation in which detailed measurements were obtained. Following a brief description of the experimental work, details of the development of suitable finite element models are presented and associated limitations are highlighted. Careful attention is given to thickness idealisation as well as the introduction of geometric imperfections into the numerical models. Both linear eigenvalue analysis and geometrically nonlinear simulations are undertaken using a general purpose finite element program. The correlation between numerical and experimental results is discussed in terms of buckling strength, axial stiffness, buckling deformations and surface strains. The analysis is shown to give a good representation of the buckling behaviour of GFRP cylinders of the type examined. It is also concluded that whereas the cylinders appear to be less sensitive to the effects of initial geometric imperfections than their isotropic counterparts, including such imperfections in a geometrically nonlinear analysis does improve the comparison between tests and finite element results, and is considered essential for the derivation of numerical ‘knockdown’ factors.

ABSTRACT: The results of a numerical simulation study for the buckling behaviour of laminated composite cylinders are presented in this paper. The laminates are made from glass-reinforced plastic (GFRP) of type ‘DF 1400’ consisting of woven glass fibre roving within a polyester resin matrix. Two-ply cylinders with various laminate orientations, subjected to axial compression, are considered. The numerical simulations are compared to the results of a previous experimental investigation which is briefly described. The finite element model, used to carry out the numerical simulations, is presented and associated limitations are discussed. Linear eigenvalue analysis as well as geometrically non-linear simulations are undertaken using a general purpose finite element program. Detailed measurements of thickness variations and geometric imperfections, carried out within the experimental study, are directly introduced in the analysis. Several thickness representations are considered and their influence on the results is assessed. The correlation between numerical and experimental results is also discussed in terms of buckling strength, axial stiffness, buckling modes and surface strains. In addition to demonstrating the influence of various modelling idealisations on the results, this numerical study highlights the effect of the specific material and laminate construction detail on the buckling behaviour of composite cylinders.

PARTIAL INTRODUCTION: Glass fibre-reinforced plastic (GFRP) shells could be an attractive structural form for a number of applications in construction due to their good strength-to-weight ratio, inherent corrosion resistance, and relatively low cost compared to other composite systems. However, their efficient use is restricted by the limited availability of design criteria and by fairly scant test data on which any such criteria can be validated…

ABSTRACT: Observations of failure mechanisms in monotonic loading are reported for graphite/epoxy composites containing three-dimensional (3D) interlock weave reinforcement. The key phenomena are delamination and kink band formation in compression, tow rupture and pullout in tension, and combinations of these in bending. The materials exhibit great potential for damage tolerance and notch insensitivity. This is partly due to the presence of geometrical flaws that are broadly distributed in strength and space; and partly to the coarseness of the reinforcing tows, which leads to extensive debonding and reduced stress intensification around sites of failure. Rules of mixture corrected for the effects of tow irregularity suffice to estimate elastic moduli. Rough estimates of the stress at which the first failure events occur in compression or tension can be made from existing micromechanical models. Ultimate tensile failure might be modeled by regarding failed tows that are being pulled out of the composite as a cohesive zone. The characteristic length estimated for this zone, which is a direct measure of damage tolerance and notch insensitivity, has very large values of order of magnitude 0.1–0.5 m.

ABSTRACT: The paper is concerned with the structural response of a composite shell structure intended as a model of an under-water vehicle for service in sea environment. The main objective of the research is the prediction of the collapse pressure using both analytical expressions and linear or non-linear numerical analysis and the following comparison with the experimental pressure obtained in off-shore tests. The structure is composed of three basic parts with regular geometry: a cylindrical part (with the following geometrical properties: R/t=30.5, L/R=2 being the internal radius 305 mm, the length 610 mm and the thickness 10 mm) and two conical and spherical end-closures with the same thickness. The cylindrical shell was made up of 7 plies of E-glass woven roving with polyester resin. Various structural analyses were conducted before performing the experiment in the sea to verify the reliability of the analytical and numerical tools. Firstly the entire model was analysed to predict the nature of the collapse (material failure or elastic buckling) and it was stated that the collapse was due to elastic buckling of the cylindrical part. Consequently, the attention was focused on this component and approximation formulae for the evaluation of the linear buckling pressure of isotropic and composite cylindrical shells were used together with finite element models. Afterward the study was enlarged to consider the effects of the recorded geometric imperfections into a non-linear buckling analysis. The collapse pressures were compared to the design values derived from the available recommendations and to the experimental result obtained in an off-shore test (1.3 MPa).

ABSTRACT: The thermal buckling of uniformly heated, clamped, truncated conical shells with axisymmetric initial deflections is theoretically studied. The axisymmetric initial deflections are represented by a cosine function. The Donnell-type basic equations governing the finite deformation of conical shells are solved by means of a finite difference procedure. It is found that the effect of axisymmetric initial deflections on the thermal buckling of truncated conical shells is quite significant for the axially constrained case, but negligible for the axially free one except very shallow cones. The thermal buckling of a clamped annular plate with the axisymmetric initial deflection is also examined.

ABSTRACT: Dimensional analysis is applied to a simple model of stiffened laminated cylindrical shells to determine the dimensionless parameters that characterize the buckling of these structures. Donnell shell theory is used to describe the kinematic deformation of the shells. The axial and ring stiffeners are modeled using the smeared technique. A nondimensional load is defined as a function of nine nondimensional parameters, which are a combination of the material and geometric properties of the shell. Additional assumptions regarding the construction of the shell walls can be used to reduce the number of nondimensional parameters. Some simply supported shells subjected to hydrostatic pressure are examined to demonstrate the use of the dimensionless parameters. Estimates of the imperfection sensitivity of these shells are made using Koiter's asymptotic theory. The dimensional analysis provides a framework for the systematic investigation of the relationship between material, geometry and the buckling loads of stiffened composite shells. The results of this analysis are intended to provide information that can be used in the preliminary stages of a shell design.
ABSTRACT: Three different methods are employed to estimate the buckling loads of several ring stiffened and orthotropic cylindrical shells using finite elements. The methods used are a nonlinear bifurcation analysis and two linearized buckling analyses, one that ignores the initial displacement stiffness matrix, and one that includes it. Large differences are observed between the predictions made by the two linearized buckling analyses for a range of shell geometries. Detailed studies of a shell with six stiffeners demonstrate that these differences are caused by different versions of the linearized eigenvalue problem, rather than by the use of different numerical formulations.…
ocean structures by finite element method”, Ocean Engineering, Vol. 28, No. 6, 1 June 2001, pp. 621-638, doi:10.1016/S0029-8018(00)00021-4

ABSTRACT: Static analysis of stiffened shells has been carried out using an eight-noded isoparametric element for the shell and a three-noded curved beam element for the stiffener. A same displacement function is used for the shell and the stiffener elements. A modified technique has been followed to analyse the shell, which is an improvement over the degenerated shell concept. The stiffness matrix of the curved beam element is generated irrespective of its position and orientation within the shell element. The stiffness matrix of the stiffener is then transferred to all the nodes of the shell element. Numerical examples of stiffened shells with concentric and eccentric stiffeners have been analysed and the results presented together with those available in published literature.

ABSTRACT: A new approach for the large deflection analysis of isotropic and composite arbitrary orientated stiffened plates is presented. Non-linear equilibrium equations are derived using the principle of virtual work applied to a continuum with a total Lagrangian description of motion. Eight node isoparametric plate elements are combined with three node beam elements, using the concept of equal displacements at the plate–stiffener interface, to represent the stiffened plate. The stiffness of the beam element is computed first irrespective of its position within the plate element and then transferred to the plate nodes depending on its orientation and position within the plate element. The Newton–Raphson incremental-iterative solution technique is used to obtain the non-linear response path. Results obtained by the present approach are compared with those available in the open literature to demonstrate the validity and efficiency of the proposed approach and good agreement is found in all the investigated cases.

ABSTRACT: (same as above)

ABSTRACT: A finite element method for the buckling loads on a longitudinally square stiffened plate with square cutouts is investigated under various combinations of biaxial loading at the plate boundary. The forces are assumed to act in the plane of the undeformed middle surface of the plate. The characteristic equations for the natural frequencies, buckling loads and their corresponding mode shapes are obtained from the equation of motion. The buckling load parameter for various modes of the stiffened plate with square cutouts subjected to in-plane biaxial loads, has been determined for various edge conditions. Numerical results are presented for a range of hole to plate size from 0 to 0.8. In the structural modeling, the plate and the stiffeners are treated as separate elements where the compatibility between these two types of elements is maintained. The present approach is more flexible than any other finite element modeling in that the mesh division is independent of the location of the stiffeners.

ABSTRACT: The paper presents finite element free vibration and buckling analysis of laminated hat-stiffened shallow and deep shells using arbitrarily oriented stiffener formulation. Modified approach for modelling the curved stiffener is implemented using necessary transformations. A simplified stiffener formulation is presented to accommodate various shapes of stiffener shapes in developing the rigidity matrix for the finite element formulation. Investigation has been carried out on free vibration and buckling analyses of laminated composite stiffened shell structures with laminated open section (rectangular or ‘T’ shaped) and closed section (‘hat’ shaped) stiffeners. Parametric study on the hat-stiffened panels for the free vibration and buckling analyses confirms that the closed section stiffener being torsionally rigid is found to show better performance over open section stiffeners.

ABSTRACT: Fracture mechanics-based predictive methodologies are commonly employed to estimate onset of interlaminar damage growth in composite structures. Full implementation of interlaminar fracture mechanics in design requires the continuing development of codes to calculate energy release rates and advancements in
delamination growth criteria under mixed mode conditions. In this research, an analytical crack tip element (CTE) methodology was evaluated and applied to predict skin-to-stiffener separation, which is a typical failure mode in aerospace structures. The methodology was correlated against empirical data obtained from structural testing of a single blade stiffened panel with an embedded artificial debond. Failure initiation occurred at the location predicted by the CTE and the predicted load for initiation agreed with the average of a set of experimental results.

ABSTRACT: Significance of using higher-order shear deformation theory (HSDT) over the first-order shear deformation theory (FSDT) for analyzing laminated composite stiffened plates is brought out using the finite element method (FEM). For this purpose, a C0 HSDT, is extended for application to stiffened configurations, for linearly elastic static and natural vibration analysis. The spatial displacement fields of both the plate and the stiffener are derived as functions of reference plane variables using Taylor series expansion. The developed computational tool is employed for analyzing systems having varying configurations using the FSDT and two different HSDTs, and their comparative effects are systematically studied, demonstrating the need for using HSDT instead of FSDT, for obtaining accurate structural response of such stiffened configurations.

ABSTRACT: The behaviour of Steel I-Beams exhibiting lateral-torsional buckling at elevated temperature has been studied by means of experimental and numerical analysis. The authors in an earlier paper have presented an analytical formula for the buckling resistance moment in the fire design situation. This new proposal, different from the actual proposal of the Eurocode 3 Part 1.2 has been validated in this work by comparison with the results from a set of 120 experimental and numerical tests performed on IPE 100 beams, submitted to temperatures varying from room temperature to 600 °C. The numerical simulations have been based on the measured geometrical dimensions of the cross-sections, the longitudinal imperfections, i.e. the out of straightness of the beams, the residual stresses and the yield strength. The Eurocode simple model promotes ultimate loads that depend mainly on the non-dimensional slenderness of the beams. The analytical results provided by the Eurocode 3, for a certain range of the slenderness, appear to be unsafe when compared with the numerical and experimental results. It is shown that the new proposal is safer than the Eurocode 3 formulas.

“New proposals for the design of steel beam-columns in case of fire, including a new approach for the lateral-torsional buckling”, Computers and Structures, Vol. 82, pp 1463-1472, 2004
DOI: 10.1016/j.compstruc.2004.03.042

ABSTRACT: The possibility of having, in parts 1-1 and 1-2 of Eurocode 3, the same approach for the design of beam-columns and for lateral–torsional buckling, was investigated by the authors in previous papers using a numerical approach, where it was concluded that those assumptions could be made. In the present paper, a new approach for lateral–torsional buckling has been used with the formulae for the design of beam-columns at elevated temperature based on prEN 1993-1-1 combined with the formulae from prEN 1993-1-2. In both cases the results obtained are much better than the current design expressions, when compared with those obtained in the numerical calculations.

ABSTRACT: An updated Lagrangian formulation of a quadratic degenerated isoparametric shell element is presented for geometrically nonlinear elasto-plastic shell problems. A finite rotation effect is included in the formulation by adopting a co-rotational scheme. The load stiffness matrix has been derived for the treatment of a pressure load. For elasto-plastic behavior, the layered element model is used. The Newton-Raphson iteration method is employed to solve incremental nonlinear equations. For tracking of post-buckling behavior, the work control method is taken into account. Verification of the present technique is obtained by analyzing the available reference problems. Good correlations between the computed results and referenced data can be drawn.

ABSTRACT: In this work, the search for the optimal form for torispherical dome ends under external pressure load is conducted. Based on the fabrication and strength requirements, a group of ‘compromised’ contours are considered. With the adoption of both the BS5500 and ASME Section VIII Pressure Vessel codes, a reasonable buckling pressure range is proposed. The geometry of the dome end is described by the four-centered ellipse method which is commonly used in engineering drawing. A minimum weight optimization problem is studied by the discrete backtrack programming method; the optimal forms are obtained under buckling constraints. The elastic buckling analysis of the dome end is carried out by the finite element method using doubly-curved truncated shell elements. Two different sized dome end examples are studied. The developed optimal search procedure is found to be very efficient and easy-to-use for the applications, such as torispherical dome and subjected to externally pressurized loading.

ABSTRACT: In this study, we proposed a minimum weight design of a submarine pressure hull under hydrostatic pressure with constraints on factors such as general instability, buckling of shell between frames, plate yielding, and frame yielding. A typical submarine pressure hull is also adopted for a prototype model. This design problem is not only formulated as a discrete nonlinear, nondifferentiable, multimodal constrained minimization problem, but also solved by using the backtrack programming method. Results in this study indicate that the solution for the optimal model's weight reduces an average 6.65% more than the prototype model. The process in this study is favorable for the submersible pressure hull design process.

ABSTRACT: In order to increase the flight range of aerospace vehicles and the efficiency of solid rocket motors, designers attempt to reduce the weight of solid rocket motors. A skirt is a potential element for weight reduction in rocket motors as it leads to reduction of the total weight of solid rocket motor. Due to its significance for solid rocket motors, the objective of this paper is to investigate the optimal design of a fiber-reinforced composite cylindrical skirt subjected to a buckling strength constraint and an overstressing strength constraint under aerodynamic torque and axial thrust. The present optimal design problem involve in determining the best laminate configuration to minimize the weight of the cylindrical skirt. To find the optimal solution accurately and quickly, the hybrid genetic algorithm (HGA) is employed in this work. Buckling strength and overstressing strength of the fiber-reinforced composite cylindrical skirt are analyzed using classical laminate theory and elastic stability theory of thin shells. The Tsai-Wu failure criterion is employed to assess the first ply failure, and an overstressing load level factor is introduced to describe the failure strength. In addition, a buckling load factor is introduced to describe the buckling strength. Due to the critical issue of buckling strength, the effects of the design parameters on the buckling strength are investigated in this work. Finally, a practical design example of the proposed fiber-reinforced composite cylindrical skirt is investigated using the present analysis procedure. Results reveal that the fiber-reinforced composite cylindrical skirt laminated symmetrically with both cross-ply layers [0/90∞] and angle-ply layers [+45/−45∞] can sustain a great buckling load. Furthermore, the buckling strength of the skirt shell laminated with equal-hybrid between the angle-ply layers and the cross-ply layers is greater than that of the skirt shell laminated with over-weighted hybrid between the angle-ply layers and the cross-ply layers. Results provide a valuable reference for designers of aerospace vehicles.

ABSTRACT: The multiple intersecting spheres (MIS) pressure hull is a logical derivative of the single unstiffened sphere, which is frequently used for deep operating, small submersibles because of its attractive low buoyancy factor. This paper investigates the optimum design of an MIS deep-submerged pressure hull subjected to hydrostatic pressure, using a powerful optimization procedure combined the extended interior penalty function method (EIPF) with the Davidon-Fletcher-Powell (DFP) method. In this study, the thickness of the shell, the width of the rib-ring, the inner radius of the rib-ring and the angle of intersection of the spherical shell are selected as design variables, and structural failure and human requirements are considered to minimize the buoyancy factor. Additionally, a sensitivity analysis is performed to study the influence of the design variables on the optimal structural strength design. The results reveal that the shell thickness is most important to lobar buckling strength, and that rib-ring width, rib-ring inner radius and spherical shell intersection angle are most important to rib-ring hoop strength. Optimization results may provide a valuable reference for designers.

ABSTRACT: A method is developed for the static stress and deformation analysis of axisymmetric shells under axisymmetric loading by reduction of the shell to ring sections. In particular, the wall thickness of the shell may vary and the method is applicable to the analysis of shells with irregular meridional geometry. Explicit expressions for the influence coefficients for each ring element are derived. In the development of these expressions, exact evaluation of stresses in the circumferential direction of the ring is used. The distribution of stresses in the meridional direction of the ring element is assumed to be linear with each element. By using the derived influence coefficients, the unknown forces at the junctures of the ring elements are found by the standard flexibility method of indeterminate structural analysis. Subsequently, the displacements and internal stresses are determined. Example solutions for a flat circular plate under transverse loading and for a cylindrical shell under a boundary edge loading show excellent agreement with solutions found by solving the governing differential equations.

ABSTRACT: The critical states of cylindrical shells with initial imperfections having plastic and creep deformations are investigated. These states are defined as the load values at which the shell deflections rise
The method of successive loading for which the reaction of the shell to small loading steps is studied and the process of deformation is considered is used. Some experimental results for shells with irregular imperfections are given.

ABSTRACT: The main propositions of Rabotnov’s two-layer model of a shell are given. It is shown that the Rabotnov’s functional can be obtained from the mixed variational principle of creep theory. The notion of critical time is introduced and a procedure for obtaining an explicit formula for it using a variational equation is described.

ABSTRACT: This paper intends to present an effective analysis of the buckling phenomenon in wind loaded cylindrical storage tanks in the form of a program package based on general purpose finite element codes. This program, namely TK-INDUSTRIAL, written in ANSYS Parametric Design Language (APDL), aims to evaluate the buckling response of storage tanks under wind or hurricane. As a major result, the critical buckling wind speed and the influence of using ring stiffeners to increase this critical speed were assessed. The proposed program was shown to provide appropriate results and can be used as a strong tool to simulate the buckling of wind loaded cylindrical storage tanks.

ABSTRACT: This paper is concerned with estimating the elastic buckling pressures of large liquid natural gas (LNG) storage tanks which are used by the British Gas Corporation for seasonal demand peak shaving. They consist of two concentric ring stiffened cylindrical shells separated by substantial thermal insulation which maintains the LNG within the inner shell at \( _{\sim}165^\circ\)C with minimal boil off. There is natural gas vapour above the LNG and throughout the tank interior which is normally at just above atmospheric pressure. The shell walls increase in thickness from the top to the bottom and are fabricated from very thin steel or aluminium alloy plates (diameter to thickness ratio \(\sim4000\) at the top) since they are usually in hoop tension, but under certain conditions this can become compressive making elastic buckling a possible mode of failure. The individual buckling pressures for the two shells can be estimated using standard procedures but in these LNG tanks the annular insulation transfers loads between the shells enhancing their individual strengths. A numerical method using the finite difference code BOSOR4 and a simple analytical method have been used to estimate these pressures.

ABSTRACT: In order to provide some insight into the effect of an impulsive disturbing load on the stability of a structure which is already subjected to major static loads near its critical state, the response of an imperfection sensitive idealized model with one degree of freedom was examined using the analytical approximation method. Conclusions regarding the response and the stability under the arbitrary form of the impulse are presented.

ABSTRACT: In Part I of this article (November 1987 Experimental Techniques) the manufacture of thin shells by electro-plating has been described. The testing techniques and some typical results are now presented. The buckling strength of thin-walled shells is known to depend on manufacturing imperfections and is difficult to assess by mathematical modeling alone. An experimental procedure, using accurate electro-deposited models is described in this paper.

ABSTRACT: Numerical, analytical and experimental techniques have been combined to find the strength of thin-wall cylindrical shells under blast loading. Two types of load are considered: rotationally symmetrical and sideways. The first type can be modelled analytically and the theoretical results are compared with those obtained from electro-formed copper shells loaded in a pressure chamber. The second type can be treated only by numerical analysis, backed by experiments using similar models loaded in an open shock tube apparatus.

ABSTRACT: A simple analytical method has been developed to estimate the response of cylindrical storage tanks to axisymmetric external blast loads. Included in this is the response of an inner vessel and annular insulation of the type used for storing large quantities (about 20,000 te) of liquid natural gas (LNG). Although complex, the response has simplifying features which have been fully exploited. In particular existing elastic shell solutions have been modified to model the initial response which is dominated by non-axisymmetric elastic buckling of the thin-walled shells. Then limit analysis has been used to model the final collapse which is dominated by the formation of axial plastic hinges in the shells. The method has been verified using physical tests on 1/150th scale models of the prototype tanks. These have been loaded with external axisymmetric blasts in a shock chamber. Special techniques were used to generate accurate model shells with very thin walls (about 50 _°m thick) by electro-deposition of copper onto removable wax cores.

ABSTRACT: A simple plastic damage analysis of a spherical shell under the impact of a flat-nosed missile is
presented in this paper. Based on the conservation of energy, a relationship between the permanent central deflection of a shell and the initial missile kinetic energy is established and shown to agree with other more complex theoretical methods. The present analysis is shown to agree with some available experimental results and can thus be used to predict the degree of damage of missile impacted spherical shells.

ABSTRACT: The present study is concerned with nonlinear analysis of toroidal shells and storage tanks. The study serves to demonstrate the usefulness of the differential quadrature method in this area of computational mechanics. The problem of the response of axisymmetric toroidal shells to uniform external pressure forms the first part of this study. Nonlinear thin shell theory, accounting for large displacements, is employed. The new differential quadrature method is used to obtain numerical results. For validation a bifurcation solution is found using the finite element method. The commercial code ADINA is used for this purpose. Finally the two methods are used to provide results for eight cases of toroidal shells. An axisymmetric analysis of a liquid storage tank with a circular base plate resting on an elastic foundation forms the second part of this study. Nonlinear shell theory is used for the tank wall and base plate, while a linear model is used for the foundation. A convergence study is carried out to determine the appropriate analysis parameters for the method. Partial validation is obtained by comparison with previously published results. These results are compared with finite element method results. Additional results are presented covering a wide range of tank geometric parameters.

ABSTRACT: In this paper, a finite element formulation is given in detail for the creep buckling of an axisymmetric shell. A special emphasis is placed on the bifurcation mode of creep buckling. A bifurcation point is determined by examining the shape of the potential energy in the vicinity of an axisymmetric equilibrium state obtained from a creep deformation analysis in the prebuckling stage. To illustrate the capability of the finite element formulation, a numerical example is presented for the creep buckling of a shallow spherical shell subjected to a uniform external pressure. In this analysis, not only the axisymmetric snap-through type but also the asymmetric bifurcation one are considered as buckling modes.

ABSTRACT: The finite element method is applied to the creep buckling of circular cylindrical shells under axial compression. Not only the axisymmetric mode but also the bifurcation mode of the creep buckling are considered in the analysis. The critical time for creep buckling is defined as either the time when a slope of a displacement versus time curve becomes infinite or the time when the bifurcation buckling occurs. The creep buckling analyses are carried out for an infinitely long and axially compressed circular cylindrical shell with an axisymmetric initial imperfection and for a finitely long and axially compressed circular cylindrical shell. The numerical results are compared with available analytical ones and experimental data.

ABSTRACT: Creep buckling analyses under stepwise varying loads are performed on a circular cylindrical shell with initial imperfection subjected to axial compression and a partial spherical shell under uniform external pressure. The finite element method is applied to a creep deformation analysis to obtain the critical time when creep buckling occurs. The results show that a linear cumulative damage rule for creep buckling can be well applied to the creep buckling of the circular cylindrical shell, but cannot to that of the partial spherical shell.

ABSTRACT: In this paper the bifurcation buckling pressure for the torispherical head of the Mark II type BWR containment vessel subjected to dynamically applied internal pressure is calculated, using a finite element program for a dynamic analysis. Three kinds of dynamic loadings, that is, step loading, ramp loading and pulse loading are considered in the present analysis. The minimum bifurcation buckling pressure is predicted for the respective loadings. The minimum bifurcation buckling pressure for dynamic loading is much lower than the bifurcation buckling pressure for static loading.

ABSTRACT: In the present work, analytical and experimental investigations were performed on creep buckling. Special attention was focussed on bifurcation behavior during creep deformation. The finite element method was used to analyze creep buckling of circular cylindrical shells without initial imperfection. The number of circumferential waves obtained from the analyses agrees well with those of the experiments. The present experimental investigation shows that the circumferential waves are suddenly caused near a bulge. It is also found that there is no correlation between the wavelength of the circumferential waves observed at creep buckling and that of the circumferential initial imperfection. Deformation patterns at the bifurcation creep buckling obtained from the analyses are analogous to those of the experiments. It is concluded from the analyses and the experiments that the circumferential waves observed in creep buckling experiments are due to bifurcation buckling during creep deformation.

ABSTRACT: Cylindrical tanks with conical roof shells are utilized as oil storage tanks and for some containment vessels. It is known that conical roof shells and torispherical shells subjected to static internal pressure buckle into a displaced shape with circumferential waves caused by an instability condition commonly called bifurcation buckling. It can be important to obtain the dynamic bifurcation buckling load in designing conical roof shells. In this paper, the bifurcation buckling pressure is calculated for dynamic pressure during accident conditions as characterized by step pressure loading, ramp pressure loading and pulse pressure loading. The minimum bifurcation buckling pressure is shown to be a linear function of radius-to-thickness ratio $R/h$ of the shell in a linear fashion on a logarithmic scale. The minimum bifurcation buckling pressure is minimum for conical roof shells subjected to the step loading. The minimum dynamic bifurcation buckling pressure for step loading is about half of the static bifurcation buckling pressure.

ABSTRACT: The pressure-radius relation of spherical rubber balloons has been derived and its stability behavior analyzed. Here we show that those features are practically unchanged for thick spherical shells of Mooney-Rivlin materials. In addition, we also show that eversion of a spherical shell is possible for any incompressible isotropic materials if the shell is not too thick.

ABSTRACT: This paper presents a numerical study of the dynamic contact instability of shallow spherical shells. The problem considered is that of a spherical shell loaded through a massless rigid circular plate by a sudden step load acting in the direction normal to the loading plate and along the axis of symmetry of the shell. Thus, the spherical shell is subjected to a dynamic contact loading. The interaction characteristic of the circular plate and the spherical shell is described and the snap-through instability of the spherical shell due to the dynamic contact loading is discussed in detail. The numerical analysis demonstrates that the system may be dynamically stable even if local snap-through buckling occurs in the central area of the spherical shell. Dynamic instability occurs only in the case where the spherical shell exhibits an overall snap-through buckling.
ABSTRACT: This paper presents a numerical study which is concerned with the prediction of the response and instabilities in long circular cylindrical shells under dynamic pure bending. Of particular interest is the response of such shells, bent into the plastic range of the material, and the various instability characteristics of the shells under dynamic bending (sudden step load). It was found that the major deformation characteristic of the shells is essentially similar to that observed in the static bending when the applied moment is much smaller than the critical dynamic moment. However, when the applied moment is close to the critical dynamic moment, the ovalization of the shell cross-section was found to be localized over a length of several shell diameters in the central region, even though the response of the shell curvature was shown to be still stable in this case. When the applied moment reaches the critical dynamic moment, the response of the shell curvature was shown significantly increasing with time and the shell buckled catastrophically. For thicker shells, it was found that the development of localized ovalization of the shell cross-section is the major factor that causes shell dynamic instability. For thinner shells, however, besides the localized ovalization, the bifurcation induced by short wavelength ripples on the compressed side of the shell was also observed in the initial buckling patterns. After the bifurcation, the initial buckling pattern was replaced by the final postbuckling mode characterized by a localized sharp cupping in the centre of the shell.

ABSTRACT: This paper presents a numerical study of the dynamic snap-through instability of cylindrical panels subjected to the combined loading of uniform pressure and a central concentrated load. All static and dynamic (sudden step load) combinations of the concentrated load and the uniform pressure are considered. The characteristics of the dynamic instability of the panel are described for the two cases of static pressure with dynamic concentrated load and dynamic pressure with static concentrated load. The critical load curves for both cases are presented. To explain the effects of the initial static loads on the critical dynamic loads, the static and dynamic critical loads corresponding to both static loads or both dynamic loads are also calculated. The Budiansky-Roth criterion is employed in all these studies to determine the critical dynamic loads. The numerical results show that the static critical load curve gives an upper-bound whereas the dynamic critical load curve offers a lower-bound. Both the compound critical load curves lie between the static and dynamic critical load curves.

ABSTRACT: (cannot cut and paste)
ABSTRACT: In this paper we investigate the dynamic instability problems of long circular cylindrical shells subjected to sudden step bending moments. The expressions to predict the critical dynamic moments are derived. The dynamic instability model is established on two basic assumptions. One is the Brazier’s deformed kinematic assumption. The other is the dynamic characteristic assumption in which we assume the longitudinal curvature and ovalisation vibrations reach their extreme values simultaneously when the dynamic instability occurs. Thus, the dynamic instability problem is reduced to the solution of two static equilibrium equations and an energy balance equation. The present results show that the dynamic instability of the long circular cylindrical shells occurs at a moment about 80% of the corresponding critical static moment.

ABSTRACT: In this paper, the nonlinear bending response of finite length cylindrical shells with stiffening rings is investigated by using a modified Brazier approach. The basic assumptions for the present study are that the deformation of a shell subjected to pure bending can be simplified into a two-stage process. One is that the shell ovalizes but its axis remains straight; the other is that the bending of the shell is regarded as a beam with nonuniform ovalization. The nonlinear bending response is derived by applying the minimum potential energy principle and the corresponding critical moment, associated with local buckling, is determined by employing the Seide–Weingarten approximation. Numerical results are shown and compared with those obtained from other methods, which demonstrates that the assumptions used in the present study are reasonable.

ABSTRACT: External pressure buckling, free vibration, and external pressure-vibration interaction data were obtained on a sixth scale Lexan model of the Titan IV (Prototype) nose cone fairing. The objectives of these experiments were to validate analytical models used in the prototype design and also to provide experimental data on the effects of discontinuous circumferential rings, flexible ring to shell attachment, separation rails, and skin splices. In addition a nondestructive buckling load predictive test technique based on natural frequencies was evaluated using the Lexan model. The advantage of a Lexan model is that it can be buckled without sustaining damage, thus allowing repeated buckling experiments to be performed. Correlation studies were carried out using NASTRAN finite element and BOSOR finite difference models. Buckling and frequency data showed good agreement between analysis and experiment. Pressure-vibration interaction data were obtained to investigate an experimental procedure for extrapolating the interaction curve to predict the critical buckling load. While it was found that extrapolation of these data always overpredicted the buckling pressure, the data were used to develop a procedure that was successfully applied as stop-test criteria in the prototype test.
ABSTRACT: A combined analytical and experimental programme on the buckling of cylinders under axial compression, external pressure, and combined loading was conducted to develop a methodology for predicting the buckling of shell structures with manufacturing induced imperfections. A unique method of fabricating test cylinders from Lexan without longitudinal seams was developed. Cylindrical blanks formed by blow moulding were thermoformed and machined to the correct wall thickness to form perfect cylinders. The co-ordinates were measured and the cylinders tested. After testing, the cylinders were thermoformed on a second mandrel containing the desired imperfection shape and amplitude, remeasured, and tested. Excellent correlation to predictions from the BOSOR4 and ABAQUS computer codes was achieved.

ABSTRACT: Starting out from recent experimental results according to which thin-walled spherical shells subjected to a uniform external pressure deform in an axisymmetric mode at the beginning of the buckling process, the buckling and the postbuckling behavior of complete spherical shells were investigated under the assumption that both the unintentional, random initial deviations from the exact shape, and the following elastic deformations are symmetric to some radius of the shell. The shell was imagined to be decomposed into a cap which shows large deformations, and into a remainder in which the displacements are so small that in their analysis a linear theory can be used satisfactorily. The total potential energy of the system was minimized numerically and in the minimization process the conditions at the boundary between cap and remainder were enforced rigorously. Complete and continuous postbuckling curves were obtained in a number of cases and the maximal value of the pressure parameter was determined in a sufficiently broad range of the geometric parameter to draw conclusions regarding the practical behavior of spherical shells under external pressure. Comparison with earlier theoretical and experimental work yielded satisfactory agreement.

ABSTRACT: An experimental investigation into the plastic buckling of cylindrical tubes subjected to bending moments at the ends is reported on. Suitable parameters by means of which the buckling moment may be represented are first discussed, and after a description of the apparatus and the testing procedure, the results of tests on stainless steel and aluminium alloy tubes are given. These results are compared with analytical results for the collapse of cylinders under pure bending, and uniform axial compression. The mode of deformation of the cylinders is discussed and the experimental strains are compared with those of others for tests on axially compressed cylinders as well as cylinders in pure bending. The strains lie within ± 30% of those predicted by J2 deformation theory for cylinders in axial compression: the corresponding range of stresses is about ± 5%.

ABSTRACT: An approximate analysis is presented of the bifurcation of an elastic-plastic circular cylindrical shell subjected to pure bending. The method of analysis is an extension into the plastic range of an earlier analysis[8]; a relatively simple solution is obtained by making various approximating assumptions, and by a judicious choice of the eigenmode. The results show that the critical outer fibre stress is up to about 35% greater than the critical stress of an axially compressed cylinder, using J2 flow theory, in contrast to the elastic or elastic-plastic (deformation theory) cases, where these two stresses are practically equal.

ABSTRACT: Bifurcation under axial compression of discretely stringer-stiffened cylinders in the elastic and plastic ranges is studied. The stiffeners are treated as long plates. Small-strain J2 flow and deformation theories of plasticity are used. The effect of stiffener size on the critical stress is investigated; this is discussed with reference to the critical stresses of an equivalent simply-supported panel, and of a long plate simply-supported on three edges and free along one longitudinal edge. The effects of stiffener eccentricity, and of the number of stiffeners, is also discussed.

ABSTRACT: The behavior in the plastic range of axially compressed stringer-stiffened cylinders is investigated. The shell under consideration is assumed to have an initial imperfection in the form of sinusoidal deviation both axially and circumferentially. The constitutive relation employed here is J2 deformation theory of plasticity. This relation, as well as kinematic assumptions regarding the behavior of the panels and stiffeners that constitute the stiffened shell, is used in the principle of virtual work to obtain a set of nonlinear algebraic equations whose solution provides complete information about the prebuckling equilibrium path. Bifurcation from the primary path is examined by making use of a functional whose first variation is zero when two solutions to the problem are possible. This leads to an eigenvalue problem, the eigenvalue being the critical compressive load and the eigenfunction being the corresponding buckling mode. Results are presented for shells of different geometries and material properties, and a comparison of results is made with results obtained by others. The imperfect shells analyzed all exhibit stable behavior, with sufficiently large imperfections having a beneficial effect. Results for bifurcation from these paths are also discussed.

ABSTRACT: The paper deals with buckling of antisymmetric angle- and cross-ply, simply supported rectangular flat plates under shear and compressive loads. The Rayleigh-Ritz energy method is used to find the buckling load, by assuming a double series form of trial functions for the buckled displacement field. Both the symmetric and antisymmetric buckling modes are considered. The effect of the number of layers, the aspect ratio and the lamination angle on the buckling load is studied. Results are presented for plates subjected to (i) shear loads only and (ii) both shear and uniaxial compressive loads; for the latter case, the results are presented in the form of interaction curves.

ABSTRACT: This paper is aimed at the development of an analytical method to handle thermal buckling of laminated composite circular cylindrical shells. An eighth-order governing differential system for predicting this response is formulated from an energy approach. With the focus on simply-supported, antisymmetric angle-ply laminated composite cylinders subjected to circumferentially-varying temperatures, Galerkin's method is employed, where the corresponding numerical results provide insight into the response of the critical buckling temperature to such factors as lamination angles, number of layers, stacking sequence, geometric aspect ratios and various temperature functions. For example, in the case of antisymmetric laminates, the coupling effect between bending and compression vanishes as the number of layers increases. This phenomenon is confirmed for common composite materials such as Graphite/Epoxy and Boron/Epoxy.

ABSTRACT: Thermal buckling of a laminated cylindrical plate subjected to a temperature change is studied. The governing differential equations for Donnell-type laminated cylindrical shells are used and Galerkin's method is employed to determine the critical buckling temperature. Clamped and simply supported boundary conditions are both considered. The effects of various parameters on thermal buckling are examined.

ABSTRACT: By adopting the energy method, a method of calculating the stability of the rotational composite shell is presented that takes into account the influence of nonlinear prebuckling deformations and stresses on the buckling of the shell. The relationships between the prebuckling deformations and strains are calculated by nonlinear Kármán equations. The numerical method is used to calculate the energy of the whole system. The
nonlinear equation is solved by combining the gradient method and the amended Newton iterative method. A computer program is also developed. Examples are given to demonstrate the accuracy of the method presented in this paper.

ABSTRACT: The instability of a cylindrical shell under three point bending is considered. The problem has application to the industrial pipe ram bending process. The loading is idealized as a set of pads of uniform radial pressure in the regions of die-shell contact. A theoretical solution for the smallest buckling load is developed, using the Donnell and Sanders linearized stability equations. A finite element solution is also presented. The paper concludes with a discussion of results, from the two methods.

ABSTRACT: The elastic instability of a thin curved pipe under three-point bending is considered. The problem has application to the industrial ram pipe bending process. The loading is idealized as a set of pads of uniform pressure applied radially on discrete regions of the pipe surface. A shell-theory solution for the lowest buckling load is developed, using the Donnell-type linearized stability equations in toroidal coordinates. Sample results are presented for a specific pipe and these results are compared with ones for a geometrically similar straight pipe.

ABSTRACT: A study is conducted of the linear elastic buckling of circular cylindrical shells by the new Differential Quadrature Method (DQM). To date this numerical method in the area of buckling analysis has been applied only to rectangular plates. The Fluegge shell stability equations serve as the basis of the analysis. By assuming the form of the buckling modes in the circumferential direction the stability equations are transformed into ones dependent only on the axial coordinate of the shell. The resulting ordinary differential equations are then solved using the one-dimensional DQM approach. Results are first given for shells with simple or clamped boundary conditions, and these are compared with previously published results. Finally, new results are presented for shells with clamped-free boundary conditions, which have relevance to the buckling analysis of liquid storage tanks.

ABSTRACT: The free vibration characteristics of linear elastic toroidal shell panels are determined. A solution based on the Mushtari–Vlasov–Donnell shell equations is developed using the Differential Quadrature Method. The work represents the first application of this method to problems in shell theory with variable coefficients in the governing equations. Numerical results are calculated using the method, and these are compared with results found using a Fourier series and a finite element solution.

H.S. Shin and D. Redekop, “Nonlinear analysis of axisymmetric toroidal shells using the DQM”, Proc. CSME Forum, Montreal, Canada, May 2000, 10 pages

ABSTRACT: A method is developed to predict the buckling characteristics of an orthotropic shell of revolution of arbitrary meridian subjected to a normal pressure. The solution is given within the context of the linearized Sanders–Budiansky shell buckling theory and makes use of the differential quadrature method. Numerical results for buckling pressures and mode shapes are given for complete toroidal shells. Both completely free shells and shells with circumferential line restraints are covered. The loadings considered consist either of uniform pressure or circumferential bands of constant pressure. It is demonstrated that the differential quadrature method is numerically stable and converges. For isotropic toroidal shells, good agreement is observed with previously published analytical and finite element results. New results for buckling pressures and mode numbers are given for orthotropic shells and for band loaded shells.

ABSTRACT: The linearized buckling problem is considered for an isotropic clamped-clamped cylindrical shell with an oblique end. A theoretical solution based on the Budiansky shell theory is developed, and numerical results are determined using the differential quadrature method. In formulating the solutions, the surface of the shell is developed onto a plane, and the resulting irregular domain is then mapped, using blending functions, onto a square parent domain. The analysis is carried out in the parent domain. Convergence, validation, and parametric studies are conducted for a uniform external pressure loading. Results determined are compared with finite element results. The paper ends with an appropriate set of conclusions.

ABSTRACT: The finite element method (FEM) is used to predict free vibration and buckling characteristics of complete circular toroidal shells with meridional ring stiffeners. New vibration results are presented in the paper which indicate the effect on the natural frequencies of ‘rigid’ meridional ring stiffeners, and of equatorial lines of support. New buckling results are presented which indicate the effect on the buckling pressure of meridional ring stiffeners, and of equatorial lines of support. Results for the natural frequencies and the critical buckling pressure are given for shells covering a wide range of the geometric parameters. Close agreement of results is observed in comparisons with previously published results.

DTIC Accession Number: ADA187801

ABSTRACT: The specific impetus for this work was a conceptual design of a submarine using the toroid as the pressure hull. The designers could not find a ready body of knowledge to obtain scantlings for their pressure hull. This work began with a review of efforts to solve complete toroidal structures. Several works were found which addressed general shells and extended into partial toroids, but the solution of a complete toroid was not found to be a common exercise. Some of the these works are briefly reviewed. An attempt was then made to solve for the displacements in a thin walled circular toroid using the energy method. Several problems were identified associated with the structure geometry which make the solution for the complete toroid difficult. In addition, the functional used for the energy method needs to be more complex than the simple trigonometric or power series functionals used in this work. These two areas, geometry and functionals, are fertile areas for further study.

DTIC Assessment Number: ADA200586

ABSTRACT: The specific impetus for this work was a conceptual design of a submarine using the toroid as the pressure hull. This work is a continuation of the work started by Bowen (1987). As such, it is hoped that a better understanding of the behavior of a toroid under hydrostatic pressure can be realized. This work began with a review of efforts to solve complete toroidal structures. A specific toroid was then modeled in the BOSOR4 computer program to obtain displacements of the meridian under hydrostatic pressure. Functions were then derived that described the general form of these displacements. Using these functions as the assumed solution for the energy method an energy balance was made and a program was written to solve the displacements of a generic toroid under hydrostatic loading.

ABSTRACT: In this paper, the free vibrations of elastic in vacuo circular toroidal shells under different boundary conditions are studied using the linear Sanders thin shell theory. Beam functions are used to describe the motion along the meridional direction whilst trigonometric functions are used to represent the deformation
of the cross section. It is shown that both the natural frequencies and the mode shapes can be accurately predicted as long as the employed beam functions satisfy the boundary conditions at the ends of the shells. The dependence of the free vibration characteristics of an elastic toroidal shell upon boundary conditions and toroidal to cross-sectional radius ratio is also illustrated and explained in this paper.

ABSTRACT: Cylindrically curved unstiffened and stiffened plates are often used in ship structures. For example, they can be found at deck with a camber, side shell at fore and aft parts and bilge circle part of ship structures. It has been believed that such cylindrically curved plates can be modelled fundamentally by a part of a circular cylinder. From the estimations using cylindrically curved plate models, it is known that, in general, curvature increases the buckling strength compared to a flat plate under axial compression. Existence of the curvature is also expected to increase the ultimate strength as well as buckling strength. In the present paper, series of Finite Element analyses are performed on stiffened curved plates varying several parameters such as curvature, panel slenderness ratio as well as web height and type of stiffener. The results of numerical calculations on stiffened and unstiffened curved plates are examined to clarify the influences of these parameters on characteristics of their buckling/plastic collapse behaviour and strength under axial compression.

DOI: 10.4028/www.scientific.net/AMR.33-37.1195

ABSTRACT: In the present paper, to clarify and examine the fundamental buckling behaviours of cylindrically curved plates subjected to axial loading, a series of elastic and elasto-plastic large deflection analyses as well as elastic eigen buckling analysis are performed together with the comparisons with the buckling behaviours of circular cylinder. On the basis of the numerical results, the effects of curvature, magnitude of initial imperfection, slenderness ratio and aspect ratio on the characteristics of the buckling and post buckling collapse behavior of cylindrically curved plates and circular cylinders under axial compression are discussed. The buckling strength and ultimate strength formulae of the cylindrically curved plate are empirically derived based on the FEM series analysis by curve fitting using least square method. The validity of the ultimate strength formulations developed in this study has to some extent been verified through comparison with nonlinear numerical solutions.

ABSTRACT: Geometrically nonlinear free vibrations of closed isotropic cylindrical shells are investigated through an analytical–numerical model. The method developed is a combination of Sanders–Koiter nonlinear shell theory and the finite element method. The cylindrical shell is subdivided into cylindrical finite elements
and the displacement functions are derived from exact solutions of Sander's equations for thin cylindrical shells. Expressions for the mass, linear and nonlinear stiffness matrices are determined by exact analytical integration. Various boundary conditions of shell and in-plane effects are considered. Nonlinear responses are analyzed using the Runge–Kutta numerical method. The nonlinear frequency ratio is determined with respect to the amplitude thickness ratio of the motion for different study cases. Detailed numerical results are presented for various parameters for a closed isotropic shell, indicating either hardening or softening types of nonlinear behaviors, depending on the structure data. The present results show good agreement with the published ones for several cases of shells. This research clarifies the current disagreement about various types of cylindrical shells with geometric nonlinearities.

ABSTRACT: Based on the First-order Shear Deformation Theory (FSDT) this paper focuses on the dynamic behavior of moderately thick functionally graded conical, cylindrical shells and annular plates. The last two structures are obtained as special cases of the conical shell formulation. The treatment is developed within the theory of linear elasticity, when materials are assumed to be isotropic and inhomogeneous through the thickness direction. The two-constituent functionally graded shell consists of ceramic and metal. These constituents are graded through the thickness, from one surface of the shell to the other. A generalization of the power-law distribution presented in literature is proposed. Two different four-parameter power-law distributions are considered for the ceramic volume fraction. Some material profiles through the functionally graded shell thickness are illustrated by varying the four parameters of power-law distributions. For the first power-law distribution, the bottom surface of the structure is ceramic rich, whereas the top surface can be metal rich, ceramic rich or made of a mixture of the two constituents and on the contrary for the second one. Symmetric and asymmetric volume fraction profiles are presented in this paper. The homogeneous isotropic material can be inferred as a special case of functionally graded materials (FGM). The governing equations of motion are expressed as functions of five kinematic parameters, by using the constitutive and kinematic relationships. The solution is given in terms of generalized displacement components of the points lying on the middle surface of the shell. The discretization of the system equations by means of the Generalized Differential Quadrature (GDQ) method leads to a standard linear eigenvalue problem, where two independent variables are involved without using the Fourier modal expansion methodology. Numerical results concerning six types of shell structures illustrate the influence of the power-law exponent, of the power-law distribution and of the choice of the four parameters on the mechanical behaviour of shell structures considered.

ABSTRACT: This paper focuses on the dynamic behavior of functionally graded conical, cylindrical shells and annular plates. The last two structures are obtained as special cases of the conical shell formulation. The first-order shear deformation theory (FSDT) is used to analyze the above moderately thick structural elements. The treatment is developed within the theory of linear elasticity, when materials are assumed to be isotropic and inhomogeneous through the thickness direction. The two-constituent functionally graded shell consists of ceramic and metal that are graded through the thickness, from one surface of the shell to the other. Two different power-law distributions are considered for the ceramic volume fraction. The homogeneous isotropic material is inferred as a special case of functionally graded materials (FGM). The governing equations of motion, expressed as functions of five kinematic parameters, are discretized by means of the generalized differential quadrature (GDQ) method. The discretization of the system leads to a standard linear eigenvalue problem, where two independent variables are involved without using the Fourier modal expansion methodology. For the homogeneous isotropic special case, numerical solutions are compared with the ones obtained using commercial programs such as Abaqus, Ansys, Nastran, Straus, Pro/Mechanica. Very good agreement is observed. Furthermore, the convergence rate of natural frequencies is shown to be very fast and the stability of the numerical methodology is very good. Different typologies of non-uniform grid point distributions are considered. Finally, for the functionally graded material case numerical results illustrate the influence of the power-law exponent and of the power-law distribution choice on the mechanical behavior of shell structures.

ABSTRACT: In this paper, the Generalized Differential Quadrature (GDQ) method is applied to study the dynamic behaviour of laminated composite doubly-curved shells of revolution. The First-order Shear Deformation Theory (FSDT) is used to analyze the above mentioned moderately thick structural elements. The governing equations of motion, written in terms of stress resultants, are expressed as functions of five kinematic parameters, by using the constitutive and kinematic relationships. The solution is given in terms of generalized displacement components of points lying on the middle surface of the shell. The discretization of the system by means of the Differential Quadrature (DQ) technique leads to a standard linear eigenvalue problem, where two independent variables are involved. Results are obtained taking the meridional and circumferential co-ordinates into account, without using the Fourier modal expansion methodology. Examples of hyperbolic, catenary, cycloid, parabolic, elliptic and circular shell and panel structures are presented to illustrate the validity and the accuracy of the GDQ method. Furthermore, GDQ results are compared with those presented in literature and the ones obtained by using commercial programs such as Abaqus, Ansys, Nastran, Straus and Pro/Mechanica. Very good agreement is observed.

ABSTRACT: In this paper, the Generalized Differential Quadrature (GDQ) method is applied to study the dynamic behaviour of laminated composite doubly-curved shells of revolution. The First-order Shear
Deformation Theory (FSDT) is used to analyse the above mentioned moderately thick structural elements. In order to include the effect of the initial curvature a generalization of the Reissner–Mindlin theory, proposed by Toorani and Lakis, is adopted. The governing equations of motion, written in terms of stress resultants, are expressed as functions of five kinematic parameters, by using the constitutive and kinematic relationships. The solution is given in terms of generalized displacement components of points lying on the middle surface of the shell. The discretization of the system by means of the Differential Quadrature (DQ) technique leads to a standard linear eigenvalue problem, where two independent variables are involved. Results are obtained taking the meridional and circumferential co-ordinates into account, without using the Fourier modal expansion methodology. Comparisons between the Reissner–Mindlin and Toorani–Lakis theory are presented. Furthermore, GDQ results are compared with those presented in literature and the ones obtained by using commercial programs such as Abaqus, Ansys, Nastran, Straus and Pro/Mechanica. Very good agreement is observed.

ABSTRACT: This work presents the static and dynamic analyses of laminated doubly-curved shells and panels of revolution resting on Winkler-Pasternak elastic foundations using the Generalized Differential Quadrature (GDQ) method. The analyses are worked out considering the First-order Shear Deformation Theory (FSDT) for the above mentioned moderately thick structural elements. The effect of the shell curvatures is included from the beginning of the theory formulation in the kinematic model. The solutions are given in terms of generalized displacement components of points lying on the middle surface of the shell. Simple Rational Bézier curves are used to define the meridian curve of the revolution structures. The discretization of the system by means of the GDQ technique leads to a standard linear problem for the static analysis and to a standard linear eigenvalue problem for the dynamic analysis. Comparisons between the present formulation and the Reissner-Mindlin theory are presented. Furthermore, GDQ results are compared with those obtained by using commercial programs. Very good agreement is observed. Finally, new results are presented in order to investigate the effects of the Winkler modulus, the Pasternak modulus and the inertia of the elastic foundation on the behavior of laminated shells of revolution.

[61] X. Wang, X. Wang and X. Shi, “Accurate Buckling Loads of Thin Rectangular Plates under Parabolic Edge Compressions by

ABSTRACT: The pure complete toroidal shell and the compartment of toroidal shell with ring stiffener, with circular meridian cross-section, have been investigated respectively by the numerical analysis method in this paper because of the difficulty of the theoretically solution. The thin shell element was adopted to obtain elastic analysis of a closed toroidal shell due to external pressure, which confirms the conclusion of membrane theory. Based on the nonlinear finite element method (FEM), the structural characteristics of the ring-stiffened toroidal shell have been carried out. In presented analyzing, adopting the elastic-plasticity stress-strain relations, the influences between material nonlinearity and geometry nonlinearity of the stability of structure hull are also considered. Comparing with the traditional cylindrical pressure hull, the ring-stiffened toroidal pressure hull is superior in resisting influences of the initial deflection to a certain extent and having larger reserve buoyancy. It means that the ring-stiffened toroidal shell could be used to realize better performance in the general structural form with its specific shape in underwater engineering.

ABSTRACT: A plastic buckling analysis for axially compressed square tubes is described in this paper. Deformation theory is used together with the realistic edge conditions for the panels of the tube introduced in our previous paper (Li and Reid, 1990), referred to hereafter as LR. The results obtained further our understanding of a number of problems related to the plastic buckling of axially compressed square tubes and simply supported rectangular plates, which have remained unsolved hitherto and seem rather puzzling. One of these is the discrepancy between experimental results and the results of plastic buckling analysis performed using the incremental theory of plasticity and the unexpected agreement between the results of calculations based on deformation theory for plates and experimental data obtained from tests conducted on tubes. The non-negligible difference between plates and tubes obtained in the present paper suggests that new experiments should be carried out to provide a more accurate assessment of the predictions of the two theories. Discussion of the results herein also advances our understanding of the compact crushing behavior of square tubes beyond that given in LR. An important conclusion reached is that strain hardening cannot be neglected for the plastic buckling analysis of square tubes even if the degree of hardening is small since doing so leads to an unrealistic buckling mode.

ABSTRACT: This paper is concerned with the membrane shell analysis of filament overwound toroidal pressure vessels and optimum design of such pressure vessels using the results of the analysis by means of mathematical nonlinear programming. The nature of the coupling between overwind and liner has been considered based on two extreme idealizations. In the first, the overwind is rigidly coupled with the liner, so that the two deform together in the meridional direction as the vessel dilates. In the second, the overwind is free to slide relative to the liner, but the overall elongations of the two around a meridian are identical. Optimized designs with the two idealizations show only minor differences, and it is concluded that either approximation is satisfactory for the purposes of vessel design. Aspects taken into account are the intrinsic overwind thickness variation arising from the winding process and the effects of fiber pre-tension. Pre-tension can be used not only to defer the onset of yielding, but also to achieve a favorable in-plane stress ratio which minimizes the von Mises equivalent stress in the metal liner. Aramid fibers are the most appropriate fibers to be used for the overwind in this type of application. The quantity of fiber required is determined by both its short-term strength and its long-term stress rupture characteristics. An optimization procedure for the design of such vessels, taking
all these factors into account, has been established. The stress distributions in the vessels designed in this way have been examined and discussed through the examples. A design which gives due consideration of possible mechanical damage to the surface of the overwind has also been addressed.

ABSTRACT: We analyze the potential for liner buckling in a 40-in Kevlar49/epoxy overwrapped spherical pressure vessel (COPV) due to long, local depressions or ‘valleys’ in the titanium liner, which evidently appeared after proof testing (autofrettage). We begin by presenting the geometric characteristics of approximately 20 mil (0.02 in.) deep depressions measured by laser profilometry in several vessels. While such depths were more typical, depths of more than 40 mils (0.02 in.) were seen near the equator in one particular vessel. Such depressions are largely the result of overlap of the edges of crossing overwrap bands (with rectangular cross-section prepreg tows) from the first or second wrap patterns particularly where they begin and end. We then discuss the physical mechanisms of formation of the depressions during the autofrettage process in terms of uneven void compaction in the overwrap particularly around lines of tow overlap, and the resulting 10-fold increase in through-thickness stiffness of the overwrap. We consider the effects of liner plastic yielding mechanisms on residual bending moments and interface pressures between the liner and overwrap, both at the peak proof pressure (~6500 psi) and subsequently when reducing the pressure back to 0 psi. During depressurization, the Bauschinger effect becomes very important wherein extensive prior yielding in tension reduces the magnitude of the yield threshold in compression by 30 to 40% compared to the virgin annealed state of the titanium. In the absence of a depression, the liner is elastically stable in compression even at overwrap-liner interface pressures up to 6 times the ~ 1000 psi interface pressure that exists at 0 psi following proof. Using a mechanics model based on a plate on an elastic foundation, we develop an extensive analysis of the possible destabilizing effects of a frozen-in liner depression. The analysis treats the perturbing effects of the residual bending moments and interface pressures remaining after the proof hold as well as the Bauschinger effect on the compressive yield threshold when depressurizing to 0 psi. The key result is that depression depths of up to 40 mils can be tolerated by the liner, but above 40 mils, the Bauschinger effect drives destabilization, and buckling becomes increasingly likely depending on the details of depression formation during autofrettage. It is almost certain that destabilization leading to buckling will occur for depression depths beyond 55 mils.

ABSTRACT: The process of filament winding has gained broad support among a wide range of applications from rocket propellant tanks and automobile natural gas storages tanks to SCUBA and firefighting equipment. The high stiffness-to-weight characteristic of these pressures vessels makes them ideal for such applications. Many failure criteria have to be considered when designing composite pressure vessels. These include, but are not limited to, fiber rupture, liner fatigue, liner buckling, overwrap leakage, and composite crack propagation
resulting in burst. In order to simulate a number of these failure mechanisms, the debonding between the liner a composite overwrap must be modeled. In this paper, the use of surface based cohesive behavior in Abaqus to model the debonding between a metallic liner and a carbon fiber composite overwrap will be investigated. The deformation behavior across the bond will be examined along with the effects of bond failure. A procedure will be developed to systematically set up a simulation of the debonding of a liner from a composite overwrapped pressure vessel due to phenomenon such as cylinder buckling and surface defects which effect the liner-to-composite bond.

ABSTRACT: Since the recognition that local buckling of plate elements can significantly reduce the column buckling load of thin walled beams and columns, significant research has established a firm basis for understanding the interplay between buckling modes in classical built-up structures. Recent work on a modal projection procedure for representing the results of both static and dynamic nonlinear collapse computations has demonstrated that for structures whose collapse process includes a predominantly linear prebuckling domain, the failure process can be well understood by tracking the growth of the bifurcation eigenvectors in the solution. It has recently been observed that for structures which exhibit mode coupling characteristics, the bifurcation eigenvectors by themselves do not form a set of orthogonal functions when their inner product is evaluated. For complex structures or structures exhibiting complex multi-modal postbuckling behavior, this procedure provides an approach to evaluate the design basis for buckling mode interactions. Examples are shown illustrating this for collapse analyses involving both the classical case of geometric imperfections and material imperfections such as delaminations in composite structures.

ABSTRACT: A method for determining the resistance of an imperfect isotropic steel shell is proposed in this paper. The following hypotheses are supported: hypothesis on dominant characteristics of the usual initial geometric imperfection; hypothesis on the equivalent axisymmetric calculation model; and hypothesis on the general rules that govern the relationship between the mean value of the amplitude on the critical cross-section and the wall thickness, for different r/t relations. The correctness of the above hypotheses is proven by numerically simulated experiments using the computer program BOSOR5, for characteristic r/t relations.

ABSTRACT: This paper reports the results of a numerical study undertaken on the buckling behaviour of lightly stiffened elliptic paraboloidal steel panels intended for use as long-span shuttering for lightweight concrete bridge decks, walkways and floors. Steel panel shutters of double curvature may allow the casting of concrete over relatively large spans while avoiding the use of supporting scaffolding and other intermediate props. Such long-span shutters are desirable when the ground below the deck cannot adequately support scaffolding, or the space below the deck carries traffic carriageways which should not be obstructed by scaffolding. In this study, the effect of the wet concrete is simulated as a uniform pressure normal to the shell surface (limiting case), while the dead weight of the hardening concrete is simulated as a uniformly distributed loading on the horizontal projection of the shell surface. The results show that panel rise and aspect ratio have a considerable influence on the buckling strength of the shutter. Tentative viability limits are established.

ABSTRACT: A postbuckling analysis is presented for a stiffened cylindrical shell of finite length subjected to combined loading of external pressure and a uniform temperature rise. The formulations are based on a boundary layer theory of shell buckling, which includes the effects of nonlinear prebuckling deformations, nonlinear large deflections in the postbuckling range and initial geometrical imperfections of the shell. The “smeared stiffener” approach is adopted for the stiffeners. The analysis uses a singular perturbation technique to determine the interactive buckling loads and the postbuckling equilibrium paths. Numerical examples cover the performances of perfect and imperfect, stringer and ring stiffened cylindrical shells. Typical results are presented in dimensionless graphical form.

ABSTRACT: Stability equations for toroidal shells under hydrostatic pressure are derived from Sanders'1 non-linear equations of equilibrium and kinematic relations of the middle surface for general shells. The stability equations are solved by use of the asymptotic method. Theoretically predicted buckling pressures are in good agreement with experimental results obtained by Fishlowitz.2 The influence of prebuckling deflection on the critical load is investigated.

ABSTRACT: In the present investigation on the dynamic plastic buckling of cylindrical shells under axial compression waves, the critical axial stress and the exponential parameter of inertia terms in stability equations are treated as a couple of characteristic parameters. The criterion of transformation and conservation of energy in the process of buckling initiation is used to derive the supplementary restraint equation of buckling
deformation at the fronts of axial elastic and plastic compression waves. The supplementary restraint equation, stability equations, boundary conditions and continuity conditions constitute the necessary and sufficient conditions of determining the two characteristic parameters. Two characteristic equations are derived for the two characteristic parameters. The critical axial stress or the critical buckling time, the exponential parameter of inertia terms and the initial modes of buckling deformation are calculated quantitatively from the solution of the characteristic equations.

ABSTRACT: The relations of the critical stress and transverse inertia effect to the loading duration are investigated for the dynamic buckling of thin cylindrical shells under axial step loading. The critical stress and the inertial exponent are treated as the two characteristic parameters. The criterion of energy conservation is used to derive the supplementary restraint condition for buckling deformations at compression wave front. By use of the Galerkin method, an algebraic eigenvalue problem for the two characteristic parameters is derived from the governing equations and boundary conditions. The solution of the eigenvalue problem, which satisfies the supplementary restraint condition, gives the values of the critical stress and the inertial exponent for the dynamic buckling. The relation of critical stress to loading duration, predicted by the theoretical analysis, is in reasonable agreement with the experimental results.

ABSTRACT: Buckling behavior of cross-ply cylinders under hydrostatic pressure is investigated using a semi-analytical finite element based on a consistent first order shear deformable shell theory. Potential loss due to external pressure, also called pressure stiffness (PS) is taken into account by making use of Koiter's related energy expression. A number of verification problems are solved and the numerical results are compared with the analytical results available in the literature and excellent agreement is observed. New numerical results are presented to assess the effect of PS on buckling due to hydrostatic pressure. It is shown that PS causes a decrease in the buckling load and this decrease depends on the size of the cylinder and the material. Also, issues related to thickness optimization are examined and optimal lamina thicknesses are determined for a number of cases with and without PS taken into account.

ABSTRACT: A curved axisymmetric shell finite element based on a consistent first-order shear deformable shell theory is developed for the linear stability analysis of cross-ply laminated shells of revolution under compressive loads. Finite element analysis results are presented for isotropic, orthotropic and cross-ply
laminated shells of revolution in comparison with the analytical and numerical results found in the literature. These comparisons demonstrate the applicability and the high performance of the element in stability analysis of thin and moderately thick cross-ply laminated composite shells of revolution under compressive loads.

ABSTRACT: The elastic buckling and initial post-buckling behavior of clamped shallow spherical shells under concentrated load is considered. It is found that bifurcation into an asymmetric deflection pattern will occur before axisymmetric snap-buckling unless the ratio of the shell rise to the thickness lies within a narrow range corresponding to relatively thick shells. The initial post-buckling analysis indicates that the shell retains its load carrying capacity as it makes the transition to asymmetric behavior. These results are in qualitative agreement with available experimental data.

ABSTRACT: This work presents an analysis and numerical results for the buckling of longitudinally stiffened prismatic structures that consist of an assemblage of flat plate and cylindrical panel components. The applied loading is assumed to induce uniform in-plane biaxial stresses, and all types of buckling modes (general, local, and coupled) are automatically accounted for in the analysis. Previous analyses of such problems by the exact (Wittrick) and approximate (Cheung) finite strip methods are based on the assumption that the structure is simply supported on the transverse ends by diaphragms (SS3 classical simple supports). The present work extends these analyses to include the case of completely clamped transverse ends (CC4), as well as simply supported ends. A one term Galerkin method is used to replace the governing partial differential equations of equilibrium for each component by ordinary differential equations in terms of the transverse coordinate, and the ordinary equations are solved exactly. The principle of virtual work is employed to obtain the stiffness matrix for each component. Numerical results are presented for a wide variety of CC4 and SS3 prismatic structures. These results compare favorably with available solutions.

H.A. Ashour (Faculty of Engineering, Qatar University, P.O. Box 2713, Doha, Qatar), “Creep buckling of cylindrical panels under multiaxial loading”, Computers & Structures, Vol. 52, No. 1, July 1994, pp. 139-148, doi:10.1016/0045-7949(94)90265-8
ABSTRACT: This work presents an analysis of the creep buckling problem of geometrically imperfect circular cylindrical panels under multiaxial loading with simple support boundary conditions. The analysis is based on a nondimensional form of Donnell-type equations for a slightly imperfect cylindrical panel. The elastic constitutive equations for a thin panel are employed. The basic elastic equilibrium equations in the middle surface displacement components are derived through the employment of the principle of virtual displacements. For creep deformations, Odqvist's constitutive equations for steady creep are employed. In the present analysis, creep buckling is characterized by either reaching a maximum deflection limit or experiencing a bifurcational buckling state. Based on the present analysis, a computer program has been developed for the creep buckling
analysis of cylindrical panels. The panel ends are assumed to be simply supported. The applied loading is assumed to be axial compression and lateral pressure. Numerical results are presented for imperfect isotropic panels under both uniaxial and multiaxial loading. For the case of uniaxially compressed plates, the present results are generally in good agreement with previous experimental and analytical results. These results suggest that each of the level of the axial compressive load, the level of the lateral pressure, the amplitude and direction of the initial imperfection, and the panel curvature greatly affect the creep buckling times of cylindrical panels. The results presented indicate that avoiding negative (toward the centre of curvature) initial imperfections would help to suppress the creep buckling process for cylindrical panels under multiaxial loading conditions. It would also help to eliminate the possibility of a bifurcational buckling state to exist. This can be achieved by intentionally introducing a small positive initial imperfection in the form of a simple out of roundness.

ABSTRACT: An infinitely long, axially compressed, circular cylindrical shell with an imperfection in the shape of the axisymmetric classical buckling mode, undergoing steady or nonsteady creep, is analyzed. The axisymmetric problem is solved incrementally using nonlinear shell equations The ratio of the applied stress to the classical buckling stress determines if the shell will collapse axisymmetrically or if it will bifurcate into a nonaxisymmetric mode, and whether or not bifurcation will result in instantaneous collapse. The bifurcation problem is formulated exactly and the initial postbuckling behavior is investigated via an asymptotic elastic analysis, based on Koiter's general theory. Numerical results are compared with available experimental data.

ABSTRACT: A problem-oriented method for the nonlinear elastic-plastic analysis of nonsymmetrically loaded shells of revolution is described. It is based on an approximation of the circumferential distribution of the loads and variables by Fourier series. Ring finite elements are used in the axial direction. Their stiffness matrices are obtained by accurate numerical integration rather than by trial functions. To be able to take full advantage of the Fourier decomposition and the one-dimensional discretization, all nonlinearities are treated iteratively in the form of pseudo-load vectors. Thus, the various Fourier harmonics are governed by uncoupled algebraic equations and no explicit knowledge of the nonlinear global tangent stiffness matrix is required. Convergence problems of the iterative procedure are avoided by employing a sort of conjugate gradient method with a special preconditioning within each increment. Numerical examples involving strongly nonlinear behavior and highly nonsymmetric states of stress and deformation are given which demonstrate the effectiveness of the method.

ABSTRACT: This paper addresses the nonlinear dynamic analysis of shells of revolution. Starting from a discretization procedure which is tailored to the particular geometry of these shells, a direct time integration
procedure is discussed. It employs the Newmark temporal operator, and a modified preconditioned conjugate-direction method is used to solve the resulting algebraic equations. Subsequently, a closely related reduced basis technique is presented which combines some of the features of the direct integration procedure with those of the standard reduction methods.

ABSTRACT: An analysis of the elastic–plastic load-carrying behaviour of thin-walled spatial beam structures is presented. It is based on a beam theory valid for large displacements and rotations, which admits arbitrary cross-sections, curved axes, initial imperfections, a general material description, and which fully accounts for the influence of warping constraints as well as the stress-history dependence of the elastic–plastic shear moduli. An incremental updated Lagrangian viewpoint is adopted in the derivation of the basic beam equations from a generalized variational principle, and in the numerical solution procedure the displacement–finite element approach is followed. The associated tangential stiffness matrices are obtained by direct numerical integration of the governing incremental differential equations rather than through the use of shape functions in connection with a virtual work principle. Applications of the theory are given in which the influence of the loading configuration, material parameters, geometric nonlinearities and warping constraints on the load-carrying behaviour and on the bifurcation and ultimate loads of thin-walled beam structures is explored.

Lehrstuhl für Statik, Technische Universität München, Germany

ABSTRACT: The paper deals with the results of a systematic numerical investigation of the nonlinear elastic and elastic plastic load-carrying behaviour and imperfection sensitivity of torispherical pressure vessel heads under uniform external pressure. In particular, the presentation focuses on the qualitative and quantitative influence of the radius-to-thickness ratio R/t, the yield stress σ0 and the magnitude of initial geometric imperfections (in the shape of the elastic bifurcation mode) on the elastic-plastic load-carrying behaviour. It is found that thinner shells are more sensitive to the value of the yield stress and the magnitude of initial geometric imperfections, but their load-carrying capacity, relative to the elastic bifurcation pressure, may also be significantly higher than that of thicker shells.

H. Obrecht, B. Rosenthal, P. Fuchs (Baumechanik-Statik, Universitaet Dortmund, D-44221 Dortmund, Germany), “Buckling And Imperfection-Sensitivity Of Axially Compressed Cylindrical Shells With Compliant Cores”, (no date or publisher given, latest reference is 2001, fluid.ippt.gov.pl)

ABSTRACT: The extent to which the mechanical properties and dimensions of compliant cores influence the load-carrying capacity and imperfection-sensitivity of axially compressed cylindrical shells is analyzed numerically for a wide range of configuration parameters. It is found that a comparatively thin layer of core material is sufficient to achieve substantial increases in the buckling loads while at the same time the
imperfection-sensitivity is significantly smaller than for the unfilled shell.

References listed at the end of the paper:

ABSTRACT: From the point-of-view of economy and safety it is desirable to employ structural configurations with a favorable strength-to-weight ratio and a sufficiently small imperfection-sensitivity. The presentation focuses on two examples falling into this category: The axially compressed cylindrical shell filled with – and/or surrounded by - a compliant core, and auxetic structures. Both exhibit unexpected aspects in their load-carrying behavior and have a significant weight-savings potential.

H. Obrecht, P. Fuchs, U. Reinicke, B. Rosenthal and M. Walkowiak (Lehrstuhl für Baumechanik-Statik, Technische Universität Dortmund, August-Schmidt-Strasse 6, D-44221 Dortmund, Germany), “Influence of wall constructions on the load-carrying capability of light-weight structures” (Dedicated to Professor Choon Fong Shih, President of the National University of Singapore on the occasion of this 60th birthday.), International Journal of Solids and Structures, Vol. 45, No. 6, March 2008, pp. 1513-1535, doi:10.1016/j.ijsolstr.2007.10.017
ABSTRACT: Results of systematic numerical studies are presented which suggest that suitable alternative wall constructions may lead to elastic load-carrying capacities of light-weight structures which significantly exceed those of conventional monocoque constructions, and that in certain cases this improvement may also be accompanied by a decrease in imperfection-sensitivity. Two kinds of wall modifications are considered: a hybrid wall construction where the skin of a light-weight structure is coated with a low-density material, and nonhomogeneous – in particular lattice and biaxially corrugated – wall constructions. The paper focuses on the elastic load-carrying behavior of shell- and plate-like structures, and structural efficiency is assessed on the basis of their bifurcation buckling resistance while other design criteria, such as e.g. stiffness and plasticity, are not taken into account.

Hailan Xu, “Buckling, postbuckling and imperfection sensitivity analysis of different type of cylindrical shells by Hui’s postbuckling method”, 2013 Ph.D. dissertation, University of New Orleans
ABSTRACT: Buckling and postbuckling has been critical design parameters for many engineering structures. In recent years, this topic has continued to be of major concern due to (1) the discovery of new materials with amazingly superior properties, (2) increasingly more stringent safety requirements, (3) lighter, and more durable
requirements. Such applications can be routinely found in aerospace, naval, civil, and electrical, and nuclear engineering structures and especially in the vehicle industries. Koiter is the first one to show that the imperfection-sensitivity of a structure is determined by its initial postbuckling behavior. In Koiter’s 1945 general postbuckling theory, it defines the initial postbuckling behavior and imperfection sensitivity behavior by the postbuckling b coefficient. Hui and Chen (1986) were the first to show that the well-known Koiter’s General Theory of Elastic Stability of 1945 can be significantly improved by evaluating the postbuckling b coefficient at the actual applied load, rather than at the classical buckling load. The reason for such significant improvement in predicting the imperfection sensitivity is due to the fact that for an imperfection-sensitive structure, the slope of the buckling load versus imperfection amplitude curve approaches negative “infinity” as the imperfection amplitude approaches to zero. Thus for “finite” amplitude of the geometric imperfection, the applied load is significantly lower than the classical buckling load, leading to significant overestimate of imperfection using Koiter’s General theory of 1945. Such improvement method was demonstrated to be (1) very simple to apply with no tedious algebra, (2) significant reduction in imperfection sensitivity and (3) although it is still asymptotically valid, there exists a significant extension of validity involving larger imperfection amplitudes. Strictly speaking, Koiter’s theory of 1945 is valid only for vanishingly small imperfection amplitudes. Hence such improved method is termed Hui’s Postbuckling method. This study deals with the Postbuckling and imperfection sensitivity of different kinds of cylinders by using the Hui’s postbuckling method. For unstiffened cylinder and laminate cylinder, the solution of Hui’s postbuckling method is compared with ABAQUS simulation result. A parameter variation of stringer/ring stiffened cylinder is also evaluated. A positive shift of the postbuckling b coefficient has been observed, which indicates a significant overestimate of the imperfection sensitivity by Koiter's general stability theory. More importantly, the valid region is significantly increased by using Hui's postbuckling method compared with the Koiter's general stability theory.

ABSTRACT: An axisymmetric shell optimization procedure is developed which is a fast, user-friendly and practical tool for design use in disciplines including aerospace, mechanical and civil engineering. The shape and thickness of a shell can be optimized to minimize shell mass, mass/volume ratio or stress with constraints imposed on von Mises stress and local buckling. The procedure was created with the aid of the GENOPT optimization development system (Dr. D. Bushnell, Lockheed Missiles and Space Co) and uses the FAST1 shell analysis program (Prof. C. R. Steele, Stanford University) to perform the constraint analysis. The optimization method used is the modified method of feasible directions. The procedure is fast because exact analysis methods allow complex shells to be modelled with only a few large shell elements and still retain a sufficiently accurate solution. This is of particular advantage near shell boundaries and intersections which can have small regions of very detailed variation in the solution. Finite element methods would require many small elements to capture accurately this detail with a resulting increase in computation time and model complexity. Reducing the complexity of the model also reduces the size of the required input and contributes to the simplicity of the procedure. Optimization design variables are the radial and axial coordinates of nodes and the shape parameters and thicknesses of the elements. Thickness distribution within an element can be optimized by specifying the thickness at evenly spaced control points. Spline interpolation is used to provide a smooth thickness variation between the control points. An effective method is developed for reducing the number of required stress constraint equations. Various shells have been optimized and include models for comparison with published results. Shape, thickness and shape/thickness optimization has been performed on examples including a simple aerobrake, sphere-nozzle intersections, ring reinforced cylinder and elliptical and torispherical tank heads. Convergence of different initial designs to one final design is demonstrated for a shape, thickness and shape/thickness optimization problem. The sphere-nozzle intersection is investigated in detail and the equal area replacement rule for reinforcement is verified for most intersection geometries.

ABSTRACT: With the stability analysis of hyperbolic cooling tower shells with ring-stiffeners, our paper proposes the linear pre-buckling consistent theory. The numerical result shows that this linear analysis method is very effective and practical in engineering, for its precision of computation is up to the level of the nonlinear analysis when it is used for the study of critical loads of the hyperbolic cooling tower which is mainly governed by wind pressure and for the study of the effect of some other factors concerned in design on the buckling of shells. Based on that, we have obtained a series of conclusions which will greatly benefits the engineering design when discussing the effect on the critical wind loading of the shell which is caused by the following factors such as the position of rings, the number of rings and the dead weight.

References listed at the end of the paper:

ABSTRACT: Design and construction of efficient and economic Reinforced Concrete (R.C.) Hyperbolic Cooling Towers have driven the engineers toward the design of tall and thin-shell towers which have considerable high slenderness aspect ratio. Consequently, the shell of R.C. Cooling Towers with relative high slenderness aspect ratio is extremely prone to buckling instability due to wind loading. To increase the structural stability or buckling safety factor, one economic approach is to design and construct stiffening rings for the R.C. Hyperbolic Cooling Towers. Despite the research previously performed to determine the effect of stiffening rings on the buckling behavior of the R.C. Hyperbolic Cooling Towers, information resulting in maximum buckling stability is absent considering the optimized utilization of the quantity and dimension as well as the location of this type of stiffeners. In this paper, not only the effect of the stiffening rings on the buckling stability of the R.C. Cooling Tower is studied but also the optimized location, quantity and dimension of the stiffening rings are carried out for a sample RC Cooling Tower. The dimensions of the selected sample cooling tower are in average typical dimensions which are used in the current practice. In this study, finite element (F. E.) analyses has been carried out to define the buckling modes and resistance of this tower due to wind loading for different number of stiffening ring configurations. Based on the conducted buckling analysis, the optimized number, location and dimension of the stiffening rings that maximizes the tower.s buckling stability are defined and the methodology to achieve this information is discussed in this paper.

ABSTRACT: This paper is concerned with a numerical solution of hyperbolic cooling tower shell, a class of full nonlinear problems in solid mechanics of considerable interest in engineering applications. In this analysis, the post-buckling analysis of cooling tower shell with discrete fixed support and under the action of wind loads and dead load is studied. The influences of ring-stiffener on instability load are also discussed. In addition, a new solution procedure for nonlinear problems which is the combination of load increment iteration with modified R-C are-length method is suggested. Finally, some conclusions having important significance for
practice engineering are given.

ABSTRACT: Optimum design considerations for an underwater storage vessel to contain liquid gases and oils led to the assessment of an axisymmetric shell of revolution—the Echinodome or drop shape. Analytical treatment of the various types of loading to which the shell could be subjected indicated that buckling was the more critical design criteria. A small GRP spherical shell under hydrostatic pressure was investigated for its buckling behavior both experimentally and theoretically. In the experimental approach surface strains were measured using electric resistance strain-gage rosettes on the inner and outer surfaces. Predictions of critical buckling pressure were made from the experimental results using a Southwell technique and numerically by the finite-element method. The influence of the results on design procedures is discussed.

References listed at the end of the paper:

ABSTRACT: The paper examines theoretically the buckling behaviour of an echinodome—an optimum form of axisymmetric shell of revolution. The types of loading considered are of a concentrated nature applied axisymmetrically and symmetrically. Firstly static buckling behaviour is studied followed by dynamic buckling. Both bifurcation and non-linear collapse buckling are taken into account for static loading and only the non-linear collapse approach is pursued for the dynamic case. Comparisons are made between the corresponding dynamic and static buckling loads and the relative significance of the dynamic situation is discussed.

ABSTRACT: The buckling behavior of an underwater shell of revolution structure of optimum form—an echinodome—is examined under axisymmetric and symmetric point loads both experimentally and theoretically. For the concentrated loadings, experimental predictions of critical buckling are based on the Southwell technique and a possible alternative method is suggested. Bifurcation and nonlinear collapse buckling analyses are described theoretically. Within the bifurcation investigation both linear and nonlinear approaches are included. The effects of base fixity on the instability of the structure are considered. Comparisons are made with earlier external-pressure loading effects and the relative significance of the two forms of loading are discussed.

References listed at the end of the paper:

ABSTRACT: A two-dimensional finite-difference technique for irregular meshes is formulated for derivatives up to the second order. The domain in the vicinity of a given central point is broken into eight 45 degree pie shaped segments and the closest finite-difference point in each segment to the center point is noted. By utilizing Taylor series expansions about a central point with a unique averaging process for the points in the four diagonal segments, good approximations to all derivatives up to the second order and including the mixed derivatives are obtained. For square meshes the general derivative expressions for arbitrary meshes which were determined reduce to the usual finite difference formulae. In one example problem the Poisson equation is solved for an irregular mesh. In a second example for the first time a problem with a geometric nonlinearity, namely large deflection response of a flat membrane, is solved with an irregular mesh. The solutions compare very favorably with results obtained previously. Some discussion is given on possible approaches for determination of finite difference derivatives higher than the second.

ABSTRACT: Large deformation elastic-plastic buckling loads are obtained for axisymmetric spherical caps with initial imperfections. The problem formulation is based on equilibrium equations in which the plastic deformation is taken as an effective plastic load. Both perfectly plastic and strain hardening behavior are considered. Strain hardening is represented by the Prager-Ziegler kinematic hardening theory, so that the Bauschinger effect is accounted for. Solutions of elastic-plastic circular plates and spherical caps are in good agreement with previous results. For the spherical cap it was determined that both initial imperfection and
plastic deformation have the same effect of reducing buckling capacity; as the magnitude of the imperfection increases, the influence of plastic deformation becomes less important. It is also found that the geometric parameter $\alpha$, which is used as an important factor in elastic response, becomes meaningless for the elastic-plastic buckling analysis of spherical caps.

ABSTRACT: Dynamic buckling loads are obtained for axisymmetric spherical caps with initial imperfections. Two types of loading are considered, namely, step loading with infinite duration and right triangular pulse. Solutions of perfect spherical caps under step loading are in excellent agreement with previous findings. Results show that initial imperfections do indeed have the effect of reducing the buckling capacity for both dynamic and static responses, although they are affected in a different manner. From the solutions obtained for triangular pulse situations, it is revealed that pulse duration has a very significant impact on the magnitude of the dynamic buckling load. When comparing these solutions with those of step loading, it is concluded that the step loading with infinite duration is the limiting case of a triangular pulse, and that the step loading provides the most severe loading situation for dynamic analysis.

ABSTRACT: A finite difference method is developed for the large deformation elastic-plastic dynamic buckling analysis of axisymmetric spherical caps with initial imperfections. The problem formulation is based on governing differential equations of motion, treating the plastic deformation as an effective plastic load. Both perfectly plastic and strain hardening behavior are implemented in the program. Strain hardening is incorporated through use of the Prager-Ziegler kinematic hardening rule, so that the Bauschinger effect is accounted for. The solution for the large deformation elastic-plastic dynamic response of a spherical cap is compared very favorably with other findings. Two spherical cap models are selected to study the title problem. Results obtained indicate that both plastic yielding and initial imperfection play significant roles in reducing the load carrying capacity of these shell structures. Both increase their influence as the thickness to radius ratio and the imperfection magnitude increase, respectively. It is also found that dynamic effect has the influence of lowering load carrying capacity of perfect spherical caps; however, its influence on imperfect spherical caps depends on the magnitude of initial imperfections.

ABSTRACT: The present study investigates the effect of Winkler-Pasternak elastic foundation parameters on the nonlinear dynamic response of shallow spherical shells. The values of foundation parameters $k$ and $\beta$ have been determined for the minimaximum central response of the shallow shells for both the clamped as well as simply supported immovable edge conditions. Donnell type partial differential equations governing the moderately large amplitude behaviour of shallow spherical shells resting on Winkler-Pasternak elastic foundations under step pressure loading, have been analysed. The space and time-wise integrations of governing equations have been carried out using Chebyshev series and Houbolt techniques, respectively. It is also shown
that the present analysis can be extended to study the dynamic buckling of shallow shells resting on elastic foundations.

SUMMARY: Time dependent pressure loads may cause dynamic buckling instabilities in the response of thin-walled structures. A typical example is the dynamic snap-through of a spherical shell under sudden external pressure. Usually, the critical load is obtained performing several time step analyses under different load magnitudes to localize the critical step load. In this paper a more efficient alternative is described allowing to determine the critical load directly or with at least considerably less time history analyses. The dynamic stability is evaluated in the sense of Liapunov’s first method. The geometrically and materially nonlinear finite element method is applied. In the above mentioned simplified procedure stability criteria are evaluated parallel to one nonlinear time response analysis. Starting with the eigenproblem of the system matrix the applicability of the kinetic stability criterion is shown. The procedure can be extended to the eigenproblem for the load parameter in order to approximate the critical step load to some extent directly. Numerical examples demonstrate the quality of the proposed method.

ABSTRACT: Elastic-plastic deformation of a thin-walled sandwich toroidal shell (a curved tube) is considered. A geometrically nonlinear theory of finite displacements but small strains is applied. Deformation of the whole torus is assumed to be rotationally symmetric and, moreover, deformation of a meridional section of the tube is symmetric with respect to the symmetry plane of the initial torus. The torus is subject to simultaneous uniform normal pressure, internal or external, and in-plane bending. The process is controlled by the two independent parameters: the pressure and the change of unit toroidal angle. Depending on the choice of loading trajectory, a process of elastic-plastic deformation can be terminated in various ways. The first possible termination of a continuous process of deformation is due to the onset of local kinematic discontinuity (strain localization or onset of a plastic hinge), regarded as inadmissible. The second termination (limit point) corresponds to a maximal value of the load factor and it limits the stable precritical period of deformation. The interaction curves corresponding to different termination modes intersect at corners; some parts of these curves are concave.

ABSTRACT: Optimum laminate configurations for laminated rectangular plates under uniaxial or biaxial compression are investigated and are obtained under buckling constraints. Complete freedom is permitted in the selection of the ply angle variation through the thickness; however, it is proved that the maximum buckling load occurs when the orientation angle in each of the layers is the same. Three types of optimal angle (directions) are obtained in terms of the material properties, the geometrical properties and the type of buckling mode. They are expressed in closed analytical form.
ABSTRACT: The paper deals with the buckling analysis of axisymmetric fully clamped composite shells of revolution such as spherical caps, torispheres and hemispheres. Its first part is devoted to linear buckling analysis in order to determine the appropriate divisors for buckling pressures. Then, the effects of fibre orientation on buckling pressure calculated with the use of the BOSOR4 program are discussed for single-layered (angle-ply), two-layered and quasiisotropic composite shells made of unidirectional glass and carbon/epoxy resin. It is shown that the maximal buckling pressures occur for quasi-isotropic composite shells. The upper and lower bounds of buckling loads for arbitrary fibre orientations of composite torispheres and hemispheres are also proposed.

ABSTRACT: The paper deals with the investigations of failure modes of laminated shells of revolution subjected to external pressure. These are analysed for two typical shell forms such as fully clamped hemispheres and torispheres made of unidirectional or woven roving glass/epoxy and carbon/epoxy. The buckling pressures of composite shells are compared with the failure pressures obtained from the various failure criteria in the stress space. The effects of fibre orientation and initial geometric imperfections are also discussed. The imperfections considered are in the form of increased-radius polar imperfections and Legendre polynomial imperfections. For CFRP perfect torispherical shells the numerical results are verified by experimental tests.

ABSTRACT: The present paper deals with the static buckling and post-buckling behaviour of clamped elastic laminated shallow spherical shells subjected to a uniform external pressure. Applying the Rayleigh-Ritz procedure to Marguerre's equations combined with precise pre-buckling numerical analysis, reasonably accurate solutions are obtained for buckling upper and lower pressures. The effects of fibre orientations on pre- and post-buckling behaviour, buckling loads and modes are considered. The results for composite shells are compared with those calculated for quasi-isotropic ones.

ABSTRACT: Presents a finite element formulation of the layout optimization and design sensitivity applied to doubly-curved shells of revolution. The objectives of the optimization are to maximize buckling pressures and first-ply-failure pressures. The problem is formulated and solved with the use of geometrically non-linear transverse shear shell theory. However, the optimization method proposed limits the sensitivity analysis to a geometrically linear problem. Focuses special attention on the formulation of the optimization problem taking into account various factors, such as the form of geometrical and physical relations, types of design variables and the finite element discretization. Demonstrates several numerical examples to illustrate the capability of the proposed optimization procedures.

ABSTRACT: This paper presents optimization problems of cylindrical shells subjected to buckling and ply failure constraints. The objective is to maximize failure load. The layers are assumed to be oriented at 0 °, 90 ° and ± 45 °, so that the locations of plies in the laminate (3N variables) are design variables. The aim of the present work is to discuss the influence of various formulations of governing equations on optimal solutions including the effects of transverse shear deformations and to present the use of different variants of genetic algorithms, i.e. different selection, mutation and crossing. A series of numerical examples illustrates the discussed problem.

ABSTRACT: A thin-walled sandwich plate having laminated composite faces and subject to axial compression is studied. The first part of the work is devoted to the discussion of the 2-D geometrically nonlinear formulation of governing equations with the use of the Hamilton and the Lagrange variational principles. It allows us to compare and verify values of buckling loads and natural frequencies obtained with the use of different variants of sandwich plate theory. The analytical results are also confronted with the FE computations conducted with the use of the NISA II package. Then, we consider also the problems of local failure damage of sandwiches basing on the 3-D FE analysis. The aim of those investigations is to point out the effects of the normal stresses and their influence on the sandwich behaviour.

ABSTRACT: The first part of the paper is devoted to the presentation and discussion of various problems encountered in theoretical and numerical modelling of fatigue phenomena and failure modes in the 2-D description of composite structures. Then, a numerical FE model is proposed based on the progressive pure deterministic evaluation of the stiffness degradation of structures. Using the proposed formulation logarithmic fatigue life contours have been estimated for composite plates subjected to shear loads or tension.

ABSTRACT: A new optimization problem for laminated multilayered structures having surface bounded piezoelectric (PZT) patches have been formulated and solved. The present formulation introduces boundaries of PZT patches as new class of design variables. In addition, classical design variables in the form of ply orientation angles of orthotropic layers are also taken into account. The design objective is the minimization of normal maximal deflections. The standard Rayleigh–Ritz method is used; however, the accuracy of optimal design are verified with the aid of the FE package ABAQUUS. Examples are presented to illustrate the performance of the proposed model. For the actuator/actuator configuration, it was shown that the PZT actuators can significantly reduce deformations of the composite plate. Those effects were dependent on the value of the applied voltage. It was demonstrated that the proper choice of the actuator form is more efficient in reducing deflections. The influence of the fiber orientation and their material properties on the optimal design is also presented and discussed. The growth of the plate geometrical ratio \(a/b\) results in the increase of the effectiveness of the optimization procedure based on the appropriate choice of the boundary curve of the PZT patch.

ABSTRACT: In this paper the problem of the optimal design of thin-walled tubular columns under axial compression and torsion controlled by displacements is investigated. A radius of cross-sectional circular profile varying along the axis of the shell-column as well as a wall thickness, which lead to the maximal displacements caused by loadings before the structure buckles are sought. both global (buckling of a column) and local (wall
buckling of a shell) stability of a structure are taken into account. the geometry of the structure is approximated by the convex Bézier polynomial. the results are obtained using the simulated annealing method.

ABSTRACT: In this study, effective computational procedures are introduced and used to characterize the dynamic behavior of cylindrical panels with circular cross-section having the single delamination between laminate layers. Based on the computed results it is possible to determine the effect of delamination on the overall structural dynamic behavior. Those results are used to quantify the difference between the results of the relevant parameters in the cases of perfect and defected structures. Usually, the wave propagation can be observed with the use of piezoelectric sensors. Therefore, in the next step of our analysis we modeled delaminated structures with a finite number of PZT sensors to consider also their influence on the structural dynamic response. The numerical analysis have been conducted with the use of 3D finite elements. A lot of numerical results allow us to understand better the influence of various parameters on the form of wave propagation in cylindrical multilayered shells.

INTRODUCTION: Many laminated composite structures are assembled from parts that are thin. These assembled structures, loaded e.g. in compression, can buckle overall. For isotropic stiffened structures a variety of buckling interactions can occur involving local and overall deformations of both plate or shell sheet and stiffeners. In the case of laminated multilayered structures, being more complex built-up than isotropic ones, plated or shell structures can buckle in more complex and subtle ways. In addition, buckling modes can be preceded or associated with other failure modes, such as e.g. the First-Ply-Failure, delaminations or local buckling of sublaminates. For sandwich structures having faces made of multilayered laminates the number of possible failure modes even increases due to the existence of face wrinkling and/or core shear instability. It is necessary to emphasize also that the effects of local geometrical imperfections have been to cause discrepancies between experimental tests and theoretical predictions. Other uncertainties dealing with geometrical properties (e.g. length or shell ovalisation) and material properties will not be studied herein. The designer of any structure susceptible to buckling must have a certain knowledge/intuition about buckling behavior. With enhanced intuitive knowledge about shell buckling, the designer should have an improved ability to foresee situations in which buckling might occur and thus modify a design to avoid it. In this way they will be able to set up more appropriate models for experimental test and for analytical predictions. The general objective of this paper is to convey to the designer a “feel” for multilayered laminated plate and shell buckling. An understanding of instability can be developed by study of large number of examples involving a variety of plated and shell structures. The experimental results are based mainly on the tests conducted by Muc [1, 2, 3] and on the review of the most representative examples presented in the literature. Emphasis is given here to nonlinear behavior of structures caused by both large pre-buckling deflections and/or large deformations (strains), understood in the sense of 2D approach to the analysis of plated and shell structures. The present paper deals with the presentation of experimental tests for various composite structures, i.e. rectangular and square plates, cylindrical shells, cylindrical sandwich panels and various types of domed heads (spherical, ellipsoidal and torispherical) having different geometrical ratios. A number of examples involves practical shell structures (especially for pressure

ABSTRACT: The present effort focuses on the development of finite element models to implement in the bifurcation and post buckling nonlinear analysis of laminated shells. This paper deals with the two aspects of the numerical simulation of the buckling and post buckling response of layered composite structures. The first aspect is the formulation and evaluation of an efficient shell finite element valid for geometrical nonlinear analysis of laminated shells. The formulation of the element is based on the third order shear deformation theory with the assumption of moderately large deflections but small rotations. The theory allows parabolic description of the transverse shear stresses, and therefore the shear correction factors of the usual shear deformation theory are not required in the present theory. Since the formulation is based on the third order theory, applicability is extended to moderately thick to thin situations using a discrete Kirchhoff technique. The second aspect pertains to the prediction of the onset of local delamination in the post buckling range and accurate determination of transverse shear stresses in the lamina ted structures. The accuracy and effectiveness of the finite element and the strategies developed are demonstrated by means of detailed numerical and experimental examples.

ABSTRACT: The paper presents general design criteria for designing pressure vessels to withstand external pressure. Combinations of dome ends, cones and cylinders are considered. The criteria reduce to those given in BS 5500 for simple geometries. General criteria are given for the design of ring stiffening including the choice of stiffener proportions. The use of sophisticated analytical techniques to assist in meeting those criteria is demonstrated by means of numerical examples.

“Marguerre shell type secant matrices for the postbuckling analysis of thin, shallow composite shells”, Structural Engineering and Mechanics (an international journal), Vol. 18, No. 1, pp 41-58, July 2004

ABSTRACT: The postbuckling behaviour of thin shells has fascinated researchers because the theoretical prediction and their experimental verification are often different. In reality, shell panels possess small imperfections and these can cause large reduction in static buckling strength. This is more relevant in thin laminated composite shells. To study the postbuckling behaviour of thin, imperfect laminated composite shells using finite elements, explicit incremental or secant matrices have been presented in this paper. These incremental matrices which are derived using Marguerre.

ABSTRACT: Even a weak disturbance caused by an asymmetric mesh is enough to break structural symmetry, which triggers the bifurcation buckling and post-buckling behavior of composite laminated cylindrical shells under compression loading by ABAQUS. The mesh perturbation is more objective and authentic; it will not destroy the original model structure in Finite Element Analysis, comparing with the traditional perturbation method by introducing the initial imperfections into the model. A series of numerical experiments are performed to investigate the influence of different types of asymmetric mesh on the predicted secondary buckling load. The predicted secondary buckling load agrees better with analytical solution than predicted
primary buckling load and the results from the traditional perturbation method respectively. Therefore, secondary buckling load provides the key design criterion for composite laminated cylindrical shells. Primary and secondary post-buckling patterns of different complexity are explored, which agrees well with experimental buckling modes. Our major conclusions can be summarized briefly: different types of asymmetric mesh have little influence on the predicted secondary buckling load; Care must be exercised regarding the mesh density in order to produce the secondary buckling mode as well as the reliable secondary buckling load.

ABSTRACT: This paper gives the perturbation formulation of continuation method for nonlinear equations. Emphasis is laid on the discussion of searching for the singular points on the equilibrium path and of tracing the paths over the limit or bifurcation points. The method is applied to buckling analysis of thin shells. The pre-and post-buckling equilibrium paths and deflections can be obtained, which are illustrated in examples of buckling analysis of cylindrical and toroidal shells.

ABSTRACT: Flat shell strips are combined with flat shell elements in the buckling analysis of ring-stiffened cylindrical shells with cutouts. The influence of the ring-stiffeners is smeared over the whole shell and the stiffened shell is treated as an orthotropic shell. The region of the shell without cutouts is analysed by the finite strip method and the region with cutouts by the finite element method. On the interfaces of the two regions, finite strips and finite elements are connected together by specially developed transition elements. Numerical examples are given to verify the accuracy and efficiency of this method. Buckling loads of an axially compressed ring-stiffened cylindrical shell with one cutout under various cutout radiuses are calculated by the present method. The curve predicting the relationship between buckling loads and the dimension of the cutout is drawn.

ABSTRACT: Numerical aspects of initial stability analysis of a cylindrical shell of non-constant parameters along the generator and under non-symmetrical loads are considered. A variational approach based on Sanders’ and Donnell’s non-linear equations of thin, elastic shells is applied. The problem is decomposed to determine: the stability vectors in the axial direction in the first step, and the critical load and the stability vector in the circumferential direction in the second step. The discretization is based on finite Fourier representations and the finite difference method. To find the approximate stability vector in the axial direction an auxiliary problem for axisymmetric loads is solved. The error of the method is defined and the effectiveness of the method is estimated. The decomposition leads to small and fast algorithms suitable for personal computers. Shells with constant and stepped thicknesses under wind loads are calculated as examples. Tested algorithms show considerable effectiveness and good accuracy of results.

ABSTRACT: A finite element formulation applicable to the general shell of revolution is presented for the stress and stability analysis of toroidal pressure vessels under hydrostatic pressure. Considering the follower force effect of the external pressure, linear bifurcation buckling loads and corresponding mode shapes have been obtained in both axially and equatorially symmetric as well as antisymmetric buckling modes. Calculated critical values are compared with results of other investigations.

ABSTRACT: The subject of this paper is the buckling behavior of thin-walled beams with an enforced axis of rotation subjected to longitudinal compressive loadings. The stiffeners are mathematically modeled by a refined nonlinear beam theory recently derived. An analytical solution is obtained to the beam buckling equations. This solution is expressed in terms of a simple formula which yields the tripping loads of T, angle, I, Z, and other open cross-sections. These predictions are shown to agree with those of other authors and with a finite element code.

ABSTRACT: The subject of this paper is the buckling behavior of a rectangular plate, with parallel thin-walled stiffeners attached to one side, subjected to a combination of axial compression and lateral pressure. The plate is modeled by the Von Kármán plate equations and the stiffeners by a nonlinear beam theory recently derived. An analytical solution is obtained for the buckling load corresponding to a torsional tripping mode of the stiffeners. This solution is compared with the experiments and theories of other researchers.

ABSTRACT: The subject of this paper is the buckling behavior of a rectangular plate, with parallel thin-walled stiffeners attached to one side, subjected to a combination of axial compression, lateral pressure and bending moment. The plate is modeled by the Von Kármán plate equations and the stiffeners by a nonlinear beam theory recently derived. An analytical solution is obtained for the buckling load corresponding to a torsional tripping mode of the stiffeners. The effects of various boundary conditions, imperfections and residual stress are included.

ABSTRACT: A geometrically nonlinear shear deformation theory has been developed for elastic shells to accommodate a constitutive model suitable for composite shells when modeled as a two-dimensional continuum. A complete set of kinematical and intrinsic equilibrium equations are derived for shells undergoing large displacements and rotations but with small, two-dimensional, generalized strains. The large rotation is represented by the general finite rotation of a frame embedded in the undeformed configuration, of which one axis is along the normal line. The unit vector along the normal line of the undeformed reference surface is not in
general normal to the deformed reference surface because of transverse shear. It is shown that the rotation of the frame about the normal line is not zero and that it can be expressed in terms of other global deformation variables. Based on a generalized constitutive model obtained from an asymptotic dimensional reduction from the three-dimensional energy, and in the form of a Reissner-Mindlin type theory, a set of intrinsic equilibrium equations and boundary conditions follow. It is shown that only five equilibrium equations can be derived in this manner because the component of virtual rotation about the normal is not independent. It is shown, however, that these equilibrium equations contain terms that cannot be obtained without the use of all three components of the finite rotation vector.

ABSTRACT: A new, simplified version of Reissner's equations for the torsionless, axisymmetric deformation of elastically isotropic shells of revolution suffering small strains but large angles of rotation is specialized to clamped spherical caps under uniform outward pressure. The non-dimensional equations contain a thickness parameter, a shallowness parameter, and a load parameter. The latter two are written as powers of the former and the dependent variables scaled so that as the thickness parameter goes to zero, meaningful limit equations emerge. Seventeen distinct sets of simplified equations are found. In thirteen cases these are linear and the solutions are listed. These results should provide a useful set of benchmarks for testing the efficacy of numerical codes which often have difficulties with very thin shells.

ABSTRACT: Motivated by applications to seed germination, we consider the transverse deflection that results from the axisymmetric indentation of an elastic membrane by a rigid body. The elastic membrane is fixed around its boundary, with or without an initial pre-stretch, and may be initially curved prior to indentation.
General indenter shapes are considered, and the load–indentation curves that result for a range of spheroidal tips are obtained for both flat and curved membranes. Wrinkling may occur when the membrane is initially curved, and a relaxed strain–energy function is used to calculate the deformed profile in this case. Applications to experiments designed to measure the mechanical properties of seed endosperms are discussed.

ABSTRACT: The unwrinkled transition zone between the rigid boundaries and the wrinkled portion of a spherical membrane subjected to a pulling force is analyzed. The strains are first assumed to be small, and two cases are considered: (a) a spherical membrane barrel pulled into a wrinkled cylinder and (b) a hemispherical membrane pulled into a wrinkled cone. It is shown that in both cases the angular size of the transition zone is $O(\epsilon)$, where $\epsilon$ is the prevailing strain, rather then $O(\sqrt{\epsilon})$ as in the usual nonlinear membrane edge effect problem. Large rotations and substantial variations in the circumferential stresses and strains take place in this narrow zone. The extension to the case of “moderate” strains is then made for the spherical barrel, using a power series approach. It follows from the results that the size of the transition zone becomes $O(\sqrt{\epsilon})$ as the wrinkled region shrinks to zero. Finally, a complete large strain analysis of a partly wrinkled spherical barrel membrane is made. Included are both the transition zone and the interior wrinkled region. The analysis establishes the ranges of validity of the previous solutions and demonstrates the deterioration of the “edge effect”. A formula for the “wrinkle strain” in the interior is included. Interestingly, the deviation of the slope of the deformed membrane from the wrinkled direction is shown to be always small, so that the problem can be assumed to be geometrically linear in $\cot(slope)$, but materially nonlinear.

ABSTRACT: A procedure is presented for obtaining mixed, nonlinear variational principles for elastic shells based on the intrinsic formulation of the shell equations. The applicability of the procedure is demonstrated by developing specific principles for shells of weak curvatures and for circular cylindrical shells in regular and extended forms. Other cases are also discussed. The principles are developed within the scope of small-strain, large-rotation theory for shells under the Kirchhoff-Love hypothesis and require the availability of curvature functions for the given classes of shells. No other restrictions need be placed, except for those related to the geometries of the shells under investigation. Specifically, subject to the limitation of small extensional strains, the displacements and rotations may be large and no particular mode of shell behavior is postulated. The variational functional basically contain the strain energy of bending and the complementary energy of the membrane force resultants. These functionals are formulated in terms of curvature and stress functions and their Euler-Lagrange equations are those of normal equilibrium, Gauss compatibility and associated boundary conditions. All may be nonlinear. Using the extended principle as a starting point, approximate principles and equations are developed in Part II for the nonlinear, nonuniform bending of orthotropic circular cylindrical tubes of finite length (extended Brazier effort). The semi-membrane approximation, with membrane-type shear
deformation retained, is used in the analysis, plus some added restrictions of the Rayleigh-Ritz type on the curvature and stress fields. The results can be used for problems involving tubes subjected to various beam and shell type boundary conditions. The specific example of a clamped tube subjected to pure beam bending is calculated, using solutions of the equations for weak nonlinearity and a Rayleigh method for strong nonlinearity. Application of some of the results to the nonlinear “local buckling” analysis of a finite-length tube subjected to bending compare favorably with published results. Besides the interest in the specific problem, this demonstrates the applicability of the mixed principle for obtaining direct, approximate nonlinear solutions to useful ongoing problems, as a complement to more exact, but cumbersome, finite element or series solutions.

ABSTRACT: A procedure for deriving mixed variational principles for nonlinear shell analysis was presented in Part I and formulated in more detail for shells of weak curvatures and for circular cylindrical shells. The cylindrical shell principle is extended here to accommodate those special cases in which the retention of mixed terms in the compatibility equations is of significance. Emphasis is put on the interaction of longitudinal extensional strains with large circumferential changes of curvature. As a simple first example, it is applied to the orthotropic Brazier process, for which an Euler-Lagrange equation and perturbation solution are also derived. Variational principles have important uses for providing direct, approximate “engineering solutions” to highly nonlinear problems. Such solutions complement the more exact but cumbersome finite element or double series techniques. In the present case, reasonable simplifying assumptions are introduced in the extended principle to construct approximate principles and equations for the problem of strong, nonlinear, nonuniform bending of finite-length orthotropic tubes. As a specific example, the pure bending of a clamped, finite-length tube is studied. Approximate analysis is carried to collapse (or local buckling). Some of the local buckling results are compared with numerical results from the literature.

ABSTRACT: Starting from the equations of general elastic nonlinear membrane theory in intrinsic form, the equations governing the incremental state of stress in an orthotropic circular membrane tube are derived and discussed. The tube is initially subjected to uniform internal pressure and to longitudinal extension, which lead to large homogeneous deformation. Then some changes in loading and/or geometry are considered, e.g. an additional load is applied, the shape of the boundary is changed or a slit is formed in the membrane. These changes are regarded as small perturbations on the initial homogeneous state of stress. The general form as well as some simplified forms of the equations are presented, leading finally to a set of two equations in terms of two scalar potential functions. Two different variational formulations for the problem are also presented, each of which may serve as a basis for numerical treatment.

ABSTRACT: In Part I of this article (1995, Int. J. Solids Structures 32, 1907–1925) a simplified theory for the incremental state of stress in an orthotropic circular membrane tube was presented. In this second part, a numerical method is devised to solve the resulting elliptic sixth-order system of equations, for tubes which contain no slits or holes. In this method, Fourier decomposition is used in the circumferential direction and finite element discretization is used in the longitudinal direction. Special finite elements with six degrees-of-freedom are employed. Using this numerical method, the solutions of several specific problems of membrane tubes are obtained, presented and discussed. These include two problems concerning the decay of boundary disturbances. The theoretical treatment of such decay is also discussed.

ABSTRACT: The nonlinear behavior of an axisymmetric hyperelastic membrane subjected to pulling forces is analyzed. The membrane is considered to be ideal in the sense that it cannot carry compressive stress resultants. If the membrane has a positive initial Gaussian curvature, the pulling gives rise to wrinkles which form over parts of the surface. The full nonlinear equations governing the membrane behavior in the doubly tense and in the wrinkled regions are formulated, and then solved using a numerical integration procedure. Solutions for various examples are presented, with Hookean and neo-Hookean constitutive behavior. These include a few examples of wrinkled membranes with positive initial Gaussian curvatures, and one example of a membrane with a negative initial Gaussian curvature, where no wrinkles are formed.

ABSTRACT: This paper investigates the effects of the bending-stretching coupling on the imperfection sensitivity of axially compressed laminated, thin, rectangular flat plates. In particular, it is found that under certain circumstances this coupling phenomenon results in a nonzero cubic term of the potential energy, so that the structure may be imperfection sensitive depending on the sign of the imperfection. The analysis considers a nonlinear prebuckling state due to bending-stretching coupling of the structure. The buckling and initial postbuckling problem is solved using Koiter's theory of elastic stability.

ABSTRACT: This paper deals with the effects of initial geometric uni-directional imperfections on vibrations of a pressurized spherical shell or spherical cap. The analysis is based upon shallow shell theory. Frequency vs applied pressure interaction curves are plotted for various values of the imperfection amplitude. Imperfections are shown to have a severe effect in reducing the natural frequencies similar to that demonstrated in the buckling behavior of spherical shells.

ABSTRACT: This paper aims to review Koiter’s theory of amplitude modulation of the local mode and present it in a form suitable for general application. Various features of this theory are compared with Koiter’s general theory of 1945. The amplitude modulation theory is applied to two-mode buckling of stringer stiffened cylindrical shells under axial compression. New mode interaction results are reported involving the simultaneous local and overall buckling in which the local mode is postbuckling unstable.

ABSTRACT: This paper deals with the effects of initial geometric imperfections and in-plane boundary conditions on the large-amplitude vibration behavior of angle- and cross-ply rectangular thin plates. It is found that the presence of imperfection amplitudes of the order of only half the total laminated-plate thickness may significantly raise the vibration frequencies and change the large-amplitude vibration behavior from the well-known hard-spring to soft-spring behavior. The effects of fibre angles and bending-stretching coupling for angle-ply plates and Young's moduli ratios and number of layers for antisymmetric cross-ply plates are examined.

David Hui (The Ohio State University, Department of Engineering Mechanics, Boyd Laboratory, 155 W. Woodruff Ave., Columbus, Ohio 43210, USA), “Asymmetric postbuckling of symmetrically laminated cross ply, short cylindrical panels under compression”, Composite Structures, Vol. 3, No. 1, 1985, pp. 81-95, doi:10.1016/0263-8223(85)90029-7
ABSTRACT: Buckling and initial postbuckling behavior of symmetrically laminated, thin cross ply cylindrical panels under axial compression are investigated. The panels are simply supported at all four edges. Closed form solutions are obtained for the buckling loads. The initial asymmetric postbuckling behavior is demonstrated by computing the postbuckling coefficients within the context of Koiter's theory of elastic stability. Parameter studies involving the flatness parameter, the length-to-width ratio, number of layers and Young's moduli ratio are presented for typical cross ply cylindrical panels likely to be encountered in practice.

ABSTRACT: This paper deals with the two-mode initial postbuckling analysis of geometrically imperfect beams on elastic foundation under compression. By adjusting the beam length to the characteristic length ratio, it is found that the resulting two-mode stability problem may be classified as the double-cusp model in catastrophe theory. The appropriate postbuckling coefficients are computed with the use of Koiter's theory of elastic stability. The equilibrium paths and the critical sets are plotted and analysed. Eight independent control parameters are suggested. The paper is the first in the open literature to apply the double-cusp model to a two-mode stability problem which displays imperfection-sensitivity.

ABSTRACT: This paper deals with the use of Koiter's improved postbuckling theory in axial buckling of integrally stiffened cylindrical panels. According to Koiter's improved theory, the postbuckling coefficients are evaluated at the actual applied load rather than at the classical buckling load. Substantial positive shift of the postbuckling is found which indicates that the imperfection sensitivity predicted by Koiter's 1945 general theory may significantly overestimate the degrading effects of these imperfections. Such a positive shift is especially crucial in studying mode interactions such as local and overall buckling mode interactions of stringer-reinforced cylindrical shells.

ABSTRACT: This study deals with the postbuckling behavior of infinite beams on non-linear elastic foundations subjected to axial compression. The analysis utilizes an improved Koiter's postbuckling theory such that the postbuckling coefficients are evaluated at the actual applied load rather than at the classical buckling load. The improved postbuckling paths are found to agree well with the non-linear large deflection solution using the Ritz procedure. This paper substantiates Koiter's conjecture that the general theory of elastic stability may be improved. The implications of various lower-bound buckling loads are examined.

ABSTRACT: This work deals with the effects of shear loads on the vibration and buckling of typical antisymmetric cross-ply thin cylindrical panels, subjected to combined loads. Changes in the buckling loads due to geometric and material parameter variations are investigated with particular emphasis on distinguishing the symmetric and antisymmetric modes. The paper presents the first known results on shear buckling of cross-ply cylindrical panels as well as vibrations of these structures under shear loads. The resulting interaction curves will allow one to formulate effectively a preliminary design of these panels which will withstand shear loads.

ABSTRACT: A theoretical and experimental study of the buckling and postbuckling behavior of unidirectionally laminated graphite/epoxy plates was conducted under combined thermal cooling and compressive loading. The rectangular plates were simply supported at the loaded edges and free in the remaining edges. The plates were found to bend during cooling even without mechanical loads because of the negative thermal expansion coefficient of the material in the loading direction and the in-plane end constraints at the two-loaded edges. Such bending from thermal load was treated as an initial geometric imperfection, and
the analysis was based on Koiter's theory of elastic stability. The experimental postbuckling curves agreed well with the theoretical values.

ABSTRACT: Domes are efficient structural systems for long clear-span buildings. The introduction of laminated timber highlighted the economic advantages of this material and led to the use of timber domes even for very large spans. In this paper, reticulated timber domes of triangular network shape with decking and bottom tension ring are considered. These types of domes have high stiffness in all directions along the surface and are kinematically stable. The dome is subjected to uniformly distributed load over the entire structure. The dome model is generated with a preprocessor program called DOME-IN and analysed with ABAQUS. The focus of this paper is to evaluate the behaviour of reticulated timber domes with respect to different stiffnesses of the bottom ring beam, here defined as a non-dimensional ring beam area parameter Ar*, which is shown to be a very well adapted design parameter for the ring beam. As far as global buckling is concerned, the critical pressure is sensitive to the bottom ring beam stiffness only if the latter is within a certain range. In terms of design, the stiffness of the ring beam should exceed Ar* > 2 in order to utilise the full buckling load capacity of the dome system itself. The maximum deflection, normal forces and bending moments versus the ring beam area parameter are also evaluated. The maximum values of the deflection and the internal actions next to the bottom ring are very sensitive to the bottom ring beam stiffness only if the latter is less than about Ar* < 10. A
recommended value for the design of the bottom ring beam is $A_* > 20$.

ABSTRACT: The use of fibre-reinforced polymer (FRP) composites in the pressure hulls of submersible vehicles is examined with reference to material and fabrication options, alternative structural configurations, evaluation of stresses, deformations and buckling behaviour and other aspects of design. The performance of FRP is contrasted with that of steel and light alloy construction. Reference is made to two illustrative trial designs, one corresponding to a manned submersible for shallow-water operation and the other to a deep-water autonomous underwater vehicle.

ABSTRACT: DRA Dunfermline has had a continuing involvement in the development of deep diving composite pressure hulls through the NERC Autosub project and as part of the MAST II programme which culminated recently in the testing of a relatively large scale model pressure hull. This paper describes analytical models which were developed in conjunction with a series of model tests and used in the design of the large scale hull model. Comparisons between theoretical predictions and experimental data are also given. In keeping with the topic of the workshop the emphasis is on buckling with stress and failure analysis being reported more fully elsewhere.

ABSTRACT: This paper describes the application of finite element (FE) analysis to the prediction of the non-linear elasto-plastic collapse of ring-stiffened cylinders under hydrostatic loading. A range of legacy experimental test models have been analysed using FE idealisations generated using measured as-built shape data including out-of-circularity (OOC), frame alignment and tilt and other scantlings. The FE models also explicitly included the residual stresses caused by cold bending. Short and long ring-stiffened cylinders, which were designed to isolate interframe and overall collapse modes, respectively, were considered as were some intermediate length cylinders where the possibility of interactive collapse was also present. In general, the collapse pressures were predicted to within 6%. However, for some of the interframe collapse models, it was necessary to use the minimum measured plate thickness to achieve this. This was largely attributable to the limited measured plate thickness data.

ABSTRACT: The paper outlines the fundamentals of the method of solving static problems of geometrically nonlinear deformation, buckling, and postbuckling behavior of thin thermoelastic inhomogeneous shells with
complex-shaped midsurface, geometrical features throughout the thickness, or multilayer structure under complex thermomechanical loading. The method is based on the geometrically nonlinear equations of three-dimensional thermoelasticity and the moment finite-element scheme. The method is justified numerically. Results of practical importance are obtained in analyzing poorly studied classes of inhomogeneous shells. These results provide an insight into the nonlinear deformation and buckling of shells under various combinations of thermomechanical loads.

ABSTRACT: The article is devoted to the geometrically and physically linear and nonlinear formulations of the problems regarding the dynamic loading of shells of revolution. Analytical and numerical methods of solving the problems of impact buckling and supercritical behavior of elastic and elastic-plastic shells of revolution following axisymmetric and non-axisymmetric forms are considered. The role of boundary, wave, geometrically and physically nonlinear effects is assessed, as well as the effect of the bound nature of axisymmetric and non-axisymmetric forms in the process of buckling with multistage loss of stability. The non-axisymmetric forms of the loss of stability of cylindrical shells in the elastic-plastic region are realized according to the second and third forms both for static and dynamic loading, and, hence, the theory of shallow shells is not applicable for analyzing these processes.

ABSTRACT: A method for analyzing the elephant-foot buckle failure of ground-supported, broad cylindrical liquid storage tanks under horizontal excitation is presented. The method is based on Sanders' nonlinear thin shell theory and an idealized fluid model. Following the ring finite element discretization in the shell and the boundary solution technique in the fluid region, the matrix equations of motion are derived. An iterative formulation for the solution of the equations is proposed in terms of pseudo-loads. The dynamic response of the tank at each iterative step can be obtained by means of the mode-superposition procedure and direct time integration method. Numerical results show that the effects of cos ntheta modes due to the geometrical nonlinearity of the shell are of great significance on the axial and hoop membrane forces near the elephant-foot buckle region of the broad liquid storage tanks.

ABSTRACT: A study of plastic buckling of a circular cylindrical shell subject to axial, torsional and circumferential loading stresses is presented. In the deformation model, the transverse shear is taken into account by a first-order theory with a correction factor. For the buckled equilibrium, the contributions of both v (circumferential displacement) and w (normal displacement) to the buckling are included so that a better accuracy can be achieved. J2 deformation theory and J2 flow theory of plasticity are used for the establishment of the constitutive relations for buckling analysis. With the existence of torsional load, the equation of radial equilibrium includes the term of mixed second-order derivative ∂²w/∂x∂y and the plastic in-plane stress–strain relations are anisotropic, and therefore a handy form of solution in terms of trigonometric functions is no longer possible. Consequently, the finite difference method is used. To improve the accuracy, a five-point finite difference scheme is employed instead of the conventional central difference. Numerical results of examples show the interactive roles of the in-plane loads in the plastic buckling.

ABSTRACT: In this paper, a shell finite element is designed within the total Lagrangian formulation framework to deal with the plastic buckling and post-buckling of thin structures, such as cylindrical shells. First, the numerical formulation is validated using available analytical results. Then it is shown to be able to provide the bifurcation modes—possibly the secondary ones—and describe the complex advanced post-critical state of a cylinder under axial compression, where the theory is no longer operative.

ABSTRACT: The present study deals with the severity of cracks in pressure equipments, where such defects are often involved. Our work is particularly concerned with the problem of cylindrical shells and also the little well-known problem of spherical shells, including all sorts of practical defects, namely axisymmetric or semi-elliptic, both internal and external cracks. The stress intensity factor in the linear elastic domain and the J integral in the elastoplastic range are performed using the finite element method and compared to the results provided by the application of the semi-analytical A16 or R6 simplified criteria, depending on a limit load calculation. The nocivity of the defects depends on the crack shape and size and other structural geometrical parameters. Use is made of a polynomial decomposition of the stress field in the vicinity of the crack in order to cover all industrial loadings. All the numerical results, for a wide range of shell and crack geometries, are depicted using appropriate tables and curves in order to check the fracture criteria more easily.

“Elastoplastic collapse of cylindrical tubes under external pressure”, 7th EUROMECH Solid Mechanics Conference J. Ambrosio et.al. (eds.) Lisbon, Portugal, 7–11 September 2009
ABSTRACT: The buckling problem of a circular cylindrical shell has long been widely investigated due to its great importance in the design of aerospace and marine structures. But very little attention has been paid until now on the influence of residual stresses on the critical and often unstable response of such structures. In this paper, a shell finite element is designed within the total Lagrangian formulation framework to deal with the elastoplastic buckling and post-buckling of thin cylindrical tubes under external pressure and axial compression. A specific experimental process will be introduced in order to measure residual stresses in the shell very
accurately, so as to include them in the numerical calculations. The present formulation will enable us to describe the complete non-linear solution, namely the critical load, the bifurcation mode and the bifurcated equilibrium branch up to an advanced post-critical state corresponding to collapse. Comparisons will be made between numerical results and the experimental critical value and deformation patterns of a new generation profiler. Furthermore, the combined effects of geometric imperfections, residual stresses and plasticity will be analyzed.

ABSTRACT (Note: This abstract is very similar to that in the previous entry. Is this a different paper?): The buckling problem of a circular cylindrical shell has long been widely investigated due to its great importance in the design of aerospace and marine structures. Geometric imperfections and residual stresses are inevitable in practice and have been so far frequently considered in analytical and numerical predictions. But little attention has been paid until now on the combined influence of such initial defects on the critical and often unstable response of such elastoplastic structures. In this paper, a shell finite element is designed within the total Lagrangian formulation framework to deal with the elastoplastic buckling and post-buckling of thin cylindrical tubes under external pressure and axial compression. A specific experimental process will be introduced in order to measure residual stresses in the shell very accurately, so as to include them in the numerical calculations. The present formulation will enable us to describe the complete non-linear solutions, namely the critical pressures (bifurcation and limit (collapse) loads), the bifurcation modes and the bifurcated equilibrium branches up to advanced post-critical states. Comparisons will be made between numerical results and the experimental critical value and deformation patterns of a new generation profiler. Furthermore, the combined effects of geometric imperfections, residual stresses and plasticity will be analyzed.

Kahina Sad Saoud and Philippe Le Grognec (Mines Douai, Polymers and Composites Technology & Mechanical Engineering Department, 941 rue Charles Bourseul - CS 10838, 59508 Douai Cedex, France), “A unified formulation for the biaxial local and global buckling analysis of sandwich panels”, Thin-Walled Structures, Vol. 82, pp 13-23, September 2014, DOI: 10.1016/j.tws.2014.03.009

ABSTRACT: Sandwich structures are increasingly employed in many practical applications thanks to their interesting compromise between lightweight and high mechanical properties. However, due to some specific geometric and material features, such structures are subject to global as well as local buckling phenomena, which lead to collapse in most cases. The buckling analysis of sandwich panels is therefore an important issue for their mechanical design. In this respect, this paper is devoted to the theoretical study of the elastic local/global buckling of rectangular sandwich plates under uniaxial or biaxial compression(-tension). Only classical sandwich materials are considered with homogeneous and isotropic core/skin layers. In the present formulation, a Love–Kirchhoff plate model is used to represent the thin skins, whereas the relatively thick core is modeled as a 3D continuous solid. Furthermore, the proposed approach is based on the elastic bifurcation theory in a general 3D framework, and leads to closed-form analytical expressions of the critical loadings and the corresponding bifurcation modes. The accuracy of the derived formulae is checked for both local and global modes by comparison with the results of finite element computations. Parametric analyses are finally performed, investigating primarily the influence of the aspect ratio of the plate and the ratio of the compressive (or tensile) loadings between both directions on the first buckling mode type and the associated minimum critical value.

ABSTRACT: A collection of all available literature data upon experiments of composite cylinders under axial
compression is performed. Theoretical estimation of bifurcation load for all the tested cylinders is achieved solving stability differential equations with the use of a combined “bi-modal and torsion” solution and Galerkin approximation. Experimental knockdown factors with respect to theoretical predictions are derived and they are used to tune the imperfection amplitude of an in-house code, which computes collapse load of imperfect cylindrical composite shells using an axy-symmetric sine-shaped imperfection. “Equivalent imperfection amplitudes” are statistically analysed and with the help of imperfections sensitivity curves, Monte Carlo simulations are performed in order to obtain new reliability-based knockdown factor for cylinders with different stacking sequences. The values obtained directly by statistical analysis of the tests results and the ones derived by the statistical analysis of the calibrated imperfection amplitudes represent an improvement with respect to old design values extrapolated from isotropic shells.

ABSTRACT: Local force introduction in cylinders has received relatively little attention in the past and the designer often finds himself lost by the lack of design regulations or experimental evidence. This research activity, starting at the Ghent University, examines this stability problem and its purpose is to develop simple recommendations in order to assist designers in the steel industry. A short overview of the available literature on this particular topic is brought into the present contribution, together with our preliminary experimental observations and theoretical analyses with respect to unstiffened cylindrical shells subjected to local forces.

ABSTRACT: Cylinders on discrete supports are prone to local instability. This failure phenomenon can be avoided by reinforcing the cylindrical wall by means of stringer stiffeners in combination with ring stiffeners. The goal of our research is to find design rules for this kind of shell structures. For this purpose, a numerical model was developed. In this contribution, the numerical model is validated by verifying the correspondence with the results of experiments on scale models. Two experiments are here discussed. The corresponding failure patterns are examples of the two possible patterns that were found in all the experiments. For the numerical simulations of these experiments, the measured geometrical imperfections and the real stress-strain relationship of the steel were incorporated into the numerical model. The results of the simulations show that the correspondence between experiments and simulations is sufficient.

ABSTRACT: Frequently the governing failure mode of liquid-filled conical tanks is associated with buckling near the lower rim due to compression of the shell wall in meridional direction notwithstanding the stabilizing tension in circumferential direction. But important axisymmetric imperfections may increase the circumferential tensile stresses in such a way that local yielding precipitates a buckling failure. This failure mode is of the same
kind as the “elephant’s foot” buckling at the support of axially compressed thin steel cylinders with internal pressure. This paper gives numerical results for a series of imperfect conical tanks. The collapse is in some cases of the type “elephant’s foot” buckling. The paper explains why the imperfections can cause large circumferential tensile stresses leading to plastic collapse of the tank.

ABSTRACT: The influence of interactive buckling on the postbuckling behaviour of thin-walled elastic beams with imperfections is studied. The investigation is concerned with thin-walled closed and open cross-section beam-columns under axial compression and a constant bending moment. The beams are assumed to be simply supported at the ends. The asymptotic expansion established by Byskov and Hutchinson is employed in the numerical calculations in the form of the transition matrix method. The paper's aim is to achieve the improved study of the equilibrium path in the postbuckling behaviour of imperfect structures with regard to the second-order approximation. The calculations are carried out for several types of beams.

ABSTRACT: The influence of modification of boundary conditions at both ends of the structures regarding interactive buckling on the postbuckling behaviour of thin-walled elastic columns with imperfections is studied. The investigation concerns thin-walled closed and open cross-section columns under axial compression. The columns are assumed to be simply supported at the ends. The asymptotic expansion established by Byskov and Hutchinson is employed in the numerical calculations in the form of the transition matrix method. The aim of the paper is to improve the study of the equilibrium path in the postbuckling behaviour of imperfect structures regarding the second order approximation.

ABSTRACT: The design of thin-walled beam-columns must take into account the overall instability and the instability of component plates in the form of local buckling. This investigation is concerned with interactive buckling of thin-walled closed cross-section beam-columns with central intermediate stiffeners under axial compression and constant bending moment. The beams are assumed to be simply supported at the ends. The asymptotic expansion established by Byskov and Hutchinson is employed in the numerical calculations performed using the transition matrix method. The paper's aim is to contribute to the study of the equilibrium path in the post-buckling behaviour of imperfect structures using the first order approximation. The calculations are carried out for a few closed beam-columns.

ABSTRACT: For anisotropic materials, Tsai-Wu [1] proposed the failure criterion that takes into account the difference in strength due to positive and negative stresses. Hashin [2] pointed to some internal incoherencies of the function of material effort with respect to stress parameters. The minimum of the External Function does not coincide with the unstressed state. Therefore, the criterion presented by Tsai-Wu [1] has limited possibilities of application for optimization purposes. A modification of the Tsai-Wu criterion, needed in the case of the multicriterion optimal design of thin-walled composite structures, has been presented. A proposal of the evaluation of the load carrying capacity of multi-layered composites with respect to their failure mode has been put forward.

ABSTRACT: The design of thin-walled beam–columns must take into account the overall instability and the instability of component plates in the form of local buckling. This investigation is concerned with interactive buckling of thin-walled beam–columns with central intermediate stiffeners under axial compression and a constant bending moment. The columns are assumed to be simply supported at their ends. The asymptotic expansion established by Byskov and Hutchinson (AIAA J. 15 (1977) 941) is employed in the numerical calculations performed by means of the transition matrix method and Godunov’s orthogonalisation. Instead of the finite strip method, the exact transition matrix method is used in this case. The most important advantage of
this method is that it enables us to describe a complete range of behaviour of thin-walled structures from all global (flexural, flexural-torsional, lateral, distortional and their combinations) to local stability. In the presented method for lower bound estimation of the load carrying capacity of structures, it is postulated that the reduced local critical load should be determined taking into account the global pre-critical bending within the first order non-linear approximation to the theory of the interactive buckling of the structure. The paper’s aim is to expand the study of the equilibrium path in the post-buckling behaviour of imperfect structures with regard to the second order non-linear approximation. In the solution obtained, the transformation of buckling modes with an increase of the load up to the ultimate load, the effect of cross-sectional distortions and the shear lag phenomenon are included. The calculations are carried out for a few beam–columns. The results are compared to those obtained from the design code and to the data reported by other authors. The results discussed in the present study represent the most important results obtained by the authors in earlier investigations devoted to central intermediate stiffeners (Int. J. Solid Struct. 32 (1995) 1501; Eng. Trans. 43 (1995) 383; Int. J. Solid Struct. 37 (2000) 3323; Int. J. Solid Struct. 33 (1996) 315; Thin Wall. Struct. 39 (2001) 649; Arch. Mech. Eng. XLVIII (2001) 29).

ABSTRACT: The influence of modal interactive elastic buckling on the post-buckling behaviour of thin-walled composite beam-columns with imperfections is studied when the distortional deformations are taken into account. The investigation is concerned with open cross-section columns under an axial compression or/and a constant bending moment. The beam-columns are assumed to be simply supported at the ends. The asymptotic expansion established by Byskov and Hutchinson [Mode interaction in axially stiffened cylindrical shells, AIAAJ, 15(7) (1977) 941–948] is employed in the form of the numerical transition matrix method. The paper’s aim is to improve the study of the equilibrium path in the post-buckling behaviour of imperfect structures with regarding the second order non-linear approximation and the effect of cross-sectional distortions. The principal goal of numerical analysis is to investigate the influence of the wall orthotropy factor of columns upon the all buckling modes from global (flexural, flexural–torsional, lateral, distortional and their combinations) to local and upon the coupled post-buckling state. In the solution obtained the transformation of buckling modes with the increase of load up to the ultimate load and shear lag phenomenon is included.

“Interactive buckling of thin-walled beam-columns with intermediate stiffeners or/and variable thickness”, International Journal of Solids and Structures, Vol. 37, No. 24, pp 3323-3344, June 2000

DOI: 10.1016/S0020-7683(99)00044-X

ABSTRACT: The design of thin-walled beam-columns must take into account the overall instability and the instability of component plates in the form of local buckling. This investigation is concerned with interactive buckling of thin-walled beam-columns with central intermediate stiffeners or/and variable thickness under axial compression and a constant bending moment. The columns are assumed to be simply supported at the ends. The asymptotic expansion established by Byskov and Hutchinson (1977: Byskov, E. and Hutchinson, J. W. (1977).

ABSTRACT: In the paper the influence of following factors: initial imperfections, shape and duration of pulse loading on the dynamic response of plate structures is presented. The effect of material properties in the plastic range and the estimation of structure capacity to sustain dynamic pulse loadings based on different dynamic stability criteria is discussed as well.

References listed at the end of the paper:

ABSTRACT: In the paper, the buckling phenomenon for static and dynamic loading (pulse of finite duration) of functionally graded plates subjected to uniform temperature increment is presented. The work deals with thin rectangular plates with unmovable edges, simply supported or clamped along all edges. The material properties varying smoothly across the thickness are assumed to be temperature-independent. The investigations are conducted for different values of volume fraction index and uniform temperature rise in form of rectangular pulse of finite duration.

References listed at the end of the paper:

ABSTRACT: In the paper some basic ideas in approach to stability, post buckling behaviour and load carrying capacity of thin-walled composite structures are presented. Authors do not present equations that could only
make the understanding of this issue “harder”. Thin walled composite beam-columns with open and closed cross-section (channel and square cross-section) are calculated as an example. In order to analyse the stability and the structure performance after its loss, the ANSYS 5.7 package and authors' software has been used. Results obtained from both applied methods are compared. Presented examples show that the sole application of the FEM does not guarantee to obtain correct results of load carrying capacity and postbuckling path.

ABSTRACT: The interactive buckling of prismatic, thin-walled composite columns with open sections, reinforced with intermediate stiffeners and with edge reinforcements, has been considered. The columns are assumed to be simply supported. The nonlinear problem has been solved with the Koiter’s asymptotic theory within the first order approximation. The asymptotic theory of the first order nonlinear approximation allows for simultaneous evaluation of the effect of imperfections and interactions of various modes of buckling on the behaviour of thin-walled structures. This evaluation can be only the lower bound estimation of the load carrying capacity. Detailed calculations have been made for several cases of columns.

ABSTRACT: The problem of buckling and initial post-buckling equilibrium paths of thin-walled structures built of plate and/or shell elements subjected to compression and bending has been solved. Plate and shell elements can be made of multi-layer orthotropic materials. A method of the modal solution to the coupled buckling problem within the first-order approximation of Koiter’s asymptotic theory, using the transition matrix method, has been presented. In the solution obtained, the effect of cross-sectional distortions and a shear lag phenomenon is included. The calculations are carried out for a few thin-walled structures.

ABSTRACT: The static and dynamic problem of interaction of global buckling modes in compressed columns with complex open and closed cross-sections was considered in the paper. The columns made of laminate composites were assumed to be simply supported at both loaded ends. A plate model was adopted in the analysis. The equations of motion of individual plates (Schokker et al., 1996; Sridharan and Benito, 1984) were obtained from Hamilton’s Principle, taking into account all components of inertia forces (Teter and Kolakowski, 2005). Within the frame of the first order nonlinear approximation, the dynamic problem of modal interactive buckling was solved by the transition matrix using a perturbation method. Distortions of cross-sections and the shear-lag phenomenon were taken into consideration in the problem solution. A modification of the quasi-bifurcation dynamic Kleiber-Kotula-Saran criterion (Kleiber et al., 1987) was proposed. A
comparison of the proposed modification to the Budiansky-Hutchinson criterion (Budiansky and Hutchinson, 1966; Hutchinson and Budiansky, 1966) was presented for a rectangular pulse loading.

ABSTRACT: The paper deals with dynamic buckling of thin-walled structures (plates and beam-columns with open cross-section) subjected to compressive rectangular pulse loading. The local, global and interactive dynamic buckling was analysed. Author proposes the new criterion for critical amplitude of pulse loading leading to stability loss. The proposed criterion is a modification of quasi-bifurcation criterion formulated by Kleiber, Kotula and Saran. Results obtained using proposed criterion were compared with other well-known criteria (Volmir (V) and Budiansky–Hutchinson (B–H) criterion).

ABSTRACT: The study is concerned with the finite element analysis of complex axisymmetric structures subjected to arbitrary static or dynamic loadings. The structures are assumed to be made of elastic or elasto-plastic material. For large deformation analysis the total Lagrangian description is utilized. Five types of axisymmetric finite elements are employed: triangular and quadrilateral solid rings, a conical thin shell element and two transition elements. A combination of a two-dimensional finite element process and a Fourier series in the circumferential direction, well known in linear applications, is shown to be effective also in the fully nonlinear range of structural behaviour. Some numerical illustrations are given.

ABSTRACT: The results of the stability analysis of simply supported layered isosceles trapezoidal plate subjected to axial in-plane compression are presented. The layup configuration is confined to symmetric laminates. The solution has been obtained by means of the Galerkin orthogonalisation method combined with the proposed method of the coordinate system transformation. The results of the analytical solution are compared with the verifying FEM calculation. The computed results in the form of graphs of the buckling force as a function of material and geometrical parameters of the panel are included.

ABSTRACT: A theoretical analysis is presented for the behaviour after buckling of intermediately stiffened plates loaded in compression. The loaded and unloaded edges are simply supported but the unloaded edges are free to wave in the plane of the plates. A semi-energy method of analysis, based on the von Kármán's compatibility equation and the principle of minimum total potential energy, is used. The results are presented graphically for a range of plate aspect ratios and stiffener sizes and comparison is made with experimental results.

ABSTRACT: The buckling behaviour of thin-walled structural sections made from specially orthotropic material is studied using a semi-analytical, seminumerical approach. The approach used combines plate and beam theory in dealing with the out-of-plane and in-plane deformations of the walls of a cross-section, and has common features to both the finite strip approach and the generalised beam theory approach. The particular problems examined here concern the effects of directionality of the material, and for all cases considered material with stiff direction set longitudinally along the section is compared with the same material set with the stiff direction across the section. It is found that the buckling behaviour in either case can be found directly from an examination of the other case.

ABSTRACT: A brief examination of some of the research on the post-buckling elastic and plastic behaviour of plates and plate structures is outlined. This field is so wide ranging that only a very superficial examination of the early research has been carried out, and the writer has concentrated on some specific aspects of the general field of study. A very limited examination of some of the early research on rectangular cross-section tubes is also given.

ABSTRACT: A brief examination of some of the research on the post-buckling analysis of plates and plate structures is outlined. Only a very superficial examination has been carried out. The behaviour of plates and sections under eccentric load or eccentric compression is considered, and the application of plate analysis to strut, beam and column design is discussed.

ABSTRACT: A method is introduced for determining the critical initial imperfection of discretized structures that decreases the load-bearing capacity most rapidly. The effects of imperfections on simple critical points, such as limit points of loads and simple bifurcation points, are theoretically investigated based on the idea of the Lyapunov-Schmidt decomposition developed in bifurcation theory. Imperfection sensitivity varies with the types of points. Nonetheless critical imperfection pattern is expressed in the same formula regardless of the types. Among various imperfections, the most influential can be found in a quantitative manner. The validity and the usability of the proposed method are illustrated through its application to simple example structures.

ABSTRACT: This paper is a theoretical study on random initial imperfections of structures. The explicit form of probability density function of the load-bearing capacity (critical load) of structures is derived for random initial imperfections based on a decomposition of the space of imperfection vectors into two orthogonal subspaces: the subspace that asymptotically affects the load-bearing capacity and the other that does not. Tight bounds on the range of load-bearing capacity are presented for various types of simple critical points. By means of the asymptotic theory of statistics, we show the inefficiency of a conventional random method that approximates the minimum loadbearing capacity by the minimum load for a number of random initial imperfections. The theoretical and empirical probability distribution functions for simple truss structures are compared to show the validity and effectiveness of the present method.

ABSTRACT: This paper offers a theoretical study on the probabilistic nature of critical loads (buckling loads) of structures subject to normally distributed initial imperfections. Explicit form of probability density function of critical loads are derived for various types of critical points. Double bifurcation points of structures with regular-polygonal symmetry are dealt with by means of the group-theoretic bifurcation theory. The distribution of minimum values of the critical loads is investigated to present a statistical design index. The theoretical and empirical probability density functions for simple structures are compared to show the validity and effectiveness of this method. The method is quite efficient when it is directly applicable; otherwise, the explicit forms, at least, can greatly supplement the inefficiency of the conventional random method.

ABSTRACT: The author’s method of design sensitivity analysis of nonlinear coincident buckling load factors and corresponding optimization method of finite dimensional elastic structures are shown to be applicable to a structure with moderately large number of degrees of freedom. The sensitivity formulations are written in general form for coincident buckling load factors including limit points and bifurcation points. Optimum designs are found for a spherical latticed dome subjected to a concentrated load and distributed loads, respectively. The results are compared with those by linear eigenvalue formulation. An approximate optimal solution against nonlinear buckling can be obtained by only scaling the solution under linear eigenvalue formulation even for the case where the effect of prebuckling deformation is very large. It is shown that the proposed method is practically applicable to optimum design with coincident critical points especially for the case of hill-top branching where bifurcation points are located at the limit point. In this case, imperfection sensitivity is not enhanced as a result of optimization. The reduction of maximum load factor due to a minor imperfection is shown to be in the same order as that to a major imperfection. Therefore symmetric imperfection as well as asymmetric imperfection should be considered in estimating the maximum loads.

ABSTRACT: The imperfection sensitivity law by Koiter played a pivotal role in the early stage of research on initial post-buckling behaviors of structures, but seems somewhat overshadowed by numerical approaches in the computer age. In this paper, to make this law consistent with practical application, the law is extended to implement the influence of a number of imperfections, and the second-order (minor) imperfections are considered, in addition to the first-order (major) imperfections considered in the Koiter law. Explicit formulas are presented to be readily applicable to the numerical evaluation of imperfection sensitivity. A procedure to describe the probabilistic variation of critical loads is presented for the case where initial imperfections of structures are subject to a multivariate normal distribution; the formula for the probability density function of critical loads is derived by considering up to the second-order imperfections. The validity and usefulness of the present procedure are demonstrated through the application to truss structures.

ABSTRACT: The mechanism of imperfection sensitivity of elastic–plastic plates under compression is complex as they undergo elastic and/or plastic buckling, dependent on their width–thickness ratio. For elastic buckling, the Koiter power law is an established means to describe the imperfection sensitivity. Yet, for plastic buckling, there is no such an established way to describe it. In this paper, the quadratic power law is advanced to describe imperfection-insensitive plastic buckling behavior. The Koiter power law is extended by implementing the quadratic law so as to describe the elastic and plastic buckling in a synthetic manner. The finite-displacement, elastic–plastic analysis was conducted on simply-supported square plates under compression by varying the plate thickness and the initial deflection of a sinusoidal form. In association with an increase of the plate slenderness parameter (decrease of plate thickness), the predominant buckling is shown to change from (1) plastic buckling to (2) unstable elastic–plastic buckling and to (3) elastic stable bifurcation followed by a maximum point of load. In accordance with the change of the mechanism of buckling, the power law is changed pertinently to describe the complex imperfection sensitivity of the compression plates in a synthetic manner. The extended imperfection sensitivity law is thus advanced as a simple and strong tool to describe the ultimate buckling strength of elastic–plastic plates.

“Asymptotic and probabilistic approach to buckling of structures and materials”, Applied Mechanics Reviews, Vol. 61, No. 4, 16 pages, June 2008, DOI: 10.1115/1.2939583

ABSTRACT: The general theory of elastic stability invented by Koiter (1945, “On the Stability of Elastic Equilibrium,” Ph.D. thesis, Delft, Holland) motivated the development of a series of asymptotic approaches to deal with the initial postbuckling behavior of structures. These approaches, which played a pivotal role in the precomputer age, are somewhat overshadowed by the progress of computational environment. Recently, the importance of the asymptotic approaches has been revived through the extension of their theoretical background and the combination with the framework of finite element method and with group-theoretic bifurcation theory in nonlinear mathematics. The approaches serve as an efficient and insightful strategy to tackle probabilistic scatter of critical loads. We review, through the perspective of theoretical engineers, the historical development and recent revival of the asymptotic approaches for buckling of imperfection-sensitive structures and materials.

ABSTRACT: Sensitivity coefficients of a critical load factor corresponding to a degenerate critical point is shown to be unbounded even for a minor imperfection excluding very restricted case where the imperfection does not have direct effect on the lowest eigenvalue of the stability matrix. This fact leads to serious difficulty in obtaining optimum design under nonlinear stability constraints. The optimum design problem is alternatively formulated with constraint on the lowest eigenvalue of the stability matrix, and the sensitivity formula for the lowest eigenvalue is presented. The existence of a degenerate critical point and accuracy of the sensitivity coefficient are discussed through the example of a four-bar truss.

ABSTRACT: The purpose of this review paper is to summarize the existing methods of design sensitivity analysis and optimization of elastic conservative finite-dimensional systems with respect to nonlinear buckling behavior. Difficulties related to geometrical nonlinear singular behaviors are discussed in detail. Characteristics of optimized structures are demonstrated in reference to snapthrough behavior, hill-top branching, and degenerate critical points. A new optimization result of a flexible truss that fully utilizes the snapthrough behavior is also presented.

ABSTRACT: Imperfection sensitivity characteristics of the non-linear buckling load factors of non-optimal and optimal symmetric frames are investigated. The frames are subjected to symmetric proportional vertical loads. The optimization problem is formulated under constraints on linear buckling load factors. Although the buckling load factors corresponding to sway and non-sway modes coincide at the optimum design, the non-sway-type asymmetric bifurcation point disappears as a result of geometrically non-linear analysis. Therefore, the maximum allowable load factors of perfect and imperfect systems should be determined by assigning displacement constraints. It is shown that quantitative evaluation is possible for imperfection sensitivity and mode interaction based on the higher order differential coefficients of the total potential energy even for frames of which the critical points should be numerically obtained. Numerical examples are presented to show that the properties of the non-sway bifurcation point are similar to those of a symmetric bifurcation point, and the interaction between sway and non-sway modes does not always lead to enhancement of imperfection sensitivity.

ABSTRACT: Imperfection sensitivity properties are derived for finite dimensional elastic conservative systems exhibiting hill-top branching at which arbitrary many bifurcation points coincide with a limit point. The critical load at a hill-top branching point is demonstrated to be insensitive to initial imperfections when all the bifurcation points are individually symmetric. Therefore, it is not dangerous to design a frame or truss so that many members buckle simultaneously at the limit point, although the notion of the danger of optimization by compound bifurcation is widespread.

ABSTRACT: We investigate the reliability of realistic structural models with stochastic initial imperfections. The models considered here include: a column on a nonlinear elastic foundation with normally distributed imperfections with given mean and variance-covariance, and cylindrical shells possessing the realistic imperfections which are chosen, based on the available experimental measurements for shell profiles. The explicit forms of the theoretical probability density of buckling loads and the reliability functions evaluated as functions of applied loads of these structures are obtained by means of the bifurcation theory, based on the assumption that the imperfections are small and represent normally distributed random fields. The parameters for these forms are to be determined based on the analysis on a large number of structures with different initial imperfections. The former functions accurately simulate the empirical histogram of buckling loads, while the latter are compatible with the pre-existing results of the number of failed structures in the ensemble. The analytical forms, which demand minimal computational costs, are of great assistance in evaluating the reliability of structures, and appear to constitute a potential design alternative in the future.

ABSTRACT: In this paper, the nonlinear bending and stability of thin spherical shallow shell with variable thickness under uniformly distributed loads are investigated by a new modified iteration method proposed by Prof. Yeh Kai-yuan and the author [1]. Deflections and critical loads have been calculated and the numerical results obtained have been given in figures and tabular forms. It is shown that the final equation determining the central deflection and the load obtained coincides with the cusp catastrophe manifold.

ABSTRACT: In this paper, two simple models which complement one another in mirroring the plastic buckling properties of structures are analysed in detail to introduce a scheme for postbuckling and imperfection sensitivity analysis that is suitable for tackling real structures. The variation of the size of the unloading area is used as the perturbation parameter and a special perturbation scheme is designed to deal with the moving boundary problems caused by plastic unloading, so that the extension of Koiter's theory of initial elastic postbuckling to the plastic range becomes possible.

ABSTRACT: This is the sequel to the author's paper on model analysis, in the current volume. The scheme
developed there to tackle the problem of the postbuckling and imperfection sensitivity analysis of structures in the plastic range is extended to shallow shells. A parameter characterizing the extension of the unloading area is used as the perturbation parameter, and the systematic perturbation method designed in the previous paper is modified to solve moving boundary problems in two variables. Relevant formulations are presented and discussed.

ABSTRACT: Plate and shell structures are widely used in civil engineering. Their static, dynamic behavior and the stability are the most interested topics since long. Advances in several aspects are reviewed in this paper.

ABSTRACT: The objective of this investigation is to study the random vibration of a nonlinear geometrically shell structure by using the finite element method in conjunction with the equivalent linearization approach. When the shell structure is subjected to excessive loadings, the large deformations of the shell structure must be considered. In that sense, the stiffness of the governing equation of the shell structure is related to deflection; therefore, it is nonlinear and difficult to solve. In this study, the applied loadings to the shell structure are assumed to be a nonstationary random excitation to characterize many physical loadings such as earthquake, wind, aerodynamic and acoustic loadings. The equivalent linearization and the finite element method are adopted to perform the nonlinear random vibration analysis of the shell structures, which can be quite nonuniform and complex in geometry or nonhomogeneous in material. These obtained statistical dynamics responses are very useful for estimating the structure safety and reliability. Meanwhile, some statistical responses obtained by the present approach are checked by the Monte Carlo simulation technique.

ABSTRACT: The statistical dynamic responses of geometrically nonlinear shell structures with stochastic Young's modulus of elasticity are investigated in this study. In general, large deformation of the shell structures must be considered when shell structures are under excessive loading, and then the governing equations of the shell structures become nonlinear since the stiffness matrix of the system is related to the deflection. In this
paper, the stochastic finite element method along with the perturbation technique is used to deal with statistical responses of shell structures with structural randomness; in particular, the Newton–Raphson iteration procedure in conjunction with Newmark scheme is adopted to solve the nonlinearity of the dynamic governing equation of shell structures. Some results obtained by the perturbation technique and those from the Monte Carlo simulation approach show a good agreement. Finally, it should be emphasized that these statistically dynamic responses are very useful for estimating the reliability of structures.

ABSTRACT: This paper presents a multiobjective optimization methodology for composite stiffened panels. The purpose is to improve the performances of an existing design of stiffened composite panels in terms of both its first buckling load and ultimate collapse or failure loads. The design variables are the stacking sequences of the skin and of the stiffeners of the panel. The optimization is performed using a multiobjective evolutionary algorithm specifically developed for the design of laminated parts. The algorithm takes into account the industrial design guidelines for stacking sequence design. An original method is proposed for the initialization of the optimization that significantly accelerates the search for the Pareto front. In order to reduce the calculation time, Radial Basis Functions under Tension are used to approximate the objective functions. Special attention is paid to generalization errors around the optimum. The multiobjective optimization results in a wide set of trade-offs, offering important improvements for both considered objectives, among which the designer can make a choice.

ABSTRACT: A novel optimization methodology for stiffened panel is proposed in this paper. The purpose of the optimization methodology is to improve the first buckling load of the panel which is obtained by finite element method. The stacking sequence of the stiffeners is taken as design variables. In order to ensure the manufacturability of design, the design guidelines of stacking sequence are taken into account. A DOE based on Halton Sequence makes the initial points of genetic algorithm spread more evenly in the design space of laminate parameters and consequently accelerates the search to convergence. The numerical example verifies the efficiency of this method.

ABSTRACT: Cone–cylinder intersections are used commonly in pressure vessels and piping. In the case of a cone large end-to-cylinder intersection under internal pressure, the intersection is subject to a large circumferential compressive force. While both the cone and the cylinder may be locally thickened to strengthen the intersection, it is often desirable and convenient to provide an annular plate ring at the cone-to-cylinder joint to supplement local thickening or as an alternative strengthening measure, leading to a ring-stiffened cone–
cylinder intersection. Only limited work has been carried out specifically on ring-stiffened cone–cylinder intersections under internal pressure. This paper presents the first experimental study on such intersections. In addition to the presentation of test results including geometric imperfections, failure behaviour and the determination of buckling mode and load based on displacement measurements, results from nonlinear bifurcation analysis using the perfect shape and nonlinear analysis using the measured imperfect shape are presented and compared with the experimental results.

ABSTRACT: Buckling analysis of cylinders under axial compression is sensitive to the assumptions made in the modelling of initial imperfections. Normally, imperfection modes are selected solely on the basis of buckling mode considerations and their amplitudes are determined using tolerance specifications in codes or experimentally recorded values. Whilst this approach may be used for metal cylinders with some confidence, due to the many test results available for validation purposes, it is not appropriate for the analysis and design of fibre-reinforced composite cylinders where the test results are limited and the effects of manufacturing on the imperfection characteristics have not yet been studied in detail. This paper presents a methodology for probabilistic buckling strength assessment based on the results of a statistical analysis on imperfections on two groups of composite cylinders manufactured by lay-up. The dominant features are quantified and the effect of fibre orientation on imperfections is examined. Simple models describing the random variability of imperfection modal amplitudes are presented. Using these probabilistic models, characteristic imperfection shapes are developed for fibre-reinforced cylinders and their use in buckling strength prediction and tolerance specification is demonstrated.

PARTIAL ABSTRACT: Methods for calculating the buckling loads of shells with geometrical imperfections have been developed by many authors [2, 13-15]. A detailed survey of this activity and a relevant bibliography can be found in several review articles and books [2, 3, 7, 8]. In the present article we are concerned primarily with methods pioneered by Koiter [14,15]. A “special theory” is proposed in [14] for determining the maximum loads or bifurcation loads of axially compressed cylindrical shells in the presence of initial axisymmetric bending deflections. Koiter has also developed a general theory of buckling and initial postbuckling behavior [15] for investigating the influence of nonaxisymmetric initial imperfections on buckling loads...In addition to comparing the results of the calculations with Koiter’s special theory [14] and the Byskov-Hutchinson procedure [11], we propose to analyze certain details of the interaction of axisymmetric and nonaxisymmetric imperfections and the influence of the mechanical properties of composite materials on the sensitivity of shells to imperfections.
ABSTRACT: The equations for integral instantaneous characteristics of composite materials consisting of elastoplastic fibers and matrix are derived based on the known hypotheses of uniform strain or stress fields. The constitutive relations for a layered shell are obtained. The numerical algorithm elaborated is used to solve the stability problem for conical boron-aluminum shells under external pressure and axial compression. It is shown that the shells of medium thickness lose their stability under loads whose magnitude depends on the plasticity of the binder. The plasticity has a decisive influence on the choice of the optimum directions of reinforcement. If the parameters of a shell are such that the buckling occurs beyond the elastic limit, the shell must be reinforced in the direction of precritical stresses. However, this is possible only upon separate action of loads.

ABSTRACT: Three design techniques for stability analysis of longitudinally corrugated cylindrical shells are examined. The first two account for the true geometry of the shell and the third one replaces the corrugated shell with an equivalent orthotropic shell using reduction formulas. The exact formulations employ classical and Timoshenko-type theories. The techniques are analyzed by an example of sinusoidally corrugated shells. It is shown that the exact formulation permits finding practically important relations for corrugation parameters, which raises considerably the specific critical loads.

ABSTRACT: The stability problem is solved for an axially compressed cylindrical shell. Its cross section is formed by circular arcs of radius r with ends supported on a closed circle of radius R. The solution is based on the Flügge equations of the classic theory of deep cylindrical shells. It is shown that the critical axial load for shells of medium length and appropriately chosen cross-sectional profile can be increased by a factor of R/r approximately, compared with the circular shell. The shells length affects considerably the efficiency of noncircular shells of this type. This design model allows us to find out how the local properties of the shell and its stiffness are related.

ABSTRACT: The problem of buckling instability of cylindrical shells under axial compression is considered. The shells consist of cylindrical sections of smaller radius. The geometrical parameters of the shells are approximated by Fourier series on a discrete point set. A Timoshenko-type shell theory is used. The solution is obtained in the form of trigonometric series. It is shown that shells consisting of cylindrical sections have considerable advantages over circular ones. At a constant shell weight, the choice of suitable parameters of shell sections leads to a significant increase in the critical load. The composite shells considered possess higher efficiency indices in comparison with isotropic ones.

ABSTRACT: The stability of fiber-reinforced cylindrical shells under torsion is analyzed in the case where the principal directions of elasticity in the layers do not coincide with the coordinate directions. The solution to the linearized equations of the technical theory of anisotropic shells is obtained in the form of trigonometric series. It is shown that for some reinforcement configurations the critical loads may depend on the direction of the torsional moment. It is also established that the minimum (in absolute value) eigenvalue does not always
correspond to the critical load. This fact should be taken into account not only in the case of torsion but also in more complicated cases of loading.

ABSTRACT: A method for calculating the buckling stability of layered cylindrical shells made of composite materials with one plane of symmetry of mechanical characteristics is worked out. As a special case, shells made of fibrous materials by winding in directions not coinciding with coordinate axes are considered. An analysis of stability of shells under an axial compression, external pressure, and torsion is carried out. It is shown that, at a great number of layers and appropriate reinforcing angles, the shells can be considered orthotropic. The solution to the problem of the initial postbuckling behavior of shells made of composites with one plane of symmetry is also obtained. It is found that shells of this type can be less sensitive to geometrical imperfections. This fact is important from the practical point of view.

References listed at the end of the paper:

ABSTRACT: A solution is obtained to describe the stability and initial postbuckling behavior of cylindrical shells made of composites with one plane of symmetry. The solution is based on the Donnell-Mushtari-Vlasov nonlinear theory of anisotropic shells and Koiter’s theory of buckling and postbuckling behavior. Calculated results are presented for boron plastic shells with reinforcement of different types under external pressure. It is shown that the conventional model of a composite as an orthotropic material is erroneous for many types of reinforcement.

ABSTRACT: Cylindrical shells consisting of cylindrical panels of smaller radius and subjected to uniform external pressure are analyzed for stability. The geometrical parameters of the shells are approximated by Fourier series on a discrete set of points. The Timoshenko theory of shells is used. The solution is represented in the form of trigonometric series. It is shown that short-and medium-length shells with cylindrical panels are advantageous over circular shells. By selecting appropriate parameters of the panels, keeping the mass of the shell constant, it is possible to achieve a significant gain in critical loads. The shells under consideration are less effective than isotropic shells. Shells with sinusoidal corrugation under external pressure are of no practical interest.

ABSTRACT: The paper presents an analytical solution describing the stability and postbuckling behavior of a cylindrical shell made of an anisotropic material with one plane of symmetry and subjected to torques at the ends. The solution is found using Koiter's buckling theory and the Donnell-Mushtari-Vlasov theory of anisotropic shells. The force and deflection functions are approximated by trigonometric series that satisfy hinged boundary conditions. The system of algebraic equations to which the problem is reduced at the main stage of solution is analyzed. Specific results on stability and sensitivity to imperfections of boron-plastic shells consisting of layers with different reinforcement directions are obtained.

References listed at the end of the paper:
ABSTRACT: The paper proposes a method of incremental loading for solving nonlinear problems of shell theory. A feature of this method is that the same algorithm is used before buckling, at the limit point, and after buckling. The method is based on the assumption that all the unknowns, including the load parameter, are on an equal footing. It is shown that the method can be used to solve algebraic equations with Cramer's rule involved to avoid numerical instability in the neighborhood of the limit point. Test problems confirm the validity of the approach.

ABSTRACT: The problem of determining the deformation of a longitudinally corrugated, long cylindrical shell under external pressure is considered. The topics that are covered can be summarized as follows: the formulation of a boundary value problem for the incremental approach as a normal system of differential
equations under appropriate boundary conditions, the determination of postbuckling behavior characteristics for cylindrical shells using the discrete orthogonalization method, and an analysis of deformation for both closed and open cylindrical shells. In particular, we consider the stability and postbuckling behavior of both isotropic and composite shells. The solution is based on the relationships for the cubic version of nonlinear Timoshenko-type shell theory. A comparison is made with the well-established quadratic version, as well as analytical solutions where applicable. The necessity for using more precise equations to examine the postbuckling behavior of shells is shown. Using this higher-order approach, it is possible to determine the postbuckling behavior with much greater accuracy.

ABSTRACT: We study coupled extensional and flexural cylindrical vibrations of a corrugated cylindrical shell piezoelectric transducer consisting of multiple pieces of circular cylindrical surfaces smoothly connected along their generatrices. Using the classical shell theory, a theoretical solution is obtained. Based on the solution, basic vibration characteristics of resonant frequencies, mode shapes, and internal forces are calculated and examined for the corrugated transducers, consisting of a few circular pieces each about 50 mum thick, with radius of 5 mm and span angle of 120 degrees. For these transducers the first resonance is of the order of 10-100 Hz.

ABSTRACT: Shells are for the most part the deep-seated structures in manufacturing submarines, missiles, tanks and their roofs, and fluid reservoirs; therefore it is a matter of concern to bring about some basic regulations associated with the existing codes. Above all, truncated conical shells (frusta) and shallow conical caps (SCC) subjected to external uniform pressure when discharging liquids or wind loads are discussed closely in this paper concerning and thrashing out their empirical nonlinear responses along with envisaging numerical methods in contrast. The buckling aptitude of shells is contingent upon two leading geometric ratios of “slant-length to radius” (L/R) and “radius to thickness” (R/t). In this paper, developing six frusta and four shallow cap specimens and their relevant FE models, use is made of laboratory modus operandi to enumerate buckling elastic and plastic responses and asymmetric imperfection sensitivity, whose adequacy has been reckoned through comparisons with arithmetical and numerical data correspondingly. These obtained upshots were aimed at validating and generalizing the data for unstiffened truncated cones and SCC in full scale.

ABSTRACT: Large elevated steel silos generally consist of a cylindrical vessel, a conical discharge hopper and a skirt which may either be supported on the ground or by a number of columns. The cone–cylinder–skirt junction is subject to a large circumferential compressive force due to the radial component of the meridional tension in the hopper, so either a ring is provided or the shell walls are locally thickened to strengthen the junction. Many theoretical studies have examined the buckling and collapse strengths of these junctions, but no previous experimental study has been reported. This has been due to the great difficulties associated with testing these thin-shell junctions at model scale. This paper first describes the development of an experimental facility for testing model steel silo transition junctions. Issues covered include the fabrication of quality model junctions using thin steel sheets, the loading method and the precise three-dimensional measurement of geometric imperfections and deformed shapes using a laser-displacement meter. Typical experimental results of a cone–cylinder–skirt–ring junction are next presented to demonstrate the capability of the developed facility. Procedures for processing the test results to determine both the buckling load and the number of buckling waves are also presented.

INTRODUCTION: Buckling loads of elastic-plastic shells can be determined by means of two approaches. In the first one, called the constant load approach, it is assumed that the external load does not change in post-buckling state this is accompanied by arising local unloading regions (passive processes). In the second one, the so called Shanley approach is assumed [2, 3], i.e. that the load increases in the post-buckling state, and the passive processes develop only as a result of post-critical deflections. In paper [4] the Shanley approach has been used for calculating bifurcation loads of conical shells. The presented procedure account for the stability analysis of elastic-plastic shells basing on the two fundamental plasticity theories, i.e.: the incremental (plastic flow) theory, and the total strain (deformation) theory. It is also possible to use the results of paper [4] for analyzing elastic shells. The problem is quite complicated when including the effects of unloading. This leads to nonlinear differential equations; although geometrical linearity is assumed. It is the purpose of this paper to linearize these equations for a simply supported conical shell, with the assumption of a two-parametrical external load and a linear stress-deformation material hardening relation.
ABSTRACT: A method of determination of critical loads for thin-walled conical shells loaded by shear forces developed by moment of twist is presented. The three governing equations of neutral equilibrium with respect to basic displacement vector components \( u, v, \) and \( w \) are used. It is assumed that effective stress in the prebuckling state of stress in the shell can exceed the yield limit of the shell material. The use is made both of physical relations of Nadai–Hencky small elastic–plastic deformation theory of plasticity, and Prandtl–Reuss J2 incremental plastic flow theory. Also, a bilinear stress–strain material model, material compressibility and Shanley approach will be accepted in the analysis. Galerkin method is applied to solve the problem equations and iterative techniques are accepted in numerical algorithm to determine critical loads for elastic–plastic shells.

ABSTRACT: Theoretical fundamentals are presented for large deformation stability of a conical shell under assumptions of elastic-plastic properties following the Prandtl-Reuss incremental plastic flow theory and initial shape imperfections of the order of the shell thickness. The problem is reduced to a set of two nonlinear partial differential equations of the fourth order with two unknowns, i.e. the deflection function \( w \) and the stress function \( \psi \). Solution is obtained as a nonlinear relation between the load and deflection parameter. Numerical results are presented in diagrams.

ABSTRACT: The paper deals with the derivation of the basic stability equations of bi-layered elastic-plastic conical shells and a approximate solution to these equations, both theoretically and by numerical procedures. The subject of the analysis is a bilayered open conical shell under a combined load comprising longitudinal forces and external pressure. Kirchhoff-Love’s hypotheses hold for the layers, and use is made of constitutive relations in the form of generalized Hooke’s law for the elastic stability analysis, and the Prandtl-Reuss incremental plasticity theory for the stability analysis in the elastic-plastic range. The stability equations are derived using the virtual work principle, and Ritz’s method is applied to solve the equations. An iterative computer algorithm has been developed which made it possible to analyse the shells in the elastic, elastic-plastic or totally plastic prebuckling state of stress. The numerical results are presented in diagrams.

5. Zielnica J., 1999, Large deformations and stability of bilayered elastic-plastic open conical shells, Archives of Civil Engineering, 45, 3, 521-536
ABSTRACT: The paper presents stability analysis of an elastic-plastic sandwich open conical shell of a circular cross section under combined external load in the form of lateral pressure, longitudinal forces, and shear. The shell consists of two load-carrying faces made of an isotropic, compressible work-hardening material, and they are of different thicknesses and made of different material properties; the core material is of a soft type and it resists transversal forces only. It is also assumed that the shell can be deformed into plastic range before buckling. The flexural stiffness of the faces is taken into account, the Kirchhoff-Love hypotheses hold for the faces, and the active deformation processes are considered. The constitutive relations used in the analysis are those of the incremental Prandtl-Reuss plastic flow theory associated with the Huber-Mises yield condition. The virtual work principle is the basis to obtain the governing stability equations and the Ritz method is used to derive differential equations of the considered problem. An iterative computer algorithm was elaborated to analyse the shells both in the elastic or elastic-plastic prebuckling state of stress.

ABSTRACT: The paper presents a derivation of the stability equation and the solution method of the problem.
for an orthotropic elastic–plastic open conical shell. The use is made of the constitutive relations of incremental plastic flow theory, elastic compressibility of the material, and Shanley concept of increasing load are taken into account in the consideration. A variation, strain energy method is used to derive the stability equation for bilayered open conical shell with nonuniform pre-critical stress distribution. The shell is free supported at the edges and the load acting the shell, in the form of longitudinal force and lateral pressure, is active one, i.e. unloading is not considered.

ABSTRACT: The objective of this work is the stability analysis of an open sandwich cylindrical shell with unsymmetrical faces under combined load basing on moderately large deflections (geometrically nonlinear theory), and elastic-plastic properties of the material of the faces are taken into considerations. The shell consists of two load-carrying faces made of isotropic, compressible, work hardening material and they are of different thickness and made of different materials. Kirchhoff-Love (K-L) hypotheses hold for the faces, and the active deformation processes are considered. The core is assumed to be elastic, incompressible in the normal z direction and it resists transverse shear only. The elastic constants Ec and Gc of the core are taken to be variable, and the strength capacity of the shell is substantially influenced by these constants. Prebuckling stress state is taken to be membrane one and the virtual work principle is the basis to derive the strain energy expression. The resulting nonlinear stability equation is solved by Ritz method. An iterative algorithm of elastic-plastic analysis was elaborated to solve the stability equations and the final objective of the work is numerical analysis of the influence of geometrical and material parameters on critical loads and equilibrium paths.

ABSTRACT: The paper presents stability analysis of elastic–plastic, free supported sandwich cylindrical shell with unsymmetrical faces, loaded by longitudinal forces, transversal pressure, and shear. The J2 incremental Prandtl–Reuss plastic flow theory constitutive relations were used in the analysis and it was assumed that
geometrical strain-displacement relations are nonlinear ones. It was also assumed that the shell faces have different thicknesses and these are made of different isotropic compressible materials with linear stress-hardening. Active loading processes are accepted in the analysis, the stability equations are derived using strain energy formulation. Ritz method is used to solve the equations and an iterative computational algorithm was elaborated to get numerical results.

ABSTRACT: Shell structures are very interesting from the design point of view and these are well recognized in the scientific literature. In this paper the analysis of the buckling loads and stability paths of a sandwich conical shell with unsymmetrical faces under combined load based on the assumptions of moderately large deflections (geometrically nonlinear theory) is considered and elastic-plastic properties of the material of the faces are taken into considerations. External load is assumed to be two-parametrical one and it is assumed that the shell deforms into the plastic range before buckling. Constitutive relations in the analysis are those of the Nadai-Hencky deformation theory of plasticity and Prandtl-Reuss plastic flow theory with the H-M-H (Huber-Mises-Hencky) yield condition. The governing stability equations are obtained by strain energy approach and Ritz method is used to solve the equations with the help of analytical-numerical methods using computer.

ABSTRACT: This paper presents the theoretical background for elastic-plastic stability problem of a conical shell with the assumption that the shell has initial shape imperfections of the order of shell thickness. Physical relations follow Prandtl-Reuss incremental plastic flow theory of plasticity associated with Huber-Mises yield condition. The stability problem is reduced to a set of two nonlinear partial differential equations of the fourth order with the two unknown functions: deflection function and stress function. As a result of solution the nonlinear relation between the external load and deflection function parameter is obtained. The equations are solved by Galerkin method and with the help of a numerical algorithm. The approximate functions satisfy the boundary conditions of free-supported shell edges. An iterative software code was elaborated to get numerical results for elastic-plastic shells.

ABSTRACT: A nonlinear axisymmetric bending theory for a circular, planform, shallow, spherical, sandwich shell with a soft core under the action of uniform edge moments is constructed by means of calculus of variations. An analytical solution for the critical buckling edge moment is obtained by use of a modified iteration method.

Guowei Cao, Zhiping Chen, Licai Yang, Haigui Fan and Fan Zhou (Dept. of Chemical and Biological Engineering, Zhejiang University, China), “Analytical study on the buckling of cylindrical shells with arbitrary thickness imperfections under axial compression”, Journal of Pressure Vessel Technology, Vol. 137, No. 1,
ABSTRACT: This paper presents an analytical study on the buckling of axially compressed cylindrical shells with arbitrary thickness imperfections (nonaxisymmetric and axisymmetric). First, the basic governing partial differential equations, which consider thickness imperfections, are obtained. Second, a unified method that combines the perturbation method and Fourier series expansion is developed to derive buckling load, radial displacement and stress function, that are expressed by triple series in terms of thickness imperfection parameter and buckling modes up to arbitrary order. Third, two patterns of nonaxisymmetric thickness imperfections, which are modal and exponential, are, respectively, investigated. These results are absolutely new to literature. When modal thickness imperfection becomes axisymmetric, the buckling loads degenerate to the known results. In addition to the analytical investigation, analyses and comparisons are also carried out.

E. Tertel (University of Zielona Gora, Faculty of Mechanical Engineering, Poland), “Stability of elastic-plastic sandwich conical shells with a change in the thickness of face-layers”, Journal of Vibroengineering, Vol. 15, No. 2, June 2013
ABSTRACT: The paper presents an analysis of elastic-plastic stability of sandwich conical shells with a change in the thickness of face-layers. The shells under consideration consist of two load-carrying face-layers and a lightweight core layer. The thickness of those faces may vary, just as their material properties. The load-carrying faces are made of isotropic, compressible, work-hardening materials. The core layer is assumed to be elastic, incompressible in the normal z direction and it resists transverse shear only. External load is assumed to be in the form of longitudinal force and lateral pressure. Deformation of the shells within the plastic range is possible before buckling. With respect to the presented research, constitutive relations of the Nadai-Hencky deformation theory, alongside the H-M-H (Huber-Mises-Hencky) yield condition constitutive relations, are accepted in the analysis. To derive the stability equations a variation, strain energy method is accepted and the Ritz method has been used to solve the stability equations.

ABSTRACT: Three theories are presented for the analysis of ring-stiffened or monocoque cylindrical shells under hydrostatic pressure. The theories compute the stress state and the axisymmetric collapse, interbay buckling, and general instability pressures from external hydrostatic pressure loading. The theories were derived for the case of specially orthotropic material with theoretically uniform properties through the thickness; the theories apply equally to shells made of isotropic materials. A computer program, DAPS4 (Design and Analysis of Plastic Shells, Version 4), was written that incorporates these theories that can be used as an initial sizing tool or analysis of a shell's hydrostatic pressure capability. The program includes a "pseudo-plastic" method to account for the reduction of computed collapse pressures when the stress state is above the proportional limit of the material's stress-strain curve. The purpose of this report is to document the theories and the code. Correlation with numerous pressure tests is shown. A user manual with example problems is included. The theories reported herein were developed as part of the author’s independent research in the area of shell buckling over the past 22 years offering a number of improvements to the prior theories and the DAPS3 computer program. Navy projects that have benefited over the years from the application of the DAPS3 and DAPS4 codes include the CVLWT, Long Pulse, Metal Matrix Composites, MK 46 Torpedo, and MK 48 Torpedo.

ABSTRACT: A new finite element formulation for predicting the buckling pressure of axisymmetric shells is presented. The finite element proposed is double curved and has constant meridional curvature. Cubic polynomials are used for describing all the displacements. The linear part of the thin shell strain-displacement relations is adopted from Novozhilov's theory and the nonlinear part from Stricklin. Linear prebuckling stress resultants are used in this bifurcation instability analysis. Numerical examples of hemi-ellipsoidal dome heads and Echinodome tanks are satisfactorily solved.

doi:10.1016/j.tws.2006.03.003
ABSTRACT: The analysis of submarine pressure hull assumes great importance among structural engineers due to the complexity involved in the collapse mechanism of stiffened shell structures. In most of the cases, the failure of stiffened shell structures occurs due to elastic buckling. But for some combinations of shell-stiffener geometry and material characteristics, the structure can fail by inelastic buckling, for which the methods of analysis are meagre. In this paper, the analysis of submarine pressure hull structure in which the failure gets governed by inelastic buckling is demonstrated. Three different approaches have been employed to investigate the ultimate strength of the ring stiffened submarine pressure hull structure with inelastic buckling modes of failure. The methods used are ‘Johnson–Ostenfeld inelastic correction’, ‘imperfection method’ and ‘finite element approach’. A typical submarine shell structure has been analysed for the inelastic buckling failure using these three approaches and the results are discussed.

ABSTRACT: Elliptical shell structures will increasingly be used as construction elements in future aerospace concepts. The static and the stability behavior of such non-axisymmetric shells is analyzed in this paper. To describe the behavior of the shell structures a complete tensor formulated shell bending theory considering the Kirchoff-Love hypothesis is used. Examples are presented showing the mechanical behavior under thermal loads, surface loads, and a combination of these loads. The achieved results demonstrate the capability of the introduced calculation method.

ABSTRACT: Pressurized propellant tanks might become dynamically unstable with detrimental dynamic responses if a dynamic excitation leads to a coupling of pressure oscillations (especially due to the response of axisymmetric modes) with very low damped ovalizing modes. This phenomenon can be described and identified as the so-called parametric instability. During the dynamic qualification test campaign of the new Ariane 5 Cryogenic Upper Stage ESC-A, a parametric instability was observed for sinusoidal tests under certain test conditions with low static pressure in the propellant tank. The parametric instability was identified and an analytical simulation was performed that confirmed the instability. During flight, harmonic excitations might occur due to pressure oscillations within the solid rocket booster. However, the application of the analytical model on flight conditions indicates that the flight behaviour will be stable. This was confirmed by results from additional tests. This paper describes the phenomenon of the parametric instability of pressurized propellant tanks and presents an analytical methodology to assess the risk of the occurrence of a parametric instability.

PARTIAL INTRODUCTION: …The partial differential equation system of an axisymmetric shell with arbitrary meridian has been developed based on a complete and consistent second order theory using the normal hypothesis. Provided that the displacements are small and the material linear elastic, the second order theory is in many cases a good tool for stability analysis. By developing the physical states in the circumferential direction in a Fourier-series it is possible to eliminate the circumferential coordinate. This way the partial differential equations are transformed into an ordinary differential equation system of first order in meridional direction. In the case of axisymmetric prestress the equations of each wave-number can be evaluated separately…. 
ABSTRACT: Autonomous underwater vehicle (AUV) is a robot which travels underwater without requiring input from an operator. AUVs constitute part of a larger group of undersea systems known as unmanned underwater vehicles. They are controlled and powered by a remote control operator. In military applications AUVs are more often referred to simply as unmanned undersea vehicles. Applications of AUV are specifically used for different applications like, oil and gas industry uses AUVs to make detailed maps of the seafloor before they start building subsea infrastructure pipelines and sub-sea completions. Whereas defense department uses for under water surveillance. Since these vehicles travel underwater the structure need to be designed to withstand the pressure of water concealing them. In the present paper, the analysis is made on a battery composite shell (Epoxy/E-glass) (Fig.1) of AUV. Initially researchers focused on the buckling strength of filament wound cylinders by experimentally deriving composite moduli for shells of different diameter to thickness ratios [1]. A composite cylinder contains of various layers of filament layers hence layup (orientation of fiber) has significance effect on buckling of the cylinder [2]. Further the analytically characterization of cylinder buckling is explained by analyzing computation models of cracked cylinder [3], [4]. Numerical modeling of analyzing stresses in the cylinder under buckling loads is referred from H. Kanou [5]. The main objective of the paper is to reduce the weight of AUV without compromising on strength by using CFRP (Carbon fiber reinforced plastic) material in place of Epoxy/E-glass which has comparatively less density. Further modification in the shell geometry is made by adding stiffeners in an attempt to reduce more weight. The mechanical behavior of Epoxy, CFRP, shells with and without stiffeners is compared under buckling loads. For this a shell model of battery compartment with stiffeners is created in Ansys 12 software which is subjected to pressure both in circumferential and axial directions to see the buckling effect of the shells with stiffeners.

recent than that, possibly presented at one of the conferences held in Braunschweig, Germany, such as one of the “International Conference on Buckling and Postbuckling Behavior of Composite Laminated Shell Structures”

ABSTRACT: The dimensioning of an orthotropic stiffened cylindrical CFRP shell subjected to load introduction of concentrated axial loads using rapid analytical methods is presented. The dimensioning considers required constraints in the force flux distribution, strength of the laminate, general instability, panel instability (from ring frame to ring frame) and local instability. The rapid analytical methods allow for mass optimization. The final design is confirmed by detailed FE analysis. A comparison of the FE analysis with the analytical results is shown.

INTRODUCTION: Primary structures in launcher rockets consist of orthotropic stiffened shells. In order to meet lightweight targets more and more CFRP shell designs are used. For example, in the upper composite of the Ariane 5 (upper stage and payload area) all primary structures, except the propellant tanks, are built of CFRP. The Ariane 5 design of these orthotropic stiffened shells is buckling and stiffness driven. High concentrated loads due to the load introduction of the booster propulsive loads must be carried and distributed into the structure.

The solid booster loads of Ariane 5 are introduced in a cylindrical shell, the so called JAVE (Front Skirt), which is an orthotropic stiffened metallic shell (aluminium). The JAVE is connected with a 5.4 m diameter CFRP made cylindrical sandwich shell, called ISS (Inter Stage Skirt), which carries axial force fluxes due to the load introduction of more than 1000 N/mm.

For the study of a future launcher based on Ariane 5 elements, called WOTAN, the axial force fluxes introduced in the 5.4 m diameter cylindrical shell are up to 5300 N/mm. The high force fluxes have to be attenuated on an acceptable level within an axial length of only 4.5 m until entering the propellant tank structure.

Different CFRP designs are possible for the cylindrical shell: Sandwich design (CFRP face sheets with metallic honeycomb core), stringer and ring stiffened skin (all in CFRP) or a corrugated CFRP shell stiffened by CFRP rings. The design choice and the mass optimization have to consider a huge set of variable parameter and design criteria such as: 1. Axial force flux distribution (which depends on the design or stiffness, respectively), 2. Strength of the laminate, 3. General instability of the cylindrical shell, 4. Panel instability (from ring frame to ring frame), 5. Local instability.

The presentation describes the approach for dimensioning and optimization. For the parametric investigation rapid tools have been used which base on the analytical solution of shell differential equation. The rapid tools allow the dimensioning and mass optimization with an affordable effort and in a systematic manner. The final chosen design has been investigated in detail with a complex Finite Element Model. The FE model confirmed the results of the simplified tool. Comparisons of results achieved with the simplified method and with the detailed FE model are presented.

ABSTRACT: A stiffness matrix for an element of a shell of revolution has been derived, considering arbitrary load distributions and initial geometric imperfections. This element-stiffness matrix is based on the transfer-matrix method and describes the whole section of a shell of revolution between two rings in modal coordinates (a so-called super-element). The modal coordinates here are circumferential Fourier members, thus reducing the partial differential equations to ordinary ones. Several stability analyses investigating the sensitivity of composite shells to different geometric imperfection shapes were carried out. The influence of the load distribution and boundary conditions in combination with geometric imperfections was analysed by different modellings of a hypothetical Jupe Avant shell of the ARIANE 5 rocket.

ABSTRACT: This review highlights some practical aspects of the design of thin-walled shells for aerospace applications. This type of shell must comply with the mission profile. It is therefore necessary to find an optimum structural concept with low weight, high strength, high buckling load and a low imperfection sensitivity. In an optimum design, structural instability occurs slightly below the material strength or yield strength. In general, and by contrast with other structural elements such as beam and plates, a thin-walled cylindrical shell shows a high imperfection sensitivity. Hence, recommendations are given concerning the design of shells and approximate stability analyses are presented for different mechanical loading conditions.

ABSTRACT: (cannot cut and paste abstract)

ABSTRACT: The buckling and postbuckling behaviour of stiffened composite panels is investigated in this paper. For the analysis a procedure is applied that is based on the discretisation of the structure by strip elements. This procedure enables the determination of element stiffness matrices representing analytical solutions of the governing differential equations. Next to the presentation of the underlying theory, numerical results are given for a curved stiffened panel configuration. In order to verify the applicability of the approach, a comparison to experimental results is included.

ABSTRACT: In the first part of this paper, rib-stiffened thin-walled spherical shells under external hydrostatic pressure are optimized using classical approximate methods and empirical knock-down-factors. In the second part of the paper, the influence of known imperfections is investigated. The thin-walled spherical shells under external pressure are very sensitive to geometrical imperfections. Hoff recognized that for entire isotropic spherical shells the more likely imperfection will be a local circular dent, which for such shells, can always be considered as an axisymmetric one. Hoff's idea has been further investigated by Koga–Hoff, Galletly et al. These results showed that for a given depth of an imperfection a critical size of the corresponding circular dent exists, giving the minimum for the actual load carrying capacity of the shell. This paper suggests to extend Hoff's theory to isogrid and waffle-grid stiffened spherical shells. The issue of these investigations is a set of knock-down-factors plotted versus imperfection amplitude related to the total thickness of the rib-stiffened (isogrid or waffle-grid) shell. These curves fit reasonably with those established for isotropic shells by Hoff et al. or by Koiter, and enable to estimate the jeopardy of measured actual dents.

ABSTRACT: The postbuckling compressive strength and collapse phenomena of composite laminated cylindrical panels with various fiber angles and width-to-length ratios are characterized by the nonlinear finite element method. For the iteration and load increment along the postbuckling equilibrium path, a modified arc-length method in which the effect of stress unloading due to failure can be considered is introduced. In the progressive failure analysis, the maximum stress criterion and complete unloading model are used. Validity of present finite element results are verified by experiment for [0(3)/90](S) cylindrical panel and [0/90/+/-45](S) plate. The postbuckling compressive strength of composite laminated cylindrical panels is independent of the initial buckling stress but high in the panel with large value of the bending stiffness in axial direction. In several of the cylindrical panels, it is observed that the prebuckling compressive failures occur and directly result in collapse before buckling.

ABSTRACT: The postbuckling behavior of graphite-epoxy laminated stiffened panels has been studied analytically and experimentally herein. In this research, the stiffened panels were analyzed using the nonlinear finite element method. The progressive failure analysis adopted the maximum stress criterion and the complete unloading failure model. In the failure analysis, the considered failure modes were matrix failure, shear failure and fiber failure. The stiffeners were formed by the continuous lay-up of the skin to improve the integrity of the
stiffened composite panels. A shadow moiré technique was used to monitor the out-of-plane deformation of the skin panel. Piezoelectric film sensors were used to detect the failure events during experiments. The analytical results on the buckling load, postbuckling behavior, and postbuckling compressive strength showed good agreement with the experimental results. Parametric studies were conducted to show the effects of stacking sequences and stiffener shapes on the buckling load and postbuckling compressive strength of stiffened composite panels.

ABSTRACT: To estimate the overall performance of composites, it is necessary to identify the influence of the buckling and delamination failure. For that reason, a fiber optic sensor was applied to the delaminated composite beams to detect the buckling occurrence and delamination growth. The delaminated composite beams subjected to the compressive load were tested to identify the signal characteristics of the fiber optic sensor. The signals of the fiber optic sensor from buckling or delamination growth were quantitatively evaluated by short time Fourier transform and wavelet transform.

ABSTRACT: At present, the compressive strength of composite laminates containing an open-hole can be predicted theoretically by using fracture mechanics based models such as the linear softening cohesive zone model. In this approach, the inelastic deformation associated with fibre microbuckling that develops near the hole edge is replaced with an equivalent crack loaded on its faces by a bridging traction which is linearly reduced with the crack closing displacement. By making use of this model, and by establishing an equivalent hole diameter from X-radiographs and/or ultrasonic C-scan images, the residual compressive strength after impact can be predicted. This paper outlines how the ‘equivalent hole’ is determined and gives tabulated results of experimental and theoretical data. It is also shown that these data are in good agreement with each other for plain compression, open-hole compression and compression after impact strengths.

Y. Zhuk, I. Guz and C. Soutis (Department of Aeronautics, Imperial College of Science, Technology and Medicine, Prince Consort Road, London SW7 2BY, UK), “Compressive behaviour of thin-skin stiffened

ABSTRACT: The in-plane compressive behaviour of thin-skin stiffened composite panels with a stress concentrator in the form of an open hole or low velocity impact damage is examined analytically. Drop weight impact in laminated polymer composites causes matrix cracking, delaminations and fibre breakage, which together can seriously degrade the laminate compressive strength. Experimental studies, using ultrasonic C-scan images and X-ray shadow radiography, indicated that the overall damage resembles a hole. Under uniaxial compression loading, 0° fibre microbuckling surrounded by delamination grows laterally (like a crack) from the impact site as the applied load is increased. These local buckled regions continued to propagate, first in discrete increments and then rapidly at failure load. The damage pattern is very similar to that observed in laminated plates with open holes loaded in compression. Because of this resemblance, a fracture mechanics model, developed initially to predict notched compressive strength, was applied to estimate the compression-after-impact (CAI) strength of a stiffened panel; in the analysis the impact damage is replaced with an equivalent open hole. Also, the maximum stress failure criterion is employed to estimate the residual compressive strength of the panel. The unnotched compressive strength of the composite laminate required in the analysis is obtained from a three-dimensional stability theory of deformable bodies. The influence of the stiffener on the compressive strength of the thin-skin panel is examined and included in the analysis. A good agreement between experimental measurements and predicted values for the critical failure load is obtained.

ABSTRACT: The in-plane compressive strength of a stiffened thin-skinned composite panel with a stress concentrator is examined. Two possible in-plane failure mechanisms are investigated. The first one is near-surface instability at the edge of the cutout, where high stress gradients are expected because of the stress concentration and the thickness heterogeneity of the laminated skin. Analytical 3D formulas allowing simple parametrical investigation of the phenomenon under consideration are derived. The second failure mechanism is fiber microbuckling in 0°-plies. An equivalent crack model is used to predict the compressive strength of a multidirectional composite laminate. How a stiffener affects the compressive strength of the thin-skinned panel with a hole is studied for both mechanisms. Experimental and predicted values of the critical load are in good agreement.

ABSTRACT: In this study, the effect of laminate thickness on the compressive behaviour of composite laminates was investigated through systematic experimental work using the stacking sequences, [04]ns, [45/0/-45/90]ns and [45n/0n/-45n/90n]s (n=2 - 8) with a 3 mm diameter open hole at the centre. Parameters such as fibre volume fraction, void content, fibre waviness and interlaminar stresses, influencing compressive strength with increasing laminate thickness were also studied experimentally and theoretically. Furthermore the stacking sequence effects on failure strength of multidirectional laminates were examined. For this, two different scaling techniques were used: (1) ply-level technique [45n/0n/-45n/90n]s and (2) sublaminate level technique [45/0/-45/90]ns. An apparent thickness effect existed in the lay-up with blocked plies, i.e. unidirectional specimens ([04]ns) and ply-level scaled multidirectional specimens ([45/0/-45/90]ns). Fibre waviness and void content were found to be main parameters contributing to the thickness effect on the compressive failure strength. However, the compressive strength of the sublaminate level scaled specimens ([45/0/-45/90]ns) was almost unaffected regardless of the specimen thickness (since ply thickness remains constant). From the investigation of the stacking sequence effect, the strength values obtained from the sublaminate level scaled specimens were slightly higher than those obtained from the ply level scaled specimens. This applied to all specimen thicknesses regardless of the presence of an open hole. The reason for this effect was explained by the fibre waviness, void content, free edge effect and stress redistribution in blocked 0∞ plies and unblocked 0∞ plies. Finally the
average strengths of open hole specimens obtained from both stacking sequences increased with increasing specimen thickness. The measured failure strengths were compared with the predicted values.

ABSTRACT: A closed-form solution for the buckling loads of compressively loaded composite plates longitudinally stiffened by blade stringers is developed. The approach is based on adequate formulations for the buckling shapes for both the plate and the stringers in the form of rather simple functional representations. As a by-product, a closed-form solution for a clamped stringer plate is derived. Furthermore, a full series expansion is developed for comparison purposes. The method works with satisfying accuracy and requires negligible computational expenses when compared to accompanying finite element calculations.

ABSTRACT: The present contribution deals with the onset of local buckling of compressively loaded thin-walled beams with open I, C, Z, T and L-cross-sections made of laminated composite materials. The method employs a discrete plate analysis approach in the course of which each structural subelement of interest—which presently is the flange—of the thin-walled cross-section is considered as a separate composite plate with elastic rotational restraints at those edges where an adjacent substructural element is located. While in many investigations the laminate schemes of webs and flanges are considered to be purely orthotropic, in the present paper the laminate layups are allowed to be of an arbitrary non-orthotropic nature, which also allows for the analysis of laminates with inherent bending–torsion coupling. The analysis of the buckling loads of the flanges of thin-walled composite beams is performed using the Ritz-method for which some especially adjusted displacement shape functions are employed. For the case of pure orthotropy, a novel closed-form solution is described. The accuracy of the employed approaches is established by comparison with accompanying finite element simulations of thin-walled composite beams. It is revealed that the presented methodology is highly efficient in terms of computational effort and yet performs with satisfying accuracy, which makes it very attractive for actual practical applications whenever the local stability behaviour of wide-flange thin-walled composite beams is to be considered.

ABSTRACT: This paper discusses the buckling behaviour of orthotropic composite plates under uniform uniaxial compression with one free reinforced unloaded edge. A typical application example for use of such a mechanical model is the web of stiffeners and frames attached to the fuselage skin of an aircraft. The considered plates are rectangular and simply supported at the loaded transverse edges. One of the longitudinal unloaded edges is also simply supported, while the second unloaded edge is not supported at all but is reinforced by a flange of arbitrary cross-section. At first, an exact solution for the elastic buckling problem is derived from the governing differential equation by imposing the underlying boundary conditions. Thereafter, two approximate closed-form solutions for the buckling load are derived, which can be conveniently used for practical application purposes. Generic buckling curves using characteristic non-dimensional quantities are also presented. Finally, the question of the required bending stiffness $EI_{\text{min}}$ of the flange is treated, to ensure that the flange withstands buckling and provides simply supported boundary conditions to the free reinforced plate edge.

ABSTRACT: In this paper, the postbuckling behavior of rectangular orthotropic laminated composite plates with initial imperfections under inplane shear load is investigated in a closed-form analytical manner. The plates under consideration are assumed to be infinitely long in the longitudinal direction. At the longitudinal edges, two different sets of boundary conditions are considered, specifically 1) simply supported edges and 2) fully clamped edges. Using Timoshenko-type shape functions for both the initial bifurcational buckling analysis and the subsequent Marguerre-type postbuckling studies, closed-form analytical solutions for the buckling loads and for the postbuckling state variables are derived. A comparison with geometrically non-linear finite element computations shows that the derived analysis approaches are suitable for postbuckling studies in load ranges not too far beyond bifurcational buckling as they are currently relevant for e.g., composite airframe structural analysis and design. Due to their strictly closed-form analytical nature, the presented analysis methods can be used conveniently in engineering practice for all application purposes where computational time is a crucial factor, especially for preliminary analysis and design or optimization procedures.

ABSTRACT: In this paper, a closed-form method for the analysis of the local postbuckling behaviour of aircraft panels that are braced by hat-stringers is presented. The stiffened panels are loaded by transverse compression which is a load case that has been treated only scarcely in the open literature, and the corresponding buckling and postbuckling behaviour that eventually leads to failure of the panel is quite different to what is observed when a panel under longitudinal compression is considered. This contribution clarifies that the ultimate load bearing capacity of a stiffened panel with closed-profile stringers under transverse compression is governed by several consecutive stability cases. Firstly a closed-form approximate analysis method for the linear buckling analysis of the skin between two stringers taking the torsional stiffness of the hat-stringers into account is derived (stability case 1). Secondly, a simple Marguerre-type postbuckling
analysis method is presented that accounts for the geometrically nonlinear behaviour of the panel skin after buckling (stability case 2) and enables a closed-form analysis of its effective width. Thirdly, the linear buckling analysis is adapted to the analysis of the panel skin under a stringer (stability case 3). It will be shown that stability cases 2 and 3 cannot be treated independently, but have to be considered interactively which necessitates an iterative procedure. The accuracy of the proposed analysis method, relying on the simplifying assumption of a perfectly flat plate rather than considering a cylindrically curved panel is established by comparison with results of accompanying geometrically nonlinear finite element calculations.

ABSTRACT: The current paper deals with a closed-form approximate solution for the postbuckling behavior of an unstiffened, singly-curved, orthotropic shell. As loading condition the case of uniform axial compression is treated. Concerning the boundary conditions all edges are supposed to be simply supported. Additionally, geometrical imperfections in form of an initial deflection of the shell can be accounted for. Choosing rather simple shape functions for the deflection a closed-form expression for the Airy stress function is obtained from the compatibility condition. As the equilibrium condition cannot be satisfied exactly the solution procedures of Galerkin as well as Ritz are employed to obtain an approximate solution. The resulting expressions from these procedures again allow for a closed-form solution of the load-deflection-relationship. After the force and the amplitude are known all other state variables such as stresses and displacements can be evaluated in a closed-form manner. Due to the rather simple formulation of the deflection shape the algorithm is limited to cases where the qualitative shape of the deflection does not change significantly. On the other hand the very high computational efficiency of the described solution procedure makes it ideally suited for use in the field of optimization and preliminary design, if the applied load does not exceed the linear buckling load too much.

ABSTRACT: Liquid metal fast breeder nuclear reactors demand the usage of large sized thin shells for their reactor vessel components due to low operating pressure and high thermal load. Buckling is a very important aspect in the design of these vessels. In this article, analysis of the inner vessel of a typical 500 MWe fast breeder reactor is presented. Here, two different geometric configurations of the inner vessel are considered. One configuration is with the conical step joining the upper and the lower cylindrical portions, and the other is with the toroidal bottom joining the upper cylindrical part. The buckling strength of the vessel for both configurations are calculated and compared. Also, the effects of thermal load, initial geometric imperfection, geometric nonlinearity, etc. are investigated. The finite element method is used for analysis.
ABSTRACT: Thin shells are prone to fail by buckling due to compressive membrane stress. Although shells develop primarily membrane stresses, in most practical situations, they have some bending stresses as well as a result of supports, loading condition and discontinuity. In such case, the response of a shell to external loads becomes nonlinear. Linearization of the nonlinear equilibrium equations gives rise to an eigen value problem solving which buckling load is obtained. Eigen value buckling analysis is computationally faster than the nonlinear analysis involving tracing the load-deflection path and finding the corresponding collapse load. However, the buckling load estimated using the eigenvalue buckling analysis is approximate and usually overestimated. For the systems with large prebuckling rotations this approach may give highly unconservative results. Attempts have been made for better prediction of actual buckling load of shells of revolutions by combining eigenvalue buckling analysis and geometric nonlinear analysis. Such methods are computationally more efficient than the nonlinear buckling analysis but more reliable than the linear buckling analysis. This study presents an overview of the stability analysis of shells of revolution using a conical frustum shell element incorporating the linear and simplified nonlinear buckling analysis including the treatment of initial geometric imperfection.

ABSTRACT: The geometric nonlinear responses of laminated composite cylindrical panels subjected to (i) axial compression and (ii) central concentrated load are investigated in this work. The parameters considered are: number of layers, symmetric/antisymmetric laminate constructions, cross-ply/angle-ply fibre orientation, boundary conditions and central angle of panel. An eight-node degenerated layered shell element with an efficient explicit through-thickness integration scheme is employed. It has been observed that the cylindrical panels under axial compression exhibit stable post-buckling paths and the number of layers in the laminate for a given total thickness has considerable influence on the load–deflection behaviour. The strength of shallow panels with longitudinal edges hinged, curved edges free and subjected to a central concentrated load is controlled by the limit point load, whereas for deep panels with other parameters remaining the same, the strength is controlled by the bifurcation load. The boundary conditions have significant influence on the load-carrying capacity. The panels with longitudinal edges hinged and curved edges free should be avoided in construction, as they undergo either limit point or bifurcation failure at very low load levels compared with other edge conditions.

“Experimental Stuudies on LMFBR Inner Vessel Models”, Paper #1109, Transactions.. (publisher, date not given)
PARTIAL ABSTRACT: This paper presents the results of an experimental study on the buckling of scale models of Liquid Metal Fast Breeder Reactor (LMFBR) inner vessel. The inner vessel consists of two cylindrical shells. The upper and the lower shells are connected by conical and torus shells. Six identical models are tested under three loading conditions. Imperfection scans are carried out using contact type probes, before loading and during loading. Scanning is carried out simultaneously for upper cylinder, conical, torus and lower cylinder using separate LVDTs and the data scanned are stored in a PC-based data acquisition system. Strain gages are mounted at strategic locations and strains are recorder during…

ABSTRACT: In this paper we will first give a short introduction to stability phenomena and stability theory. Further we will discuss a linear buckling safety concept according to DIN 1045 (DIN 1045 1988) and VGB-BTR (VGB-BTR 1997). In this context we will present a practical procedure for determining the lower bound of the limit load of a shell structure with the concept of reduced membrane buckling. Also we will give an application of this method to find the ideal wall thickness distribution of a cooling tower shell in the first design studies. Special attention is given to the material nonlinearities with respect to buckling. The phenomena of perfect and imperfect cooling tower shells are analyzed, and the nonlinear buckling behavior will be discussed for ideal and imperfect cooling tower shells.

ABSTRACT: Natural draught cooling tower shells are loaded mainly by their dead weight and by the wind, which may both cause buckling failure. The present paper compares various numerical procedures to investigate the stability behaviour of cooling tower shells. These are a complete nonlinear analysis, a linear eigenvalue analysis for a stationary non-axisymmetric wind load, and a linear eigenvalue analysis for a wind load, approximated to be axisymmetric. The aim is to evaluate whether a geometrically nonlinear analysis can be replaced by a time-saving classical buckling analysis, probably even for an axisymmetric state of stress. The third procedure, as the most conservative, but a very effective one, will be applied to investigate the mechanical influence of ring stiffeners on the buckling behaviour of cooling tower shells. Kinetic instability phenomena will also be examined. The structural improvement resulting from ring stiffeners will be quantified and summarized in design recommendations.

ABSTRACT: Convinced of the powerful capability of modern computational techniques the question of ‘best’ physical shell models is re-raised. In the present paper, ‘best’ interior shell equations are derived by mapping a 3-dimensional body, described as a multi-director-continuum, on a Cosserat-surface kinematics. The derived shell equations hold for arbitrarily large deformations and material laws in rate-description, incorporating shear distortions and thickness changes. The optimal character of the developed model — proven by tensor norm bounding techniques — is finally demonstrated by results of numerical simulations of nonlinear shell responses.
ABSTRACT: The present essay contains a general structural stability theory for discretized structural systems. Instabilities are essential constituents of nonlinear structural responses, the computational assessment of which in a modern treatment is exclusively based on incremental-iterative (step-wise) numerical techniques, applied to the tangential equation of motion. The paper derives this fundamental equation as first variation of the nonlinear equation of motion in its standard form and its phase projection. Further, it transforms the principle of virtual work for arbitrary nonlinear (Kelvin-Voigt) continua into its incremental variant and finally into the consistent tangential equation of motion. Its various applications then are demonstrated to classes of time-independent and time-dependent, unstable structural responses, for which suitable numerical instruments are outlined. The derived algorithms are based on the concepts of Lyapunow exponents and Poincaré multipliers which are introduced as universal stability measures. Qualitative and quantitative convergence properties of perturbations in the phase space enable the proper establishment of stability definitions. The validity of the received concepts is illustrated by several examples.

ABSTRACT: The paper designs a general stability theory for discretized shell structures based on stepwise numerical solution techniques. To this purpose the nonlinear principle of virtual work is transformed into its l subprinciple and finally discretized. The resulting equation for Kelvin–Voigt material, usually denoted as tangential equation of motion, turns out to be a sufficient and suitable basis for the numerical evaluation of arbitrary nonlinear responses including their instability phenomena.

ABSTRACT: A geometrically and physically nonlinear finite element model for thin reinforced concrete shells is presented which allows simulation of the deformation history of imperfect structures up to their numerical failure. Application to the assessment of existing natural draught cooling tower shells subjected to dead weight and wind loading demonstrates the usefulness of the numerical procedure. Results showed that failure was due to a nonlinear stress problem, rather than elastic buckling. For worst-case imperfections relating to the physically nonlinear failure mode, the shells exhibited only a moderate imperfection sensitivity. Further work will concentrate on more realistic imperfection patterns, since worst-case imperfections give a rather too conservative lower bound for the collapse loads.

ABSTRACT: The present contribution is concerned with dynamic stability investigations of arbitrary structural responses, in particular shell responses. In order to trace such nonlinear fundamental processes, incremental/iterative path-following algorithms are employed to the tangential equation of motion which is derived under special regard of finite rotation shell theories, elasto-plastic material behaviour, and motion-dependent loading. Occurring instabilities can be detected with the help of Lyapunow exponents as generalized concept for the detection of quantitative stability properties. Well known investigation procedures are recognized as special cases of the Lyapunow-exponent-concept for stationary, transient, periodic, and arbitrary solution curves in the phase space. A new numerical procedure for the determination of one-dimensional Lyapunow exponents is introduced to identify critical directions in the solution space for large discretized structures by reduction to relevant manifolds

ABSTRACT: Shell structures are extremely efficient, thin walled load-carrying components, in the elastic as well as in the inelastic regime. Realistic and efficient computational strategies lately are in rapid development. Such computational strategy for modelling of nonisothermal, highly nonlinear hardening responses in elastoplastic shell analysis has been proposed in this article. Therein, the closest point projection algorithm employing the Reissner-Mindlin type kinematic model, completely formulated in tensor notation, is applied. A consistent elastoplastic tangent modulus ensures high convergence rates in the global iteration approach. The integration algorithm has been implemented into a layered assumed strain isoparametric finite shell element, which is capable of geometrical nonlinearities including finite rotations. Under the assumption of an adiabatic process, the increase of the temperature is analysed during elastoplastic deformation. Finally, numerical
examples illustrate robustness and efficiency of the proposed algorithms.

https://www.researchgate.net/publication/50838736_From_large_natural_draft_cooling_tower_shells_to_chimneys_of_solar_upwind_power_plants, Publisher and date not given.

ABSTRACT: Natural draft cooling towers (NDCTs) presently form the world-largest RC shell structures, solar updraft power plants (SUPPs) will do this in future. The paper starts with explanations of the working principles of NDCTs and SUPPs. In industrialized countries with strong legal emphasis on sustainable power production technologies, NDCTs are widely spread, while SUPPs represent future solar power generation concepts in the world’s tropical areas, using solar irradiation as power plant fuel. Consequently, the paper elaborates on recent German NDCTs, under them the world-highest tower shell. The design of such high-efficient RC tower shells will be explained including their critical response characteristics. The paper then changes to future SUPPs, describing the structural components of their solar chimneys, followed by a sketch of some of their critical response characteristics. The aim of this presentation is to draw the readers’ attention to extremely large shell structures (Mega-shells), present and in future, and to demonstrate their close structural mechanics relationship to each other.

ABSTRACT: After demonstrating how to improve simply the BS 5500 strength formulation for hydrostatically loaded fabricated ring-stiffened cylinders, a simple yet consistent strength formulation is derived for determining their strength when subjected to combined axial loading including tension and radial pressure. The quadratic Merchant-Rankine formula in generalised form as suggested by Odland is adopted as the basis of the proposed formulation. This involves knockdown factors which are derived to provide a good fit with experimental data. Its accuracy is compared with that of the DnV Rules and BS 5500. The effects of boundary conditions and residual stresses are investigated using unstiffened and stress-relieved test data respectively.

ABSTRACT: The development of a numerical model describing the large-deflection elasto-plastic behaviour of flat plates and attached flatbar stiffeners including the effects of interaction is described in this paper. The Marguerre large deflection thin plate equations are used to represent both the plate and the stiffener so enabling the lateral-torsional behaviour to be accurately modelled. Complete interaction is achieved by satisfying the full set of equilibrium and kinematic conditions acting along the intersection.

ABSTRACT: Having described, in Part 1, the theoretical basis of the method used to study the lateral-torsional behaviour of stiffeners attached to flat plating, detailed comparisons with a series of tests and other theoretical formulations are presented in this paper.

ABSTRACT: A numerical study of the effect of aspect ratio on the buckling and collapse behaviour of flatbar-stiffened plates in compression is described. The plate equations are expressed in finite difference form and the solution is obtained using a dynamic relaxation algorithm. Initial imperfections and residual stresses are also introduced in the study. It was found that, for aspect ratios between 2 and 3.5, buckling occurs in the elastic regime, with the panels exhibiting significant post-buckling strength prior to collapse. For aspect ratios between 1 and 2 buckling occurs as the plastic zone increases, followed by rapid unloading as the panel collapses suddenly. The ultimate strength of the panel reduces with increasing aspect ratio, remaining practically constant at higher aspect ratios. The latter is attributed to the initial single half-wave distortion profile that prohibits the formation of the preferred buckling mode.

ABSTRACT: Shell-like structures are prevalent in nature. However, because of their slenderness they are prone to buckling, and to such an extent that this is often the dominant consideration in their design. Early attempts to determine buckling pressures were unsatisfactory. Although initial geometric distortions are now recognised as the cause of this, little comprehensive work has been conducted on doubly-curved shells, particularly hemispheres, subjected to external pressure and having asymmetric initial shapes. This paper presents the results of such a study, in two parts. In Part I, the background research on doubly-curved shells is briefly reviewed. The kinematic, equilibrium and constitutive equations used in the work are stated. The adopted numerical procedure which can generate static or dynamic solutions is described along with the results of convergence studies. In Part II, the effect of various initial shapes and their location will be described; the critical combination will be identified. The parameters selected to nondimensionalise the results will be
indicated, followed by those of the study which primarily involve initial deformation magnitude and shell slenderness. Two strength formulations which conveniently represent the results of the study will be presented.

ABSTRACT: Shell-like structures are prevalent in nature. However, because of their slenderness they are prone to buckling, and to such an extent that this is often the dominant consideration in their design. Early attempts to determine buckling pressures were unsatisfactory. Although initial geometric distortions are now recognised as the cause of this, little comprehensive work has been conducted on doubly-curved shells, particularly hemispheres, subjected to external pressure and having asymmetric initial shapes. This paper presents the results of such a study, in two parts. In Part I, which was presented in the previous issue of Thin-Walled Structures, the background research on doubly-curved shells was briefly reviewed. The kinematic, equilibrium and constitutive equations used in the work were stated. The adopted numerical procedure which can generate static or dynamic solutions was described along with the results of convergence studies. In this Part, the effect of various initial shapes and their location is described: the critical combination is identified. The parameters selected to nondimensionalise the results are indicated, followed by those of the study which primarily involve initial deformation magnitude and shell slenderness. Two strength formulations which conveniently represent the results of the study are presented.

ABSTRACT: Results from a series of studies on stiffened plates under axial compression are presented in this paper. The large-deflection elasto-plastic behaviour of each panel component is described by the von Karman equations, thus enabling the lateral-torsional buckling of the stiffener to be modelled in a rigorous manner. Material nonlinearity is represented using the von Mises yield criterion in conjunction with the Prandtl-Reuss flow rule. Results are presented in the form of average stress-strain curves which are used to generate maximum strength curves for the stiffener and plate.

ABSTRACT: The total potential energy of buckling of a plate with variable stiffness has been discretized by the method of finite differences. According to the principle of minimum potential energy, by equating the partial derivative of total potential energy with respect to each grid point displacement to zero in succession, a set of linear homogeneous equations is obtained. This reduces to a standard characteristic value problem, the eigenvalues of which yield the buckling loads. Test problems of plates with uniform stiffness, gradually varying stiffness and abrupt variation of stiffness with different boundary conditions and a stepped column as a
degnerate case of plate have been considered. Results are compared with those of analytical and numerical methods available. Good agreement has been observed in all cases. The proposed method has the advantage that the total number of equations is far less than in finite element method and application of boundary conditions is simple.

ABSTRACT: A procedure is developed for the design of a stiffened cylinder under a given uniform axial compression with minimum weight. The approach allows the consideration of various shapes of stiffening members. The effective stiffness of the skin in its post-buckled state is taken into account in the basic analysis. The buckling analyses are accomplished as a minimum problem in the buckling mode shape parameters space using the variable metric method. A mixed procedure which combines the exterior penalty function concept and random search is used to minimize the weight of the stiffened cylinders. The design examples demonstrate the validity of the present approach.

ABSTRACT: Cylindrical shells exhibit buckling under axial loads at stresses much less than the respective theoretical critical stresses. This is due primarily to the presence of geometrical imperfections even through such imperfections could be very small (e.g., comparable to thickness). Under internal pressure, the shell regains some of its buckling strength. For a relatively large radius-to-thickness ratio and low internal pressure, the effect can be reasonably estimated by an elastic analysis. However, for low radius-to-thickness ratios and greater pressures, the elastic-plastic collapse controls the failure load. In order to quantify the elastic-plastic buckling capacity of cylindrical shells, an analysis program was carried out by use of the computer code BOSOR5 developed by Bushnell of Lockheed Missiles and Space company. The analysis was performed for various radius-to-thickness ratios and imperfection amplitudes. The analysis results are presented in this paper.

K. Bandyopadhyay, J. Xu and S. Shteyngart, “Cylindrical shell buckling through strain hardening”, Brookhaven National Laboratory Report BNL-61540, no date given (the most recent reference is dated 1994)
ABSTRACT: Recently, the authors published results of plastic buckling analysis of cylindrical shells. Ideal elastic-plastic material behavior was used for the analysis. Subsequently, the buckling analysis program was continued with the realistic stress-strain relationship of a stainless steel alloy which does not exhibit a clear yield point. The plastic buckling analysis was carried out through the initial stages of strain hardening for various internal pressure values. The computer program BOSOR5 was used for this purpose. The results were compared with those obtained from the idealized elastic-plastic relationship using the offset stress level at 0.2% strain as the yield stress. For moderate hoop stress values, the realistic stress-strain case shows a slight reduction of the buckling strength. But, a substantial gain in the buckling strength is observed as the hoop stress approaches the yield strength. Most importantly, the shell retains a residual strength to carry a small amount of axial compressive load even when the hoop stress has exceeded the offset yield strength.
ABSTRACT: Loadings to cause severe accidents on containment buildings can include combinations of uniform internal pressure, dynamic pressure, and seismic. Most studies that have been conducted to predict containment building capacity have focused on the effect of overpressurization on containment performance. A simple methodology that permits rapid and reasonably accurate analysis for assessing the capacity of steel containment buildings due to global or local uniform or spatially varying dynamic loading was developed. An axisymmetric model was used and the circumferential variation of the pressure, displacements, and stress resultants were represented by Fourier series. Shell vibration and buckling analysis were performed using modified versions of BOSOR4 and BOSOR5 finite difference codes. The modified version of BOSOR5 allows the input of pressures that vary along the meridianal direction. These pressures were increased until failure of the containment occurred. Failure was defined to occur when membrane strains reached twice the yield strain or the bifurcation point was introduced. The applicability of this analysis method was verified by analyzing several problems as well as a simplified containment building. The axisymmetric analysis demonstrated a powerful tool to access the capacity of steel containment buildings.

ABSTRACT: The high stresses at intersections are caused by discontinuity shear stresses and moments which exist to maintain compatibility at the junction. The finite element method was used to determine the stress field at the intersection of a radial nozzle attached to a torispherical crown of a cylindrical vessel. The mechanical loads acting on the structure consisted of nozzle thrust, bending moment, torsion and internal pressure. A comparison between predicted and measured readings gave acceptable results for internal pressure loading but fair for other loadings. A computer program was written to calculate interaction between any two combining loads. The results, presented graphically, could be used to predict first yield for vessels of this configuration.

ABSTRACT: In this paper, the finite element analysis is used to investigate the effect of shape of dome ends on the buckling of pressure vessel heads under external pressure. The Finite Element Analysis (FEA) with the use of elastic buckling analysis was applied to predict the critical buckling pressure. The influence of geometrical parameters such as thickness, knuckle radius, and the ratio of minor axis to the major axis of dome ends, on the weight and the critical buckling pressure of hemispherical, ellipsoidal, and torispherical dome ends, was studied. The four-centered ellipse method was used to describe the geometry of the dome end.

ABSTRACT: In this study, the elastic buckling behavior of clamped laminated composite cylindrical shells under external pressure was studied. The Finite Element Method (FEM) was used to predict the critical elastic buckling pressure behavior when composite cylindrical shells were subjected to external pressure. The edges of the cylindrical shell ends were completely constrained to simulate clamped end conditions. The influences of parameters such as wall thickness, fiber angle, number of layers and L/R ratio of laminated composite cylindrical shells on critical buckling pressure were studied. It has been found that the under external pressure, the thickness and the fiber angle of the layers have the most significant effect on the critical buckling pressure.

ABSTRACT: This paper is concerned the analysis of functionally graded cylindrical shell under impulse loads by using the Rayleigh-Ritz method. The mass density and modulus of elasticity of the FG cylindrical shell is assumed to vary according to a power law distribution in terms of the volume fractions of the constituents. Hamilton’s principle with Rayleigh-Ritz method is used to derive the equation of motion of the FG cylindrical shell. The steady responses of forced vibration can be obtained by solving the equation of motion. The considered impulse load types are step pulse, sine pulse, triangular pulse and exponential pulse. The analytical results in special case are compared and validated using finite element method.

ABSTRACT: A buckling criterion for shells with an axisymmetric middle surface and subjected to edge loads and hydrostatic surface pressure loading is formulated starting from Hill's three-dimensional continuum theory for uniqueness of deformation of inelastic solids. It turns out that a physically consistent two-dimensional set of equations may be derived for a quite general class of strain-hardening elastic-plastic solids, the only essential restriction being that of a smooth yield function. The intrinsic errors inherent in the derived rate equations, being an integral part of an eigenvalue problem, are discussed in relation to a circular cylinder under axial compression. Analytical results are given which illustrate the influence of the constitutive properties and the boundary constraints on the magnitude of the critical load.

PARTIAL ABSTRACT: Accuracies of the Southwell method and the force/stiffness (F/S) method were
examined when the methods were used in the predictions of buckling loads of hypersonic aircraft wing tubular panels, based on nondestructive buckling test data. Various factors affecting the accuracies of the two methods were discussed. Effects of load cutoff point in the nondestructive buckling tests on the accuracies of the two methods were discussed in great detail…

ABSTRACT: Buckling analysis was performed on a hat-stiffened panel subjected to uniaxial compression. Both local buckling and global buckling were analyzed. It was found that the global buckling load was several times higher than the local buckling load. The predicted local buckling loads compared favorably with both experimental data and finite element analysis.

ABSTRACT: A buckling analysis was performed on a hat-stiffened panel subjected to shear loading. Both local buckling and global buckling were analyzed. The global shear buckling load was found to be several times higher than the local shear buckling load. The classical shear buckling theory for a flat plate was found to be useful in predicting the local shear buckling load of the hat-stiffened panel, and the predicted local shear buckling loads thus obtained compare favorably with the results of finite element analysis.

ABSTRACT: In the present review we considered several problems of nonlinear shell theory, their deformation and stability. Specialists in many areas have devoted much attention recently to problems of the nonlinear behavior of evolutionary systems. New scientific trends related to the study of stability problems have been generated. They can be called the Hopf bifurcation theory; or, the theory of attractors, referring to the study of unstable trajectory behavior in phase spaces; or, catastrophe theory, applied in solving multiparametric stability problems; or, the theory of phase transitions and critical phenomena, developed in special areas of physics; or, a theory considering nonequilibrium phase transitions and self-organization complex spatial and temporal ordered structures (synergetics). The use of methods developed by these scientific trends in shell theory enables deep understanding of effects of stability loss, in both equilibrium and motion, and helps to create investigation methods. ABSTRACT: A refined Timoshenko-type model based on the straight-line hypothesis is used to develop an approach to analyzing the stress state of longitudinally corrugated cylindrical shells with elliptic cross-section. The approach is to reduce the two-dimensional boundary-value problem that describes the stress–strain state of the shell to a one-dimensional one and to solve it with the stable numerical discrete-orthogonalization method. The solutions obtained using the straight-line hypothesis and the equations of three-dimensional elasticity are compared. The dependence of the stress–strain state of the shell on the number and amplitude of corrugations and the aspect ratio of the cross-section is analyzed.

ABSTRACT: A simple, but efficient procedure for the investigation of the geometrically non-linear dynamic behaviour of thin elastic shells which can be described sufficiently accurate by the Donnell-Marguerre-Mushtari-Vlasov theory is proposed and tested. It is based on a mixed variational formulation generalizing D'Alembert's principle. The discretization with respect to the space is performed by Euler's method and that with respect to the time by means of the central difference quotient. Due to the regular and simple structure of the governing algebraic equations wave propagation phenomena can be studied adequately. The introduction of an (artificial) damping allows the approximation of pure static problems and includes as well the branching of equilibrium. Some illustrative examples are presented.

ABSTRACT: The longitudinal compressive buckling loads of thin-walled cylinders in the yield region were analyzed by using both the incremental and the finite forms of a non-classical constitutive relation of plasticity (NCP). The relations of the critical stress sigma(cr) vs the ratio between R (the radius) and h (the thickness of the wall) were derived. The critical stresses of the thin-walled cylinders made of aluminum alloys AM__ and _1T were analyzed and compared with the experimental results. Comparison shows that for the cylinders made of _1T both forms of NCP can provide reasonable prediction; but for those made of AM__, the result given by the finite form of NCP is satisfactory, while the critical stress predicted by the incremental form of NCP is about 25% higher than the experimental data. The capability of the NCP in the description of the material instability, the response of material under an abrupt strain disturbance and its easy application indicate that it may be of potential in the analysis of structural buckling.

ABSTRACT: An approach to the study of the bifurcational stability of convex shells of revolution of double curvature is proposed, taking into account the microdamageability of an isotropic material in the form of the formation of a system of elliptic chaotically distributed microcracks throughout its volume, the concentration of which increases as the load increases. The inhomogeneous material being damaged is simulated by a
continuum, the elastic symmetry and mechanism of deformation of which are associated with the character of the distribution of microstrength and the form of the interaction of the edges of the microcracks, which depends on the stressed state induced in the body. The problem of bifurcational stability in the case of shells of revolution is formulated using the concept of continued loading within the framework of the Kirchoff-Love hypothesis. As an example, problems of the stability of ellipsoidal shells in the case of an internal and external pressure are solved.

ABSTRACT: Shells of revolution made of a granular composite material with microdamageable components are studied. Microdamages are simulated by spheroidal pores filled with a damaged material. The concentration of pores increases with increasing load. The problem is formulated using the concept of continuous load and the Kirchhoff-Love hypotheses. Solutions are presented for shells of positive and zero Gaussian curvature.

ABSTRACT: Thin shell torispherical pressure vessel heads are known to exhibit complex elastic–plastic deformation and buckling behaviour under static pressure. In pressure vessel Design by Analysis, the designer is required to assess both of these behaviour modes when specifying the allowable static load. The EN and ASME boiler and pressure vessel codes permit the use of inelastic analysis in design by analysis, known as the direct route in the EN Code. In this paper, plastic collapse or gross plastic deformation loads are evaluated for two sample torispherical heads by 2D and 3D FEA based on an elastic-perfectly plastic material model. Small and large deformation effects are considered in the 2D analyses and the effect of geometry and load perturbation are considered in the 3D analysis. The plastic load is determined by applying the ASME twice elastic slope criterion of plastic collapse and an alternative plastic criterion, the Plastic Work Curvature criterion. The formation of the gross plastic deformation mechanism in the models is considered in relation to the elastic–plastic buckling response of the vessels. It is concluded that in both cases, design is limited by formation of an axisymmetric gross plastic deformation in the knuckle of the vessels prior to formation of non-axisymmetric buckling modes.

“Experimental and numerical studies on the behavior of cylindrical and conical shells with varying thickness along the length subjected to axial compression”, Global Journal of Researches in Engineering, Vol. 10, No. 4, September 2010, pp. 92-
ABSTRACT: The behavior of aluminum cylindrical and conical shells of thickness variation along their lengths subjected to quasi-static axial compression was examined. The study was conducted using experimental and FE simulation approaches. The cylinders had mean radius of 25 mm, while the cones had smaller and larger radii of 15 mm and 35 mm respectively. Their thicknesses were increased linearly from top end to bottom end with the
thickness ratio (TR) of 0.0, 0.1 and 0.2. The mean thicknesses of specimens were 1.0 mm, 1.5 mm and 2.0 mm. The numerical simulations on those experiments were also conducted using the finite element code, ABAQUS. The results from experiment and FEA simulation were compared and good agreement was achieved. It was found that the energy absorption capacity of cylinder with thickness varying along the length is increasing as the value of TR increases. In contrast, the cone with thickness varying along the length seems to lose its energy absorption capacity as the value of TR increases. In addition, their deformation histories and load-displacement curves were presented and discussed.

ABSTRACT: It is well known that the experimental buckling loads of thin-walled circular cylinders are lower than the bifurcation loads, since thin-walled cylinders are sensitive to initial imperfections. This imperfection sensitivity depends on the radius, the wall thickness and the length of the cylinders as well as on the shape and arrangement of stiffeners. Therefore in searching for the most effective stiffening, it is not sufficient to compare bifurcation loads; one has to take into account the imperfection sensitivity too.

ABSTRACT: It is known that plates are not sensitive to initial imperfections, since, after buckling, their load
The deformation curve is upwards. Flat rings on circular cylinders are circular ring plates. Therefore, their postbuckling behavior is the same. This is proved theoretically in this paper. Hence, it follows that the slenderness of flat rings is not restricted by stability considerations, in contrast to the ECCS and BS 5500 recommendations.

ABSTRACT: The buckling loads of laminated cylinders can strongly depend on the position of the differently oriented layers within the shell. This paper deals with two different laminated orthotropic cylinders with opposite stacking sequence of the laminate layers. Cylinders of this construction had been thoroughly tested within a BRITE EURAM project. Analytical and semi-analytical methods have been used to predict the buckling loads, and the results are reported in this paper as well as test results for comparison. An explanation of the striking influence of stacking sequence is given. With some more examples the findings are verified. It is suggested that the presented results can be used for benchmarking purpose.

ABSTRACT: The analysis of an axially compressed circular tube deforming in progressive axisymmetric folds carried out by Wierzbicki et al. [(1992) Int. J. Solids Structures Vol. 29, 3269–3288] assumes an eccentricity factor relating the inward and outward parts of the folds. This factor was arbitrary and was not derived from the analysis. The present work re-examines the problem and produces a value for the eccentricity factor which conforms with the experimental findings. Values of the critical angles required for the formation of the inward and outward folds obtained from the analysis were substantiated by those obtained from experiments.

ABSTRACT: The energy absorption characteristics of corrugated tubes are experimentally studied. The corrugations are introduced in the tube to force the plastic deformation to occur at predetermined intervals along the tube generator. The aims are to improve the uniformity of the load—displacement behaviour of axially crushed tubes, predict and control the mode of collapse in each corrugation in order to optimize the energy absorption capacity of the tube. Effect of heat treatment and foam filling of these tubes are also considered. Metal tubes are mostly used throughout this study, however, PVC tubes are also considered for comparison purposes. The experimental results of crushing of the corrugated tubes make these tubes a good candidate for a controllable energy absorption element.

ABSTRACT: Motivated by complex multi-fluid geometries currently being explored in fibre-device manufacturing, we study capillary instabilities in concentric cylindrical flows of N fluids with arbitrary viscosities, thicknesses, densities, and surface tensions in both the Stokes regime and for the full Navier–Stokes problem. Generalizing previous work by Tomotika (N = 2), Stone & Brenner (N = 3, equal viscosities) and others, we present a full linear stability analysis of the growth modes and rates, reducing the system to a linear generalized eigenproblem in the Stokes case. Furthermore, we demonstrate by Plateau-style geometrical arguments that only axisymmetric instabilities need be considered. We show that the N = 3 case is already sufficient to obtain several interesting phenomena: limiting cases of thin shells or low shell viscosity that reduce to N = 2 problems, and a system with competing breakup processes at very different length scales. The latter is demonstrated with full 3-dimensional Stokes-flow simulations. Many N > 3 cases remain to be explored, and as a first step we discuss two illustrative N → ∞ cases, an alternating-layer structure and a geometry with a continuously varying viscosity.

ABSTRACT: We use a fully coupled, three-dimensional, finite-element method to study the evolution of the surface-tension-driven instabilities of a liquid layer that lines an elastic tube, a simple model for pulmonary airway closure. The equations of large-displacement shell theory are used to describe the deformations of the tube and are coupled to the Navier–Stokes equations, describing the motion of the liquid. The liquid layer is susceptible to a capillary instability, whereby an initially uniform layer can develop a series of axisymmetric peaks and troughs, analogous to the classical instability that causes liquid jets to break up into droplets. For sufficiently high values of the liquid's surface tension, relative to the bending stiffness of the tube, the additional compressive load induced by the development of the axisymmetric instability can induce non-axisymmetric
buckling of the tube wall. Once the tube has buckled, a strong destabilizing feedback between the fluid and solid mechanics leads to an extremely rapid further collapse and occlusion of the gas-conveying core of the tube by the liquid. We find that such occlusion is possible even when the volume of the liquid is too small to form an occluding liquid bridge in the axisymmetric tube.

ABSTRACT: Dynamic buckling of antisymmetrically laminated angle-ply rectangular plates due to axial loads proportional to time and axial step loads is considered. The nonlinear response of initially imperfect plates is determined from the numerical solution of the governing differential equation. In the case of the step loading this equation can be solved analytically. In the particular case of a perfect plate the solution of the linear problem yields the condition of dynamic buckling. Another problem considered in the paper is the behavior of an imperfect plate initially loaded by axial static stresses. The static response is determined first and the motion of the plate is superimposed on the static displacements in the second phase of the solution.

ABSTRACT: Divergence instability of a simply supported orthotropic composite shell reinforced in both axial and circumferential directions is considered. The shell is subject to an axial static load and to the action of an external supersonic gas flow in the direction parallel to the shell axis. Two variants of the solution considered in the paper include discrete widely spaced stiffeners and closely spaced stiffeners; the latter case can be treated using a smeared stiffeners technique.

ABSTRACT: In this paper, motions of composite cylindrical panels in a gas flow are considered. It is shown that the main factor contributing to large static deformations is a nonuniform aerodynamic heating, while aerodynamic pressure is of secondary importance, at high Mach number. It was found that the main factor
resulting in the increase of deformations is the nonuniform distribution of temperature along the curved edges. Deformations decrease rapidly in shallower panels. Nonuniformly heated panels become unstable at the values of axial compressive load, which are much smaller than the static buckling value calculated in the absence of heating. The condition of panel flutter of nonuniformly heated composite panels in a gas flow is also formulated.

ABSTRACT: This paper deals with some questions arising in dealing with engineering eigenvalue problems. The emphasis is placed on the coincident or closely spaced natural frequencies from the standpoint of the normal mode method applied for determining the structural response; it concentrates on the degree of refinement in the determination theories which should be introduced, in order to obtain accurate predictions of the response of structures subjected to high-frequency excitation. Nonsymmetric eigenvalue problems arising in composite plates are considered. Some pertinent questions associated with the eigenvalue problems arising for small vibrations superimposed on the basic nonlinear state, as well as those for nonprobabilistic treatment of uncertainty are posed. Special considerations associated with interval arithmetic and convex models of uncertainty are elucidated. Each section is concluded with open problems, awaiting for their resolution by the combined efforts of mathematicians and engineers.

ABSTRACT: Bending of shear-deformable orthotropic cylindrical shells, reinforced by ring stiffeners, manufactured from a cylindrically-orthotropic material, in a steady-state thermal field, is considered. The difference between the temperatures outside and inside the shell remains constant. The material properties of the shell and the stiffeners can depend on the temperature. Closed-form solutions are obtained in a number of important particular cases. Numerical examples illustrate that even moderate differences between the external and internal temperatures can result in significant stresses and deformations of the shell.

Birman V and Simitses GJ. Dynamic stability of long cylindrical sandwich shells and panels subject to

ABSTRACT: The paper presents an analysis of dynamic stability of long cylindrical sandwich shells and shallow panels subject to a uniform periodic lateral pressure. The solution is obtained using the Sanders shell theory by assumption that the shell or panel remains in the state of plane strain during both steady-state and perturbed motion. The steady-state motion of a shell is axisymmetric, while perturbed vibrations superimposed on the steady response are asymmetric. The analysis of perturbed motion is reduced to specifying the conditions of stability of the Mathieu equation. Subsequently, the criteria of dynamic stability and the boundaries of the regions of unstable motion in the pressure amplitude–pressure frequency plane are immediately available. A shallow panel subjected to hydrodynamic pressure experiences forced vibrations. However, these vibrations can become unstable. Dynamic stability of such vibrations is investigated through the solution of the linearized equations for perturbed motion. It is shown that these equations can be reduced to a system of Mathieu equations.

ABSTRACT: This paper presents a review of the principal developments in functionally graded materials (FGMs) with an emphasis on the recent work published since 2000. Diverse areas relevant to various aspects of theory and applications of FGM are reflected in this paper. They include homogenization of particulate FGM, heat transfer issues, stress, stability and dynamic analyses, testing, manufacturing and design, applications, and fracture. The critical areas where further research is needed for a successful implementation of FGM in design are outlined in the conclusions.
ABSTRACT: The paper presents an analysis of stability and free vibrations of rectangular functionally graded panels reinforced by a system of parallel stringers. The exact solution of the problem is illustrated for large aspect ratio panels with simply supported long edges and arbitrary boundary conditions along the short edges (hereafter the reference to an “exact solution” implies a closed-form solution in the content of the theory of plates). The spacing between the stringers and the cross sections of individual stringers can be arbitrary. In the particular case where identical stringers are equally spaced, the solution is simplified using the smeared stiffeners technique. The optimization problem concerned with the choice of stringers and their spacing in the situations where the buckling loads or fundamental frequencies are prescribed is also considered. The closed-form solution of the optimization problem is shown in the case of blade stringers.

ABSTRACT: The chapter outlines the foundations of the theory of plates and shells. The general approach employed in all versions of the relevant theories leads to particular cases including the classical (technical) theory of isotropic and composite plates and shells. Examples of solutions of linear bending and buckling problems are illustrated. The effect of large nonlinear deformations on the response of plates and shells is reviewed. The analysis of stiffened plates and shells is discussed, including the method modeling discrete reinforcements and the smeared stiffeners technique applicable to closely spaced identical stringers. It is shown that openings and cut-outs influence the behavior and strength of plates and shells, both locally through the stress concentration as well as globally through their effect on the stiffness. The concepts of composite and sandwich plates and shells are elucidated, providing insight on the peculiarities of mechanics of these structures.

ABSTRACT: The torsional buckling of a plastically deforming cruciform column under compressive load is investigated. The problem is solved analytically based on the von Kármán shallow shell theory and the virtual work principle. Solutions found in the literature are extended for path-dependent incremental behaviour as typically found in the presence of the vertex effect that is present in metallic polycrystals. At the critical load for buckling the direction of straining changes by an additional shear component. It is shown that the incremental elastic–plastic moduli are spatially nonuniform for such situations, contrary to the classical J2 flow and deformation theories. The critical shear modulus that governs the buckling equation is obtained as a weighted
average of the incremental elastic–plastic moduli over the cross-section of the cruciform. Using a plasticity model proposed by the authors, that includes the vertex effect, the buckling-critical load is computed for an aluminium column both with the analytical model and a FEM-based eigenvalue buckling analysis. The stable post-buckling path is determined by the energy criterion of path-stability. A comparison with the experimentally obtained classical results by Gerard and Becker (1957) shows good agreement without relying on artificial imperfections as necessary in the classical J2 flow theory.

ABSTRACT: A method is proposed for the determination of plastic bifurcation buckling load of metal matrix composite plates. The metallic matrix behavior is described by an elastic-viscoplastic constitutive law, while the fibers are assumed to be either elastic or elastic-viscoplastic material. The approach is based on the load level and history dependent instantaneous effective properties of the inelastic plate, which are established by a micromechanical analysis. An incremental procedure is developed in which a buckling condition has to be established and its fulfilment must be checked at each increment. The method is applied for the prediction of the plastic buckling of boron/aluminum composite plates in various situations, by employing the classical and higher order shear deformation plate theories.

ABSTRACT: The postbuckling behavior of viscoelastic composite laminated plates is considered. The viscoelastic behavior of the single ply is characterized by a micro-mechanical theory, in conjunction with the properties of the fibers and viscoelastic resin matrix. Higher-order shear-deformation theory is employed to study the post-buckling phenomenon. The resulting viscoelastic effects are shown, and comparison with lower order theories is presented.

ABSTRACT: The plastic bifurcation buckling loads of ARALL (aramid aluminum laminate) plates are predicted. The plastic behavior of the plate is caused by the significant plasticity effects of the aluminum strips. The critical load level at which the ARALL plate loses its stability is determined from the material properties of the elastoplastic aluminum alloy strips and the elastic unidirectional aramid/epoxy composite layers, in conjunction with their geometric characteristics.
Esther Feldman and Jacob Aboudi (Department of Solid Mechanics, Materials and Structures, Fleishman Faculty of Engineering, Tel Aviv University, Ramat Aviv 69978, Israel), “Postbuckling analysis and imperfection sensitivity of viscoplastic plates and cylindrical panels”, Thin-Walled Structures, Vol. 17, No. 4, 1993, pp. 273-290, doi:10.1016/0263-8231(93)90007-W

ABSTRACT: The postbuckling behaviour of elastic-viscoplastic rectangular plates and cylindrical panels is analysed. The rate-dependent inelastic material behaviour is modelled by a unified theory of viscoplasticity. Initial geometrical imperfections of the inelastic structure are included and their effect on the postbuckling behaviour is investigated. The analysis relies on an incremental approach in which at each loading increment the Galerkin method is employed. Results are presented for a plate made of an elastic-viscoplastic material and subjected to a uniaxial compression, applied at a constant strain rate on both edges. The results display the applied loading against the out-of-plane displacement, and the effects of loading rate and imperfection sensitivity. It turns out that there is a significant difference between the postbuckling behaviour of a plate in the two cases: (1) when the bifurcation buckling of a geometrically perfect plate occurs in the elastic region, and (2) when it occurs after a plastic flow takes place.

ABSTRACT: The postbuckling behaviour of metal matrix composite (MMC) laminated cylindrical panels under quasistatic in-plane loading is investigated. A micro-to-macro analysis is used to obtain the response of the composite structure. The micromechanical analysis allows us to establish the overall instantaneous elastic-viscoplastic behaviour of the MMC composite at each load increment. The macromechanical analysis provides the response of the geometrically imperfect cylindrical panel to the applied external loading. Results are presented for unidirectional and antisymmetric angle-ply SiC/Ti composite panels, subjected to uniaxial compressive loadings. The effects of the panel curvature, initial imperfections and rate of loading on the postbuckling response are illustrated. Comparisons with the response of the corresponding perfectly elastic panels are shown.

ABSTRACT: A micromechanical approach is combined with a structural analysis in order to investigate the time-dependent response and dynamic buckling of structures composed of nonlinear polymeric matrices (e.g. epoxy) reinforced by elastic fibres. The composite structures considered herein are either plates or cylindrical shells both of which are under cylindrical bending conditions. Results are given which illustrate the effect of nonlinear behaviour on the dynamic response of the composite structure.

ABSTRACT: Deformation theories are known to give solutions similar to flow theory for proportional loading where the components of the stress tensor at all points grow proportionally. However, if buckling is involved, deformation theories generally give better agreement with experiments. In this study, a deformation theory has been successfully employed for the elastic-plastic buckling analysis of plates under nonproportional external loading and nonproportional stresses. Loading, unloading, and reloading situations have been conveniently considered via conducting multistage analysis after casting the constitutive relations of a deformation theory in an incremental form. In order to achieve an economical solution the modified Newton-Raphson method has been generally used when the structure is loading (or reloading) everywhere while the initial stress method has been employed if unloading due to changes in the external loads takes place. The procedure has been applied in several cases and displayed accuracy and reliability. Three comparisons with experiments are shown to demonstrate the applicability of the integrated procedure.

ABSTRACT: Optimization of the axial buckling load of composite, cylindrical shells through a judicious choice of laminate configuration is often associated with increased imperfection sensitivity. Current approaches of combining postbuckling theory with an optimization program demand highly sophisticated analytical and computational methods, yet are insufficient to provide a rational theme that can be used to derive general design guidelines. The present paper is an attempt to explore the subject matter via a different avenue, such that various nonlinear effects may be understood in physical terms which require relatively little in the way of advanced mathematics and computation. The paper proposes to study the problem using a simple, but intuitively appealing, reduced stiffness analysis of cylinder buckling which recognizes the physical characteristics present in advanced postbuckling and uses them in an equivalent linear, eigenvalue analysis. This investigation highlights the specific relationship between laminate stiffness parameters, efficiency of buckling resistance and imperfection sensitivity in postbuckling deformation. It is observed that the criteria for optimality and reduced imperfection sensitivity are often opposed to each other. The reduced buckling load appears to be a useful indicator for evaluating qualitatively the relative imperfection sensitivity of various nearly optimal laminated shell designs which would be of great interest to designers. Another interesting feature is the analytical study in terms of bounded generic orthotropic constants which furnishes a general theme on the issue. A comprehensive discussion on the theoretical foundation of the reduced stiffness approach and other similar approximate methods is provided. It has been shown throughout this paper that the proposed physical approach successfully and consistently explains most of the observations reported in the literature which were based on nonlinear postbuckling analyses.

ABSTRACT: In the literature, the linear buckling load of rectangular plate elements is maximized by optimizing fibre orientation and thickness in a preselected lamination sequence. The paper considers the effects of laminate optimization on the postbuckling behaviour of biaxially compressed, specially orthotropic laminates and suggests modifications of the lamination parameters to improve postbuckling performance. Postbuckling studies, in general, involve the formal derivation of nonlinear equilibrium paths using, say, the methods of
Galerkin, finite element, etc. In contrast, a simpler but effective method is proposed whereby the initial postbuckling stiffness, defined by the slope of the postbuckling load-end shortening relation at bifurcation, is adopted as a qualitative index characterizing postcritical behaviour. An explicit solution is described for simply supported plates. It is established that the postbuckling stiffness and linear buckling load are governed by completely different functions: the former depends exclusively on inplane (membrane) stiffness while the latter is a function of bending stiffness only. It has been suggested that unfavourable postbuckling performance usually follows optimization of the buckling load. A detailed parametric study substantiates this proposition by illustrating that laminates, optimal in linear buckling, do exhibit inferior postbuckling characteristics due to reduced stiffness. Improved laminate designs are suggested that exhibit superior performance in both pre- and postbuckling.

ABSTRACT: In this paper, a description of how the curvilinear finite difference (CFD) energy method can be applied to the geometrically nonlinear analysis of general thin shells of arbitrary geometry will be given. The main features of the present finite difference formulation are its ability to implement the most general nonlinear strain-displacement relationship that is valid for any arbitrarily large finite deformation and out-of-plane rotation, its ability to model any kind of shell geometry and its capability to work on irregular computational meshes. A series of numerical examples are also included to verify the computer programming work developed here in this work.

ABSTRACT: Damage to the thin-walled cylindrical shells is addressed in this dissertation with reference to the possible collision of supply ships with the main legs of fixed or floating types of offshore platforms. Towards this end experimental and analytical investigation are carried out to give insight to the mechanics of the cylinder to withstand the impact force induced during the collision. The subsequent residual load carrying strength and the fatigue integrity of the damaged shell when subjected to external loading are also considered. The research investigation presented is divided into three phases. Firstly, localized damage are introduced to some of the test models, mostly through a knife edge indenter representing an idealized side-edge impact of a ship. A theoretical formulation based on a rigid plastic mechanism approach has been developed which provide a close correlation with the observed relationship between the residual dent depth and the corresponding impact load, from the tests on the unstiffened models. The application of this method to ring-stiffened models is also examined. Numerical simulation of the denting test, by using finite element method, are also carried out by using a commercial finite element programme.

Some of the dented models are subsequently tested under combinations of axial loading and external pressure for the investigation of the collapse behavior of the damaged shells. Undamaged shells are also tested in order to complement the experimental observations by providing a basis of comparison for the damage induced strength reduction. Numerical analysis of the intact model are performed with the incorporation of the initial imperfection in the test models. For the damaged shells, the effect of residual stresses due to denting is also examined. Together with the experimental observations, the effect of the localized damage in the load carrying capacity of cylindrical shells has been examined.

The final phase of the investigation examines the likelihood of fatigue cracking when the damaged cylinders are...
subjected to cyclic loading. Experiments are carried out on damaged shells, retrieved from the denting tests. Based on the correlation of strain-gauge data obtained during the test and the results from numerical analysis, the major factors responsible for the fatigue crackings on the test models have been identified. 157 References are listed at the end of the dissertation. Unfortunately, these cannot be cut and pasted.

ABSTRACT: The geometric nonlinear buckling problem of a thin doubly curved shallow shell with all edges hinged is complicated and difficult to obtain an exact analytical solution. Thus, differential equations are solved incrementally by using the differential quadrature method in this paper. Detailed formulations are worked out. Convergence study is performed. Several examples with various material properties, curvatures and dimensions are investigated. Comparisons are made with existing semi-analytical data or finite element data. It is shown that the critical loads are lower than the data obtained by either so-called Adjacent Equilibrium Method or Partitioned Solution Method. The possible reasons to cause the difference are discussed.

ABSTRACT: An analytical study of nonlinear flexural vibrations of cylindrical shells to random excitation is presented. Donnell's thin-shell theory is used to develop the governing equations of motion. Thermal effects for a uniform temperature rise through the shell thickness are included in the formulation. A Monte Carlo simulation technique of stationary random processes, multi-mode Galerkin-like approach and numerical integration procedures are used to develop nonlinear response solutions of simply-supported cylindrical shells. Numerical results include time domain response histories, root-mean-square values and histograms of probability density. Comparison of Monte Carlo results is made to those obtained by statistical linearization and the Fokker–Planck equation.

The paper presents the creep-stability analysis of viscoelastic cylindrical shells under axial compression. The mechanical properties of the material are described by the constitutive equations of the linear viscoelastic theory in terms of convolution integral operators. The approximate analytical solution to the problem is obtained by means of a modification of the quasi-elastic method. As a result, the instability condition for the shell is formulated. It is shown that for viscoelastic materials with limited creep, there is a safe load limit below which the structure is asymptotically stable. Any load above the safe load limit leads to buckling at the
corresponding critical time.

ABSTRACT: Stresses and deformations in composite cylindrical tubes as a result of combined loading (internal and external pressure, axial load, applied torque) and a temperature gradient through the wall thickness are studied. The composite tubes studied are, in general, long thick-walled cylinders made of arbitrarily oriented— with respect to the tube axis—orthotropic plies. A displacement-based linear elasticity solution is used in the analysis. Classical Laminated Plate Theory (CLPT), which assumes the composite laminate to be in a state of plane stress, does not predict any stresses in the thickness direction; however, in thick-walled tubes, through-the-thickness stresses may not always be negligible. The elasticity solution has shown that, under internal pressure only, in angle-ply and single-ply tubes, the resulting radial stress is virtually independent of the ply fiber orientation. In cross-ply tubes, these stresses show significant differences. In the case of a uniform temperature change only, the nonlinear distribution of the radial stress changes substantially depending on the ply fiber orientation. Another difference between the CLPT and Elasticity Theory for the analysis of cylindrical tubes is found in predicting the maximum twist rate of the cylinder with unbalanced wall laminate. Elasticity Theory has shown that for thick-walled, single-ply cylinders subjected to a uniform temperature change, the maximum twist rate occurs at the ply orientation angle greater than 45°, depending on the wall thickness and the mean radius of the cylinder, as opposed to 45° as predicted by the CLPT. The twist rate in thin-walled tubes subjected to internal pressure only is found to be much greater than in thick-walled tubes, due to the presence of large radial and hoop stresses in thick walls. In multi-layer cylinders, jumps in hoop and axial stresses have been observed at ply interfaces. Their magnitudes are shown to depend on the angles of fiber orientation.

ABSTRACT: The literature pertaining to the collapse of thick wall pipes in deep water is evaluated. The subject matter is categorized by type of loading: (1) pure external pressure, (2) pressure plus tension, and (3) pressure plus bending. The study focuses on the buckling or yield type of failure rather than fracture; and with well casing as well as conventional high strength line pipe. The failure theories are discussed and summarized; and the data and theories are compared. It is found that elastic stability should be based on mean diameter. Although not sensitive to elastic imperfections, plasticity effects especially prevalent in thick wall pipe are recognized as a cause of substantial imperfection sensitivity with respect to initial ovality. The abundance of data for oil well casing is found to contrast sharply with the lack of data for line pipe. Tension plus pressure appears to be amenable to a tangent modulus approach. Bending plus pressure is found to be the least well documented both in terms of theory and testing.
ABSTRACT: Finite element analyses of the collapse behaviour for long, relatively thick-walled metal tubes are presented under combined external pressure, tension and bending loads. The effects of initial ovality, residual stress, strain-hardening, yield anisotropy and load paths have been accounted for in the analyses. The analysis procedure has been validated using experimental results. Collapse envelopes for thick tubes under combined external pressure, tension and bending loads are presented in the form of pressure-moment-tension interaction, pressure-tension-curvature interaction and pressure-axial strain-curvature interaction. Factors affecting collapse envelopes are identified by means of parametric studies. Interaction equations to predict collapse envelopes are proposed based on the present finite element analyses considering major factors. The interaction equations are verified against finite element results and good agreement has been achieved for tubes with various geometric and material parameters and initial imperfections.

PARTIAL INTRODUCTION: This study originated from a specific problem that arose in conjunction with the IRIS (International Reactor Innovative and Secure) project (Carelli et al., 2004; Carelli, 2009). IRIS adopts an integrated primary system reactor (IPSR) configuration with all the primary loop components of a classical Pressurized Water Reactor (PWR) contained inside the vessel (Fig. 1). Among the reactor core internals are the steam generator (SG) units (Cinotti et al., 2002) with the primary fluid flowing outside the tube bundles and subjecting them to significant external pressure. In this situation buckling affects the tube collapse modality and codes become extremely conservative, to the point that up to five years ago design procedures based on the ASME Boiler & Pressure Vessel code (Section III) required an external diameter to thickness ratio ($D/t$) less than 8.5, leading to an increased thermal resistance in the heat exchange process between primary and secondary fluids, with detrimental consequences on the dimensioning of the heat transfer surface. A reduction in the tube thickness would allow the reduction of the overall heat transfer surface needed to exchange the same amount of power, with consequent saving on tube lengths and/or number of tubes. On the other hand, if the design of the steam generator units is not modified, an increase in the exchanged thermal power and a consequent up rating of the reactor can be obtained. Besides IRIS, other recent proposals for next generation power plants based on PWR technology consider an IPSR design (Ingersoll, 2009; Karahan, 2010; Ninokata, 2006). Such integrated design is particularly suitable for small sized units, i.e., reactors with a power less than 300 MWe following the IAEA’s definition (IAEA, 2007). A significant number of small sized PWR IPSRs is currently under development (e.g., RITM-200, ABV, CAREM, SMART, MRX, NHR-200, Westinghouse SMR, mPower, NuScale, see http://www.world-nuclear.org/info/inf33.html). Packing all the PWR primary components into the reactor pressure vessel (RPV) (Fig. 2) offers several advantages (Ingersoll, 2009): (i) all large coolant pipes are eliminated (only small feed water and steam outlet pipes penetrate the vessel wall); (ii) the total inventory of primary coolant is much larger than for an external loop PWR (this feature increases the heat capacity and thermal inertia of the system and hence yields a much slower response to core heat-up transients); (iii) typically the heat exchangers are placed above the core creating a relatively tall system that facilitates more effective natural circulation of the primary coolant in the case of a coolant pump failure; (iv) the vessel accommodates a relatively large pressurizer volume that provides better control . . .

Arve Bjorset (Department of Structural Engineering, Faculty of Civil and Environmental Engineering, The Norwegian University of Science and Technology, N-7491 Trondheim, Norway), “Capacity assessment of titanium pipes subjected to bending and external pressure”, (no publisher given), March 2000 (dissertation?) ABSTRACT: Exploration for oil and gas is moving towards deeper waters. Steel has been the most common riser material. Related to deep water concepts titanium has become an alternative to steel for these applications. Several codes exist today for predicting collapse loads for marine pipes. However, the capacity formulas are developed for steel. If the formulas are applied directly to titanium several parameter uncertainties will be
unknown. Ideally, extensive model testing of titanium pipes is required. This thesis discusses and investigates utilisation of experimental material test data and a supplementary numerical approach based on finite element analysis. The relationship between material model parameters as input to the analysis and the collapse capacity is investigated by performing a series of nonlinear FEM analyses. Statistical models for the input material model parameters are established based on tests on small specimens cut from titanium pipes. These models are subsequently combined with results from the FEM analyses by application of response surface methods. As output from the analysis, the probability distributions of the pipe capacity with respect to local buckling/collapse are obtained. Finally, the data from the nonlinear finite element analyses are compared to a relevant design code. Suggestions for a possible basis for design formulas to check for the local collapse capacity of deep water titanium risers are provided.

ABSTRACT: It has been observed in experiments that the localization of plastic buckling patterns has a large influence on the strength deterioration of steel structures under cyclic loading. In this study the theoretical aspects of this cyclic localization phenomenon were investigated. The localization behavior is caused by a plastic bifurcation on the decreasing equilibrium path subsequent to the maximum load point. Thus, we first show a precise numerical method based on the finite element method for analysis of the plastic bifurcation. Then, using this method, we examine the localization behavior of cylindrical shells and plates under cyclic loading. Specifically, we investigate the effect of structural parameters and that of constitutive models on the strength deterioration.

ABSTRACT: The study of the seismic response of broad, anchored, cylindrical liquid-storage tanks has large practical significance because these structures are used in many critical engineering applications (petroleum industries, nuclear power stations, municipal water supply systems, wine industries ...). The performance of such tanks during recent earthquakes and in experiments has indicated that the existing codes for designing tanks are in need of improvement. Due to the complexity of the dynamic analysis, several researchers have used a static approach to predict the dynamic buckling load. It has been demonstrated that such a static analysis yields useful information. On the basis of this finding, an approximate analytical method is developed to study the buckling of broad, anchored, cylindrical liquid-storage tanks subjected to horizontal ground motion. The solution is based on the linearized Donnell's shell stability equations and Galerkin's approach. The smallest buckling load (or the critical load factor) is calculated using the inverse iteration method. Theoretical results are then determined for two cases of broad tanks presented as examples. The validity of the findings of the present work is checked through comparison with results obtained by the numerical Finite Element Method (FEM).

ABSTRACT: Stress analysis of a water storage structure has been carried out for static and seismic loading. Based on the stress analyses results, assessment of most likely failure modes for the structure caused by seismic event has been carried out. An attempt has been made to quantify the initial leakage rate and average emptying time for the structure during seismic event after evaluating the various crack parameters, viz., crack-width and crack-spacing at the locations of interest. Finally, the seismic fragility of the structure is developed as families of conditional probability curves plotted against peak ground acceleration (PGA) parameter at the location of interest considering the randomness and uncertainty associated with various parameters that could affect the seismic structural response.

ABSTRACT: If the parameter epsiv2, which measures the thickness-to-rise of the shell, is small, the axisymmetric polar dimpling of shallow spherical shell due to quadratic pressure distribution is dynamic instability, i.e., a small perturbation can change it to an asymmetric polar dimple mode. In two cases, the problem can be reduced to an eigenvalue problem Twn=cn wn, where T can approximately be reduced to a Sturm-Liouville operator if epsiv2Lt1. The existence of at least one real eigenvalue of T, which means that the axisymmetric polar dimpling is dynamically unstable, is proved by spectral theorem or Hilbert theorem. Furthermore, an eigenfunction, which represents one of the asymmetric modes of the unstable dimple shell, belonging to an eigenvalue of T is found.

ABSTRACT: Stiffened composite panels are often used as structural components in aircraft in order to avoid buckling. It is well known that stacking sequence optimizations are indispensable for laminated composite structures. Stiffened composite panels usually have more than two stacking sequences because they consist of a panel skin laminate and stiffener laminates. This means that the stacking sequences need to be jointly optimized to achieve structural optimization of the stiffened composite panel. The authors have proposed a new stacking sequence optimization method, called the fractal branch and bound method, for optimizing a single laminate. In the present study, the fractal branch and bound method is extended to optimizing multiple stacking sequences. The extended method is applied for obtaining two optimal stacking sequences for the maximization of the buckling load of a hat-stiffened composite panel. The improved method successfully provides two optimal stacking sequences determined in a short period of time.

ABSTRACT: The fractal branch-and-bound method has been developed by the authors for stacking-sequence optimizations of symmetric and balanced composite laminates comprise of two in-plane and two out-of-plane lamination parameters. Cylindrical structures such as tanks or pipes, however, are usually made from balanced laminates. In the present study, therefore, we focus on the stacking-sequence optimizations of unsymmetrical composite laminates. In the unsymmetrical laminates, nine lamination parameters including three coupling-lamination parameters exist, and its feasible design region of fractal pattern is unrevealed. The paper clarifies the feasible region in which the in-plane, out-of-plane and coupling lamination parameters create fractal patterns of tetrahedrons or tetradecahedrons. Using the fractal patterns of lamination parameters, the improved fractal branch-and-bound method is proposed for unsymmetrical laminates including coupling lamination.
parameters. This new method is applied to stacking-sequence optimization problems of maximization of buckling load of cylindrical laminated shells. As a result, the method is successfully applied, and a practical optimal stacking sequence is obtained with low computational cost.

ABSTRACT: Laminated carbon fiber reinforced polymer (CFRP) composites have widespread applications in aerospace structures, and thus optimization of the stacking sequences in these composites is indispensable. Here, a fractal branch and bound method (FBB) is proposed for optimizing the stacking sequences. This method requires only low computational costs, and an optimal result can be obtained rapidly by means of the deterministic process. For practical stacking sequence optimizations, more than two laminates have to be optimized, because a practical aerospace structural component usually comprises a panel and stiffeners made from composite laminates. Since the stacking sequences of the skin panel and stiffeners affect the buckling load of the stiffened panel, the optimization of both laminates must be performed simultaneously. In the present study, a new method to implement a strength constraint for the FBB method is proposed for the simultaneous optimization of more than two laminates (such as a panel and stiffeners). Moreover, a quadratic polynomial objective function, which includes lamination parameter variables of the two laminates: the stiffeners and the panel, is adopted. The strength constraint is implemented by means of a response surface. The new method is applied to the buckling load maximization of a blade-stiffened composite panel, in which the strength constraint is demonstrated as a feasibility study. The method successfully obtained optimal stacking sequences with the strength constraint at low computational cost.

ABSTRACT: The optimization method for composite structural components described herein uses modified efficient global optimization with a multi-objective genetic algorithm and a kriging response surface. For efficient global optimization using kriging, the kriging response surface is used as a representative of the function value. The stochastic distribution of the kriging is used to improve the estimation error of the kriging surrogate model. Using efficient global optimization, a hat-stiffened composite panel was optimized to reduce the weight with the buckling load constraint. The expected improvement was used as a single objective function of a particle swarm optimization. Nevertheless, it is difficult to obtain a feasible solution that satisfies buckling load constraints with the progress of optimization. Using a multi-objective genetic algorithm, we obtain the feasible optimal structure satisfying the constraints. The expected improvement objective function is divided into two objective functions: weight reduction and the uncertainty of satisfaction of the buckling load constraint. Kriging approximation, which is improved with the selected Pareto optimal frontier, reduces the computational cost. Also, a genetic algorithm is used to optimize the stiffened panel configuration. The fractal branch-and-bound method is used for stacking sequence optimizations. This method obtained a feasible optimal structure at a low computational cost.

ABSTRACT: For cylindrical shell, because of its structure characteristic (i.e. long and thin-walled), it has low stiffness, bad fabrication procedure. And it’s very easy to cause vibration in the cutting process, especially the type of regenerative vibration. So, it’s vital for the surface quality of work-piece and cutting stability to select cutting parameter reasonably. The paper proposed a dynamic optimization method, which aimed at maximization of material removal rate. This method could guarantee the maximum material removal rate under the condition of cutting stability based on Particle Swarm Algorithm (PSA). In the end, it verified the optimization results by the experiments.

ABSTRACT: This study focuses on the improvement of the axial buckling capacity of elliptical composite cylinders through the use of a circumferentially-varying lamination sequence. The concept of varying the lamination sequence around the circumference is considered as a viable approach for off-setting the disadvantages of having the cylinder radius of curvature vary with circumferential position, the source of the reduced buckling capacity when compared to a circular cylinder with the same circumference. Post-buckling collapse behavior and material failure characteristics are also of interest. Two approaches to implementing a circumferential variation of lamination are examined. For the first approach the lamination sequence is varied in a stepwise fashion around the circumference. Specifically, each quadrant of the cylinder circumference is divided into three equal-length regions denoted as the crown, middle, and side regions. Eight different cylinders designs, whereby each region is constructed of either a quasi-isotropic or an axially-stiff laminate of equal thickness, are studied. Results are compared to the baseline case of an elliptical cylinder constructed entirely of a quasi-isotropic laminate. Since the thickness of the quasi-isotropic and axially-stiff laminates are the same, all cylinders weight the same and thus comparisons are meaningful. Improvements upwards of 18% in axial buckling capacity can be achieved with one particular stepwise design. The second approach considers laminations that vary circumferentially in a continuous fashion to mitigate the effects of the continuously-varying radius of curvature. The methodology for determining how to tailor the lamination sequence circumferentially is based on the analytical predictions of a simple buckling analysis for simply-supported circular cylinders. With this approach, axial buckling load improvements upwards of 30% are realized. Of all the cylinders considered, very few do not exhibit material failure upon collapse in the post-buckled state. Of those that do not, there is little, if any, improvement in bucking capacity. Results for the pre-buckling, buckling, post-buckling, and material failure are obtained from the finite-element code ABAQUS using both static and dynamic analyses. Studies with the code demonstrate that the results obtained are converged.

ABSTRACT: The results of optimization of thin-walled sandwich cylindrical shells under the combined loads of axial compression and external pressure are presented. The face layers of the shell are made of aluminium alloy, and the core is made of foamed plastic. The thicknesses of layers are taken as design variables. The weight of the shell is taken as the objective function, and stability condition and strength conditions are taken as the main constraints. The system of stability equations is obtained based on the condition of the minimum of shell potential energy. The problem of general stability is solved in an approximate manner by means of the Bubnov-Galerkin method. The initial imperfections are treated with the knockdown factors. For the the optimization, a method of systematic search is used. The results are discussed.

ABSTRACT: Thin-walled sandwich structures have become extremely useful because of their high strength-to-mass and stiffness-to-mass ratios. The results of the bicriteria optimization of thin-walled sandwich cylindrical panels under combined loads are presented in this article. Panel mass and panel deformability are two objective functions, where panel deformability is defined with the help of bending rigidity. A set of constraints includes stability and stress conditions, a constraint connected with the importance of applied theoretical models, and technological and constructional requirements. The optimization problem was solved using the Pareto concept of optimality and application of the OPTIKON computer program, which implements elements of an expert system. The OPTIKON program was designed to solve multicriteria optimization problems for non-linear engineering models with discrete and continuous sets of design variables. The results of numerical calculations are presented as tables and diagrams.

ABSTRACT: Evidence is presented and arguments advanced to support the proposition that vibration induced by turbulence in the air stream plays a significant role in initiating the collapse of open-topped oil storage tanks in high winds. On this basis a new criterion is suggested for calculating the size of the circumferential strengthening members of tanks (wind girders). It is pointed out that a new criterion for calculating the wind speed at which tanks fail can only be couched in probabilistic terms and while it is not yet possible to derive such a criterion, the necessary steps and research to do so are discussed. Some interesting results on flow-induced vibrations in circular cylindrical structures are derived and discussed in the light of other relevant research to gain a clearer understanding of such phenomena.

ABSTRACT: The paper addresses a computational model for elasto-plastic large deformation analysis of thin
shells. The large displacement, large rotation but small strain shell theory is developed from the three dimensional continuum theory via standard assumptions on the displacement field (see for example [1] for details). A model for thin shells is obtained by approximating the terms describing the shell geometry. The resulting strain measures are identical to those that may be obtained by a Cosserat surface approach [2].

ABSTRACT: The theory of structural stability is both an important and a difficult subject, whose main field of application is found in the design of thin wall lightweight structures and shells. It is unavoidable to employ nonlinear model and to use finite element numerical method in order to obtain the critical load under the action of which the instability of structures will occur. Thus, it becomes very important how to simplify such a nonlinear problem that appears in instability analysis. In this paper, an improvement on previous nonlinear buckling analysis is proposed, in which the emphasis is on the shortcut of calculation of pre-buckling fundamental path. The nonlinear equation used to solve the displacement vector is translated into the linear one to solve the load factor by means of the concept of energy conservation. The detailed procedure to calculate the nonlinear buckling load is presented and two simple examples are also shown as the application of suggested method. The theoretical analysing and numerical examples show that the suggested method is valid for predicting the nonlinear critical loads of structures.

References listed at the end of the paper:

ABSTRACT: A 64-dof isoparametric quadrilateral finite element is presented for the analysis of generally laminated shells of revolution. The effects of shear deformation and rotary inertia are accounted for by using shear deformation theory that employs the parabolic shear strain variation across the thickness. The classical thin shell theory is the special case of shear deformation theory used in the present study. Thus, the thin shell element also can be obtained from the present thick shell element by simply having the displacement parameters (u1 and v1,) associated with the shear rotations as zeros. The numerical results presented illustrate the performance of the element and the effects of shear deformation.

ABSTRACT: The paper presents a theoretical and an experimental analysis of the buckling of 4 thin-walled circular cylinders, which were tested to destruction under uniform external hydrostatic pressure. The mode of failure of the vessels was lobar buckling or shell instability, where the vessel imploded inwards with evenly spaced waves spaced around its circumference. The theoretical analysis adopted the finite element method, where the commercial computer package, namely ANSYS was used. The theoretical work involved the inclusion of both material and geometrical non-linearity, using an incremental step-by-step method. About 50 steps were used per model. Comparison between theory and experiment was good and this appeared to indicate that the method could be applied to full-scale vessels.

References listed at the end of the paper:

ABSTRACT: The article reports on two theoretical investigations and an experimental investigation into the collapse of six circular conical shells under uniform external pressure. Four of the vessels collapsed through plastic non-symmetric bifurcation buckling and one vessel collapsed through plastic axisymmetric buckling. A sixth vessel failed in a mixed mode of plastic non-symmetric bifurcation buckling, combined with plastic axisymmetric buckling. The theoretical and experimental investigations appeared to indicate that there was a link between plastic non-symmetric bifurcation buckling and plastic axisymmetric buckling. The theoretical investigations were via the finite element method and were used to provide a design chart for these vessels.

Carl T.F. Ross and J.R. Sadler (Department of Mechanical and Manufacturing Engineering, University of Portsmouth, Portsmouth, PO1 3DJ, UK), “Inelastic shell instability of thin-walled circular cylinders under

ABSTRACT: The paper describes experimental tests carried out on three ring-stiffened circular conical shells that suffered plastic general instability under uniform external pressure. The cones were carefully machined from EN1A mild steel to a very high degree of precision. The end diameters of the cones, together with their thicknesses were the same, but the size of their ring stiffeners was different for each of the three vessels. In the general instability mode of collapse, the entire ring-shell combination buckles bodily in its flank. The paper also provides three design charts using the results obtained from these three vessels, together with the results obtained for twelve other vessels from other tests. All 15 vessels failed by general instability. One of these design charts was based on conical shell theory and two of the design charts were based on the general instability of ring-stiffened circular cylindrical shells, using Kendrick’s theory, which were made equivalent to ring-stiffened circular conical shells suffering from general instability under uniform external pressure. The design charts allowed the possibility of obtaining plastic knockdown factors, so that the theoretical elastic buckling pressures, for perfect vessels, could be divided by the appropriate plastic knockdown factor, to give the predicted buckling pressure. The theoretical work is based on the solutions of Kendrick, together with the finite element program of Ross, namely RCONEBUR and the commercial finite element package ANSYS. This method can also be used for the design of full-scale vessels.

References listed at the end of the paper:

ABSTRACT: The paper presents new experimental results on the collapse of unstiffened aluminum alloy
circular cylinders suffering elastic and plastic nonsymmetric bifurcation buckling under external hydrostatic pressure. These results complement the results given in two previous Marine Technology papers written by the senior author, which were intended for the structural design of near-perfect unstiffened and ring-stiffened circular conical shells under external hydrostatic pressure. The present paper presents a structural design chart for geometrically imperfect circular cylinders under uniform external pressure, which is more likely to be used than the design charts for the previous near-perfect vessels because it represents the more "usual" case. In addition to an experimental analysis, theoretical analyses were also carried out. An analytical solution by von Mises was used, together with a finite element analysis solution, using the Shell 93 element of the ANSYS computer package. Comparison between ANSYS and the analytical solution was reasonable. A design chart is provided, which looks like it could be quite useful for practical purposes.

ABSTRACT: The paper presents the experimental results for 15 ring-stiffened circular steel conical shells, which failed by non-linear general instability. The results of these investigations were compared with various theoretical analyses, including an ANSYS eigen buckling analysis and another ANSYS analysis; which involved a step-by-step method until collapse; where both material & geometrical nonlinearity were considered. The investigation also involved an analysis using BS5500 (PD 5500), together with the method of Ross of the University of Portsmouth. The ANSYS eigen buckling analysis tended to overestimate the predicted buckling pressures; whereas the ANSYS nonlinear results compared favourably with the experimental results. The PD5500 analysis was very time consuming and tended to grossly underestimate the experimental buckling pressures and in some cases, overestimate them. In contrast to PD5500 & ANSYS, the design charts of Ross of the University of Portsmouth were the easiest of all these methods to use and generally only slightly underestimated the experimental collapse pressures. The ANSYS analyses gave some excellent graphical displays.

ABSTRACT: Nonlinear behavior of deep orthotropic spherical shells under inward radial concentrated load is studied. The singular perturbation method is developed and applied to Reissner’s equations describing axially symmetric large deflections of thin shells of revolution. A small parameter proportional to the ratio of shell thickness to the sphere radius is used. The simple asymptotic formulas describing load–deflection diagrams, maximum bending and membrane stresses of the structure are derived. The influence of boundary conditions on the behavior of the shell by large deflections is considered. Obtained asymptotic solution is in close agreement with the experimental and numerical results and has the same accuracy (in the asymptotic meaning) as the given equations of nonlinear theory of thin shells.

ABSTRACT: The system of differential equations governing the analysis of rotationally symmetric shells under time-dependent or static surface loadings is formulated with the transverse, meridional, and circumferential displacements as the dependent variables. The thickness of the shell may vary, and four homogeneous boundary conditions may be prescribed at each boundary edge of the shell. The governing differential equations for each Fourier harmonic are obtained by use of Fourier series in the circumferential direction of the shell. Influence coefficients at each of the node points along the shell meridian are obtained for each Fourier component by employing ordinary finite difference representations for the meridional co-ordinate derivatives. With these influence coefficients, a set of homogeneous flexibility equations governing the free vibration characteristics of the shell is obtained and solved for the frequencies and mode shapes for each Fourier component. The solutions under time-dependent or static surface loadings and due to initial displacements and velocities are then obtained by expanding the solutions in terms of the modes of free vibration of the shell for each Fourier component. The solution for the total shell response is obtained by Fourier series summation. Solutions for typical shells have been found to be in excellent agreement with solutions by the method of temporal and spatial finite differences. Solutions for a parabolic shell are presented as an example. The solution is also presented for a published cylindrical shell example and is seen to be in excellent agreement with the published finite element method results.

“Optimal weight design of laminated composite panels with different stiffeners under buckling loads”, ICAS 2010, 27th International Congress Of The Aeronautical Sciences, 2010

ABSTRACT: The present investigation is devoted to development of new optimal design concepts that exploit the full potential of advanced composite materials in aircraft lateral wing upper covers. Three rib bays laminated composite panels with T, I and HAT-stiffeners are modelled with ANSYS and NASTRAN finite element codes to investigate their buckling behaviour in dependence on skin and stiffener lay-ups, stiffener height, stiffener top and root width. Due to the large dimension of numerical problems to be solved, an optimisation methodology is developed employing the method of experimental design and response surface
technique. Weight optimisation problems are solved for laminated composite panels with three types of stiffeners, two stiffener pitches and four load levels taking into account manufacturing, repairability and damage tolerance requirements. Optimal results are verified using ANSYS shared-node and NASTRAN rigid-linked models.

ABSTRACT: The superior performance of the consistent shell element in the small deflection range has encouraged the authors to extend the formulation to large displacement static and dynamic analyses. The nonlinear extension is based on a total Lagrangian approach. A detailed derivation of the non-linear extension is based on a total Lagrangian approach. A detailed derivation of the non-linear stiffness matrix and the unbalanced load vector for the consistent shell element is presented in this study. Meanwhile, a simplified method for coding the nonlinear formulation is provided by relating the components for the nonlinear B-matrices to those of the linear B-matrix. The consistent mass matrix for the shell element is also derived and
then incorporated with the stiffness matrix to perform large displacement dynamic and free vibration analyses of shell structures. Newmark's method is used for time integration and the Newton-Raphson method is employed for iterating within each increment until equilibrium is achieved. Numerical testing of the nonlinear model through static and dynamic analyses of different plate and shell problems indicates excellent performance of the consistent shell element in the nonlinear range.
